Infectious/hematologic complications. Conventional wisdom holds that the patient should be afebrile at the time of the blood patch procedure. Many anesthesia providers believe that it is wise to avoid the epidural injection of blood in the presence of systemic infection. Meningitis has been reported after a blood patch procedure.[35] After conservative measures have failed, the optimal treatment of a febrile patient with severe, persistent PDPH is controversial. Epidural infusion of saline involves the use of an indwelling epidural catheter for many hours, which also may be undesirable in a febrile patient. A patch using dextran-40 may be an alternative in febrile patients, but further experience is needed in healthy patients before this technique can be recommended.

The presence of high fever and/or other evidence of sepsis contraindicate the performance of a blood patch procedure. However, we do not believe that a low-grade fever of known etiology is an absolute contraindication to epidural blood patch, provided the patient is receiving appropriate antibiotic therapy. Management should be individualized, and the known benefits of blood patch should be weighed against the unknown risk for infection.

The risks associated with epidural blood patch therapy in the presence of human immunodeficiency virus (HIV) infection have been debated (see Chapter 36). However, the central nervous system is infected with HIV at the time of primary infection; therefore, it seems unlikely that the injection of autologous blood into the epidural space would alter progression of the disease. Successful use of blood patch therapy, without sequelae, has been reported in patients with acquired immunodeficiency syndrome (AIDS) or who are HIV positive.[200]

The incidence of cancer during pregnancy is increasing, likely secondary to advancing maternal age. The development of PDPH in this population has raised a theoretical concern about seeding the neuraxial space with neoplastic cells if a blood patch procedure is performed. This concern should be discussed with the patient and her oncologist before the procedure. Bucklin et al.[201] reported the conservative management of a woman with acute leukemia and PDPH; the investigators discussed the therapeutic options for this immunocompromised patient. The use of epidural fibrin glue was reported in a nonobstetric patient with metastatic breast cancer and PDPH,[202] whereas a blood patch was performed for PDPH in a young woman with rhabdomyosarcoma.[203]

Neurologic complications. Serious or permanent problems after epidural blood patch therapy are rare. Diaz and Weed[204] wrote a review of case reports of adverse neurologic complications after epidural blood patch procedures. These authors identified 26 reports published between 1966 and 2004 and stratified the complications into neurologic, neurovascular, or inflammatory events. The events occurring in obstetric patients included lumbovertebral syndrome (defined as low back pain with neurologic impairment of the lower extremities), subdural hematoma, arachnoiditis, radicular back pain, pneumocephalus, seizures, and acute meningeal irritation. Compressive complications (e.g., lumbovertebral syndrome, subdural hematoma, cauda equina syndrome) were associated with larger blood patch volume (mean of 35 mL) than noncompressive complications (17 mL). Cranial nerve palsy symptoms that were present before blood patch administration did not uniformly resolve. The delay in performing the blood patch may have been a significant factor. Two patients who were treated within 4 days of the onset of PDPH symptoms recovered within 6 weeks, whereas three patients treated on days 9 to 11 had palsy that persisted for 3 to 4 months. Two obstetric patients experienced new facial nerve palsies, which manifested as facial weakness after administration of an epidural blood patch.[204]

Abouleish et al.[173] reported the results of the long-term evaluation of 118 patients who had received an epidural blood patch. Back pain was the most common complication; it occurred during the first 48 hours in 35% of patients and persisted in 16% of patients, with a mean duration of 27 days. These investigators also noted cases of neck pain, lower extremity radicular pain, and transient temperature elevation.

Epidural space scarring is also a possibility after placement of a blood patch. Although subsequent epidural analgesia is generally successful (see earlier discussion),[199] Collier[205] reported two cases of unsuccessful epidural analgesia related to suspected scarring of the epidural space. In both women, the initial epidural catheter placement was complicated by unintentional dural puncture and PDPH treated with epidural blood patch. During a subsequent pregnancy, epidural catheter placement was complicated by inadequate analgesia, and an epidurogram revealed limited spread of the contrast media, suggesting epidural space scarring.

The development of an inflammatory reaction to epidural blood can cause acute arachnoiditis, an entity that can present several days after epidural blood patch.[206] This phenomenon is believed to be caused by free radical damage to spinal root nerves in the intrathecal space after hemoglobin degradation. Obstetric patients with this entity who required analgesic therapy for prolonged periods have been reported.[207] The diagnosis is made with a presenting history of severe back pain, often with radicular pain, and characteristic MRI findings such as nerve root clumping in the intrathecal space and adhesions between nerve roots.

The occurrence of new neurologic symptoms appearing after an epidural blood patch should prompt consideration of the presence of other intracranial pathology. Such symptoms may include (1) mental deterioration caused by increased ICP from an intracranial tumor[208] and (2) seizures caused by late-onset eclampsia or PRES.[209]

Diaz[210] described a woman in whom permanent paraparesis and cauda equina syndrome developed after an epidural blood patch with 30 mL of blood injected slowly and without symptoms. Low back pain and leg pain developed after the blood patch procedure, and later the patient also experienced incontinence. Twelve days after the procedure, a subdural hematoma at L2–L4 was diagnosed and surgically treated. Six months later, the patient still had marked symptoms. Although a larger volume of blood than usual was injected, the technique appears to have been within normal practice standards. Other long-term sequelae reported in obstetric patients include a cerebral ischemic event after two blood patches that resulted in permanent hemianopsia[211] and a calcified epidural blood patch leading to chronic back pain.[212]

Alternatives to Epidural Blood Patch

Alternatives to an epidural blood patch may be considered if a blood patch is contraindicated or fails. The sphenopalatine ganglion block, in particular, has received increased consideration in patients suffering from PDPH. In extreme cases, surgery may be needed to close the dural tear.

Sphenopalatine ganglion block. The sphenopalatine ganglion (SPG) block has become a useful adjunct in the treatment of cluster and migraine headaches. This parasympathetic ganglion is located in the pterygopalatine fossa, immediately adjacent to the posterior component of the middle turbinate of the nose (Fig. 30.4).[213] Blocking the ganglion inhibits parasympathetic outflow to cerebral vasculature and prevents vasodilation. A simple technique, the operator places a cotton pledget soaked with local anesthetic in the nose and allows diffusion across nasal mucosa. Cohen et al.[214] offered SPG block to 32 obstetric patients suffering with PDPH after dural puncture with a 17-gauge epidural needle before planned epidural blood patch; 69% did not require the blood patch. Pledgets saturated with 5% water-soluble lidocaine ointment were applied to each nostril for 10 minutes. Although prospective study is required to evaluate its role in the treatment of PDPH, SPG block may be useful in providing symptom relief for those with severe, early symptoms following dural puncture.

Dextran/gelatin patch. Dextran-40 and gelatin-based solutions, including Gelfoam and Plasmion, have been

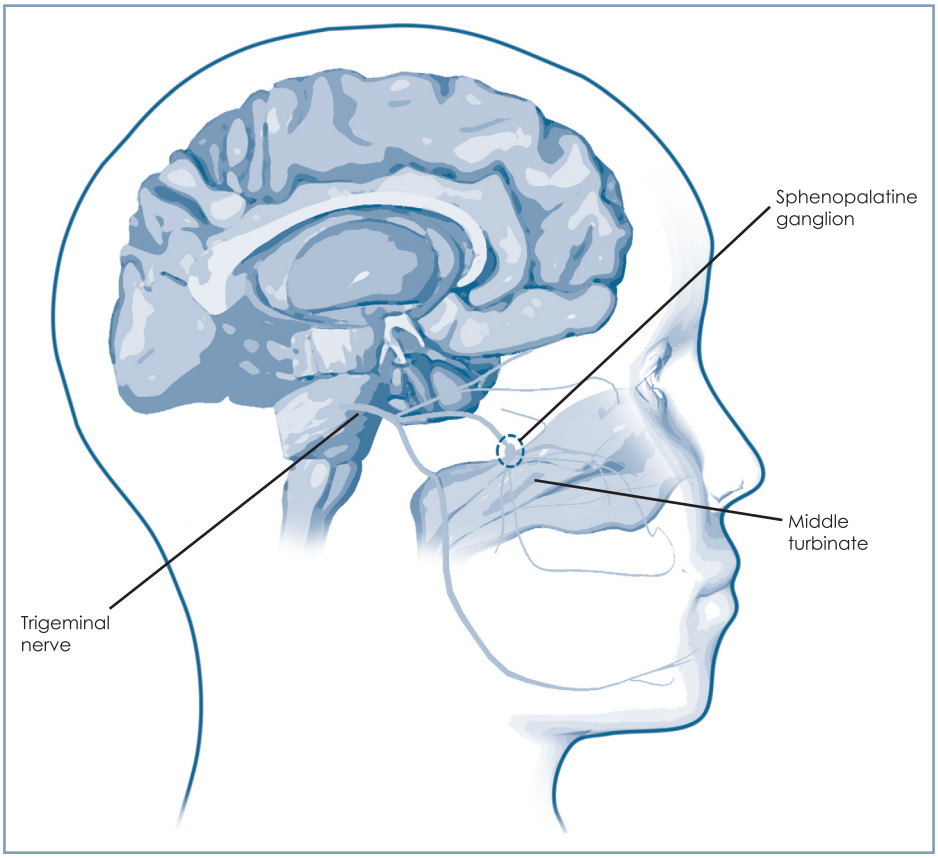

Fig. 30.4 Anatomy of the sphenopalatine ganglion block. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

substituted for blood in epidural patches.[145,215] These solutions were chosen as alternatives to blood owing to relative contraindications to injection of blood. The use of these agents appears to be more common in countries outside North America. In an observational study of 56 patients, Barrios-Alarcon et al.[216] reported that epidural administration of 20 to 30 mL of dextran-40 was safe and effective for the relief of PDPH; all headaches were relieved permanently. The only side effect was a transient discomfort or burning sensation at the time of injection in 6 patients. Some physicians have treated intractable PDPH successfully by performing a dextran-40 patch followed by epidural infusion of dextran at 3 mL/h for 5 to 12 hours.[217,218]

Information on neurotoxicity of these materials is scant; Chanimov et al.[219] did not observe neurotoxicity after infusion of dextran-40 or polygeline, a gelatin powder, into the rat intrathecal space. However, further information is needed before these materials can be widely adopted for epidural administration in humans. From MRI studies in patients with an epidural blood patch, we can anticipate that some dextran will enter the subarachnoid space. The small but definite risk for anaphylaxis after the injection of dextran also must be considered, although the risk appears minimal with dextran-40.

Fibrin sealant patch. Fibrin sealant is composed of fibrinogen and thrombin. Several commercial products are prepared from human pooled plasma. Products may also contain antifibrinolytics, such as animal aprotinin.[220] When injected, these products form a firm, nonretractable fibrin clot. Epidural injection of fibrin glue in rats produces a sustained rise in CSF pressure comparable to the increase that occurs after injection of blood.[221] Fibrin sealant has been evaluated for its effectiveness in preventing dural leaks after spinal surgery.[222] An epidural fibrin glue patch has been used successfully to treat recurrent PDPH,[223] spontaneous intracranial hypotension,[224] and CSF leak after long-term intrathecal catheterization.[225] In the future, fibrin glue may have a role in patients with intractable PDPH, but further study is required before it can be recommended for routine use.

Surgery. There are rare reports of curative surgical closure of a dural rent for intractable PDPH. In one case, the interval between dural puncture and surgery was 5 years.[226]

Summary of Treatment

The parturient with PDPH should be actively managed with scheduled analgesics and should receive psychological support as she cares for her newborn and manages her symptoms. If the headache is severe, the physician can consider additional agents, such as caffeine or SPG block, or proceed directly to an epidural blood patch. Epidural administration of fluids other than blood, such as saline or dextran, typically is not first-line therapy but may be considered if there are contraindications to the epidural injection of autologous blood or if an epidural blood patch procedure fails. The accuracy of PDPH diagnosis

must always be considered when atypical symptoms present or when therapy fails. The Obstetric Anaesthetists' Association and the Association of Anaesthetists of Great Britain and Ireland[227] have recommended that each facility providing obstetric anesthesia services should have an institution-specific protocol for the management of PDPH to facilitate the identification of parturients with this complication and to provide consistent care.

UNANSWERED QUESTIONS

Important information about PDPH is still lacking. A large, detailed prospective study of PDPH and epidural blood patch, with a long follow-up period (e.g., 1 year), is needed in obstetric patients. What are the long-term effects of both PDPH and blood patch therapy? How common are residual back pain, neurologic symptoms, and auditory/visual symptoms, and do they interfere with the activities of daily living? New therapies, including intravenous cosyntropin, epidural morphine, and SPG block have been described, but have not been rigorously studied. Answers to these questions are needed to give our patients reliable information, a sound basis for informed consent, and the best possible care.

KEY POINTS

- Dural puncture is only one of many causes of postpartum headache, although many are quick to blame postpartum headaches on dural puncture. A detailed history and physical examination as well as indicated neuroimaging should ensure diagnostic accuracy.
- A patient with post–dural puncture headache experiences an exacerbation of symptoms when she moves from the horizontal to the upright position, possibly owing to decreased intracranial pressure and secondary cerebral vasodilation, which affect pain-sensitive intracranial structures.
- Anesthesia providers should use a small-gauge (24-gauge or smaller), noncutting (pencil-point) spinal needle whenever possible to decrease the risk for post–dural puncture headache.
- No therapies reliably prevent the development of post–dural puncture headache after unintentional dural puncture with an epidural needle.
- The initial therapy for post–dural puncture headache consists of psychological support and scheduled oral analgesics. Although dehydration should be avoided, no evidence supports a role for vigorous hydration for prophylaxis or therapy for post–dural puncture headache.
- The gold standard therapy for post–dural puncture headache is an autologous epidural blood patch. A second blood patch may be performed—and typically is successful—if the first one fails. If the second procedure fails, alternative diagnoses should be excluded. Other therapies have not proved as safe or as effective as the epidural blood patch for treatment of post–dural puncture headache.

Neurologic Complications of Pregnancy and Neuraxial Anesthesia

Hans Sviggum, MD, Felicity Reynolds, MD, MBBS, FRCA, FRCOG ad eundem

CHAPTER OUTLINE

Neurologic complications of childbirth may be associated with neuraxial analgesia and anesthesia or may result from childbirth itself. Complications of neuraxial anesthesia may be immediate, such as an unexpectedly high block or seizures after unintentional intravenous injection of local anesthetic, or they may be delayed. Immediate complications of neuraxial anesthesia are described in Chapter 23; here the discussion is focused on neurologic sequelae.

Although neurologic disorders after childbirth are more likely to have obstetric than anesthetic causes, neuraxial anesthesia is frequently suspected and often blamed. For example, Tubridy and Redmond[1] described seven women referred with neurologic symptoms after childbirth, all of which had been attributed to epidural analgesia. The women suffered from brachial neuritis, peroneal neuropathy, femoral neuropathy, neck strain, and leg symptoms for which there was no obvious physical cause. In such circumstances, a careful history and neurologic examination, together with diagnostic aids such as electromyography, nerve conduction studies, and imaging techniques, can localize the lesion and differentiate obstetric from anesthetic causes. For example, it should be possible to distinguish by simple clinical means between a mononeuropathy, which is likely to have an obstetric cause, and a radiculopathy, which might result from neuraxial blockade. Accurate and prompt diagnosis is essential to increase the likelihood of the best possible outcome.

THE INCIDENCE OF NEUROLOGIC SEQUELAE

Patients frequently ask obstetricians and anesthesia providers about the incidence of complications of neuraxial anesthesia. However, even if accurate data were available, the question has no true answer. The incidence of neurologic complications varies widely according to local practice and the skill and training of the practitioners. Some older surveys are based on accurate local records, but the data relate to a time when obstetric and anesthetic practices, equipment, and drugs were radically different. The incidence of serious complications is now too low to be estimated accurately on a local basis. Nonetheless, anesthesia providers have a duty to inform patients of the complications associated with a proposed procedure and are expected to give some estimate of the level of risk.

Obstetric Surveys

The reported incidence of neurologic deficits in obstetric patients varies widely depending on the source and the complications that are being measured. Many surveys have attempted to assess the incidence of neurologic complications of neuraxial anesthesia, but these surveys share common limitations, including low response rates, lack of control groups who did not receive neuraxial anesthesia, and inaccurate diagnosis (Box 31.1). Moreover, bias is

BOX 31.1 Limitations of Surveys of Neurologic Sequelae of Neuraxial Anesthesia in Obstetrics

- Poor response rate
- Positive reporting bias
- Absence of controls without neuraxial anesthesia
- Greater attention given to those who received neuraxial anesthesia
- Inadequate investigation and lack of accurate diagnosis
- Variable skill and care of obstetric and anesthetic providers
- Older surveys relate to outdated obstetric and anesthetic practices
- Lack of statistical power to assess incidence of rare disorders
- Inaccurate counting of numerator and denominator
- Likelihood of missing cases that arise after hospital discharge

created when more attention is paid to patients who received neuraxial blockade than to those who did not. Some of the more relevant surveys are listed in Table 31.1.[2–15] Although each survey is distinct in its population, measurements, and reporting, some generalizations can be made. Most of the neurologic complications in these reports were transient, most occurred in patients who labored, and only a very small minority were attributable to neuraxial anesthesia. Peripheral nerve damage was more common than central cord or plexus damage.

One of these reports from Leeds in the United Kingdom involved 3991 women who delivered in one center in a 1-year period.[10] Twenty-one women presenting with symptoms after neuraxial blockade were matched with 21 asymptomatic control patients who had also received neuraxial blockade and 21 additional women who had not. Only one woman who had not had a neuraxial block had symptoms, and she was found to have foot drop after a vacuum extraction. Typical peripheral neuropathies occurred among those who delivered vaginally; sacral numbness was most commonly detected after cesarean delivery. All changes were transient, and none could be attributed to neuraxial anesthesia. Similar neurologic deficits were detected among the randomly selected, asymptomatic 21 control patients who had not undergone an anesthetic intervention. In contrast, negligible deficits could be detected among the 21 asymptomatic control women who *had* undergone an anesthetic intervention. These results demonstrate that minor neurologic deficits are to be found postpartum quite frequently if sought, but only those who have had anesthetic intervention are likely to complain or be questioned.

A prospective survey among 6057 women who delivered in one year in Chicago corroborates the findings of the Leeds study.[10,12] The incidence of lower limb nerve injuries was approximately 1% (24 lateral femoral cutaneous nerve, 22 femoral nerve, 3 peroneal nerve, 3 lumbosacral plexus, 2 sciatic nerve, 3 obturator nerve, and 5 radicular injuries).[12] Significant risk factors identified by logistic regression analysis included nulliparity and a prolonged second stage of labor but *not* neuraxial anesthesia.

A UK national audit of neuraxial blocks, without controls, published in 2009, found that the risk for major complications was 6- to 14-fold higher for perioperative than for obstetric procedures. Among the obstetric patients, the risk was highest for combined spinal-epidural (CSE), intermediate for spinal, and lowest for epidural procedures.[14] Finally, the Serious Complication Repository (SCORE) project sponsored by the Society for Obstetric Anesthesia and Perinatology collected data from 30 institutions and more than 250,000 neuraxial blocks in the United States over a 5-year period (2004 to 2009); the incidence of anesthesia-related nerve injury for obstetric patients was approximately 1 in 35,000 deliveries.[15] Four cases of epidural abscess/meningitis and a single case of epidural hematoma were reported.

Several conclusions can be drawn from these surveys. Despite an increased cesarean delivery rate in the past several decades, obstetric palsies still occur, and the reported frequency of neurologic sequelae depends on how hard one seeks them. The risk for transient mild deficits after childbirth may be quite high.[10,12] A true figure for anesthetic complications cannot be calculated, even from thorough surveys, because (1) the diagnosis is rarely accurate and (2) definitions, severity, and duration are often ill defined. Table 31.1 demonstrates a variation in the incidence of neurologic sequelae from 1 in 3 for mild symptoms with no neuraxial block[10] to 1 in 200,000 for spinal hematoma.[13]

Other Surveys

Modern surveys of neurologic complications of spinal and epidural anesthesia among nonobstetric populations may yield more reliable results but still lack sensitivity to detect all potential problems and are commonly conducted in relatively elderly and sick populations. Auroy et al.,[11] Moen et al.,[13] Cook et al.,[14] and Pitkanen et al.[16] surveyed mixed populations and found a lower incidence of serious sequelae in obstetric than in nonobstetric patients. It is therefore invalid to extrapolate findings from one population to the other. The reported risk for neurologic problems varies greatly with the patient population, local practice and skill, completeness of detection, and inclusion criteria. Hence, it is difficult to put any firm figure on the risk for neurologic complications after neuraxial anesthesia in obstetric patients.

PERIPEHRAL NERVE PALSIES

Postpartum nerve injury is often assumed to be caused by neuraxial anesthesia, but peripheral nerve palsies, which generally have obstetric causes,[17] are much more common than anesthesia-related injury, with a reported incidence between 0.6 and 92 per 10,000.[18] They may arise from compression in the pelvis by the fetal head, or from more distal compression, the signs of which may be overlooked in the presence of neuraxial anesthesia. Proposed risk factors for postpartum neuropathies include a prolonged second stage of labor,

TABLE 31.1 Surveys of Neurologic Complications of Childbirth and of Neuraxial Blocks in Obstetrics

Study	Type of Study	Population	Number of Neurologic Deficits (Risk Ratio)
Ong et al., 1987[2]	Medical record review of all patients, interview of those receiving anesthesia in one center (1975–1983)	23,827 deliveries	45, all transient (1/530)
		12,964 inhalational or no analgesia	5 (1/2593)
		9403 epidural procedures	34 (1/277)
		1460 general anesthetics and other	6 (1/243)
Scott and Hibbard, 1990[3]	Retrospective multicenter review (1982–1986), no control group	505,000 epidural procedures	47 (1/10,745)
			1 anterior spinal artery syndrome
			1 epidural abscess, 1 epidural hematoma (unconfirmed)
			38 mononeuropathies, 5 cranial nerve palsies
			1 subdural hematoma
MacArthur et al., 1992[4]	Questionnaire sent in 1987 to mothers delivering in one center (1978–1985)	11,701 women (39%) who responded	Tingling/paresthesias
		4766 epidural procedures	143 upper limb, 23 lower limb
		6935 no epidural procedures	150 upper limb, 3 lower limb
Palot et al., 1994[5]	Questionnaire listing possible complications sent to hospitals with obstetric beds (1988–1993), no control group	288,351 epidural procedures	92 (1/3134)
			1 cranial subdural hematoma
			88 temporary radiculopathy (1/3277)
			3 meningitis (1/96,117) (also reported negligence cases: 1 sciatic nerve palsy, 1 intracranial hematoma)
Scott and Tunstall, 1995[6]	Prospective multicenter review (1990–1991), no control group	467,491 deliveries	46 neuropathies (details for procedures not given)
		108,133 epidural procedures	38 (1/2846)
		14,856 spinal procedures	8 (1/1857)
Holdcroft et al., 1995[7]	Regional community and hospital-based trawl (1991–1992)	48,066 deliveries	10 new neurologic complications (1/4807)
		34,430 no neuraxial block	1 foot drop, 1 cervical nerve lesion (1/17,215)
		13,007 epidural procedures	1 paresthesia of nerve root distribution (1/13,007) (Disorders unrelated to anesthesia: 2 cranial nerve palsies, 1 hypotensive cord damage; 5 peripheral nerve lesions)
		629 spinal procedures	0
Paech et al., 1998[8]	Prospective local audit (1989–1994), no control group	10,995 epidural procedures	1 traumatic "mononeuropathy" (1/10,995)
Holloway et al., 2000[9]	Retrospective multicenter trawl, elastic time frame, no control group	29,698 spinal procedures	4 unrelated to anesthesia (3 meralgia paresthetica, 1 peroneal neuropathy), 10 ?root damage, 1 conus damage, 22 uncertain (overall incidence ?1/986)
		12,254 CSE procedures	5 unrelated to anesthesia (1 femoral neuropathy, 2 foot drop, 2 paresthesia), 6 root damage, 1 meningitis, 1 conus damage, 6 uncertain (overall incidence ?1/901)
Dar et al., 2002[10]	Prospective local audit of immediate symptoms (1998–1999)	1376 vaginal deliveries without anesthesia (random sample of 21 examined + 1 complaint)	4 peripheral neuropathy, 1 foot drop, 2 vague (1/3)
		2615 regional blocks (all followed up)	21 had neurologic symptoms
		1782 vaginal deliveries	7 peripheral neuropathies, 1 foot drop, 3 vague (1/162)
		833 cesarean deliveries	8 numb areas, 2 vague (1/83)

TABLE 31.1 Surveys of Neurologic Complications of Childbirth and of Neuraxial Blocks in Obstetrics—cont'd

Study	Type of Study	Population	Number of Neurologic Deficits (Risk Ratio)
Auroy et al., 2002[11]	Prospective multicenter survey, no control group	29,732 epidural procedures	0
		5640 spinal procedures	2 "peripheral neuropathy"
Moen et al., 2004[13]	National postal survey and search of administrative files (1990–1999), no control group	205,000 epidural procedures	1 epidural hematoma (HELLP), 1 epidural abscess, 2 cord damage, 2 intracranial subdural hematoma, 1 abducent nerve palsy (1/29,286)
		50,000 spinal procedures	1 spinal hematoma (HELLP), 1 cord damage (1/25,000)
Wong et al., 2003[12]	Prospective 1-year survey (1997–1998) at a single institution	5603 laboring patients (72% with neuraxial blocks) and 454 nonlaboring patients	66 nerve injuries (63 in laboring, 3 in nonlaboring). Lateral femoral cutaneous nerve (24) and femoral nerve (22) injuries most common
Cook et al., 2009[14]	National audit of major complications of neuraxial blockade over 1 year (unstated), obstetric and nonobstetric, no control group	329,425 obstetric procedures	1 epidural abscess, 2 nerve injury, 1 unknown
		161,550 epidural procedures	Possible harm per 100,000 (95% CI), 0.6 (0–3.4)
		133,525 spinal procedures	Possible harm per 100,000 (95% CI), 1.5 (1–5.4)
		25,350 CSE procedures	Possible harm per 100,000 (95% CI), 3.9 (1–22)
D'Angelo et al., 2014[15]	Prospective multicenter survey (2004–2009)	307,495 deliveries	27 cases of serious neurologic injury (1/11,389); 7 related to anesthesia (1/35,923), 1 epidural hematoma, 4 epidural abscess/meningitis
		131,460 epidural procedures	
		35,369 spinal procedures	
		84,634 CSE procedures

difficult instrumental delivery, nulliparity, and prolonged use of the lithotomy position.[18]

Reference to the distribution of spinal dermatomes and peripheral nerve sensory innervation demonstrates the distinction between peripheral and central lesions (Fig. 31.1). Central lesions are most often bilateral, create weakness or paralysis from the site of the lesion distally, are often associated with autonomic dysfunction, and may be associated with upper motor neuron signs such as spasticity, brisk reflexes, and bowel and bladder dysfunction. In contrast, peripheral nerve lesions are typically unilateral, with weakness or paralysis limited to a single muscle or muscle group that the peripheral nerve innervates. Peripheral injuries create sensory deficits in the distribution of the specific nerve, while central lesions typically involve multiple dermatomes with a defined sensory level. Spinal nerve root lesions are also manifested by weakness that involves several lower extremity joints and movements (Fig. 31.2). Obstetric peripheral nerve injuries include compression of the lumbosacral trunk and palsies of the obturator, femoral, lateral femoral cutaneous, sciatic, and peroneal nerves.

Compression of the Lumbosacral Trunk

Compression of the lumbosacral trunk by the fetal head at the pelvic brim (Fig. 31.3) preferentially affects the more medial fibers that make up the peroneal rather than the tibial nerve.[18] In addition to weakness that predominantly affects ankle dorsiflexion (foot drop), compression of the lumbosacral trunk produces sensory disturbance mainly involving the L5 dermatome (see Fig. 31.1). This palsy most often results from cephalopelvic disproportion and is therefore typically seen after prolonged labor and difficult vaginal delivery.[8–10,12]

Obturator Nerve Palsy

The obturator nerve is susceptible to compressive injury as it crosses the brim of the pelvis and within the obturator canal (see Fig. 31.3). The mother may complain of pain when the damage occurs, followed by weakness of hip adduction and internal rotation, with sensory disturbance over the medial thigh (see Fig. 31.1). She may have an abnormal gait secondary to weakness of thigh adduction. Cases are reported after both labor and cesarean delivery[19,20]; three of 66 new nerve injuries detected in a prospective study by Wong et al.[12] were obturator nerve injuries. The most likely cause of obturator nerve palsy is compression of the nerve between the pelvis and fetal head or forceps applied to the fetal head.

Femoral Nerve Palsy

The femoral nerve does not enter the true pelvis and is therefore not vulnerable to compression by the fetal head but rather is vulnerable to stretch injury as it passes beneath the inguinal ligament. The femoral nerve may be injured

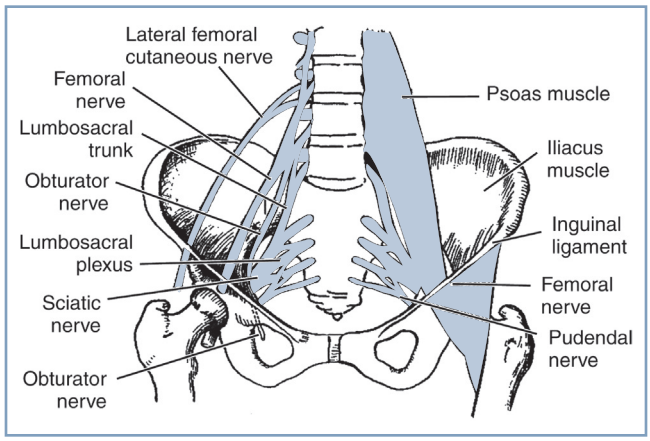

Fig. 31.3 The principal nerves in the pelvis. The lumbosacral trunk (L4 to L5) and obturator nerve (L2 to L4) are vulnerable to pressure as they cross the pelvic brim, particularly in cases of cephalopelvic disproportion. The femoral (L2 to L4) and lateral femoral cutaneous (L2 to L3) nerves are particularly vulnerable in the lithotomy position, where they pass beneath the inguinal ligament. (Modified from Cole JT. Maternal obstetric paralysis. *Am J Obstet Gynecol.* 1946;52:374.)

proximal to or at the inguinal ligament. Proximal injuries are associated with weakness of hip flexion, whereas more distal injuries spare the motor supply to the iliopsoas muscle. The patient with a femoral neuropathy may walk satisfactorily on a level surface but may be unable to climb stairs; the patellar reflex is diminished or absent. Although the incidence of femoral nerve palsy has decreased as a result of changes in obstetric management (e.g., fewer deliveries with prolonged second stage), it is still one of the most common obstetric nerve injuries. Approximately one-third of the postpartum palsies detected by Wong et al.[12] were femoral nerve palsies. Dar et al.[10] detected five cases in their small population, although the symptoms were transient. Damage may result from prolonged flexion, abduction, and external rotation of the hips during the second stage of labor and also during procedures conducted in an excessive lithotomy position.[21] The hips should therefore never remain continuously flexed during the second stage of labor.

Meralgia Paresthetica

Meralgia paresthetica is a neuropathy of the lateral femoral cutaneous nerve, a purely sensory nerve also known as the lateral cutaneous nerve of the thigh. First described more than 100 years ago, meralgia paresthetica is commonly encountered in pregnancy and childbirth.[10,12] It is the most common nerve injury of pregnancy.[12] The palsy may arise both during pregnancy, typically at about 30 weeks' gestation, and intrapartum, in association with increasing intra-abdominal pressure.[12,22] The distribution is unlike that of a nerve root lesion (see Fig. 31.1), yet the disturbance is commonly misattributed to neuraxial blockade. Meralgia paresthetica manifests as numbness, tingling, burning, or other paresthesias affecting the anterolateral aspect of the thigh. The most likely cause is entrapment of the nerve as it passes around the anterior superior iliac spine beneath or through

the inguinal ligament, where its vulnerability is increased by a gravid uterus or by retractors used during pelvic surgery. The compressive effect of edema may also contribute. The condition can be expected to resolve after childbirth.

Sciatic Nerve Palsy

Sciatic nerve palsy arises from compression of the nerve, usually in the buttock. It is not commonly mentioned in surveys or generally recognized as a complication of childbirth, possibly because it is mistaken for a lesion of the lumbosacral trunk. It gives rise to loss of sensation below the knee with sparing of the medial leg, and loss of movement below the knee. Posterior cutaneous nerve and gluteal function are preserved, implying damage distal to the lumbosacral plexus, where the gluteal nerves branch off the sciatic nerve (Fig. 31.4). Three cases out of 66 new nerve injuries were detected by Wong et al.[12] It has occurred during childbirth with neuraxial blockade, either from sitting in one position too long[23] or from a hip wedge misplaced during cesarean delivery.[23–25] It has also been reported after iliac artery balloon placement for cesarean delivery in a woman with placenta percreta.[26]

Peroneal Nerve Palsy

The common peroneal nerve is vulnerable to compression as it passes around the head of the fibula below the knee. It is also susceptible to damage while it still forms part of the sciatic nerve as it leaves the pelvis. When the peroneal nerve is damaged at the knee, there is sensory impairment on the anterolateral calf and the dorsum of the foot. Foot drop may be profound, with steppage gait and weak ankle eversion, but plantar flexion and inversion at the ankle are preserved. Peroneal nerve palsy may be caused by prolonged squatting,[27] sometimes popular in "natural childbirth," by excessive knee flexion for any reason, by compression of the lateral side of the knee against any hard object, even the patient's hand,[28] and by prolonged use of the lithotomy position. The incidence of peroneal nerve palsy is lower than that of lateral femoral cutaneous and femoral nerve palsy.[12]

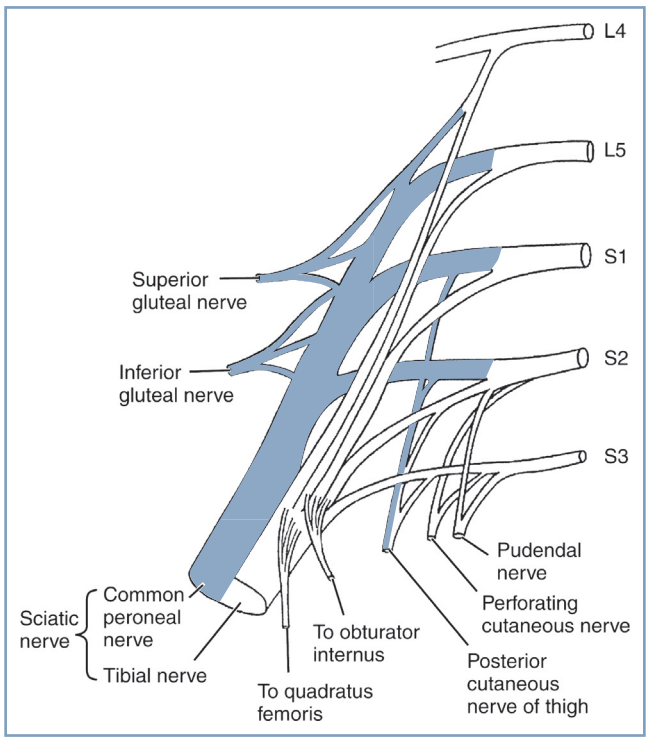

Fig. 31.4 The sacral plexus. The dorsal divisions of the anterior primary rami are shaded. (From Silva M, Mallinson C, Reynolds F. Sciatic nerve palsy following childbirth. *Anaesthesia.* 1996;51:1144–1148.)

Compression as a Risk Factor for Peripheral Neuropathy

During pregnancy, nerve compression caused by edema may be a factor in the genesis of several peripheral neuropathies, such as carpal tunnel syndrome, Bell's palsy, and meralgia paresthetica.[22,29,30] Neuraxial blockade may indirectly contribute to compression injuries because it may decrease the ability of a woman to perceive that her legs are in a position that contributes to compression-induced neuropathy. Practices that providers should observe to lessen the risk for compression-induced neuropathy are listed in Box 31.2.

POSTPARTUM BLADDER DYSFUNCTION

There are several mechanisms by which bladder function may be disturbed postpartum (Fig. 31.5). In theory, neuraxial blockade (1) may provoke the need for bladder catheterization with increased risk for infection, (2) may allow bladder distention to go undetected, and (3) on very rare occasions, may be associated with cauda equina syndrome (see later discussion). However, several postpartum studies of bladder function have found no association with neuraxial analgesia[31,32] or only a weak correlation between epidural analgesia and an increased residual volume immediately postpartum.[33] In contrast, a prolonged second stage of labor, instrumental delivery, and perineal damage have been identified as significant factors for postpartum bladder dysfunction.[31,33] No association has been found between epidural analgesia and stress incontinence or urinary frequency.[6,34]

BOX 31.2 Safeguards to Minimize Peripheral Nerve Compression

- Be mindful of patient positioning that could contribute to nerve compression, particularly with neuraxial blockade.
- Avoid prolonged use of the lithotomy position; regularly reduce hip flexion and abduction.
- Avoid prolonged positioning that may cause compression of the sciatic or peroneal nerve.
- Place the hip wedge under the bony pelvis rather than the buttock.
- Use low-dose local anesthetic/opioid combinations during labor to allow maximum mobility.
- Encourage the parturient to change position regularly.
- Ensure that those caring for women receiving low-dose local anesthetic/opioid combinations understand that numbness or weakness may be signs of nerve compression; such symptoms should prompt an immediate change of position.

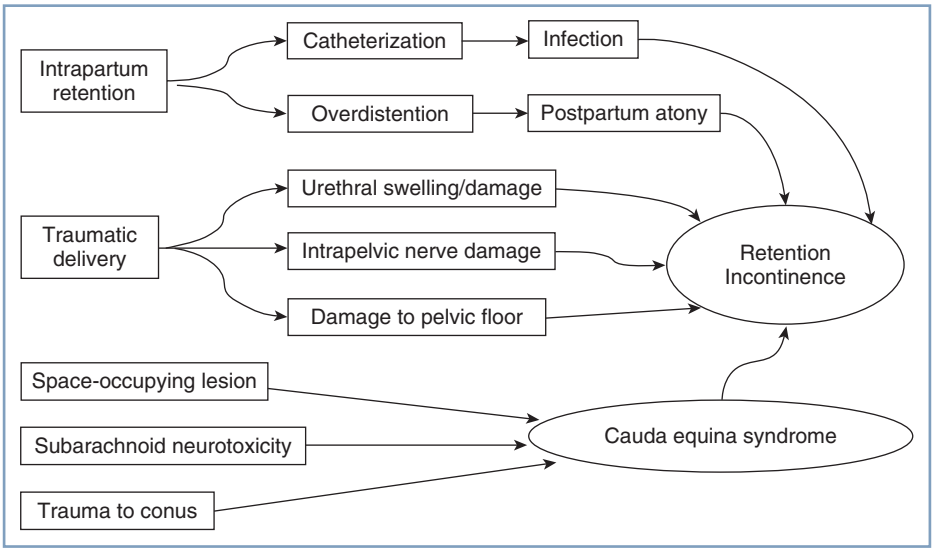

Fig. 31.5 Mechanisms by which bladder function may be disturbed after parturition.

CENTRAL NERVOUS SYSTEM LESIONS

Lesions of the central nervous system (CNS) after childbirth have complex causes (Fig. 31.6), and may be classified as traumatic (to nervous tissue, meninges, or blood vessels), infectious, ischemic, or chemical (to nervous tissue or meninges). Anesthesia providers should bear in mind that even central lesions may have causes other than neuraxial block, for example a prolapsed intervertebral disc. Apart from sequelae of dural puncture, serious iatrogenic complications related to neuraxial analgesia and anesthesia are remarkably rare.

Neurologic Sequelae of Dural Puncture

The subject of post–dural puncture headache is discussed in detail in Chapter 30. Other neurologic sequelae of dural puncture include meningitis (see later discussion), cranial nerve palsies, and subdural hematoma. These often present as headache but are distinct from disorders that should be included in the differential diagnosis for postpartum headache, including tension/stress and migraine headaches, cortical vein and venous sinus thrombosis, preeclampsia, hypertensive encephalopathy, intracerebral or subarachnoid hemorrhage, internal carotid artery dissection, and posterior reversible encephalopathy syndrome. It can be difficult to distinguish post–dural puncture headache from other serious causes of headache because signs and symptoms overlap.

Cranial Nerve Palsy

Major loss of cerebrospinal fluid (CSF), usually following unintentional dural puncture with a large-bore needle, may cause a number of cranial nerve palsies; those affecting cranial nerves VI, VII, and VIII are the most frequently reported.[35–41] Because of its long course within the cranium, the abducens nerve (VI) is the most vulnerable. All cranial nerve palsies require prompt PDPH treatment (e.g., epidural blood patch), but even after the blood patch recovery may be delayed. In the case of cranial nerve VIII dysfunction, tinnitus may not resolve.[40,41] Trigeminal nerve dysfunction is usually a transient effect of high neuraxial blockade, but trigeminal and facial nerve palsies have also been reported in relation to post–dural puncture headache and subdural hematoma.[42]

Cranial Subdural Hematoma

More seriously, reduced CSF pressure may cause rupture of bridge meningeal veins and result in cranial subdural hematoma, a rare but potentially fatal condition.[43] Palot et al.[5] identified one case in 288,351 obstetric epidural procedures. In 2000, Loo et al.[17] identified eight cases in their systematic review of published cases of neurologic complications in obstetric regional anesthesia. Although commonly believed to result only from dural puncture with a large-bore needle or a cutting spinal needle, subdural hematoma requiring craniotomy has been reported after puncture with a small-gauge, pencil-point spinal needle[44] and after an unintentional dural puncture that had been appropriately treated with an epidural blood patch.[45] A thorough review of 56 cases of subdural hematoma in obstetric patients who received neuraxial blocks (34 epidural, 20 spinal, 2 CSE) published in 2016 showed that predisposing risk factors such as coagulation disorders, aneurysms or arteriovenous malformations, or head trauma were present in only a minority of patients.[46] Persistent headache was present in more than 80% of cases, and focal neurologic signs were present in nearly 70%. Whenever headache persists after treatment with an epidural blood patch (particularly if the headache is accompanied by altered consciousness, seizures, or other focal neurologic findings), magnetic resonance imaging (MRI) is warranted to exclude subdural hematoma, which may be fatal without urgent surgery.

Trauma to Nerve Roots and the Spinal Cord

Insertion of a spinal needle or epidural catheter may be accompanied by paresthesia that is sometimes painful. However, such a paresthesia is neither sensitive nor specific

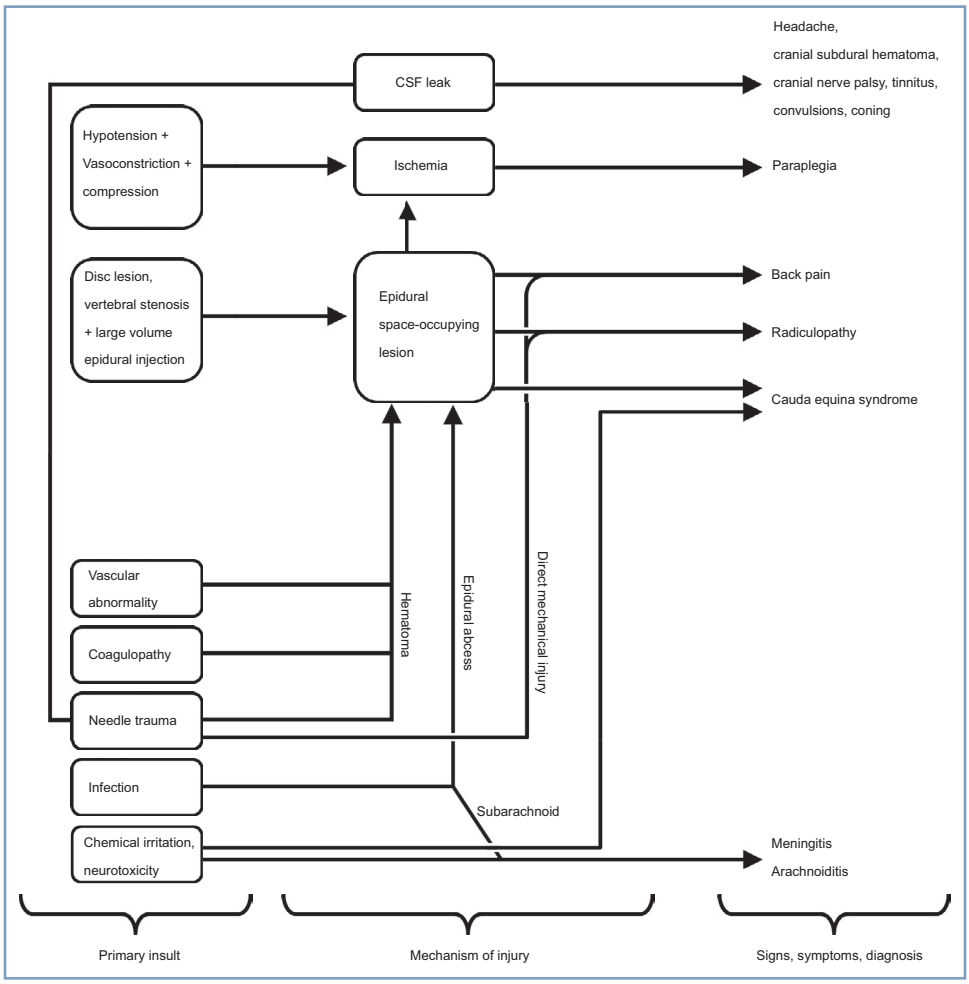

Fig. 31.6 Mechanisms by which lesions of the central nervous system may arise in parturients. *CSF,* Cerebrospinal fluid.

for nerve injury.[47] If a paresthesia is encountered, advancement of the needle or catheter should be halted. It is generally deemed appropriate to then continue spinal or epidural catheter placement after the paresthesia subsides. Continued paresthesias should prompt removal and redirection of the needle. Although a flexible catheter is unlikely to do lasting damage to a nerve root in the epidural space, nerve roots in the subarachnoid space are more vulnerable.

Trauma Associated with Attempted Epidural Catheter Insertion

An epidural catheter may injure nerve roots either because it is inappropriately rigid[48] or because an undue length is advanced and ensnares a root.[49] A catheter seemingly advanced into the epidural space may lodge in an intervertebral foramen or even pass into the paravertebral space. In rare instances, the epidural catheter and the artery of Adamkiewicz share the same foramen. If the epidural catheter is stiff enough to compress the artery within the unyielding foramen, the blood supply to the spinal cord may be impaired. This is a possible cause of anterior spinal artery syndrome. Clinical reports indicate that the condition resolves rapidly and completely if the catheter is withdrawn before permanent damage has occurred.[50,51]

Injury to the spinal cord may result from attempted identification of the epidural space in the presence of a tethered spinal cord[52] or as a result of unintentional dural puncture at a higher-than-anticipated interspace (see later discussion). Patients with spina bifida occulta may safely undergo both epidural and spinal anesthesia as the spinal cord is rarely tethered in true spina bifida occulta (see Chapter 47). However, if there is concern for occult spinal dysmorphism, which is more frequently associated with a tethered cord, it is prudent to obtain a lumbar MRI before initiating a neuraxial procedure.[53] Insertion of an epidural catheter in an anesthetized patient increases the risk for spinal cord damage, and catastrophic injury may occur with injection of fluid into the substance of the spinal cord.[54]

Trauma Associated with Spinal Anesthesia

Insertion of a spinal needle below the level of the spinal cord sometimes causes brief radiating pain or paresthesia, which may be associated with persistent paresthesia in the same dermatomal distribution. Prolonged symptoms involving more than one spinal segment suggest damage to the spinal cord itself. Damage to the terminal portion of the cord (the conus medullaris) without intracord injection has also been reported in healthy conscious parturients receiving spinal or

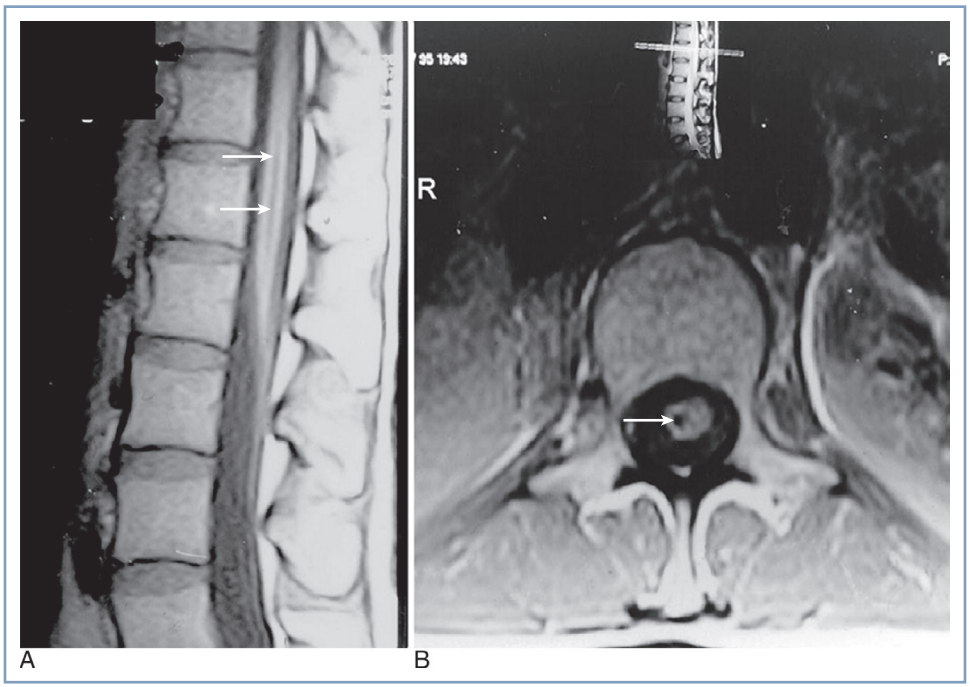

Fig. 31.7 (A and B) Magnetic resonance images of a conus medullaris lesion *(arrows)*. (From Reynolds F. Damage to the conus medullaris following spinal anaesthesia. *Anaesthesia.* 2001;56:238–247.)

CSE anesthesia using a pencil-point needle.[9,13,55,56] Typically, the patient complains of pain on needle insertion before any fluid is injected, often followed by the normal appearance of CSF from the needle hub, easy injection of the local anesthetic agent, and a normal onset of neural blockade. On recovery, there is unilateral numbness, which is succeeded by pain and paresthesia in the L5 to S1 distribution and foot drop, and in some cases urinary symptoms; sensory symptoms may last for months or years. The MRI appearance is one of a small syrinx or hematoma within the conus on the same side as the pain on insertion and subsequent leg symptoms (Fig. 31.7).[56] In the majority of cases, the anesthesia provider believed the interspace selected was L2–L3. In one patient who subsequently died of other causes, hematomyelia was confirmed at autopsy.[57] After a rash of cases of conus damage in the 1990s, the practice of spinal needle insertion may have been modified by aware providers, but an abnormally long cord may still be damaged with the best of techniques.[58]

These injuries may have occurred for the following reasons:

- Identification of lumbar interspaces was far from accurate. Studies showed that it was common to select a space that is higher than assumed by one, two, or even more segments (Fig. 31.8).[59,60]
- Although the spinal cord typically ends level with the lower body of L1 or the L1–L2 interspace, the length varies (Fig. 31.9).[61] From the L1–L2 interspace, the needle tip can easily reach the conus in 27% of men and 43% of women.[61,62]
- The standard method of identifying lumbar interspaces involves the use of Tuffier's line, the imaginary line joining the two iliac crests. This method can be inaccurate, however, particularly in obese or pregnant women (Fig. 31.10). Moreover, even when accurately assessed, Tuffier's line is an inconstant landmark.[63] Although typically at the level of the L4 spinous process, it may lie anywhere between the L3–L4 and L5–S1 interspaces.
- Pencil-point spinal needles must be advanced further than cutting needles before the orifice is within the subarachnoid space, at which point the tip may impinge on the spinal cord.

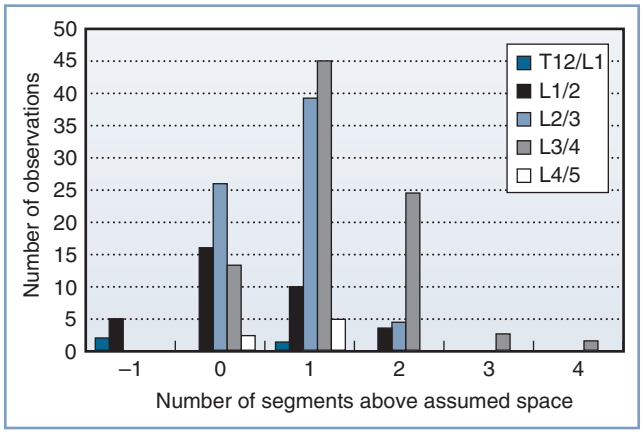

Fig. 31.8 Identification of lumbar interspaces by Oxford anesthetists. The horizontal axis shows the position of the actual interspace identified on magnetic resonance imaging, relative to the assumed space, in 200 observations. (Data from Broadbent CR, Maxwell WB, Ferrie R, et al. Ability of anaesthetists to identify a marked lumbar interspace. *Anaesthesia.* 2000;55:1122–1126.)

Given the inaccuracy of identification of lumbar interspaces and the variability of the position of the conus, it is

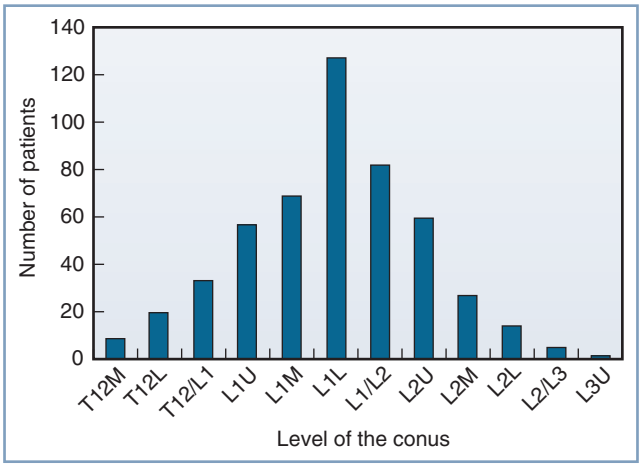

Fig. 31.9 Variation in the level of the tip of the conus medullaris assessed by magnetic resonance imaging of the lumbar spine among 504 consecutive adults. *L,* lower third of vertebral body listed; *M,* middle third of vertebral body listed; *T12/L1,* interspace between T12 and L1; *U,* upper third of vertebral body listed. (Data derived from Saifuddin A, Burnett SJ, White J. The variation of position of the conus medullaris in an adult population: a magnetic resonance imaging study. *Spine.* 1998;23:1452–1456.)

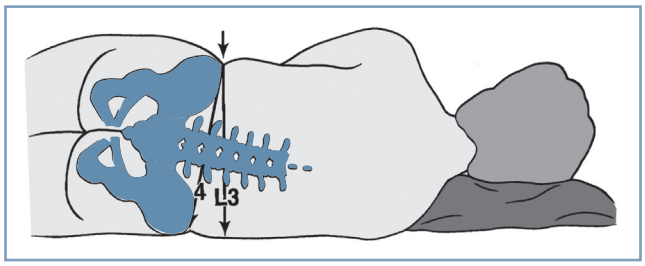

Fig. 31.10 Error that may arise if Tuffier's line is judged in a pregnant patient in the lateral position, when a line is drawn perpendicularly from the upper iliac crest rather than through both iliac crests. In pregnant patients at term, the hips may have a greater width than the shoulders. The resulting cephalad pelvic tilt may lead to an error in the cephalad direction.

both logical and prudent to insert a spinal needle into a lower lumbar interspace. Box 31.3 summarizes the problems and precautions in identifying lumbar interspaces and avoiding damage to the conus medullaris. In cases in which there is doubt about the level of lumbar interspace for injection, ultrasound guidance may be useful in accurately identifying the correct interspace.[64]

Catheters advanced into the intrathecal space theoretically would seem to place patients at risk for traumatic nerve injury. However, a retrospective study of 761 short-term intrathecal catheters placed over a 12-year period found no neurologic or serious complications.[65] Transient paresthesias with catheter placement into the intrathecal space have been reported; whether long-term consequences occur is not known.[66]

Space-Occupying Lesions of the Vertebral Canal

Space-occupying lesions of the vertebral canal include intraspinal hematoma (epidural or subdural), epidural abscess, and intraspinal tumors, any of which, within the rigid confines of the bony spinal canal, can cause dangerous compression of nervous tissue and its blood supply. Urgent laminectomy is required to avoid permanent neurologic damage. Delayed recognition and treatment (more than 6 to 12 hours after onset of symptoms) may have a catastrophic outcome.

Epidural analgesia in labor does not normally behave like a space-occupying lesion and produces no lasting deformation of the thecal sac on MRI.[67] Nevertheless, in the presence of vertebral stenosis or lumbar disc protrusion, a large volume injected into the epidural space may tip the balance and produce signs of nervous tissue compression that normally resolve in a few hours.[68,69]

The neurologic deficit that may arise from a compressive lesion depends on the vertebral level; lower thoracic lesions are associated with leg weakness or paraplegia, and lumbar lesions with cauda equina syndrome, including urinary retention and incontinence. Back pain (often radiating to the legs) is a common feature.

BOX 31.3 Points to Remember to Reduce Risk for Damage to the Conus Medullaris during Spinal Anesthesia

- The conus medullaris reaches L2 in 27% of men but in 43% of women.
- Tuffier's line is not in a constant position relative to the spine.
- The interspace chosen is usually higher than supposed.
- The spinal needle should be inserted into a lower lumbar level.
- Advancement of the spinal needle should be halted immediately, and the stylet removed to check for CSF, if entry of the needle tip into the subarachnoid space is suspected.
- The procedure should be abandoned if the patient is unable to cooperate.

Neuraxial Hematoma

Neuraxial hematoma is fortunately very rare, and even rarer in pregnant patients than in the general population. During pregnancy and the peripartum period, spontaneous neuraxial hematoma is reported more frequently than hematoma associated with neuraxial blockade. Loo et al.[17] reported three cases in 2000, which may have been included in another review,[70] and more have been reported in the past two decades.[71–75] Epidural hematoma in pregnancy associated with coagulopathy but not neuraxial anesthesia has also been reported.[76,77]

Epidural Hematoma after Neuraxial Blockade

Incidence. Epidural hematoma after neuraxial blockade typically causes neurologic deficit in elderly patients with arterial disease; it is very rare in obstetric patients, despite the engorgement and possible fragility of epidural veins. Ten surveys, covering 1,462,631 obstetric epidural procedures, identified three cases (see Table 31.1), two without

confirmatory details[3,15] and the other in a patient with HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome.[13] This gives an incidence of 0.205 per 100,000 epidural procedures.

Causation. Risk factors identified from comprehensive reviews of case reports include (1) difficult or traumatic epidural needle/catheter placement, (2) coagulopathy or therapeutic anticoagulation, (3) spinal deformity, and (4) spinal tumor.[17,78,79] Antiplatelet therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) does not appear to be associated with an increased risk for hematoma after neuraxial anesthesia.[80]

Of the five cases of epidural hematoma in obstetric patients identified by Loo et al.,[17] four were without details and the other was associated with coagulopathy. In the most recent analysis from the American Society of Anesthesiologists' (ASA) Closed-Claims Project database,[81] there were four cases of epidural hematoma, of which only one had coagulopathy; again, other details were not provided. The SCORE project reported a single case of epidural hematoma in more than 215,000 epidural and CSE procedures; again, details were not provided.[15] Two further case reports are of interest. An eclamptic patient with thrombocytopenia suffered a persistent lower limb deficit after a traumatic epidural catheter insertion using the loss-of-resistance-to-air technique.[82] Laminectomy revealed multiple bubbles and a 4-mL blood clot, the exact site of which was not stated. Such a small volume could have caused neurologic deficit only if it was subdural rather than epidural. In another case, an epidural hematoma was reported presenting 9 days after removal of an epidural catheter that had been sited and used uneventfully for labor analgesia.[83] Apparently the only risk factor was a traumatic insertion. The coagulation assessment was normal, but the hematoma was extensive and required decompressive surgery. It is possible that this was a spontaneous hematoma and neuraxial analgesia was coincidental.

Both vessel damage and coagulopathy (whether inherited, acquired, or caused by anticoagulation) are usually necessary to produce a hematoma large enough to cause a neurologic deficit in the parturient. Safe epidural catheter insertion in coagulopathic parturients has often been recorded, but the frequency of vessel trauma is rarely mentioned.[84–86] Although vessel trauma can occur during removal of the epidural catheter, intuitively there is likely to be a higher chance for vessel trauma with needle placement and catheter insertion. In a series of 4365 nonobstetric patients receiving warfarin anticoagulation, epidural catheters were removed with a mean INR (international normalized ratio) of 1.9 (range of 1.5 to 7.1) without any observed epidural hematomas.[87] The increasing number of women receiving pharmacologic thromboprophylaxis in the peripartum period has important implications for anesthesiologists. Although there is obvious concern that these patients may be at increased risk for bleeding complications, a systematic review published in 2017 revealed no cases of spinal-epidural hematoma associated with neuraxial anesthesia and thromboprophylaxis with unfractionated or low-molecular-weight heparin in obstetric patients.[88] Caring for obstetric patients receiving anticoagulation requires a thoughtful weighing of risks and benefits before deciding to proceed with a neuraxial anesthetic technique.

Protective factors. Some epidural hematomas may occur that are too small to cause neurologic deficit. One factor may be the hypercoagulable status of parturients. Another is the ease with which a large volume of anticoagulated blood may flow out of the unrestricting intervertebral foramina in young patients. Injected blood is known to disappear from the epidural space rapidly in the parturient.[67,89] During performance of an epidural blood patch, 20 mL of blood is commonly injected with impunity. Although compressive symptoms may be experienced with a volume larger than 20 mL, they do not normally presage any neurologic deficit in obstetric patients.

Subdural and subarachnoid hematoma. Spinal subdural hematoma has been reported in obstetric patients, one in association with an ependymoma,[17] one after spinal anesthesia and an epidural blood patch,[90] and another in a woman with preeclampsia, known vessel puncture during epidural catheter insertion, and mild coagulopathy.[91] A subarachnoid hematoma after spinal anesthesia was reported in a patient with HELLP syndrome.[92] A fourth report described a healthy woman who suffered major subarachnoid hematoma after apparently straightforward CSE anesthesia.[93] All four patients developed cauda equina syndrome, and laminectomy was required in three.

Dural puncture (with or without arachnoid puncture) is a prerequisite for subdural and subarachnoid hematoma. However, coagulopathy may *not* be a prerequisite, because the extravasated blood is confined in a small space in which even a small volume may compress adjacent nerve roots.

Prevention, diagnosis, and management. It is clearly important to assess the coagulation status in an at-risk parturient before initiating a neuraxial procedure, and possibly when removing the epidural catheter as well. If neuraxial blockade is found to have been conducted in the presence of risk factors for spinal hematoma, it is a responsibility of the anesthesia provider to examine the lower extremities after delivery, to confirm and document the return of normal motor and sensory function, and to request subsequent regular checks by the nursing staff, typically for 24 hours. Severe back pain and a significant delay in normal recovery or deterioration of lower extremity or bladder function signal the need for emergency imaging of the spine. If intraspinal compression is confirmed by MRI, a neurosurgical opinion must be urgently sought.

Neuraxial anesthesia in the presence of coagulopathy and anticoagulant treatment are discussed in Chapters 38 and 44.

Infection

Neuraxial infection (epidural abscess and meningitis) was identified as the most common cause of neuraxial injury in obstetric cases in the ASA Closed-Claims Project database between 1980 and 1999.[94] Infections that have been reported include epidural abscess, paraspinal and other epidural-related infection, and meningitis.

Epidural Abscess

Frequency. Epidural abscess may occur spontaneously in pregnancy and the puerperium as at other times.[17,95] An analysis of 915 reports of spinal-epidural abscess published between 1954 and 1997 found that epidural blockade had been performed in only 5.5% of cases.[96] After neuraxial blockade, epidural abscess, like neuraxial hematoma, appears to be rare in obstetric patients. Seven cases were found among 1,462,631 epidural procedures listed in ten surveys summarized in Table 31.1, a frequency of 0.479 per 100,000. The incidence among general surgical patients has been reported as 10-fold[13] to 100-fold[97] higher, with most cases arising in elderly and immunocompromised patients. A 4-year Australian study of 9482 obstetric patients who underwent childbirth in a center where correct sterile procedures were used found 49 epidural catheter–related infections (0.52%): 45 superficial, 2 epidural, and 2 paraspinal, giving an epidural infection rate of 21 per 100,000,[98] which was 100-fold higher than the calculated frequency from larger, but potentially less sensitive, surveys.

Multiple case reports of epidural abscess after epidural analgesia in obstetric patients illustrate that even when the principal risk factors of prolonged catheterization, suboptimal aseptic technique, and traumatic insertion are avoided, epidural abscess still may occur.[99–106] A comprehensive review of epidural abscess cases after neuraxial anesthesia details that all cases occurred after epidural catheterization, with three following CSE anesthesia; none followed spinal anesthesia alone.[107]

Possible risk factors identified from these cases are summarized in Table 31.2. An epidural abscess typically follows prolonged epidural catheterization, usually between 1 and 4 days in obstetric cases. Other possible etiologic factors are traumatic or difficult insertion of the catheter,[100,102] and diabetes or immunosuppression from any cause.[97,104] Inflammation at the epidural catheter entry point may presage epidural space infection.[98,100,103] In light of these reports, it may be prudent to avoid prolonged epidural catheterization in the patient with other risk factors for infection.

Clinical presentation. In contrast to epidural hematoma, symptoms of epidural abscess are more insidious.[108] Severe backache (with local tenderness) and fever, with or without radiating or root pain, are the presenting features. The catheter entry point may be inflamed with some fluid leak, and a hematology screen typically reveals leukocytosis and increased C-reactive protein. Fever, neck stiffness, headache, and signs of inflammation serve to differentiate epidural abscess from hematoma. These signs and symptoms should prompt MRI, which may allow early diagnosis before the onset of neurologic changes (Fig. 31.11).[109] If untreated, symptoms may progress to leg weakness, paresthesias, bladder dysfunction, and other evidence of cauda equina syndrome. Blood culture may identify the organism before or without surgical drainage.

Etiology. *Staphylococcus aureus* is the most common causative organism in cases of epidural abscess, with the occasional infection with *Streptococcus* and *Pseudomonas* species. The skin appears to be the most likely source of infection.[17]

The skin is commonly colonized by *Staphylococcus epidermidis* and other weakly pathogenic bacteria and occasionally by *Staphylococcus aureus.* The highest concentration of colonies is found in the hair follicles,[110] where organisms may be protected from poorly applied disinfectants. Infectious organisms from the skin can reach deeper tissue planes via the needle track or an implanted epidural catheter to create a localized abscess in the paraspinal or epidural space. Despite all aseptic precautions, some level of detectable bacterial colonization of the epidural catheter is very common, but robust host defenses normally prevent infection. When defenses are weak and infection containment breaks down, epidural abscess formation begins.

Management. As with spinal hematoma, once neurologic signs are present, early diagnosis with prompt laminectomy is essential to recovery. In the presence of mild symptoms without neurologic changes, successful conservative treatment with antibiotics[101] and successful percutaneous needle drainage[111] of epidural abscesses have also been reported, although only laminectomy can ensure that all loculations are

TABLE 31.2 Possible Etiologic Factors for Epidural Abscess and Meningitis

	Epidural Abscess	Meningitis
Entry point	Through the epidural catheter or along its track	Via dural puncture
Usual causative organism	*Staphylococcus aureus*	*Streptococcus salivarius*
Possible source of infection	Patient's skin, tracking along the catheter entry point Epidural equipment contaminated by operator's skin Body fluids in the bed Injectate without racemic local anesthetic	Operator's mouth Talking without a mask Blood borne Vagina
Risk factors	Prolonged catheterization Poor aseptic technique Multiple attempts at insertion, traumatic insertion No bacterial filter Lying in a wet, contaminated bed Polyurethane occlusive dressing Immunocompromise: corticosteroids, diabetes, acquired immunodeficiency syndrome	Dural puncture Labor No face mask Manual removal of the placenta Vaginal infection Bacteremia Immunocompromise

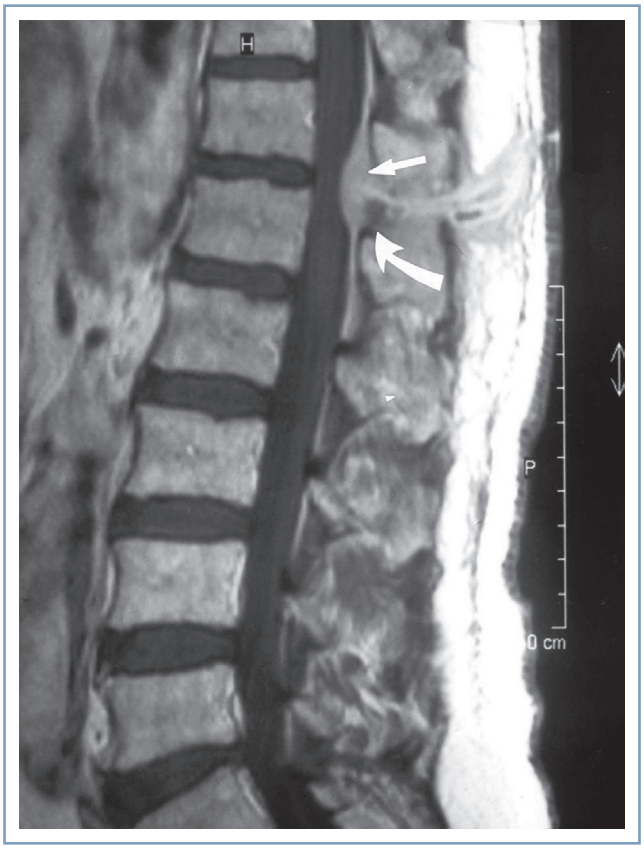

Fig. 31.11 Epidural abscess. Mid-sagittal T1-weighted magnetic resonance image of the lumbar and lower thoracic region, after intravenous gadolinium DTPA. Note the dorsal epidural mass located at T12–L1 *(arrows),* convex anteriorly but not compressing the conus. Normal epidural fat is flat anteriorly. drained under direct vision. Prompt identification of the infectious organism(s) and directed antibiotic therapy are mandatory. The duration of antibiotic therapy should be determined on a case-by-case basis, but is usually 4 to 6 weeks if there are no complications.

Other Epidural-Related Infections

Paraspinal abscess and osteomyelitis after epidural analgesia[112,113] and discitis after spinal blockade[114] have been reported in obstetric patients. Catheter-site inflammation is relatively common with prolonged postoperative epidural analgesia.[98,115] One report described both a subdural abscess after CSE anesthesia and infection in the subcutaneous tissues after an apparently misplaced epidural blood patch.[116]

A variety of organisms have been associated with epidural-related infections.[107] All such conditions are associated with back pain and signs of inflammation and pose a threat of spread to the epidural space. Moreover, paraspinal abscess may itself cause neurologic deficit.[117]

Meningitis

Although not consistently included in surveys, post–spinal meningitis has become a cause for concern[118] and is a serious neurologic complication of neuraxial labor analgesia. It was suspected in two cases in the prospective survey of 108,133 epidural procedures and 14,865 spinal anesthetic procedures by Scott and Tunstall,[6] although the specific type of anesthesia was not stated. Palot et al.[5] reported three cases of meningitis among 288,351 obstetric epidural procedures but did not state whether they followed dural puncture. One case was identified in a survey of spinal and CSE anesthesia (1/42,000 procedures).[9] A 2008 review found an incidence derived from surveys of spinal and CSE anesthesia in obstetrics of 1 in 39,000.[107] Table 31.3 summarizes 54 published reports of post–spinal meningitis in obstetric patients.[118–145]

Causative organisms. Community-acquired meningitis may occur in pregnancy as at other times. It is commonly caused by *Neisseria meningitidis, Streptococcus pneumoniae,* or *Haemophilus influenzae,* while occasional cases caused by tuberculosis, several β-hemolytic streptococci, and viruses are also reported in pregnancy. Post–spinal meningitis, by contrast, is most commonly caused by streptococci of the viridans type (α-hemolytic streptococci such as *S. salivarius, S. sanguis,* and *S. uberis*) (see Table 31.3). These organisms are found in the upper airway and the vagina. *Pseudomonas* meningitis has also been reported.[122] Neither *Pseudomonas* nor α-hemolytic streptococci are normally virulent; they do not, for example, cause wound infection, but they thrive in a watery medium and flourish if introduced into CSF. In several early cases (before the use of the polymerase chain reaction), no organisms were grown on culture and chemical meningitis was diagnosed. In most cases, however, there were features of bacterial meningitis, including low CSF glucose concentration. Of note, streptococci of the viridans type do not grow readily in conventional culture media and may well have been present but not detected.

Risk factors. Dural puncture is probably a prerequisite for iatrogenic meningitis. A retrospective review of surgical patients in one hospital in Brazil found three cases among 38,128 patients receiving spinal anesthesia (1/12,709) and none among 12,822 patients receiving other types of anesthesia.[146] Among 73 women with β-hemolytic streptococcal infections in the puerperium identified in a survey from Iowa,[147] the only woman who suffered meningitis had received spinal anesthesia. In normal circumstances, the blood-brain barrier (the endothelial lining of the capillaries, which are continuous with tight junctions and no pinocytotic vesicles) protects the CNS against weakly pathogenic bacteria. The dura mater should not be confused with the blood-brain barrier, but dural puncture is commonly associated with vascular trauma,[148] which allows blood to enter the CSF.

Of the 54 published cases of puerperal post–spinal meningitis for which details are available (see Table 31.3), 48 occurred after known dural puncture. Among the six cases that followed apparently uncomplicated epidural analgesia, one was viral and may have been a chance event,[141] one was probably an epidural abscess,[142] and two were blood borne from vaginal infection caused by group B streptococcus.[143,144] Uncomplicated epidural catheterization itself is unlikely to

increase the risk for puerperal meningitis. Although spinal analgesia is used less commonly than epidural analgesia during labor, case reports of meningitis after spinal analgesia far outnumber those after epidural analgesia. A causative relationship between epidural catheterization and meningitis after vaginal delivery may be attributed to unrecognized dural puncture, which may occur during multiple attempts at epidural catheter insertion or even with apparently uncomplicated catheter insertion.

Labor may also be a risk factor for meningitis. The great majority of parturients with nosocomial meningitis had labored (see Table 31.3). Meningitis appears surprisingly rare

after elective cesarean delivery, despite the extensive use of spinal anesthesia in this context.

The possible reasons why meningitis is reported more commonly in laboring women than among those undergoing elective cesarean delivery are as follows:

1. The vagina may be colonized by streptococci, and vaginal delivery is commonly followed by mild bacteremia. Thus labor, with its potential for vaginal trauma, is clearly an important risk factor. Unlike vaginal delivery, elective cesarean delivery is not normally associated with streptococcal bacteremia.
2. For elective cesarean delivery, spinal anesthesia is administered in the operating room, which is a cleaner environment than the labor and delivery room.
3. The anesthesia provider is more likely to wear a face mask in the operating room.
4. The nonlaboring patient is not thrashing about in a (possibly) contaminated bed.
5. An antibiotic is usually administered immediately before or after cesarean delivery.

Infection at a remote site may also be a risk factor for meningitis. Bacteremia has been detected in approximately 8% of women with chorioamnionitis,[149] although two small studies found no evidence of spinal infection among 12 women with bacteremia who received epidural blockade without antibiotic treatment.[150,151] Although such negative findings are reassuring, they are not conclusive and do not apply to spinal anesthesia. Human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) should not be regarded as contraindications to neuraxial analgesia, in view of the early presence of the virus within the CNS.[152] Performing an epidural blood patch in the presence of bacteremia is also a theoretical risk for both meningitis and abscess, but neither has been reported in this context. Neuraxial analgesia in the presence of maternal fever is discussed in detail in Chapter 36.

Other risk factors for meningitis include faulty technique, in particular failure to wear a mask (see later discussion). Manual removal of the placenta is a postulated risk factor for meningitis, and one such case has been reported,[134] although given the popularity of spinal anesthesia for this indication, one would perhaps expect a higher frequency. It may be postulated that use of the CSE technique, with the presence of a foreign body next to a dural hole, may increase the risk for meningitis.

Clinical presentation and management. Fever, headache, photophobia, nausea, vomiting, and neck stiffness are typical symptoms of meningitis; when they are accompanied by confusion, drowsiness, and Kernig's sign (inability to straighten the knee when the hip is flexed), meningitis should be strongly suspected. The onset of nosocomial meningitis may be 12 hours to a few days after delivery. Diagnostic lumbar puncture (best avoided in the presence of raised intracranial pressure or suspicion of epidural abscess) shows increased CSF pressure, increases in CSF protein level and white blood cell count (mainly polymorphonuclear leukocytes in patients with bacterial meningitis), and a CSF glucose concentration that is lower than that in the blood. Because of the nature of the *S. viridans* group, culture on plates rather than in broth may have negative results, particularly if antibiotics have been given.[118] Treatment with an appropriate antibiotic should not await the microbiology results and should result in full recovery.[17] Vancomycin and third-generation cephalosporins have been recommended as first-line treatment.[146] The treatment regimen should be adjusted according to results of culture and sensitivity testing.

Prevention of Intraspinal Infection after Neuraxial Anesthesia

Measures to prevent intraspinal infection are summarized in Box 31.4. Means of preventing meningitis and epidural abscess are not identical, because abscess usually follows epidural catheterization and is commonly caused by *S. aureus,* which enters via the skin, whereas meningitis classically follows dural puncture, is caused by vaginal or nasal organisms, may be blood borne, and is usually caused by streptococcus and never by *S. aureus.*

Because adverse outcomes are rare, the use of sterile precautions can rarely be supported by evidence from randomized trials. The components of good sterile technique should be guided by common sense and the best available indirect evidence. It is notable that in many case reports of neuraxial infection, sterile precautions used in initiating neuraxial blockade receive no mention.

A practice advisory published in 2017 by the ASA Task Force on Infectious Complications Associated with Neuraxial Techniques[153] concerns prevention, diagnosis, and management of infectious complications. Certain key aspects are discussed here.

Mask. Several surveys indicate widespread disregard of surgical masks for infection control during neuraxial block administration.[146,154,155] Among case reports of nosocomial

BOX 31.4 Procedures to Decrease the Risk for Infection after Neuraxial Anesthesia

- Wear an effective mask; wear a new mask for each patient.
- Remove hand jewelry and watches, and wash hands with an alcohol-based scrub solution.
- Consider wearing a sterile gown.
- Use sterile gloves in correct manner.
- Apply chlorhexidine-in-alcohol solution to the patient's skin, following the package instructions, and allow the skin to dry after application.
- Make sure the back is securely draped.
- Avoid contaminating any equipment that is used in the procedure, and minimize touching parts of the equipment that will enter the patient.
- After the procedure, apply a suitable dressing to the catheter entry point.
- Bacterial filters may be considered during extended continuous epidural infusion.
- Remove the epidural catheter shortly after delivery unless there are specific indications for not doing so.

meningitis, a mask was not mentioned[121,134,140-142] or was not worn ("as it is of doubtful value"[127] or because it "contributes little to prevent infection during spinal or epidural anesthesia,"[124] or is not considered part of "full aseptic technique"[143]).

Confusion has arisen because randomized trials have demonstrated that omission of masks in the operating room does not increase the occurrence of wound infection.[156] This is not surprising, however, because organisms from the upper airway do not cause wound infection, but they certainly do cause nosocomial meningitis. The effect of wearing a mask in the prevention of such rare complications cannot readily be ascertained by a randomized controlled trial. Nevertheless, the obvious value of masks in reducing the dispersion of bacteria from the mouth and nose has been well demonstrated.[157,158] A mask is an essential part of aseptic precautions that should be taken for neuraxial needle and catheter insertion.[118,153]

Sterile gown. Although undeniably part of "full aseptic precautions" employed by surgeons, a sterile gown is rarely worn for spinal needle placement. For insertion of an epidural catheter, a gown is commonly worn in the United Kingdom, although rarely in the United States. The value of wearing a gown is not supported by evidence, but some postulate that wearing one may be safer than not doing so.

Sterilizing the skin. Evidence from laboratory and clinical studies show that chlorhexidine in 70% alcohol consistently outperforms povidone-iodine for skin disinfection.[110,115,159] The concentration of chlorhexidine used varies from 0.5% to 2%. It is superior in speed of onset and duration of action and is less likely to provoke a skin reaction. Unlike povidone-iodine, it is effective in the presence of blood or pus, it stays sterile in the container, and bacterial resistance to it is unlikely.[107] Alcohol provides the rapid onset, and chlorhexidine provides the longer duration of action.

Concerns have been raised about its neurotoxicity. Both chlorhexidine and iodine have been shown to damage neuronal cells during *in vitro* experiments.[160] Neither chlorhexidine nor iodine is licensed for skin sterilization before neuraxial block administration. Although there are a few case reports of adhesive arachnoiditis in which chlorhexidine was suspected as a possible cause, the only clinical study performed supports its safety for use before spinal anesthesia.[161] Additionally, the risk for infection usually outweighs that for neurotoxicity, and the superiority of chlorhexidine as an antiseptic should be paramount. It is appropriate, nevertheless, to take precautions, such as using the lowest effective concentration available and not allowing the solution to come into contact with solutions or equipment that will enter the patient's neuraxis. Use of a single application "swab stick" overcomes this concern; if such an applicator is not used, the aqueous chlorhexidine container must be removed from the immediate area before equipment for neuraxial insertion is deployed. Adequate drying time should be allowed after application of the antiseptic solution to the skin.[153]

Maintaining sterility of the epidural catheter, its contents, and the entry point. The entry point of the epidural catheter clearly needs to be protected from contamination by a suitable dressing.[162] For prolonged analgesia, racemic bupivacaine may be safer than an opioid alone or the pure L-isomers of local anesthetics, which are more likely to permit bacterial growth in the solution.[107] Although it would seem logical, there is no evidence to support or discourage the use of a bacterial filter during a short-term (1 to 2 days) epidural infusion.[162] Prolonged catheterization is best avoided after dural puncture, whether unintentional or deliberate, and when sepsis or immunocompromise is present or suspected.

Vascular Disorders

Ischemic Injury to the Spinal Cord

Ischemic injury to the spinal cord is typically seen in elderly patients after epidural or spinal anesthesia, or after general anesthesia with accompanying hypotension. It is rare in the obstetric population, in whom arterial disease is unusual and hypotension is treated aggressively.

The blood supply to the spinal cord depends on a single anterior spinal artery and bilateral posterior spinal arteries. The arteries arise from the circle of Willis and receive reinforcements during their descent in the spinal canal. The posterior spinal arteries receive regular contributions from radicular arteries, but the single anterior spinal artery, which supplies the anterior two-thirds of the spinal cord, receives only sporadic reinforcement. Anterior spinal artery syndrome, which may result from arterial compression or hypotension, is characterized by a predominantly motor deficit, with or without loss of pain and temperature sensation, but with sparing of vibration and joint sensations, which are transmitted in the posterior columns. The condition has been reported among obstetric patients with particular risk factors (see later discussion).[3,17,163] In one report[164] a parous woman received epidural analgesia with lidocaine, then bupivacaine with epinephrine, followed by 2-chloroprocaine when she required urgent cesarean delivery. Hypotension caused by blood loss from a placenta previa and a ruptured uterus was followed by typical irreversible anterior spinal artery syndrome. The use of epinephrine may have contributed to the adverse outcome in this case.

Chemical Injury

Many substances, primarily drugs, have been injected in error in the neuraxial canal. In a review covering the years 1950 to 2014, 29 case reports of drug errors during obstetric neuraxial procedures were identified. Drugs injected in error included ephedrine, magnesium sulfate, antibiotics, labetalol, ondansetron, and tranexamic acid, among others.[165]

The Epidural Space

The epidural space is remarkably tolerant of foreign and potentially neurotoxic substances because of two protective factors. First, vascular uptake and outward flow via the intervertebral foramina remove a large proportion of solutions deposited in the epidural space. Second, nerve roots within the epidural space are protected by a cuff of dura

and arachnoid as well as pia mater. Severe neuraxial damage occurs only when these defenses are overwhelmed either by gross overdose or if there is unintentional contamination of the subarachnoid space. There are many case reports of unintentional epidural injection of the wrong substance, including the following:

1. **Vasopressors (ephedrine and metaraminol).** Epidural administration resulted in severe hypertension.[166]
2. **Potassium chloride.** At least four well-documented cases have been reported.[167,168] All patients had profound motor and sensory block with pain or depolarizing spasms. Only one, who received the largest epidural dose (15 mL of 11.25% KCl), remained permanently paraplegic.[168]
3. **Other potentially noxious substances.** Administration of an unknown substance, possibly paraldehyde, given in error as an epidural bolus injection during labor, resulted in permanent painful quadriplegia and the largest monetary award for damages in the United Kingdom at that time.[169] Additionally, the inadvertent administration of a large volume of chlorhexidine resulted in severe adhesive arachnoiditis.[170] Unintentional misconnections of intravenous and epidural infusion systems have led to large-volume epidural infusions of potentially harmful substances, including total parenteral nutrition solutions with a high osmolality[171] and ranitidine in a phenol-containing solution.[172] Fortunately, in most cases of this type of drug error, neurologic sequelae have not been reported.

With these few exceptions, the epidural space appears to be tolerant of most inadvertent administrations. Nevertheless, the possibility of occult dural puncture means that unintentional administration of a potentially neurotoxic substance (e.g., traces of alcohol, antioxidant, or preservative) may migrate into the subarachnoid space. Vigilance and systems to avoid these errors are mandatory.

The Subarachnoid Space

The subarachnoid space, with its poorly protected nerve roots and direct communication with intracranial structures, presents a greater risk than the epidural space for adverse outcome after unintentional injection of toxic substances. Intrathecal potassium can be lethal.[173] A 2015 review of neuraxial drug administration errors[165] identified four reports of intrathecal injection of tranexamic acid (all caused by misidentification of the drug ampule). All four cases were fatal; the patients ultimately died from refractory ventricular tachycardia and fibrillation.

Nerve roots within the subarachnoid space are highly vulnerable to chemical damage, particularly the sacral roots, which are poorly myelinated. Irritant solutions may cause neurotoxicity and arachnoiditis. Neurotoxicity may manifest as **cauda equina syndrome** or, if more extensive, as paraplegia or quadriplegia. For example, in 1937, 14 cases of severe cauda equina syndrome were reported after spinal anesthesia using a solution called "heavy duracaine," a mixture (in 15% ethanol) of procaine, glycerin, and gliadin or gum acacia, which presumably was added in an attempt to prolong the action of procaine.[174] In the 1940s and 1950s in the United Kingdom, spinal injection of 10 mL of hypo-osmolar dibucaine was associated with paraplegia, but whether the paraplegia resulted from disturbance of the intrathecal milieu or contamination with phenol is argued.

More recently, there were numerous reports of cauda equina syndrome after intrathecal injection of lidocaine (all types of administration, both intended and unintended, most commonly hyperbaric 5%)[175–177] and occasionally after intrathecal administration of other local anesthetics.[178,179] None of these cases involved obstetric patients. In all cases, other causes of neurologic deficit (trauma, ischemia, infection, compression, contamination, and adverse positioning) were excluded. An upper safe dose limit for intrathecal lidocaine of 60 mg[176,180] has been recommended. More concerning, cauda equina syndrome has also been reported after CSE anesthesia with spinal levobupivacaine for cesarean delivery.[181] Postpartum MRI showed contrast enhancement in the cauda equina fibers concordant with arachnoiditis; the patient made a complete recovery after 8 weeks of rehabilitation therapy. A similar presentation has also been reported after CSE anesthesia with hyperbaric bupivacaine for cesarean delivery.[182] The various risk factors for neurotoxic damage are summarized in Box 31.5.

Conus damage and cauda equina syndrome may appear similar—back pain, leg weakness and numbness, and/or bowel and bladder dysfunction. Although conus damage may involve upper motor neuron signs, these are not always present, and both conditions may have unilateral or bilateral features.[56] However, the causation is different. Whereas conus damage may result from ischemia or trauma, cauda equina syndrome typically results from either compression or chemical damage within the lumbar spinal canal.

Transient Neurologic Syndrome

Transient neurologic syndrome (also called transient radicular irritation) is not associated with any detectable neurologic deficit, but the distribution of pain in the back, buttocks, and thighs mirrors the distribution of nerve damage in cauda equina syndrome sufficiently to support the theory

BOX 31.5 Risk Factors for Chemical Damage to the Cauda Equina

- Poor spread of local anesthetic
  - Block failure, followed by repeat injection
  - Fine-gauge or pencil-point needle
  - Microspinal catheter
  - Continuous infusion
  - Hyperbaric solution
  - Lithotomy position
- Unintentional intrathecal injection of a large volume intended for the epidural space
- Incorrect formulation, with unsuitable preservative or antioxidant
- Intrathecal injection of lidocaine, particularly 5% (possibly also tetracaine or dibucaine)

that the nerves are indeed irritated by a noxious intrathecal injection. Like cauda equina syndrome, it follows spinal anesthesia, most commonly with lidocaine. Moreover, other risk factors for cauda equina syndrome and transient neurologic syndrome are similar (see Box 31.5), although transient neurologic syndrome may be less dependent on lidocaine dose or the presence of a vasoconstrictor.[183] Transient neurologic syndrome occurs more than four times more frequently with spinal lidocaine than with other local anesthetics.[184] It is, however, much more common in surgical than obstetric patients, with a median frequency, according to one review, of 22%.[183] Parturients are not exempt from transient neurologic symptoms, with reported frequencies of 0%,[185] 4.2%,[186] 5.3%,[187] and 8.9%.[188]

Arachnoiditis

Arachnoiditis is a disastrous condition, usually with a delayed onset of permanent quadriplegia. It is extremely rare and has not been detected in any surveys of neurologic sequelae of obstetric neuraxial blockade. Among parturients, chronic adhesive arachnoiditis of chemical origin has arisen after unintentional intrathecal injection of a large dose of 2-chloroprocaine with antioxidant and preservative intended for the epidural space,[189] while seven cases have been reported after epidural analgesia for childbirth with 2% lidocaine, probably with preservative.[190] Six cases were reported among Italian surgical patients after apparently standard epidural anesthesia with bupivacaine and/or mepivacaine, usually with epinephrine.[191] The local anesthetic agents, however, were obtained from multidose vials containing parabens as preservative, and the glass syringes used for loss-of-resistance identification of the epidural space had been washed in detergent. With earlier publications, it is not always possible to distinguish the cause of arachnoiditis, but it seemed to appear in clusters, suggesting that there may have been shortcomings in anesthetic technique. In a more recent case, a woman suffered severe arachnoiditis after spinal anesthesia for elective cesarean delivery.[192] Her skin had been cleaned with iodine and then chlorhexidine in alcohol and allowed to dry. It was unclear whether the tray containing antiseptic solutions was removed before the rest of the procedure. Because of pain during attempted insertion of the spinal needle, the skin was infiltrated at least three times with lidocaine before intrathecal bupivacaine was given. Shortly thereafter, she became disturbed and experienced a severe headache, so she was given general anesthesia for the operation. Postpartum she developed obstructive hydrocephalus and extensive adhesive arachnoiditis. The judge determined that, on balance of probabilities, there must have been contact in some way between the chlorhexidine and the local anesthetic solution.

Vulnerable Patients

Various conditions may render some women more vulnerable than normal to neurologic injury precipitated by neuraxial anesthesia. The following discussion of conditions is not exhaustive.

Vertebral Abnormality

Skeletal abnormalities involving the spine, including congenital anomaly, trauma, and back surgery, can make epidural or spinal needle insertion difficult. Patients with spinal dysraphism are at risk for accidental dural puncture and nerve root damage unless the needle is inserted above the defect (see Chapter 47). Those with tethered cord syndrome are at risk for cord damage if the spinal or epidural needle is inserted at a vertebral level that would normally be expected to be below the conus.[52] Occasionally, a low-lying conus may be present without any premonitory signs.[58] Pressure from spinal stenosis or prolapsed intervertebral disc, coupled with a large-volume epidural injection, may result in spinal cord compression and neurologic deficit.[69]

Vascular Abnormalities

Vascular disease and malformation are risk factors for spinal cord ischemia, hematoma, and compression. The major supply to the lumbar enlargement of the spinal cord is the artery of Adamkiewicz, a unilateral structure that typically arises from the lower thoracic or upper lumbar portion of the aorta between T9 and L2. Compression of this single vessel may therefore jeopardize the blood supply to the lower cord in susceptible individuals. In 15% of individuals, a secondary blood supply to the spinal cord that ascends from the internal iliac arteries[193] assumes a major role. These ascending arteries lie close to the lumbosacral trunk and are, in theory, vulnerable to pressure from the fetal head or damage by obstetric instrumentation, thus causing conus ischemia.

A neuraxial arteriovenous malformation is an obvious cause for concern for the obstetric anesthesia provider.[194] Small arterial feeders from a segmental intercostal artery supply dilated serpiginous epidural veins that may extend over many segments of the spinal canal.[195] The resulting hemangioma raises the pressure on epidural veins and reduces spinal cord blood flow. Oxygen delivery to local tissues is reduced, and the risk for spinal hematoma or ischemic damage and compression is increased. Pregnancy and epidural analgesia have been known to precipitate paraplegia in previously asymptomatic patients[196,197]; aortocaval compression, a large blood volume, and a large epidural injection (which may cause severe pain) all increase epidural pressure.

The preanesthesia examination should include inspection of the back for cutaneous angiomas or macular areas of skin discoloration, which may suggest the presence of an underlying spinal angioma at the same segmental level. Because spinal cord capillary flow is compromised in the drainage area of an arteriovenous malformation, systemic arterial pressure should be kept close to normal throughout the peripartum period, regardless of anesthetic technique.

Spinal Tumor

Epidural blockade has been reported to precipitate neurologic symptoms in the presence of previously undiagnosed spinal tumors. Spinal tumors also predispose to spinal hematoma after neuraxial blockade,[17] and epidural analgesia may precipitate extreme pain.[198]

Coagulopathy or Anticoagulation

The risk associated with neuraxial procedures in patients with a preexisting coagulopathy or anticoagulation therapy is discussed earlier in this chapter and in Chapters 38 and 44.

Immunocompromise. Most cases of epidural infection that have been reported in surveys involve elderly patients with immunocompromise.[13,97] It is advisable to avoid prolonged epidural catheterization in immunocompromised patients, although prophylactic antibiotic therapy is not warranted.

Preexisting neurologic disorder. Patients with hereditary neuropathy with liability to pressure palsy are particularly sensitive to compression neuropathy during the course of labor and delivery.[199]

It is postulated that patients with preexisting peripheral neuropathies may be more susceptible to nerve injury when exposed to a second insult, the so-called *double crush phenomenon.*[200] To explore whether neuraxial anesthesia represented such an insult, Hebl et al.[200] reviewed the medical records of 567 patients with peripheral neuropathies who had spinal or epidural blockade, including 12 obstetric patients. There were two instances of worsening neurologic status, both in elderly diabetic patients. There were no control patients, but clearly, if there is a risk that neuraxial anesthesia will exacerbate a neuropathy, it is very small. The exception may be patients with **spinal stenosis.** Reports of worsening neurologic status after spinal anesthesia should cause providers to think carefully before initiating neuraxial blockade in patients with known spinal stenosis.[201] Fortunately, spinal stenosis is rare in the obstetric population.

Relapse rates in patients with multiple sclerosis are increased in the postpartum period, and the fear is that neuraxial blockade will be blamed (see Chapter 48).[202] Epidural rather than spinal anesthesia has traditionally been recommended in patients with multiple sclerosis because the concentration of local anesthetic in the white matter of the spinal cord is less after epidural than after spinal injection, and exposing demyelinated spinal cord to local anesthetics could theoretically worsen disease.[203] However, although many providers are reluctant to perform spinal anesthesia in patients with multiple sclerosis, there is no good evidence that it will worsen the neurologic conditions in these patients.[204] In fact, the most recent study showed no new or worsening symptoms in 35 patients with multiple sclerosis undergoing a variety of surgical procedures.[205] Similarly, no association between worsening multiple sclerosis symptoms and any form of neuraxial anesthesia was found in a study cohort limited to obstetric patients.[203] It is clearly important to document neurologic status and to discuss relapse rates with the mother before and after any anesthetic intervention, but patients can be reassured that no type of anesthesia has been shown to increase postpartum relapse risk or negatively influence long-term disease progression.

Diabetes. Diabetic patients are vulnerable to neurologic injury for three reasons. They are susceptible to infection, they may have vascular disease, and they may have a peripheral neuropathy. Diabetic spinal artery syndrome has also been described in diabetic parturients,[163] and worsening neuropathy has been observed in diabetic surgical patients.[200] Patients with gestational diabetes alone are unlikely to have developed chronic vascular or neurologic sequelae that would place them at high risk for neurologic injury.

RISK MANAGEMENT AND FOLLOW-UP

High-risk women should be referred to the obstetric anesthesia clinic during pregnancy, so that an anesthesia provider can obtain a thorough history, examine the patient, organize consultations or imaging studies as needed, and discuss and plan the anesthetic strategy with the patient and her obstetric providers. The recommended points to explore during the history and physical examination are summarized in Boxes 31.6 and 31.7.

BOX 31.6 Topics to Explore in the Preanesthesia History

- Allergies, medications, and use of recreational drugs
- Diabetes or cardiovascular disorder
- Previous spinal or epidural anesthetics (what was the outcome?)
- Preexisting neurologic signs or symptoms (e.g., sciatica, leg weakness)
- Skeletal abnormality or back surgery
- Anticoagulant medication or easy bleeding/bruising
- Possibility of immunocompromise

BOX 31.7 Preanesthesia Neurologic Examination

- If there is a question of neurologic disorder, examine the lower limbs:
  - Sensation to pinprick or ice, and vibration sense using a tuning fork
  - Knee and ankle tendon reflexes and Babinski reflex
  - Motor power of hips, knees, and ankles
- Examine the back for:
  - Signs of infection (pustules to be avoided)
  - Nevi suggestive of arteriovenous malformation
  - Midline hair tuft or fat pad, suggesting dysraphism (e.g., spina bifida occulta)
  - Scoliosis
  - If the spine looks technically difficult, as in severe scoliosis, is there an easily palpable sacral hiatus as an alternative to the lumbar epidural space?
  - Range of motion and maneuvers that might aggravate radicular pain
- Look for signs of bleeding tendency
- Document:
  - The history and physical examination
  - Abnormalities and treatment decisions
  - Differences of opinion
  - The reasons the anesthetic is administered despite a relative contraindication

In addition to minimizing risk by adopting good and safe practices, vigilance must be extended postpartum to detect, diagnose, and treat any disorders that may arise. It is important that those caring for women in the puerperium are taught to look for signs of neurologic pathology and that the women themselves, once home, are taught to recognize symptoms that might be attributable to anesthetic complications, and to contact an anesthesia provider if they experience them.

Diagnosis of Possible Neurologic Injury

Through clinical examination coupled with knowledge of basic neuroanatomy outlined in this chapter, it should be possible to distinguish peripheral from central lesions. Preanesthesia history (see Box 31.6) and physical examination (see Box 31.7) may reveal some helpful clues, and any preexisting signs or deficits documented in the record will narrow the search or even provide an immediate answer. The history and physical examination are integral to establishing associations between the complaint and the manifested physical signs and symptoms as well as helping to determine the site of injury and cause.

The basic physical examination should be repeated postpartum (see Box 31.7), and the results should be compared with the preanesthesia findings. Additionally, nerve conduction studies can be helpful in localizing and differentiating injuries. Significant back pain with unexplained fever, worsening neurologic symptoms, coagulopathy, and immunosuppression are red flags that suggest spine imaging is indicated.[206] Pain radiating to the legs or buttocks is a late and urgent sign of spinal cord or cauda equina compression. Headache, fever, and neck stiffness suggest meningitis.

MRI has revolutionized the speed and precision with which intraspinal lesions can be identified, and gadolinium enhancement further improves its sensitivity. MRI cannot distinguish clearly between blood and other fluid, although the distinction can usually be made on other grounds. In the presence of meningitis, MRI with gadolinium enhancement shows swelling of the cord and punctate areas of increased density, reflecting inflammatory cell infiltrates. Arteriovenous malformations of the cord or dura may be visible, and the enlarged veins draining them may be seen as serpiginous signal voids.

KEY POINTS

- The vast majority of maternal nerve injuries can be attributed to the process of labor and delivery. Some patients may have preexisting maternal disease that predisposes to nerve injury.
- Intrapartum symptoms of nerve compression may go unnoticed, particularly when neuraxial analgesia/anesthesia is used. Therefore, neurologic status should be regularly assessed, and the patient should be encouraged to change positions.
- Postpartum neurologic deficit is most often transient in nature and likely to be a result of causes other than anesthesia. Nevertheless, there is a tendency to attribute neurologic deficits to neuraxial anesthesia.
- The exact incidence of neurologic complications caused by neuraxial anesthesia is difficult to determine because of wide variations in practice, accuracy of records, and overall low frequency of serious injury.
- Neuraxial anesthesia is more likely to cause central than peripheral nerve injuries, which are more likely to have obstetric causes.
- Proper sterile technique involves wearing a face mask, hand washing, donning sterile gloves, and cleansing the skin with chlorhexidine in alcohol and allowing it to dry before initiating neuraxial blockade.
- Choosing a lower lumbar interspace (L2–L3 or below) for insertion of the spinal needle minimizes the risk for trauma to the spinal cord.
- The risk for meningitis may be decreased by avoiding dural puncture during labor in a patient with systemic infection who has not received appropriate antibiotic treatment.
- The results of the history and physical examination, the rationale behind the chosen anesthetic procedure, and the details of all procedures should be thoroughly documented.
- Rapid diagnosis and treatment are essential to minimizing permanent neurologic sequelae. Compressive intraspinal lesions with neurologic changes require urgent laminectomy within 6 to 12 hours of the onset of symptoms.

Shared Decision-Making and Communication

Vilma E. Ortiz, MD, Joshua Abrams, JD, May C. M. Pian-Smith, MD, MS

CHAPTER OUTLINE

The relationship between a physician and his or her patient is rooted in common moral principles of autonomy, beneficence, nonmaleficence, and justice. Respect for a patient's autonomy underscores the patient's right to be involved in decisions that affect her welfare. Throughout history, the role of this relationship during times of decision-making has ranged from paternalism, wherein the physician makes decisions for the patient, to full autonomy, wherein the physician provides the medical facts and the patient makes the decision with little or minimal input from her caregiver. Now, a healthy doctor-patient encounter falls somewhere in between: neither completely autonomous nor devoid of a touch of paternalism.[1] Current focus on consumerism and a rise in patient advocacy have caused the foundation for patient-centered care to involve the creation of a partnership between the patient and her medical team. Meaningful dialogue is at the core of this relationship.[2]

INFORMED CONSENT AND SHARED DECISION-MAKING

Informed Consent

Though conspicuously absent from the Hippocratic Oath, the concept of informed consent is the backbone of the ethical practice of modern medicine in the United States. Its purpose is to facilitate care in a manner that honors the autonomy of the patient while acknowledging the expertise of the provider. As opposed to words signed on a form by the patient, true informed consent is a process whereby a patient and her health care provider engage in information exchange and discuss the patient's condition and the nature of the proposed treatment, risks, benefits, and alternatives, including lack of treatment.[3] The form is merely evidence of this discussion.

When engendered by a strong informed consent process, patient-physician communication has been associated with more realistic patient expectations, improved satisfaction, and a lower rate of medical malpractice claims.[4-6] Evidence of this process and the physician's involvement may be found among consultation notes (paper or electronic), informational aids shared with patients, and signed consent forms acknowledging that the process has occurred.

A solid and meaningful informed consent process[7] includes the following hallmarks:

1. A patient who has capacity and is able to understand the nature and consequences of the proposed therapy/procedure, and of alternatives, including no therapy
2. A physician who tailors his or her disclosure to the patient's particular competency, comprehension, and need and desire for detail
3. Freedom from external influence (meaning it is given voluntarily)
4. Understanding that consent can be withdrawn at any time before the therapy/procedure has occurred.

Legal precedent establishes what risks are essential to disclose during an informed consent discussion, specifically any

risk that a "reasonable patient would consider reasonable and material to the decision of whether to consent to a procedure offered."[1] Dornette[8] suggested that significant risk is one that poses a high (greater than or equal to 10%) incidence of a transient complication or a low (0.5% to 1%) incidence of permanent consequences. Broaddus and Chandrasekhar[9] have recommended discussion of risks with high incidence, high morbidity, or adverse fetal effects.[9]

Shared Decision-Making

Shared decision-making (SDM) is a process by which the physician expands upon the requirements of informed consent to establish a collaborative decision-making partnership.[10] SDM shifts the focus in the delivery of care away from the disease process itself, and toward the patient and family navigating health care decisions. When ideally executed, SDM establishes a longitudinal partnership to address a series of decisions throughout the health care encounter. Recent advocacy efforts have defined patient- and family-centered care as a major component of health care quality and safety, and embraced SDM as a quality indicator.[11–13]

At a minimum, SDM requires a patient and her clinician. The clinician frames the series of health care decisions that must be made, and for each, explains the integral elements of informed consent; elicits questions, values, and preferences from the patient; and guides the discussion toward a decision that is consistent with the patient's values and preferences, and current evidence. Conversations may also involve family members, friends, and other members of the care team, according to the preferences of the patient. Clear communication is critical and requires careful attention to both verbal and nonverbal cues. Explanations must avoid language that is overly technical and clinical, but also remain specific enough to meaningfully guide the patient to an understanding of the complex clinical decisions she faces.

Decision aids may be used to facilitate SDM, and are available online, on paper, or on video. Just as cognitive aids can help guide operating room teams through the critical steps of a crisis, decision aids help patients absorb clinical evidence and communicate their preferences. The use of decision aids also helps clinicians set aside their traditional paternalistic role in order to be partners and coaches in the patient-centered process. Explicitly asking "what matters to you?" can help the team align its interventions. When SDM occurs, a properly informed patient can choose between various options (e.g., between different methods of pain management or between regional and general anesthesia) on the basis of her own values and preferences, even when the decision differs from her clinician's preferred decision.[11]

The process of SDM appears to increase patients' subsequent participation, compliance, and self-monitoring.[1] A Cochrane review of 105 trials published through 2015 demonstrated that the use of decision aids resulted in increased patient knowledge, more accurate perceptions of treatment risks, better alignment of treatments with patient values, a decreased sense of conflict for patients, and greater patient participation.[11,14]

According to observations, focus groups, and questionnaires conducted as part of the Making Good Decisions in Collaboration (MAGIC) program in the United Kingdom, even when SDM conversations are imperfect or when there is a lack of complete agreement on best choices, the process of bringing perspectives together improves the likelihood that decisions are more informed and better accepted by patients, families, and staff.[15] Using a "plan-do-study-act" rapid-cycle approach, MAGIC researchers determined that incorporating effective SDM requires a holistic bundle of interventions to drive culture change and to establish a supportive health care delivery system.[15] Younger patients, women, and those with more education are most likely to prefer SDM, according to a study of anesthesia decision-making in Germany that measured preferences using the autonomy preference index (API) and the preference for involvement in care scale (PICS).[16] Based on a Swiss study of 197 clinician-patient dyads, anesthesia clinicians frequently overestimate how much SDM occurs. In this study, Flierler et al.[17] showed that 94% of surgical patients wanted to be involved in preoperative anesthetic management decisions. Patients had a stronger desire for a "balanced" decision-making process, wherein each party would have an equal contribution to decision making (desired by 65% of patients versus 32% of clinicians). Satisfaction decreased when patients perceived insufficient opportunity for involvement, and when anesthesia providers underestimated patient preference for SDM.

Beyond patient compliance and satisfaction, the impact of SDM on clinical outcomes is less clear. A 2015 systematic review of SDM identified a positive relationship between SDM and patient outcomes for 42 of 97 unique outcomes assessed, among 39 studies that met inclusion criteria.[18] The authors noted differences in the way SDM was measured (patient-reported, observer-reported, and clinician-reported). Regardless of measurement methods, 54% of affective-cognitive outcomes were positively associated with the patient's perception that SDM had occurred; such outcomes included improved patient satisfaction, resolved concerns and anxieties about illness, resolved decisional conflict, improved knowledge, and enhanced confidence in the decision. Thirty-seven percent of the behavioral outcomes studied were improved with the presence of SDM, including greater medication adherence. Twenty-five percent of the clinical outcomes studied were improved when there was SDM, with specific improvements in patient ratings of overall health, quality of life, depressive symptoms, and physiologic measures such as blood pressure. Evidence for improved clinical outcomes appears most robust for patients with chronic conditions that require self-management,[19] such as hypertension.[20] Certainly unsatisfactory communication with patients has been associated with treatment noncompliance in diabetes,[21] asthma,[22] and chronic disease.[23]

Clinical Capacity versus Legal Capacity

For the informed consent process to be both meaningful and legal, the adult patient, or guardian for a minor patient, must have **capacity** to (1) understand the relevant information, (2)

appreciate the situation and its consequences, (3) reason about treatment options, and (4) communicate a choice.[24] *Competence* is an alternative term for capacity that is used in some legal jurisdictions. Characteristics such as an individual's level of education, intellectual ability, preferred conversational language, and cultural background may influence how the individual processes information, but should not impair legal capacity to make an informed decision. It is the provider's responsibility to make the information accessible and understandable. Translation services are a legal requirement for health care in the United States.[25]

Even when information is presented at an appropriately straightforward level, there are patients who may not have capacity to truly understand the information being disclosed by the physician. The patient's capacity may be compromised temporarily or permanently by her condition, medications, or a combination of the two.[26] By definition, incapacitated patients cannot give informed consent. In emergency situations in which there is no indication to the contrary, physicians can provide necessary care under the presumption that a reasonable person would have consented to the anticipated treatment, which is discussed further later.[27] In most clinical situations, incapacitated patients require a surrogate decision-maker who can engage with the informed consent process as if he or she were the patient.[27] Legally, it is necessary both to establish the need for a surrogate decision maker, and to identify the most appropriate person to serve in this role.

In cases of permanent impairment, a court may have already made a determination of legal incapacity of a particular patient,[28] and invested a surrogate with authority to make medical decisions on behalf of the patient. Such legal determinations are usually made in the course of a petition for guardianship filed on behalf of the allegedly incapacitated individual, supported by evidence of clinical incapacity.[29] Petitions for guardianship are sometimes made in the course of other legal proceedings, such as a motion to confirm a health care proxy (in which the health care proxy agent must prove the existence of the health care proxy document, executed at the time the patient had clinical and legal capacity to do so, as well as the fact that the patient currently lacks clinical capacity as determined by an appropriately licensed clinician).[28]

A surrogate decision maker may have been established through legal guardianship, durable power of attorney for health care, a binding living will, or other advance directive. Regardless of how decision-making authority was legally established, the named *surrogate* generally serves as the final decision maker for all health care decisions for that patient.[30]

Decision-making authority for patients who lack legal capacity can be revoked only if the patient or some other third party goes back to court and challenges the determination, either because circumstances have changed and the patient has regained clinical capacity, or because the patient or third party appeals the initial determination of the court and has it overturned.[31]

If a court has not yet made a legal determination that a patient lacks **legal capacity** (or, is legally incompetent, as termed in some states), then the determination of a patient's **clinical capacity** to give informed consent is a professional judgment made by the treating clinician. At a minimum, a judgment of clinical incapacity must be documented in the medical record by a licensed physician (or nurse practitioner in some states) before utilizing a surrogate decision maker.[31] Some states may have additional requirements detailing how such a determination is recorded and published (e.g., Minnesota requires all conditions and circumstances to be documented within the medical record).[32] It is often helpful to have a mental health clinician or, in the case of a patient with neurologic issues, a neurologist, weigh in on the determination,[33] as it will be more authoritative if reviewed in court or challenged in any way by a third party.[33]

If a surrogate decision maker has not been previously identified, then state statutes may delineate the process to identify the most appropriate surrogate. Some states designate a default list of family members and other persons (in order of priority) who may give consent.[34] Other states limit surrogate decision makers to health care proxy agents previously designated by the patient (when she had capacity to do so) on a specific health care proxy form (e.g., Massachusetts),[31] durable powers of attorney for health care (e.g., Ohio),[35] or a guardian appointed by a court after a petition has been filed and evidence regarding the incapacity presented (e.g., Arizona).[36] Even in states in which there is no line of kin prescribed by statute, there are generally provisions for how to manage consent in emergency situations (such as using available family, or presuming consent, or both).[37]

All surrogate decision makers are required to make "substituted judgment" decisions on behalf of the patient (i.e., they are obligated to decide as they believe the patient would, not according to the surrogate's own preferences).[28] This may differ from the decision the surrogate decision maker might make for himself or herself. Thus it is imperative to encourage and, where possible, require that the surrogate make decisions from the point of view of the patient: "the surrogate decision maker (judge or guardian) should attempt to determine what the incapacitated person would decide regarding the proposed treatment or procedure were he or she competent."[37] When it is impossible to determine what decision the patient would have made (e.g., the patient never had capacity as a result of an intellectual disability that has existed from birth, or the surrogate decision maker did not know the patient well enough to discern what decision she might have made when she was most capacitated) and there is little or no collateral information to help guide the surrogate, it may be necessary to switch to a "best interest" standard rather than a "substituted judgment" one.[33] Regardless, it is not appropriate for the surrogate to impose his or her own values on the decision-making process. If the surrogate seems to be unable to follow this obligation, it may be necessary to challenge that surrogate's right to make decisions for the patient, either through institutional processes governed by the policies and procedures of the institution or through the courts.[38]

It is also important to note that some decisions the surrogate decision maker might want to make, or some clinical

interventions, might require additional court involvement.[39] These kinds of decisions are often referred to as "extraordinary" decisions, and can include major surgery, general anesthesia, use of antipsychotic medications, amputation, sterilization, hysterectomy, chemotherapy, institution of comfort measures only, the removal of life-sustaining treatment, or other change of code status.[40,41] The necessity to return to court to request specific authority for these "extraordinary" decisions is driven by state law, and so it is important to determine the breadth of a surrogate decision maker's authority to consent to various treatments and care plans within the laws of the state in which the treatment is being provided.[30] The authority of a health care proxy agent or a durable power of attorney for health care may also have been limited by the patient in the language within the health care proxy or power of attorney document itself, underscoring the importance of consulting these documents as well.[30]

Finally, in states that allow for binding living wills or other advance directives, a surrogate decision maker may be bound to follow the directives within such documents that may impact the decisions being made.[42] Therefore, it is critical to know whether any such documents exist, and if they do, whether they are binding or merely evidentiary as collateral information; some states explicitly do not recognize the binding nature of these advance directives but do hold them to be persuasive in helping determine what the patient would have wanted done in a particular clinical circumstance.[43]

DECISION MAKING IN OBSTETRIC ANESTHESIA

Challenges in Obstetric Anesthesia

There are unique challenges to obtaining consent and engaging in SDM in the labor and delivery setting. These can include the balancing of competing interests of mother and fetus, the interaction with distressed patients, who can be part of a complex family system, and interdisciplinary collaboration during rapidly evolving clinical situations. The anesthesia provider must work quickly to establish trust, elicit preferences for information and decision making, and tailor SDM to the patient and her chosen support team, while coordinating decisions with other members of the interdisciplinary care team. This is no easy task. Misunderstandings, unmet expectations, patient dissatisfaction, and liability are potential outcomes.

Historically, consent for anesthesia was incorporated into consent for surgery, and direct participation of the anesthesia provider in the consent conversation was not mandated. Now most states require separate consent conversations (and forms) for surgery and anesthesia procedures.[1] This separate, focused discussion on the benefits and risks of anesthesia provides a unique opportunity to address misconceptions and discuss the facts. In a survey study of 509 English-speaking parturients (63% white, 23% Hispanic, 14% African-American) admitted to a single institution, Toledo et al.[44] showed that 39% of participants expressed concerns regarding neuraxial anesthesia. These ranged from general misunderstandings about the anesthetic (e.g., epidurals slow down labor or cause cerebral palsy), fears about long-term complications of the procedure, and lack of trust in providers, to concerns regarding fetal effects of medications administered in the epidural space.[44] Ideally, informed consent discussions about anesthesia services begin with an antepartum consultation or with the admission history and physical examination, and address possible delivery scenarios and corresponding anesthetic options in general terms. This conversation opens an ongoing dialogue to support SDM, which continues throughout the hospitalization for delivery.

The informed consent document may be amended as needed, with the additional conversations documented in the medical record. Alternatively, specific informed consent for each anesthetic procedure may be obtained shortly before the intervention. At many institutions, a separate written consent signed by the patient is not obtained before administration of anesthesia. A 1995 survey of obstetric anesthesia providers in the United States and the United Kingdom indicated that 52% of U.S. anesthesia providers (but only 15% of UK anesthesia providers) obtained a separate written consent for epidural analgesia during labor.[45] In a survey performed in the United Kingdom in 2007,[46] only 7% of obstetric units routinely obtained written informed consent for epidural analgesia during labor. In a 2004 survey from Australia and New Zealand,[47] less than 20% of anesthesia providers obtained written consent before initiating neuraxial labor analgesia. Some health care facilities and organizations have begun using a single consent form for obstetric and anesthetic procedures that may be desired or necessary during labor and delivery. The process of reviewing and signing the consent form provides a specific opportunity for the patient to ask questions. It also provides additional documentation that consent was obtained. The combined form has the additional advantage of not requiring the patient to sign multiple medicolegal documents. Although a signed consent form is not necessary, at a minimum, it should be standard practice for anesthesia providers to document that a discussion of risks and benefits of labor analgesia took place and that verbal informed consent was obtained before administration of anesthesia.

Many patients have strong opinions about their analgesic options, based on information gathered from their obstetric provider, websites, books, magazines, classes, and friends and family.[48] The nature of the consent process will differ depending on the level of prior knowledge, health literacy, decision-making preferences, and clinical circumstances, but a paternalistic approach, grounded on the premise that patients cannot have the same clinical knowledge of the clinicians, can no longer be justified.[49]

Special Situations in Obstetric Anesthesia

Patient Who Is in Pain

A study of women's preferences for labor analgesia counseling revealed that most women prefer to learn about the options for labor analgesia from their obstetric care providers.[48] This is not surprising given the trust that exists within the bounds

of an established relationship. However, a discussion of anesthetic options for the first time frequently takes place upon arrival to the labor and delivery unit. A survey of Canadian women revealed their strong preference to be informed of all possible complications of epidural anesthesia, especially serious ones, even when the risk was quite low.[50] This study and others have emphasized the parturients' desire to have these discussions as early in labor as possible.

Unfortunately, the anesthesia provider often first encounters the patient when she is in severe pain. Many have questioned the ethics and truly "informed" nature of consent when it is obtained from a patient who is experiencing severe pain (e.g., during labor). Although the provider may tailor the consent process to the circumstances, the presence of maternal pain and distress does not obviate the need for a frank discussion of the risks associated with anesthesia as well as the alternatives. A 2005 study evaluated whether labor pain and neuraxial fentanyl administration affect the intellectual function of laboring women.[51] The Mini-Mental Status Examination (MMSE) was used to evaluate orientation, registration, attention, calculation, recall, and language both before and after initiation of analgesia in 41 laboring women. There was no difference in MMSE scores before and after administration of neuraxial analgesia.

Other investigations have shown that women in labor demonstrate not only adequate understanding of options but also good recall of the discussions afterward. Gerancher et al.[52] performed a study to evaluate the ability of laboring women to recall the details of a pre-anesthesia discussion and to determine whether verbal consent alone or a combination of verbal and written consent provided better recall. The investigators randomly assigned 113 laboring women to one of two groups, those from whom verbal consent alone was obtained and those from whom verbal consent plus written consent was obtained. The verbal-plus-written consent group had significantly higher median (range) recall scores (90 [80 to 100]) than the verbal-only group (80 [70 to 90]). Only two women (both in the verbal group) believed that they were unable (because of either inadequate information or situational stress) to give valid consent. The investigators concluded that "the high recall scores achieved by the women in both groups suggest that the majority of laboring women are at least as mentally and physically competent to give consent as preoperative cardiac patients."

Clark et al.[53] randomly assigned hospital inpatients to receive either a verbal anesthesia discussion alone or both a verbal anesthesia discussion and a preprinted anesthesia consent form. In contrast with the results of Gerancher et al.,[52] these investigators found that "patients remembered less of the information concerning anesthetic risks discussed during the preoperative interview if they received a preprinted, risk-specific anesthesia consent form at the beginning of the interview." They speculated that "patients who see an anesthesia consent form for the first time during the preoperative interview may try to read and listen simultaneously, and with their attention divided, may remember less of the preoperative discussion."

Thus, it seems reasonable for the patient to provide her signature as evidence of her consent, if her condition permits. This consent can be distinguished on a separate anesthesia consent form or as part of a consent form for all obstetric care, including anesthesia. In the event that a consent form is not available, it should be standard practice for the anesthesia provider to explain the intended procedure, risks, and alternatives, and to document this discussion in the medical record.[54]

Patient Who Has Received Sedatives

Though it may be tempting to assume that a patient who has received a sedative or opioid medication is incapable of providing informed consent, this may not be the case. Judicious use of sedatives to alleviate significant anxiety or opioids to treat severe pain can enhance the patient's ability to interact and participate in SDM. Nevertheless, it is inappropriate to use sedatives to manipulate the patient's decision or to eliminate her decision-making capacity. Use of drugs with amnestic potential merit thoughtful consideration as the patient may not recall the informed consent process afterward. However, even when a patient cannot recall the details of the informed consent discussion, that does not necessarily mean that she did not, at the time consent was obtained, understand the risks, benefits, and alternatives presented.

Patient satisfaction has been used as a surrogate measure of the adequacy or effectiveness of the consent conversation. Pattee et al.[50] sought to quantify the influence of factors including pain, anxiety, opioid premedication, and patient education on patient satisfaction with the consent process. In this survey study of 60 patients, queried up to 2 months after delivery, the level of patient satisfaction was high (8.1/10) and not affected by any of these complicating factors ($r = 0.013$ for pain and $r = 0.048$ for anxiety). Subsequently, a study conducted by Gerancher et al.[52] demonstrated no difference in patient satisfaction with the consent process, whether or not the patient had received opioid premedication before obtaining consent.

Patient with a Birth Plan

The birth plan is a document wherein mothers-to-be state their wishes and preferences for the management of certain aspects of their labor and delivery course. The practice of using a formal, written birth plan dates back to the 1970s. Its intended purpose was to enhance communication between the expectant mother and health care provider.[55-57] The premise was that patient participation in childbirth decision making would result in a positive labor and delivery experience for the mother. To investigate the association between presence of a birth plan, mode of delivery, obstetric intervention, and patient satisfaction, Afshar et al.[58] prospectively studied a cohort of 300 women in a tertiary care center. Compared with the group that did not have a birth plan ($n = 157$), the 143 women with a birth plan experienced fewer intrapartum obstetric interventions such as oxytocin augmentation (61% versus 78%, $P < .01$) and artificial rupture of membranes (15% versus 29%, $P < .01$). There was no difference in the cesarean delivery rate between the groups.

Interestingly, parturients with a birth plan reported less satisfaction with their birth experience compared with parturients without one. A possible explanation for this finding may be that a departure from the expected plan may be met with disappointment, irrespective of the outcome.[59]

Although birth plan documents vary on the level of detail, a typical birth plan may include the woman's preference for pain management during labor.[60] In the previously mentioned study by Afshar et al.,[58] there was no difference between groups regarding use of intravenous analgesia; however, women with a birth plan were less likely to utilize epidural analgesia.

The birth plan is a written expression of the patient's wishes, not a binding contract that prevents her from receiving epidural analgesia at a later time. As such, it provides a good starting point for a thoughtful discussion that dispels myths, addresses anxieties, and educates the patient on the evidence-based risks and benefits of analgesia and anesthesia for labor and delivery. As a birth plan is typically drafted before admission to the labor and delivery unit, it is possible that a patient may change her mind regarding her wishes. It reflects her best assessment of the balance between risks and benefits before the onset of labor. As the pain of labor escalates, the benefit of epidural analgesia becomes increasingly salient, and she may shift her rational calculus accordingly.[61] Although she may have specifically stipulated, "I don't want any kind of anesthesia offered to me during labor," she may change her mind in the course of labor, and request and receive any anesthetic or analgesic service. This highlights an important aspect of informed consent: it must be contemporaneous with the actual situation. It is incumbent on health care providers to read this document and use it as a tool to facilitate communication during SDM. As with all decisions regarding informed consent, a surrogate decision maker can use substituted judgment, as described earlier in this chapter, to modify the birth plan for an incapacitated patient, recognizing that pain alone is not grounds to question a patient's capacity to make her own decisions. In such a case, it would be important for the clinicians involved in the patient's care to question a surrogate carefully regarding significant alterations, because the document may be the best evidence of the patient's wishes.

Emergency Procedures

Generally, health care professionals should provide emergency treatment under a "presumed consent" model, meaning that, absent any collateral information to the contrary, a patient should receive care in her "best interest" in emergent situations even if such a patient cannot provide informed consent.[62] However, in many jurisdictions, family or the decision-making surrogate can refuse such care on behalf of the incapacitated patient if they can genuinely state that they know the patient would refuse such care were the patient able to consent herself.[62] When in doubt as to the accuracy of the family's refusal, it may be necessary to preserve the best interest of the patient in the face of uncertainty as to the patient's wishes. If the health care providers' treatment was authorized under a medical emergency, the providers should carefully document their determination.[62] The documentation in the patient's medical record should contain a description of the patient's presenting condition, its immediacy, its magnitude, and the nature of the immediate threat or harm to the patient.[63] It is advisable for at least two health care providers to document this information, because the documentation would support their actions if a lack-of-informed-consent lawsuit were filed. The provider should provide only the care that is reasonable for the patient's condition.

Vulnerable Populations

Consenting Minors

Traditionally, minors have not been allowed to provide informed consent, based on concerns that they may lack the experience or capacity to inform judgments related to health care decisions.[64] Consequently, in most states, a minor child needs a parent or guardian to make legal decisions, including informed consent for treatment.[64] Exceptions to this rule are based on both statutory laws (i.e., by the state legislature)[65] and case law (i.e., decided by judges in court decisions, which then become binding precedent in the jurisdiction represented by the court).[66] In some states, pregnant women younger than 18 years of age are considered "emancipated minors" and may consent for procedures related to their prenatal, intrapartum, and postpartum care, as well as interventions that benefit the fetus.[67,68] Regulations pertaining to consent from pregnant emancipated minors vary among the individual states.[67] Minor and parental rights in Massachusetts are presented in Tables 32.1 and 32.2.

The following are the most common situations.

Mature Minor Rule. Sometimes statutory, sometimes based on case law, the Mature Minor Rule generally requires a finding that (1) the minor in question is mature enough to weigh the risks and benefits of a proposed treatment and is able to make a true informed consent decision, and (2) there is good reason not to involve the parents or guardians.[69] This rule is generally applied to adolescent minors, and when it is applied, the general rule that allows parents or guardians to control the minor's health care decisions is suspended for that course of treatment.[69] Access to information contained in the medical record by parents or guardians should be restricted for all Mature Minors, because there may be aspects of the record that contain information regarding treatment that was provided without the parents' or guardians' consent; the medical records department should have the opportunity to review such records and redact such information from the record before releasing it to the parents or guardians.[69] It is important, therefore, that any medical record relating to treatment provided under the Mature Minor Rule be flagged or otherwise indicated as such.[70] In some states, only certain health care decisions can be made by a Mature Minor, and others must include the parent or guardian.[71]

Minor who is pregnant or believes herself to be pregnant. Many states allow minors who are pregnant, or in some states believe themselves to be pregnant, to make their own health care decisions, regardless of age.[71] Sometimes those

TABLE 32.1 Minors' Rights in Massachusetts[a]

If Patient Is Younger Than 18 and…	Who Consents to Medical Treatment (and Pays)?	Access to PHI?	Restrictions	Other
No special circumstances (but see Mature Minor doctrine[69])	Parent or guardian	Parent or guardian	Parent or guardian cannot consent to sterilization; court order required	Abortion requires consent of one parent or guardian
Married, widowed, or divorced	Minor	Minor only	None	Minor can consent to abortion or sterilization
Emergency, parent/guardian not available	Treat without consent, try to reach parent as soon as possible	Parent or guardian	Only emergency treatment may be provided	
Living apart from parent or guardian and managing own finances	Minor	Minor only	Cannot consent to abortion or sterilization	
Pregnant or believes herself to be pregnant	Minor	Minor only	Cannot consent to abortion or sterilization	
A member of any of the armed services	Minor	Minor only	Cannot consent to abortion or sterilization	
Seeking care for any disease defined as dangerous to public health	Minor	Minor only	Only diagnosis or treatment of the disease may be provided	
A parent of a child	Minor	Minor only	Cannot consent to abortion or sterilization	Minor can also consent to treatment of the child
12 years or older, seeking treatment for drug dependency	Minor	Minor only	Treatment of drug dependency only; two physicians must concur in diagnosis	
Treated for a drug or alcohol overdose	Parent or guardian; N/A if emergent situation	Parent or guardian; but if seeking treatment see above	Parents must be notified of overdose regardless of Mature Minor doctrine/emancipation	See M.G.L. ch. 112, § 12E1/2

decisions are limited to decisions related to the pregnancy, and other times the statute "medically emancipates" such minors and gives them authority to consent to any and all health care on their own.[72] Pregnancy termination and permanent sterilization are notable exceptions, which are discussed in the following sections.

Other status-based exceptions. Many states have statutes that allows minors to consent to their own care under specific circumstances, such as being married/divorced, being in the military, living on their own/supporting themselves, and certain other statuses.

Medical service-based exceptions. In many states, a minor who is seeking substance use disorder treatment can receive such treatment on a confidential basis.[73] Likewise, many states allow for minors to consent to their own contraception-oriented health care services.[74] Title X under federal law explicitly stipulates that family planning services must be provided to minors on a confidential basis, and the American College of Obstetricians and Gynecologists (ACOG) stresses the importance of confidentiality in counseling adolescents about contraception.[75]

In contrast, procedures to end pregnancy or to provide permanent sterilization receive special legal treatment in many states, and require more traditional involvement of parents, guardians, and the courts, on behalf of minor patients, in the informed consent process.[76]

Abortion. A number of state legislatures have established laws that effectively restrict access to termination services for minor patients. Among a panel of statutory requirements, it is common to specifically require parental or guardian authorization and informed consent for abortion in adolescents. In some states, a judicial bypass exists to allow a minor to petition a court for the authority without involving her parents/guardians.[76,77] This approach may be particularly important in cases of incest and sexual abuse involving a parent, guardian, or other family member.

Some procedures, most notably a procedure the federal government refers to as "Partial Birth Abortion," are banned outright even if the provider and the patient agree that it is the safest care under the clinical circumstances presented.[78] The Supreme Court has thus far continued to maintain that the right to abortion "previability" generally cannot be

TABLE 32.2 Parental Rights in Massachusetts[a]

Child's Parents Are:	Which Parent Makes Medical Decisions?	Which Parent Can Access Medical Record?	Which Parent Can Visit Child?
Married[b]	Either parent (one is enough for consent to treatment)	Either parent	Either parent
Unmarried[c]	Mother only, UNLESS: If mother affirms he is the father—hospital would honor specific privileges she wants to give him; OR as specified in court document or co-parenting agreement.	Mother only, UNLESS: If mother affirms he is the father—hospital would honor specific privileges she wants to give him; OR as specified in court document	Mother only, UNLESS: If mother affirms he is the father—hospital would honor privileges she wants to give him; OR as specified in court document or co-parenting agreement.
Legally Separated	As specified in court document	As specified in court document	As specified in court document
Divorced	As specified in court document	Either parent (or as specified in court document), unless hospital has reason to believe parent requesting record is danger to the patient; if so, certain identifying information (such as address) can be omitted by court order	As specified in court document

[a]Table is representative of Massachusetts laws and regulations only.
[b]If the child's parents are separated (without a court document recognizing separation), treat the situation as if the parents are married UNLESS you have a reasonable basis to think it is inadvisable (i.e., domestic violence situation).
[c]If the child is born to unmarried parents, the father has only the privileges the mother gives him. If the father is not happy with the privileges provided by the mother, he is free to go to court to obtain a clarification of his legal rights with respect to the child.

infringed by states, but the determination of when viability is reached continues to be an issue of legal debate.[78]

Sterilization. Although adult patients with capacity can generally consent to their own sterilization procedures, most jurisdictions limit minors and incapacitated patients, relying on surrogate decision makers to make such decisions on behalf of the patient.[79] As with abortion, the adolescent parturient may petition a court for the ability to consent to sterilization, without the involvement of her parent or guardian.[79]

Language Considerations

In 2014, more than 900,000 births in the United States were to immigrant mothers, a threefold increase since 1970.[80] This rise in cultural diversity challenges the ability of health care providers and institutions to appropriately care for the migrant obstetric patient. Although some studies have shown poorer obstetric and perinatal outcomes in migrant versus native women,[81] others have found that immigrant status confers a protective factor for perinatal outcomes.[82–84] Factors associated with significant risk for poor maternal outcomes include recent arrival, limited access to health care, limited language proficiency, and poor support network.[85]

The Institute of Medicine describes patient-centered care as care that honors the individual patient and respects his or her choices, culture, ethnicity, social context, values, and informational needs.[12] Effective communication between patients and care providers is a building block of patient-centered care and a cornerstone of patient safety and optimal health care delivery. Using interviews of pregnant women of Mexican origin to explore their expectations of health care providers, Baxley and Ibitayo[86] noted that patients "wanted to hear everything, hear it directly and have it presented to them as if from a friend." For these study participants, faith was a major component of their culture and a strong influence on their perceptions of health outcomes.[86] Similarly, newly arrived Somali couples expressed the importance of their beliefs and cultural values during perinatal interviews.[87] In their culture, having many children is considered desirable. Thus a high value is placed on a vaginal delivery; a cesarean delivery can limit the number of children and, in their culture, cesarean delivery is also believed to be associated with death.[88]

The language gap between a patient and her health care provider is commonly bridged by the use of an interpreter. Use of bilingual family members, especially children, is discouraged as their unfamiliarity with medical terminology and emotional ties to the patient may hinder the accurate transfer of information from patient to doctor and vice versa.[89,90] Suboptimal interpretation not only impairs information exchange, but can undermine the SDM and informed consent processes.[91] However, use of professional medical interpreters is a resource-intensive tool not always available for all languages or after regular work hours.

In addition to language discordance, low levels of health literacy can impair the patient's ability to understand the information provided by her health care provider. Unlike functional literacy, which refers to an individual's operational capacity to function in daily life through use of basic reading, writing, and computational skills,[92] functional health literacy demands the use of more complex language skills as well

as the ability to process numerical information.[93] Basically, health literacy is defined as the "degree to which individuals have capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[94] In 2004, the Institute of Medicine reported that "nearly half of all American adults—90 million people—have difficulty understanding and using health information, and there is a higher rate of hospitalization and use of emergency services among patients with limited health literacy."[94] Low health literacy also affects immigrants with limited English proficiency.[95] In a prospective, matched cohort design investigation, Brice et al.[93] compared the health literacy level of adult English-speaking patients to Spanish-speaking patients presenting to an emergency department in suburban North Carolina. The Test of Functional Health Literacy in Adults (TOFHLA) was administered to both groups. The results revealed that 74% of Spanish-speaking participants possess less-than-adequate functional health literacy compared with 7% of the English-speaking cohort.[93] In a recent survey of medically trained interpreters and anesthesia providers at a major teaching hospital in Boston (U.S.), 43% of interpreters felt that "less than half of their patient population was sufficiently literate to read and consent in their native language."[96] Unfortunately, published materials available for public education in anesthesia are written at a level higher than what the public can understand. In a review of educational material downloaded from 24 national anesthesia society websites, Govender et al.[97] discovered all material was above an eighth-grade level, which is too complex for lay comprehension.

Educational aids such as written material (brochures, illustrations, models) and video-assisted patient education can be invaluable in the transfer of information to patients, particularly if the material is presented in the patient's own language with minimal use of medical jargon.[98–101] Additionally, use of educational videos has been shown to decrease patient anxiety and increase patient satisfaction with medical care.[102] Obstetric patients frequently need to make complex health care decisions in unfamiliar surroundings when their health care providers are burdened by time constraints. By standardizing the information presented on specific topics, supplemental educational aids can help minimize misleading information, censoring of information, or devaluing of information.

Cultural Considerations

Patient autonomy is an important principle to uphold in decision-making. In many cultures and social contexts, this autonomy is preserved even when power to make medical decisions is passed on to another individual. For example, a competent patient may choose to allow a spouse or other family member to make "first-order" decisions regarding medical care. If her decision to defer to the judgment of another person is truly free and voluntary, then this "second-order" decision is authentic and autonomous.[103] Although justified in principle, this can be difficult to carry out in practice. One can imagine a situation in which a nulliparous woman has decided with her spouse that she does not want epidural analgesia for labor pain management and that medical management decisions have been willingly relinquished to her partner. If the patient changes her mind once labor pains have started but the surrogate, with all good intentions, insists on the predetermined plan, the patient's wishes are no longer being properly represented. In this setting, the will of the patient needs to be confirmed and takes priority over predetermined proxy arrangements.[104] Strong-willed family members, intending to advocate for their loved ones, may seem angry and even threatening. Often, they respond to patience and empathy, nonconfrontational communication, and input from the laboring patient and other parties.

Religious or Culturally Based Objections to Care

When a provider is aware that a patient has expressed a religious or culturally-based objection to certain aspects of medical care (e.g., blood transfusion for a Jehovah's Witness), that portion of the care should not be provided even in an emergency context.[105] If a blood transfusion would be required to save the life of an individual who has expressed objection to blood transfusion, absent any collateral information to the contrary, it is appropriate to withhold that aspect of care.[105] Detailed lists of blood products and blood conservation therapies are available[106,107] to facilitate SDM and to clarify the specific interventions individual patients will and will not accept. Certain therapies (e.g., cell salvage with a continuous circuit) may be acceptable to some individuals.[108] It is also helpful to explicitly consider likely clinical scenarios in advance. Such patients can change their minds about receiving life-saving interventions, but the presumption is that an incapacitated patient with a clear objection to the provision of some or all care, should not have that right obviated just because he or she does not have capacity in an emergency situation.[105]

Although an adult patient can refuse some or all care on his or her own behalf, a parental refusal of care for their child is more complex. The courts generally recognize that the state's interest in protecting the life and well-being of a child outweighs the parents' right to make decisions for the child, when that decision could result in a significantly poor outcome.[109] In some jurisdictions, the default is that the parents retain such rights and providers must go to court to overcome that presumption.[110] In other jurisdictions, providers faced with a similar situation have the right to provide care to the child over the objection of the parents, and the parents or guardians must go to court to attempt to obtain an injunction to bar the provision of such care.

Gestational Carriers or Surrogates

A gestational carrier is a pregnant woman whose fetus was created from a donated ovum (rather than her own) on behalf of another family.[111] In jurisdictions in which such an arrangement is legal, the gestational carrier is considered the patient at all times throughout the pregnancy, regardless of the level of involvement of the intended parents during such

time. Although gestational carriers may, and likely do, have a contract with the intended parents that specifies the gestational carrier's obligations, such as not having an abortion, any agreement is only applicable to the gestational carrier and the intended parents.[111] The providers are not parties to such agreements, and are not bound to any provisions contained therein.[111] If a gestational carrier violates a provision, the intended parents may have a contractual recourse available to them against the gestational carrier, but this has nothing to do with the providers' obligation to treat the gestational carrier as the patient and allow the gestational carrier to remain the sole decision maker. Health care providers should always remember that the gestational carrier is their patient, and it is their obligation to only provide care to which the gestational carrier consents, irrespective of the intended parents' position.

This arrangement is distinguished from a traditional surrogate, who carries a fetus originating from her own ovum on behalf of another family. In these situations, the surrogate is a legal parent to the child even after birth, until a traditional adoption has taken place.

Conflicts Arising out of the Maternal-Fetal Relationship

Almost all pregnant women consider the welfare of their unborn child to be of utmost importance. However, there may be situations in which maternal and fetal interests appear divergent or, potentially, in conflict. One example is when a pregnant woman refuses a diagnostic procedure, a medical treatment, or a surgical procedure that is intended to enhance or preserve fetal well-being. Another may arise when the pregnant woman's behavior is considered harmful to the fetus.[112] Physicians who care for pregnant women may confront challenging dilemmas when their patients reject medical recommendations, use illegal drugs, or engage in other behaviors that may adversely affect fetal well-being.

Appellate court decisions typically have held that a pregnant woman's decisions regarding medical treatment take precedence over the presumed fetal consequences of the maternal decisions.[113] One case illustrates the evolution of this judicial approach. Angela Carder was a 26-year-old married woman with cancer since 13 years of age. At 25 weeks' gestation, she was admitted to George Washington University Hospital, where a massive tumor was found in her lung. Her physicians determined that she would die within a short time, and she expressed her wish to be kept comfortable during her dying process to which her husband, her mother, and her physician agreed. Ultimately, the hospital sought judicial review of this course of action. The hospital asked whether a surgical delivery should be authorized to save the potentially viable fetus. The situation was presented to a judge, who authorized an emergency cesarean delivery without first ascertaining (using the principle of substituted judgment) the patient's wishes. A cesarean delivery was performed without full consideration of the patient's wishes, and the infant died approximately 2 hours after delivery while the mother died 2 days later. This case spawned extensive debate as to whether coercive intervention to protect the fetus is ever morally and legally justifiable.[114] With the assistance of the American Civil Liberties Union, Angela's parents sued the hospital, 2 administrators, and 33 physicians for claims including battery, false imprisonment, discrimination, and medical malpractice. These civil lawsuits were settled after several years of litigation, and as part of this process, the hospital adopted a written policy concerning decision-making for pregnant patients.[115] The court later reversed its initial decision authorizing the surgical delivery and ultimately issued an opinion setting forth the legal principles that should govern the doctor-parturient relationship.[116] The court stated: "In virtually all cases the question of what is to be done is to be decided by the patient—the pregnant woman—on behalf of herself and the fetus. If the patient is incompetent…her decision must be ascertained through substituted judgment." In affirming that the patient's wishes, once ascertained, must be followed in "virtually all cases" unless there are "truly extraordinary or compelling reasons to override them," the court did not foreclose the possibility of exceptions to this rule.

Many contemporary medical ethicists agree that a pregnant woman's informed refusal of medical intervention should prevail as long as she has capacity to make medical decisions.[117] In the case of an incapacitated patient, a legal surrogate decision maker has the right to speak for the patient in refusing such medical intervention. Newer legislation and some high-profile legal cases (some involving criminal prosecution) have challenged this notion and have raised the question of whether there are circumstances in which a pregnant woman's rights to informed consent and bodily integrity may be subordinated to protect her unborn child. For example, in 2004, Melissa Rowland was charged by the state of Utah with murder for the stillbirth of one twin because she initially refused cesarean delivery, even though she later accepted delivery by cesarean and her second twin survived. She pleaded guilty to child endangerment in order to avoid more serious charges.[118]

Other cases have focused on prosecuting pregnant women with substance use disorders. In 1991, Regina McKnight, who was pregnant at the time, began using cocaine after her mother's death. She had a stillbirth, and the state of South Carolina charged her with homicide by child abuse, claiming that her drug use caused the stillbirth. She became the first South Carolina woman to be convicted of this crime, for what both the defense and prosecution agreed was an unintentional stillbirth, and she spent nearly 8 years in jail. In 2008, the South Carolina Supreme Court unanimously reversed her conviction on the grounds that she did not receive a fair trial, primarily on the basis that her attorney failed to challenge the science that was used to convict her.[119]

In a similar instance, Shekelia Ward delivered an infant on January 8, 2008, where both she and her newborn tested positive for cocaine during their hospital stay, and the facility reported it to authorities for possible child abuse.[120] The following day she was arrested, imprisoned, and charged with a felony—chemical endangerment of a child. The state statute

at issue was passed by the Alabama legislature in 2006, for the purpose of prosecuting parents who exposed children to the toxins associated with methamphetamine production; the statute did not mention pregnant women or their fetuses.[121] As a result, the Southern Poverty Law Center, along with 25 medical, public health, and health advocacy groups, filed an *amicus curiae* brief against the prosecution of pregnant women in Covington County, Alabama.

These statutes reflect the concept that a fetus can and should be treated as separable and legally, philosophically, and essentially independent from the mother.[113] The refinement of techniques of intrauterine fetal imaging, testing, and treatment prompted the view that fetuses are independent patients who can be treated directly while *in utero*.[122] The prominence of some ethical models with assertions that physicians have moral obligations to fetal patients separate from their obligations to pregnant women also contributed to these developments.[123] Finally, a number of laws (primarily passed at the state level) were enacted with the aim of defining fetal rights separate from a pregnant woman's rights. In 2011, the ACOG Committee on Health Care for Underserved Women issued a statement addressing the role of the obstetrician in reporting substance use.[124] This document described a "disturbing trend" in legal actions and policies that criminalized drug use during pregnancy when thought to be associated with fetal harm or adverse outcomes. Noting that women seeking obstetric care should not be exposed to criminal or civil penalties and that few treatment facilities are available to effectively treat drug abuse in pregnancy, the ACOG concluded that the use of the legal system to address alcohol and substance use issues is inappropriate and urged that policy makers and legislators instead focus on strategies to address the needs of pregnant women with addictions.

The American Medical Association (AMA) has taken a similar position, stating that (1) drug addiction is a disease amenable to treatment, rather than criminal activity; and (2) there is a pressing need for maternal drug treatment and supportive child protective services.[125] Any legislation that criminalizes maternal drug addiction or requires physicians to function as agents of law enforcement will be opposed by the AMA.[125]

During the past two decades, practitioners have only infrequently resorted to court-ordered interventions against the wishes of the pregnant woman. In overturning the previous court's decision in the Angela Carder case (mentioned earlier), the Washington, DC, Court of Appeals noted that if a pregnant woman makes an informed decision, "her wishes will control in virtually all cases."[126] The court added, "We do not foreclose the possibility that a conflicting state interest may be so compelling that the patient's wishes must yield, but we anticipate that such cases will be extremely rare and truly exceptional."[126]

There has been an evolution in the approach of the ACOG and medical ethicists on the best means to address maternal-fetal conflict. A 1999 ACOG opinion offered the following three options: (1) respect the patient's autonomy and not proceed with the recommended intervention regardless of the consequences, (2) offer the patient the option of obtaining medical care from another individual before conditions become emergent, and (3) request that the court issue an order to permit the recommended treatment.[127] In 2004, the ACOG addressed the situation in which health care providers may consider this last option (i.e., legal intervention against a pregnant woman).[112] Specifically, the ACOG stated that the following criteria should be satisfied: (1) "there is a high probability of serious harm to the fetus in respecting the patient's decision"; (2) "there is a high probability that the recommended treatment will prevent or substantially reduce harm to the fetus"; (3) "there are no comparably effective, less intrusive options to prevent harm to the fetus"; and (4) "there is a high probability that the recommended treatment [will] also benefit the pregnant woman or that the risks to the pregnant woman are relatively small." The most recent 2016 ACOG recommendations emphasize the key principles of SDM and discourage external coercion from the court system.[128]

The ACOG opinions assume the presence of competency and informed consent. Thus, if a pregnant patient is believed to be incompetent and incapable of providing informed consent, the health care providers may not be required to respect the patient's refusal of care. Moreover, if the patient is deemed incompetent and/or a medical emergency exists, care may be provided with consent from a legally authorized surrogate decision maker or as an "emergency exception." Importantly, a legally authorized surrogate decision maker may refuse care on behalf of the patient if he or she believes that he or she is making the decision the patient would make for herself if she were capable to do so.

In summary, two approaches are available to the practitioner dealing with maternal-fetal conflict. One approach is to honor a competent pregnant patient's refusal of care. The other approach (which appears least favored by many medical ethicists and the ACOG) is to seek judicial authorization of treatment, which overrides a competent pregnant woman's refusal of care.[129]

In honoring a competent patient's desires to refuse treatment, the health care providers should carefully document the woman's competency and ability to provide informed consent. Every attempt should be made to counsel her to follow the treatment recommendations. Documentation should include how, when, and what information was provided to the patient and family regarding the significant risks to both the patient and fetus if the recommended care were not provided. If time permits, the treatment options should be reevaluated with the patient at frequent intervals, with detailed documentation in the patient's medical record. Additionally, legal counsel for the health care providers and medical facility may wish to prepare an "assumption of risk" form for the patient (and, if possible, her partner) to sign. This form represents another level of documentation (beyond the detailed notes in the patient's medical record) demonstrating that the patient was fully informed about the risks associated with her refusal of treatment and that she

voluntarily elected to accept those risks. However, such a release signed by the parents may not protect the physician and medical facility from a claim brought on behalf of the child who suffers an injury as a result of nonintervention. In some cases, the court has found that physicians have a duty to provide care to the unborn child.[130]

Patient "assumption of risk" does not release a health care provider from his or her obligations to provide other treatment within the accepted standard of care. For example, in *Shorter v. Drury,*[131] a case that involved a patient's refusal of blood transfusion because of religious preferences, the court upheld the validity of an "assumption of risk" (i.e., release) that relieved the physician from liability for compliance with the patient's refusal of blood transfusion before and after surgery but nonetheless held him partially responsible for her death because of his negligent performance of the surgery.[131]

Before deciding whether to seek court review, health care providers should identify what issue they want the court to resolve. Is it whether the pregnant woman is competent? Is it whether there is a superior state interest in preserving the life of the viable fetus and/or the pregnant woman despite the (competent) patient's desire to refuse recommended care? Health care providers also should consider whether a court is the proper forum for resolving these issues or whether another forum (e.g., an institutional ethics committee) may be a better choice. If a patient care dilemma is put before a judge, the health care providers give up a large amount of control over the disposition of the case. Nonetheless, in the absence of a legally authorized decision maker, if a patient's competency is at issue and there is adequate time, court review to settle the patient's competency may be beneficial and is supported by both the ACOG guidelines[112] and the *Angela Carder* decision, discussed earlier.[126] It is beneficial to obtain authorization for the provision of medically recommended care without waiting until the situation becomes an emergency. If the patient is deemed incompetent, the court may either appoint a surrogate decision maker or directly authorize (by court order) the provision of medically indicated care.

It is not unusual for physicians to disagree with their patients' health care decisions, and such differences are expected. In some cases, physicians conclude that providing the requested care would present a personal moral problem—a conflict of conscience, which prompts them to refuse to provide the requested care. Conscientious refusals have become especially prevalent in the practice of reproductive medicine, an area characterized by deep societal divisions regarding the morality of contraception and pregnancy termination. The ACOG Committee on Ethics[132] has acknowledged that "respect for conscience is one of many values important to the ethical practice of reproductive medicine." The ACOG stated that when conscience implores physicians to refuse to perform abortion, sterilization, and/or provision of contraceptives, "they must provide potential patients with accurate and prior notice of their personal moral commitments." The ACOG committee opinion also emphasized that providers have an obligation to provide medically indicated care in an emergency that threatens the patient's health, in which referral is not possible.[132]

TEAM-BASED COMMUNICATION

Intraprofessional Collaborative Practice

Most clinical work on the labor and delivery unit is unscheduled. The evolving clinical needs of both parturient and fetus require the coordinated efforts of obstetricians, midwives, nurses, anesthesia providers, and pediatricians. Birnbach and Salas have highlighted how coordinated care in the perinatal setting can benefit from the same team-building and team-training strategies that are inherent in other high-reliability organizations (e.g., highly hazardous industries, such as nuclear power, the military, and aviation) that have far fewer accidents than would be expected (see Chapter 11).

There is increasing evidence that bringing clinical providers together, to practice the management of critical events or to debrief real events, helps ensure a more unified and effective therapeutic environment. For example, a recent simulation-based multidisciplinary obstetric team training exercise resulted in transiently improved management of real-life shoulder dystocia and obstetric hemorrhage.[133] Ackenbom et al.[134] administered a survey to labor floor providers before and after their unit's implementation of routine debriefing after all deliveries. The investigators found that universal debriefings led to better communication among providers, and in particular, more providers chose to participate in debriefings and were more likely to speak up about patient care concerns. Intraprofessional team training on the labor floor also affects worker attitudes that can secondarily affect the patient experience. Blumenthal et al.[135] used the Safety Attitudes Questionnaire (SAQ) to demonstrate that implementing collaborative training exercises led to improved perceptions of safety, error management, safety practices, job satisfaction, and working conditions.

Developing strategies that support and engage all roles, and integrate the needs and contributions of all care providers, is a key component of a strong safety culture. Institutional culture encompasses the "shared values and beliefs that interact with an organization's structures and control systems to produce behavioral norms."[136] In safe work environments where employees are free to speak up and are encouraged to collaborate, connectedness and cross-monitoring allow for team success, even during times of rapidly evolving situations or uncertainty.[137,138]

Shared decision-making is a collaborative process. In addition to bringing together the values of the patient and input of the clinicians, it requires that clinicians with varying experiences and perspectives also "be on the same page." Despite the lack of direct data regarding the impact of clinician collaboration on the SDM process or outcome, the link seems both logical and intuitive. Analysis of closed claim data has shown that communication barriers include hierarchy, intimidation, failure to function as a team, and failure to follow a chain of communication.[139] Mann et al.[140] described their experience with scheduled team meetings on

the labor floor to facilitate "situational monitoring," where collective input contributed to a "shared mental model" of patients' conditions and care plans. In particular, they discussed the importance of closed-loop communication to confirm plans and directives, the value of having standardized hand-over language, and the benefits these simple techniques can have on fostering mutual support and minimizing burnout.

Austin et al.[141] recently provided a summary of initiatives from their institution aimed at overcoming these barriers and enhancing intraprofessional collaboration and communication. Regularly scheduled intraprofessional safety rounds, including nurses, physicians, and other health care professionals, provide a standardized format with which to share information. This approach has been shown to foster a sense of "team," improve outcomes, align goals, and promote discussion, even when participants have competing priorities.[142–145] Intraprofessional discussion of patient care plans should include a discussion of patient values and goals. One can imagine a situation in which, for example, a parturient with an unfavorable airway has expressed to the anesthesia provider a desire for natural childbirth, and the anesthesia provider could then share this information with the rest of the team during intraprofessional rounds. Then, if the obstetric provider was concerned about her nonreassuring fetal heart rate tracing, the team could approach the patient in a collaborative way to readdress the increased likelihood of an operative delivery and need for an anesthetic. In this not uncommon situation, the discussion would be focused not on choices for analgesia but on potential risks and benefits of surgical anesthesia. Respect for the patient's values thus can be maintained with a new perspective informed by intradisciplinary communication.

Contemporary Risk Management Strategies

By focusing on improving the culture of safety and quality in a health care organization, comprehensive obstetric safety programs that encompass intraprofessional collaborative practice reduce liability claims and payments.[146,147] Preventing medical error is a key strategy. The use of standardized approaches such as checklists empowers members of the intraprofessional care team to cross-check clinical care for individual patients. Clear communication among providers and allied professionals has been shown to increase favorable outcomes, and certainly to increase the likelihood of meeting appropriate standards of care.[148] A 2010 Joint Commission review of obstetric malpractice risks by a major insurer found that 65% of the malpractice cases involved high-severity injuries, including maternal and infant deaths.[149] The most frequent contributing factors were substandard clinical judgment (77% of claims) and miscommunication (36% of claims). The report specifically noted: "At the intersection of individual decision-making and team communication, teamwork training fosters development of a culture and structure for effective communication and decisive action. Its hallmarks—development of shared mental models, broad situational awareness, and clear communication among team members—facilitate clinicians' ability to timely identify signs of distress and take appropriate action."[149]

The most effective safety programs establish policies and procedures to learn from medical errors and unanticipated adverse outcomes, and to improve systems of care to reduce risk for future patients. Generally this requires both effective systems for reporting and honest discussion of medical error.[150] "Peer review" confidentiality laws in most states protect such internal discussions from disclosure to outside interests, including plaintiffs in medical malpractice claims. Of note, the peer review protection does not generally apply in federal court, which can result in information that was considered confidential being disclosed in certain federal matters, such as a patient race discrimination complaint.

UNANTICIPATED OUTCOMES AND MEDICAL ERRORS

Medical Liability

Medical malpractice is a form of tort law that is based in negligence. As with all negligence claims, the plaintiff (either the patient or the patient's legal surrogate) must prove four elements: duty, breach of such duty, injury, and proximate causation (meaning that the "breach" was the "cause" of the "injury"). If the plaintiff is unable to prove even one of these elements, then the claim will fail as a matter of law.

In a malpractice case, the "duty" that must be proven to have been "breached" is the duty to provide care that meets a minimum level of competence as determined by expert opinion on both sides of the case. It does not need to be the highest level of care, nor does it even need to be the level of care provided by most clinicians. However, it must not be beneath the minimum standard of care expected of a licensed provider. The standard of care is generally defined as "that care which a reasonable, similarly situated professional would have provided to the patient."[150,151] Proving that such a standard of care has been breached is the role of experts.[152] Because medicine is a complex, continuous evolving discipline, it is the province of experts in the field to weigh in on whether the standard of care was met.[151] In making these judgments, experts can rely on their own knowledge, developed through education and practice, and on authoritative sources such as the *Physician's Desk Reference*, pharmaceutical publications and FDA-approved inserts, scientific journals, and professional organizational standards, guidelines, and practice advisories.[153] Ultimately, expert testimony and other evidence presented by both parties will be evaluated by judges or juries for their persuasiveness. If either the judge or jury determines that the standard of care was not met, then the plaintiff will still need to prove that there was an "injury" that was "caused" by the "breach."[151]

It is important to remember that the burden of proof lies with the plaintiff (i.e., the injured patient) to show that the standard of care was not met, and that such breach caused the injury from which the patient suffers.[151] The plaintiff must prove by a "preponderance of the evidence" (meaning it is more than 50% likely) that each element of the claim has

been proven.[151] Although this "preponderance of the evidence" standard is significantly lower than the criminal law standard of "proof beyond a reasonable doubt," it is still a relatively high burden to meet. The evidence presented, including the expert testimony, must be significant and objectively strong.

Some of the most common standards of care that are evaluated in a medical malpractice claim include whether an appropriate diagnosis was made, whether there was a surgical error, or whether pharmaceuticals have been prescribed and/or administered appropriately.[154]

It is also important to remember that an unanticipated outcome does not mean that malpractice has occurred. In fact, most unanticipated outcomes in medical care are a result of known risks, and despite the plaintiff's wish to establish fault through a medical malpractice claim, it is often established that the standard of care was met even though the outcome was not the desired one.

Sometimes, a physician makes a promise of a specific outcome to the patient, which could create a cause of action against the physician if such an outcome is not met.[155] But such cases are a rarity, and require the plaintiff to make the case that a reasonable patient would have understood the words of the physician to indicate a promise of that specific outcome. It is more often the case that the *process* of care is being evaluated, rather than the outcome. A physician is liable for a misjudgment or mistake only when it is proved to have occurred through a failure to act in accordance with the "care and skill of a reasonably prudent practitioner."[156]

Many potential plaintiffs struggle to file a medical malpractice claim in a timely manner.[157] Numerous factors may get in the way of bringing timely claims, not the least of which is the awareness that an unanticipated outcome has occurred.[157] Even when a medical error led to iatrogenic injury, this may never be disclosed to the patient and family, and knowing the cause of any particular outcome can be difficult for the average patient (or their legal surrogates) to discern. Injured patients may serve notice of the intent to sue for malpractice as a strategy to find out what happened, and use legal procedures to require disclosure of the details of care that may otherwise be inaccessible. Statutes of limitations, legal time frames in which legal claims must be brought for such claims to be valid, vary from state to state but are generally 2 to 3 years.[158] Most laws establish that this time frame begins when a reasonable person becomes aware of an injury that might be the result of a breach of the standard of care.[154] If this acknowledgement occurs right after care has been provided, then the time frame has begun; if it is years later (such as when the patient tries to conceive and discovers that she suffers from sterility), then the time frame will begin at the point of discovery of the injury. If a plaintiff can show that she would have been aware of an injury if not for fraudulent concealment by the provider, then the time frame may be extended to take such fraudulent behavior into account.[158] Additionally, if the plaintiff was a minor when the alleged breach occurred, then the statute of limitations does not usually begin until she reaches the age of majority.

Disclosure of Unanticipated Outcomes and Medical Errors

Most practitioners strive to provide the highest quality of care, but even with the growing focus on patient safety, unintended consequences—including patient injury and death—do occur. Unfortunately, most physicians remain largely unprepared to engage patients and their families in a timely, truthful, and candid manner in the aftermath of such events. Although many providers and medical malpractice insurers might want potential breaches of the standard of care to go unnoticed or unrecognized, emerging evidence suggests that timely disclosure may reduce legal risk.[159] In cases of unanticipated adverse outcomes, patients and families most commonly seek truthfulness, empathy, and a plan to ensure similar patients will not face similar risks in the future. Transparency, as well as a culture of accountability that includes providing apologies after such events, can mitigate distrust between the patient and provider, and ameliorate the desire to find someone to blame.[160] Many states have laws that protect providers from having disclosure and apology held against them should a malpractice claim be subsequently brought.[158] Some states even require reporting of medical errors.[161]

The ethical imperative to disclose is captured in the following passage from the *Charter on Medical Professionalism,* published by the American Board of Internal Medicine (ABIM) Foundation[162]:

> *Physicians should also acknowledge that in health care, medical errors that injure patients do sometimes occur. Whenever patients are injured as a consequence of medical care, patients should be informed promptly because failure to do so seriously compromises patient and societal trust. Reporting and analyzing medical mistakes provide the basis for appropriate prevention and improvement strategies and for appropriate compensation for injured parties.*[162]

The AMA's *Code of Medical Ethics* contains the following statement: "It is a fundamental ethical requirement that a physician should at all times deal honestly and openly with patients…. Concern regarding legal liability, which might result following truthful disclosure, should not affect the physician's honesty with a patient."[163] The Joint Commission standard RI.2.90 requires that "patients and, when appropriate, their families, are informed about the outcomes of care, treatment, and services that have been provided, including unanticipated outcomes."[164]

In 2006, the Harvard teaching hospitals and their associated Risk Management Foundation developed a document entitled, "When Things Go Wrong: Responding to Adverse Events."[165] This white paper acknowledged the presence of many barriers to disclosure, including the fear of being sued, but the authors insisted that communication with patients and their families must be timely, open, and ongoing. In addition to stressing the imperative of providing support for the patient and family involved in the unexpected

outcome, the paper emphasized the need to provide support to the health care providers involved. This concern is reflected in a 2008 survey that indicated that as many as 75% of obstetricians felt that caring for a patient with an unanticipated stillbirth exacted a large toll on them, with almost 10% of those affected considering giving up their obstetric practice.[166]

Even in the absence of laws requiring prompt disclosure of patient harm, some health care entities and their insurers have adopted disclosure policies that also contain early settlement or "offer" programs.[167] These types of programs encourage patients or their families to accept an early, modest payment for an unanticipated outcome that will eliminate the need for complex, expensive, and uncertain litigation that could take years to resolve.[167] Such offers are often protected from legal discovery, meaning the fact of such offer cannot be used against the providers in any future litigation.[167]

Regardless, team debriefing can be used to establish the need for disclosure, to clarify what is known about the event, and to decide who will lead the disclosure process. Experts advise to limit disclosure to factual information that is known at the time of the discussion, and state that discovery is ongoing and information may evolve as the discovery process unfolds. A simple apology (e.g., "I am sorry this happened") conveys empathy without laying blame or fault. It is important to maintain open dialogue with the patient and family as information is clarified, but this requires careful coordination among different members of the health care team. Conflicting information and speculation, especially speculation that places blame on other members of the health care team, can raise concerns that the entire team may be hiding the truth. The process is analogous to SDM, and effective communication established before a patient safety incident or adverse outcome will carry over into the communication that must continue after the event.

KEY POINTS

- Effective communication with the parturient and her family is an important component of obstetric anesthesia practice.
- Informed consent may be either verbal or both verbal and written. Written consent provides documentation that the consent process has occurred. If possible, it is best to obtain consent early in labor, before the onset of severe pain.
- Shared decision-making is a best practice for communication in which the clinician partners with the patient to address a series of decisions throughout the health care encounter. In addition to standard disclosure of risks, benefits, and alternatives, the clinician elicits questions, values, and preferences from the patient, and guides the discussion toward a decision that is consistent with both the patient's preferences and current evidence.
- Techniques to ensure understanding and avoid coercion are particularly important for vulnerable populations, including pregnant adolescents, non–English speakers, and women from diverse cultural backgrounds.
- Honest, caring, and comprehensive discussion with the patient before the administration of anesthesia meets legal and ethical standards, improves the image of the anesthesia provider, and reduces the likelihood of dissatisfaction and possible litigation after unanticipated complications.
- Refusal of care by pregnant patients may raise unique legal and ethical concerns. In such situations, the woman's competency or ability to make an informed medical decision may be an issue. When the patient is competent, the health care providers should attempt to resolve treatment conflicts through additional patient education and discussion. Rarely, it may be advisable to seek a court order to resolve competency or medical treatment issues.
- Effective intraprofessional team communication is essential to ensure optimal team performance, minimize the risk for medical error, and maintain consistent communication with the patient and family, all of which serves to mitigate the risk for medical liability in the event of an unanticipated adverse outcome.

Preterm Labor and Delivery

Janelle R. Bolden, MD, William A. Grobman, MD, MBA

CHAPTER OUTLINE

Preterm delivery is defined as delivery before 37 weeks' gestation. It occurs in 5% to 9% of pregnancies in developed countries[1] and is responsible for 75% to 80% of all neonatal deaths and significant neonatal morbidity.[1,2] Preterm delivery leads to a large economic burden to society. For example, in 2005, in the United States the cost associated with preterm birth was at least $26.2 billion.[3]

Preterm delivery in the United States increased 20% between 1990 and 2006 (from 10.6% to 12.8%),[3] before declining to 9.9% of all births in 2016 (Figs. 33.1 and 33.2).[4] There is notable racial/ethnic disparity in the frequency of preterm birth. In 2015, 9.0% of non-Hispanic whites, 13.8% of non-Hispanic blacks, and 9.5% of Hispanics delivered preterm. This is not explained by differential use of assisted reproductive technology.[5,6] *Late preterm* is defined as 34 0/7 to 36 6/7 completed weeks' gestation, and *early preterm* is defined as less than 34 completed weeks' gestation. Table 33.1 lists subdivisions of early preterm births. In 2016, late preterm deliveries composed 7.1% of all births, and early preterm births composed 2.8% of all births.

The concern about preterm birth is not confined to the United States; the World Health Organization (WHO) and other nongovernmental organizations have identified the frequency of preterm birth as a critical health issue. Worldwide, on a yearly basis, 15 million infants are born preterm.[7] More than 60% of preterm births occur in Africa and South Asia, with Malawi having the highest rate (18.1 per 100 live births).[7] Although truly a global problem, economic disparity exists. In lower-income countries, the preterm birth rate is 12% with a mortality rate greater than 90% in those born extremely preterm (less than 28 weeks).[8] In higher-income countries, the preterm birth rate is 9% with a neonatal mortality rate less than 10%.[8] The global neonatal mortality rate is 19 per 1000 live births. The United States has a slightly higher neonatal mortality rate than Europe (4 versus 3 per 1000 births, respectively), which reflects the higher preterm birth rate in the United States.[8]

In 2006, the Institute of Medicine recommended that investigators focus on (1) better defining the problem; (2) developing treatments to prevent both preterm delivery and morbidity for children born preterm; (3) identifying the causes of preterm birth, including modifiable risk factors and the reasons for disparity among different ethnic, racial, and socioeconomic groups; and (4) developing policies and public programs that can be used to reduce the rate of preterm birth.[3]

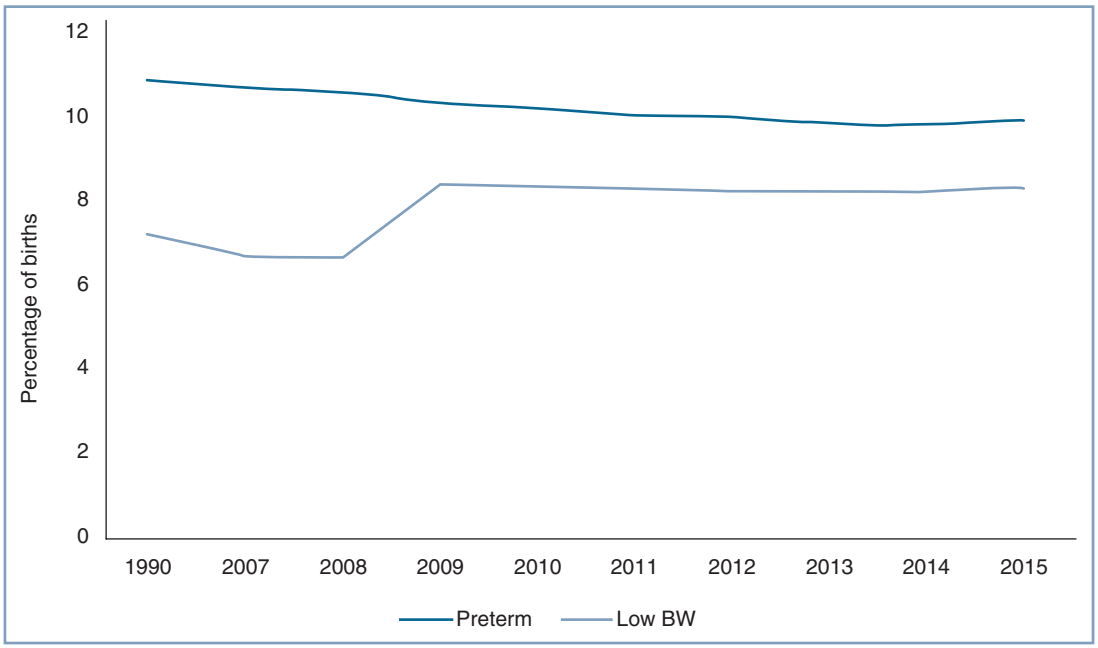

Fig. 33.1 Preterm and low birth weight rates: United States, final data from 1990 to 2015. *BW,* birth weight. (Data from Martin JA, Hamilton BE, Osterman MJ, et al. Births: final data for 2015. *Natl Vital Stat Rep.* 2017;66:1.)

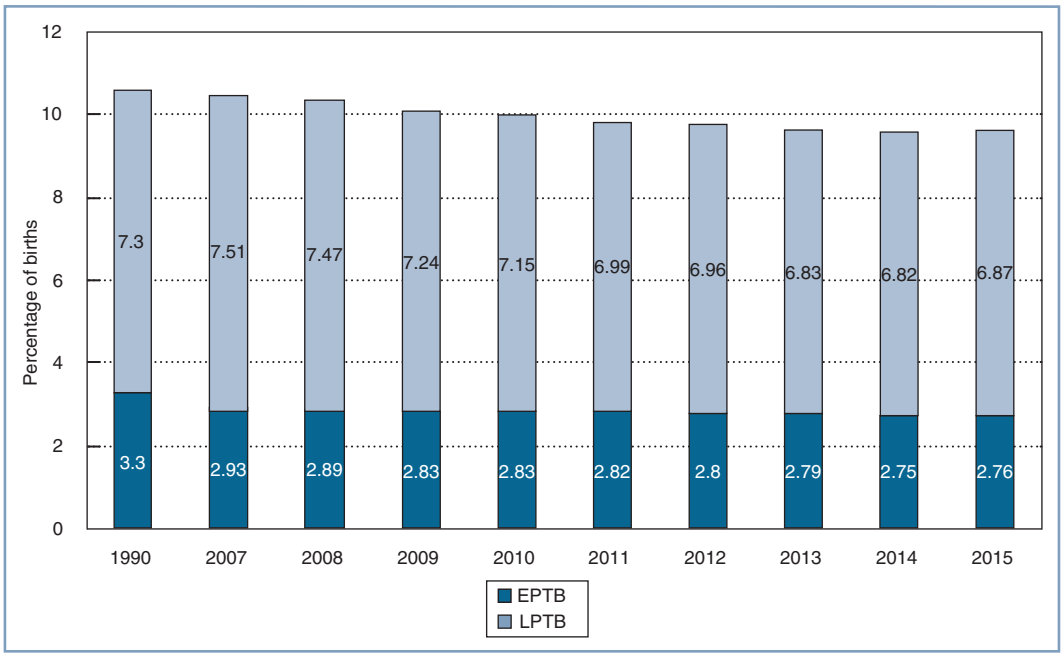

Fig. 33.2 Total, early, and late preterm birth rates: United States 1990 and 2007 to 2015. Preterm birth is defined as less than 37 weeks' completed gestation. Early preterm birth is defined as less than 34 weeks' completed gestation. Late preterm birth is defined as 34 to 36 weeks' completed gestation. *EPTB,* Early preterm birth; *LPTB,* late preterm birth. Accessed July 25, 2018.)

DEFINITIONS

A preterm infant is defined as one who is born between 20 0/7 weeks and 36 6/7 weeks, inclusive, after the first day of the last menstrual period. The American College of Obstetricians and Gynecologists (ACOG) has defined *periviable birth* as birth between 20 weeks' and 25 6/7 weeks' gestation.[9] Further classification of deliveries based on gestational age is outlined in Table 33.1. If a good basis does not exist for establishing the gestational age from either maternal history or first-trimester ultrasound, the exact gestational age is difficult to determine. A low birth weight (LBW) does not necessarily signify that a

neonate has been born preterm, because some newborns have a LBW because they are small for gestational age (SGA) rather than preterm. A neonate who weighs less than 2500 g at birth is considered to have a LBW, regardless of gestational age. Likewise, an infant who weighs less than 1500 g at birth is considered to have a very low birth weight (VLBW), and an infant who weighs less than 1000 g at birth is considered to have an extremely low birth weight (ELBW).

TABLE 33.1 Classification of Deliveries Based on Gestational Age

Classification	Gestational Age
Extremely preterm	Less than 28 weeks
Very preterm	28 0/7 weeks to 31 6/7 weeks
Moderate preterm	32 0/7 weeks to 33 6/7 weeks
Late preterm	34 0/7 weeks to 36 6/7 weeks
Early term	37 0/7 weeks to 38 6/7 weeks
Full term	39 0/7 weeks to 40 6/7 weeks
Late term	41 0/7 weeks to 41 6/7 weeks
Postterm	42 0/7 weeks and beyond

NEONATAL MORTALITY

The survival rate among neonates increases as the birth weight and/or gestational age increases (Fig. 33.3; Table 33.2).[10] After data are controlled for gestational age and weight, male infants have a higher mortality than female infants.[11] During the past three decades, there has been a significant improvement in the survival rate for preterm infants, with the greatest improvement occurring in the subgroup with a birth weight between 501 and 1250 g.[12] The rate of neonatal survival now is approximately 94% for infants born at 28 weeks' gestation.[13]

Infants born at the threshold of viability (22 to 24 weeks' gestation) continue to have the greatest risk for poor

[a]Death rate before discharge by gestational age among all infants born at the Neonatal Research Network Centers between 2008 and 2012.

Data from Stoll BJ, Hansen N, Bell EF, et al. Trends in care practices, morbidity, and mortality of extremely preterm neonates, 1993–2012. *JAMA*. 2015;314:1039–1051.

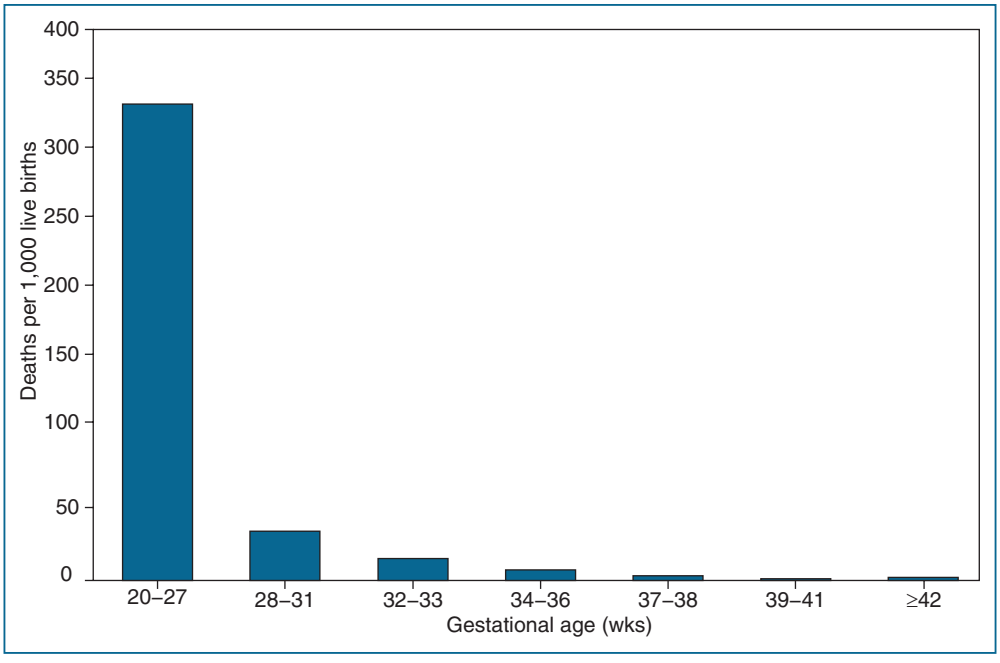

Fig. 33.3 Infant mortality rates by gestational age—United States, 2013. (From Shapiro-Mendoza CK, Barfield WD, Henderson Z, et al. CDC grand rounds: public health strategies to prevent preterm birth. *MMWR Morb Mortal Wkly Rep*. 2016;65:826–830.)

outcome.[9] A retrospective cohort study assessed survival rates for infants delivered between 22 and 28 weeks' gestation.[10] Neonatal survival was 9% at 22 weeks, 33% at 23 weeks, and then 65%, 81%, and 87% at 24, 25, and 26 weeks' gestation, respectively.[10] The majority of women received antenatal corticosteroids, and the majority of neonates received exogenous surfactant. A delay in delivery of even 1 week at this time in gestation leads to significantly better outcome and reduced cost.

Younge et al.[14] examined outcomes for infants born between 22 and 24 weeks' gestation between 2000 and 2011 (Table 33.3).[14] The mortality rate decreased over time overall (72% from 2000 to 2003 to 66% from 2008 to 2011). However, the mortality rate did not change for 22-week infants. As expected, the greatest decrease in mortality was seen in the 24-week group (55% from 2000 to 2003 to 18% from 2008 to 2011).[14] Those born later in the study period were more likely to have been exposed to antenatal maternal corticosteroids, be delivered by cesarean, and be resuscitated at birth, regardless of gestational age. Excess mortality risk for infants born preterm is concentrated in the first year.[13]

NEONATAL MORBIDITY

Approximately 84% of preterm births occur between 32 0/7 and 36 6/7 weeks' gestation.[6] Compared with earlier gestational ages, mortality is less common, but morbidity is a relatively greater concern in this gestational age range. Researchers have examined the association between late preterm birth and neurocognitive performance in late adulthood; 919 Finnish men and women were evaluated at a mean age of 68.2 years.[15] When controlling for confounders, those who were born between 34 and 37 weeks' gestation had lower scores on tests evaluating neurocognitive performance than those born after 37 weeks' gestation.[15]

As with mortality, most morbidity decreases in frequency as gestational age increases. For example, the incidence of high-grade (III or IV) intraventricular hemorrhage diminishes rapidly after 27 weeks' gestation, and grade III or IV intraventricular hemorrhages are very rare after 32 weeks' gestation. Likewise, neonatal morbidity from patent ductus arteriosus and necrotizing enterocolitis diminishes significantly after 32 weeks' gestation.[16] Data from the National Institute of Child Health and Development (NICHD) Neonatal Research Network sites from 1997 to 2002 indicate that survival without complications (e.g., bronchopulmonary dysplasia, severe intraventricular hemorrhage, necrotizing enterocolitis, or a combination of these disorders) ranged from 20% for infants with a birth weight between 501 and 750 g to 89% for those with a birth weight between 1251 and 1500 g.[2]

Piecuch et al.[17] reported data for a cohort of 138 nonanomalous infants delivered between 24 and 26 weeks' gestation between 1990 and 1994. The incidence of cerebral palsy did not differ significantly among the three groups born at 24, 25, and 26 weeks' gestation (11%, 20%, and 11%, respectively). However, the incidence of normal cognitive outcome rose with increasing gestational age at birth (28%, 47%, and 71% at 24, 25, and 26 weeks' gestation, respectively).

The EPICure study group assessed the association between extreme preterm delivery and long-term physical and mental disability in a cohort of infants delivered between 22 and 25 weeks' gestation during a 10-month period in 1995.[18] These investigators noted rates of severe disability of 54%, 52%, and 45% among infants delivered at 23, 24, and 25 weeks' gestation, respectively. In a later cohort of infants, born between 1997 and 2002, the rates of severe disability were 33%, 21%, and 12% for infants delivered at 23, 24, and 25 weeks' gestation, respectively.[19] A 6-year follow-up to the EPICure study cohort reported persistent severe disability in 25%, 29%, and 18% of infants born at 23, 24, and 25 weeks' gestation, respectively.[20]

Hack et al.[21] monitored a cohort of ELBW infants born between 1992 and 1995 until they were 8 years of age. The mean birth weight was 810 g, and the mean gestational age at delivery was 26 weeks. Compared with a cohort of age-matched children of normal birth weight, the ELBW group had a higher incidence of significant neurosensory impairment (16% versus 0%, respectively) and asthma (21% versus 9%). The ELBW children differed significantly from the cohort with normal birth weight in rates of suboptimal intelligence, academic achievement, motor skills, and adaptive functioning. These data underscore the long-term medical, educational, and social services required by these children.

TABLE 33.3 Selected Outcomes for Extremely Preterm Infants[a]

Outcome	Percent
Use of antenatal therapy:	
Maternal corticosteroid administration	64
Maternal antibiotic administration	66
Cesarean delivery	38
Male gender	52
Multiple birth	27
Surfactant therapy after birth	66
Death before discharge	64
Survival without neurodevelopmental impairment[b]	20
Survival without neurosensory impairment[c]	29

Total $N = 1348$.

[a]Gestational age between 22 and 24 weeks' gestation, born between 2008 and 2011.

[b]Neurodevelopmental impairment defined as at least one of the following conditions: moderate or severe cerebral palsy, Gross Motor Function Classification System level 2 or greater, profound hearing loss requiring amplification in both ears, profound visual impairment with visual acuity of less than 20/200 in both eyes, or cognitive impairment.

[c]Neurosensory impairment defined as moderate or severe cerebral palsy, Gross Motor Function Classification System level 2 or greater, profound hearing loss, or profound visual impairment.

Data from Younge N, Goldstein RF, Bann CM, et al. Survival and neurodevelopmental outcomes among periviable infants. *N Engl J Med.* 2017;376:617–628.

The economic costs for the care of surviving preterm infants (especially VLBW infants) can be enormous. A conservative estimate is that 7.7% of insured infants born preterm accounted for 37% of $2.0 billion spent by participating plans on the care of infants born during 2013.[22] With a mean difference in plan expenditures between preterm and term infants of approximately $47,100 per infant, preterm births cost the included plans an extra $600 million during the first year of life.[22] These figures likely will continue to rise with the escalating cost of health care.

PRETERM LABOR

Risk Factors

Box 33.1 lists factors associated with preterm labor.[1,3] These associations do not necessarily indicate cause-and-effect relationships. Significant risk factors include a history of preterm delivery, non-Hispanic black race (irrespective of socioeconomic status), and multiple gestation.

The process of normal parturition involves anatomic, physiologic, and biochemical changes that lead to (1) greater uterine contractility, (2) cervical ripening, and (3) membrane/decidual activation.[23] The fetus also appears to play a role in parturition. It is hypothesized that the mature fetal hypothalamus secretes more corticotropin-releasing hormone (CRH), which in turn stimulates fetal adrenal production of adrenocorticotropic hormone (ACTH) and cortisol.[23] Preterm labor results from the pathologic activation of one or more of these components (Fig. 33.4). Preterm delivery

BOX 33.1 Factors Associated with Spontaneous Preterm Labor

Demographic and Medical Characteristics
Non-Caucasian race
Extremes of age (less than 17 or greater than 35 years)
Low socioeconomic status
Low prepregnancy body mass index
History of preterm delivery
Interpregnancy interval less than 6 months
Periodontal disease
Abnormal uterine anatomy (e.g., myomas)
Trauma
Abdominal surgery during pregnancy

Behavioral Factors
Tobacco use
Substance abuse

Obstetric Factors
Previous preterm birth
Vaginal bleeding
Infection (systemic, genital tract, periodontal)
Short cervical length
Multiple gestation
Assisted reproductive technologies
Preterm premature rupture of membranes
Polyhydramnios

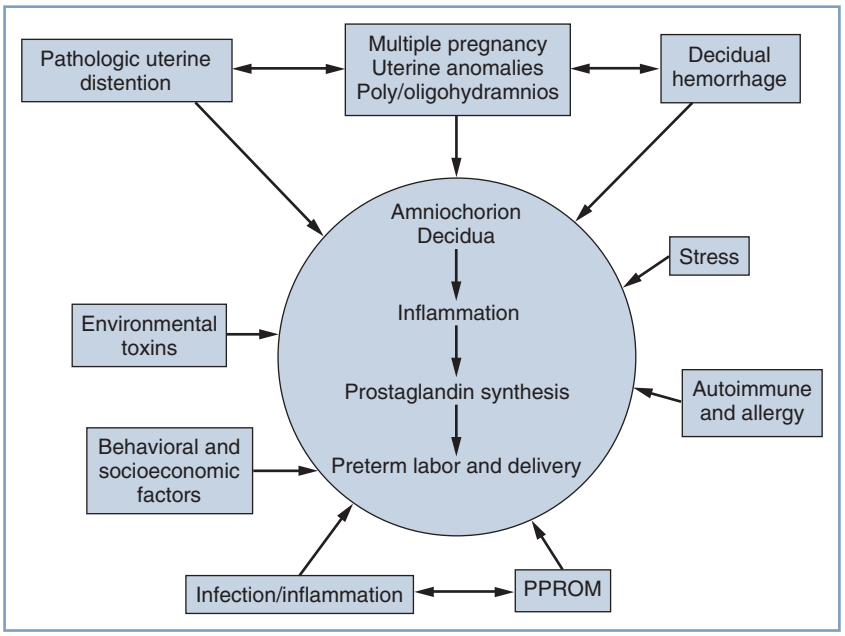

Fig. 33.4 Major etiologic factors in preterm birth, including activation of the maternal or fetal hypothalamic-pituitary axis (stress), inflammation, decidual hemorrhage, and pathologic distention of the myometrium. The pathways are not mutually exclusive and may overlap, and they share a common biochemical pathway. *PPROM,* Preterm premature rupture of membranes. (From Menon R. Spontaneous preterm birth, a clinical dilemma: etiologic, pathophysiologic and genetic heterogeneities and racial disparity. *Acta Obstet Gynecol Scand.* 2008;87:590–600.)

results from (1) preterm premature rupture of membranes (preterm PROM) in approximately 25% of cases; (2) spontaneous preterm labor in approximately 45% of cases; and (3) maternal or fetal indications for early delivery in approximately 30% of cases.[1,24] However, the "spontaneous" causes do not have a uniform underlying pathophysiology, and it appears that preterm labor is a syndrome with multiple causes influenced by a number of genetic, biologic, biophysical, psychosocial, and environmental factors.

Two factors of interest are the influences of **infection** and **uterine distention** on initiation of myometrial contractility. Infection is thought to be present in up to 40% of preterm deliveries.[1] Commonly identified organisms include *Ureaplasma urealyticum, Bacteroides* species, *Neisseria gonorrhoeae, Chlamydia trachomatis,* group B streptococci, *Staphylococcus aureus, Treponema pallidum,* and enteropharyngeal bacteria.[25–27] Although approximately 50% of preterm deliveries occur in women with no apparent risk factors, subclinical infection may precipitate preterm labor in some of these cases.[26] In addition, infection compounds the effects of preterm birth with increased rates of neurologic injury.[27]

Multiple gestation accounts for 21.6% of all preterm births.[6] In the past three decades, there was a significant rise in the incidence of multiple gestation (see Chapter 34), attributed to a shift toward older maternal age at conception, and to increased use of assisted reproductive technology (ART).[28] The twinning rate (births in twin deliveries per 1000 total births) rose 76% from 1980 to 2009 (from 18.9 to 33.2 per 1000). Recently, rates of multifetal pregnancies have started to decline. The **twin birth rate** peaked at 33.9 twins per 1000 births in 2014, and has since decreased to 33.4 in 2016.[6] Likewise, the **triplet and higher-order multiple birth rate** has fallen 48% since the 1998 peak (193.5) to a rate of 101.4 multiples per 100,000 births in 2016.[6]

Modifications in ART may be contributing to changes in the preterm birth rate and recent declines in multiple gestation.[29] In 2015, ART contributed to 1.7% of all infants born in the United States and 17.0% of all multiple-birth infants, including 16.8% of all twin infants and 22.2% of all triplets and higher-order infants.[29] Risk for preterm birth is elevated even for singleton pregnancies conceived by ART. A 2004 meta-analysis of 15 studies[30] that compared outcomes for 12,283 ART singleton pregnancies with outcomes for 1.9 million spontaneously conceived singleton pregnancies demonstrated a higher risk for preterm and SGA deliveries in the ART group. Placenta previa, gestational diabetes, preeclampsia, and neonatal intensive care unit admission were also more prevalent in the ART group.[30]

Prediction of Preterm Labor

The ability to prevent spontaneous preterm birth would be facilitated if it were possible to intervene prophylactically to prevent preterm labor or to effectively treat preterm labor once it occurs. Both prophylaxis and treatment would require the ability to accurately predict which asymptomatic or symptomatic patients will go on to have spontaneous preterm delivery. Several methods of predicting preterm delivery have been proposed, including home uterine activity monitoring and fetal fibronectin screening.[31] However, available interventional studies based on the use of these tests for screening asymptomatic women have not demonstrated improved perinatal outcomes. Thus, these methods are not recommended as screening strategies.[31]

Novel biomarkers are being investigated for their ability to predict preterm birth. A recent study found that two serum proteins (insulin-like growth factor–binding protein 4 [IBP4] and sex hormone–binding globulin [SHBG]) identified asymptomatic pregnant women at risk for spontaneous preterm delivery.[32] Although promising, these markers have yet to be used in clinical practice.

Short cervical length, as assessed by transvaginal ultrasonography, is associated with a greater risk for preterm delivery. In a 2006 systematic analysis, Kagan et al.[33] concluded that cervical length is associated with preterm delivery (i.e., the shorter the cervix the greater the risk for preterm delivery) in *symptomatic* women. Further, multiple studies have shown an increased risk for preterm delivery in asymptomatic women with a shortened cervix. A Maternal-Fetal Medicine Units Network study of nearly 3000 women found that the risk for spontaneous preterm delivery is increased in women with evidence of a short cervix detected by transvaginal ultrasonography between 24 and 28 weeks' gestation.[34] A cervical length below the 10th percentile had a sensitivity of 37% and a specificity of 92% in predicting preterm birth before 35 weeks' gestation, with a corresponding positive predictive value of 18% and a negative predictive value of 97%.[35] The cervix appears to shorten at a similar rate before preterm birth whether the presentation is preterm labor (–0.96 mm/week) or rupture of membranes (–0.82 mm/week).[34]

A history of cervical surgery, including conization and loop electrosurgical excision procedure, traditionally has been thought to be a risk factor for preterm birth because of associated cervical injury. However, this relationship may be related to environmental factors and/or behavioral factors that underlie the progression of cervical dysplasia. Uterine instrumentation, such as dilation and curettage, also has been associated with an increased risk for preterm birth in some, but not all, studies; the mechanism is unclear, but it may be a result of intrauterine microbial colonization, injury to the endometrium, or both, together with host and environmental factors.[31]

Prevention of Preterm Labor

Screening for any disease is of greatest benefit when there are interventions available to decrease the incidence of said disease. Unfortunately, few if any interventions have been shown to definitively reduce the incidence of preterm labor and delivery. Interventions that have been studied include detection and suppression of uterine contractions, antimicrobial therapy, prophylactic cervical cerclage, maternal nutritional supplements, and reduction of maternal stress. It is not surprising that most of these simple interventions have

not been shown to alter outcome, given that preterm labor is increasingly understood to be a complex syndrome with multiple, overlapping causes.

Prophylactic **cervical cerclage** in the early second trimester has been performed to prevent preterm birth, typically in women with a history of mid-trimester pregnancy loss. Evidence supporting the efficacy of this practice is weak.[36] There remains controversy with regard to whether cerclage should be placed in response to transvaginal ultrasonographic evidence of a short cervix in the second half of the mid-trimester. Data do not support such a practice in the general population, but there is some evidence that the practice may be beneficial among high-risk women, such as those with a prior preterm birth.[37]

Evidence does *not* support the administration of **prophylactic antibiotics** in asymptomatic women at risk for preterm labor.[38] Likewise, evidence does not support the prophylactic use of **beta-adrenergic receptor agonists** to prevent preterm labor in high-risk women.[39,40]

By contrast, evidence suggests that **progesterone** therapy may be effective in reducing the rate of preterm birth in some patient populations. The Maternal-Fetal Medicine Units Network performed a randomized controlled trial that compared prophylactic intramuscular 17α-hydroxyprogesterone caproate (17P) (250 mg weekly beginning at 16 to 20 weeks' gestation, and continued until delivery or 36 weeks' gestation) with placebo in women with a history of spontaneous preterm delivery.[41] The risk for delivery before 37 weeks' gestation was reduced in the 17P group (relative risk [RR], 0.66; 95% confidence interval [CI], 0.54 to 0.81). A systematic review of 11 randomized controlled trials ($n = 2425$) also concluded that progesterone administration was associated with a significant reduction in recurrent preterm birth in women with a history of spontaneous preterm delivery.[42]

Progesterone therapy also has been shown to be beneficial in reducing the incidence of preterm delivery in the subset of women with a sonographically identified short cervix. In two double-blind, placebo-controlled trials, women with a mid-trimester diagnosis of a short cervix (less than 15 mm in one trial[43] and 10 to 20 mm in the other[44]) were randomized to receive either vaginal progesterone or placebo. Women who received vaginal progesterone experienced a significant reduction in the frequency of preterm delivery before 33 weeks' gestation.[43,44] By contrast, in a trial that enrolled nulliparous women with a cervical length less than 30 mm, women randomized to receive 17P did not experience a reduction in preterm delivery compared with women who received placebo.[45]

A number of studies have examined whether progesterone is efficacious in reducing preterm birth among women with multiple gestation. A recent meta-analysis comparing progesterone (both intramuscular and vaginal preparations), pessary, and cerclage found that vaginal progesterone may be beneficial in twin pregnancy.[46]

Even among women for whom progesterone is thought to be indicated, the optimal type, timing, and dosing of progesterone is unclear. Based on existing evidence, the ACOG[31] has concluded that vaginal progesterone should be offered to asymptomatic women with a singleton gestation without a previous preterm delivery, who have a very short cervical length (i.e., less than or equal to 20 mm at or before 24 weeks' gestation).

Diagnosis

Determining whether a woman is in early preterm labor or in false labor is often difficult. Criteria for the diagnosis of preterm labor include gestational age between 20 0/7 and 36 6/7 weeks' gestation and regular uterine contractions accompanied by a change in cervical dilation, effacement, or both (or initial presentation with regular contractions and cervical dilation of 2 cm or more). Less than 10% of women with the clinical diagnosis of preterm labor actually give birth within 7 days of presentation.

Assessment and Therapy

Initial assessment of the patient with possible preterm labor includes physical examination and external monitoring of contractions with a tocodynometer (and fetal heart rate if indicated by gestational age). Acute conditions associated with preterm labor should be considered, including infection and placental abruption. Maternal physical examination may include a sterile speculum examination to exclude preterm PROM if symptoms or signs indicate this possibility. In many women who have preterm uterine contractions, these contractions will cease spontaneously. In the past, clinicians assumed that intravenous hydration was a useful component of therapy. However, there is no evidence that intravenous hydration reduces the chance of preterm delivery.[47]

Once the diagnosis of preterm labor is established, the obstetric care provider must decide whether intervention is warranted. The administration of antenatal corticosteroids for fetal lung maturation[48] and magnesium sulfate for fetal neuroprotection[49] are associated with improved neonatal outcomes. Although widely used before 34 weeks' gestation, acute tocolytic therapy remains a source of controversy. Tocolysis is currently recommended between 24 and 34 weeks' gestation. However, certain clinical scenarios may be favorable for administration of this intervention between 23 and 24 weeks' gestation as well.[9] There is no consistent evidence that the use of acute tocolysis reduces the chance of preterm birth or improves neonatal outcome. However, because acute tocolysis has been associated with a short (approximately 48-hour) prolongation of pregnancy, it may be used to facilitate transfer of the patient from a community hospital to a tertiary care facility that can provide optimal care for the preterm neonate. Moreover, a short course of tocolytic therapy may delay delivery for 24 to 48 hours, allowing maternal administration of (1) a corticosteroid to accelerate fetal lung maturity and (2) antibiotic therapy to prevent neonatal group B streptococcal infection. Thus, the ACOG[48] supports the use of acute tocolysis to allow administration of a complete course of antenatal corticosteroids, but discourages the continued use of tocolysis after corticosteroid administration is complete.

Criteria for the use of tocolytic therapy include (1) gestational age after viability (23 weeks) and before 34 weeks' gestation, (2) reassuring fetal status, and (3) no overt clinical signs of infection. The potential benefits of delaying delivery of the preterm infant (i.e., decreased neonatal morbidity and mortality) must be weighed against the maternal and fetal risks (e.g., maternal side effects of tocolytic drugs, deterioration of a compromised fetus). Box 33.2 lists contraindications to inhibiting labor.

In the setting of preterm PROM, obstetricians have worried that tocolytic therapy might increase the risk for maternal and/or fetal infection. It also seems logical that tocolytic therapy is less effective in patients with preterm PROM. Prospective, randomized studies have shown that tocolytic therapy *per se* does not improve neonatal outcome compared with conservative expectant management in patients with preterm PROM,[49] but may afford time to optimize conditions before delivery (see later discussion).

Antenatal Administration of Corticosteroids

The neonatal benefits of corticosteroid administration (Table 33.4) before preterm delivery have been clearly demonstrated in large clinical trials. The NICHD Neonatal Research Network evaluated outcomes for 11,718 preterm infants delivered after antenatal maternal corticosteroid administration between 1988 and 1992.[50] Antenatal corticosteroid treatment significantly reduced the incidence of neonatal respiratory distress syndrome, intraventricular hemorrhage, and neonatal death in all subgroups of the population studied (including male and female infants, African and Caucasian race infants, and infants delivered before 30 weeks' gestation). The reduction in neonatal morbidity and mortality from antenatal corticosteroid administration is additive to the reduction observed with the use of neonatal surfactant alone.[51] A randomized trial has demonstrated that these benefits may not be limited to those born before 34 weeks.[52] A single course of corticosteroids administered to women at risk for preterm birth after 34 weeks' but before 37 weeks' gestation resulted in a significantly lower incidence of severe neonatal respiratory morbidity.[52]

Although there is little controversy about the efficacy of a single course of antenatal corticosteroids, there remains debate over the use of multiple courses of corticosteroids for women who remain undelivered 7 days after the initial dose of corticosteroids. A large study performed by the Maternal-Fetal-Medicine Units Network randomly assigned women at risk for preterm delivery between 23 and 32 weeks' gestation to receive either a single course or repeated (weekly) courses of antenatal corticosteroids.[53] Weekly corticosteroid administration did not significantly reduce the composite primary morbidity outcome, but it significantly reduced the need for neonatal surfactant, mechanical ventilation, and continuous positive airway pressure (CPAP), as well as the incidence of pneumothorax. However, weekly corticosteroid administration was associated with an increase in the delivery of SGA infants, and there was a significant reduction in the birth weight of the infants whose mothers received four or more courses of corticosteroids.

To balance the potential beneficial effects and risks of additional courses of corticosteroids, some have advocated a *single* "rescue" course (i.e., a second course of corticosteroids), which is administered at the time of a second episode of preterm labor with a high probability of preterm delivery. A large randomized placebo-controlled trial found neonatal benefit in administering an additional course of corticosteroids.[54] Criteria for administration included absence of rupture of membranes, prior corticosteroid administration at least 2 weeks previously, gestational age less than 33 weeks, and a change in clinical scenario such that it was believed that preterm birth was likely to occur within 1 week.[55] A meta-analysis concluded that a single "rescue" course of antenatal corticosteroids should be considered in women whose prior course of antenatal corticosteroids was administered at least 7 days previously and who are at acute risk for preterm delivery before 34 weeks' gestation.[55] The ACOG[56] has stated that one rescue course of corticosteroids may be considered in these specific populations. However, regularly scheduled repeat courses or multiple courses (more than two) of corticosteroids are not currently recommended.

Antibiotic Therapy

The results of a large, multicenter, randomized controlled trial[57] and a meta-analysis[58] do *not* support the use of prophylactic antibiotic therapy in the management of preterm labor in patients with intact membranes as a method to reduce the likelihood of preterm birth. In fact, there was an increase in cerebral palsy in children born to mothers in preterm labor with intact membranes who received any prophylactic antibiotics versus no antibiotics (RR 1.82, 95% CI 0.99 to 3.34; 3173 children).[59] Accordingly, the ACOG[60] does not recommend empirical antibiotic therapy in this population. It should be

BOX 33.2 Contraindications to Tocolytic Therapy for Preterm Labor

- Fetal death
- Fetal anomalies incompatible with life
- Nonreassuring fetal status
- Chorioamnionitis
- Severe hemorrhage

TABLE 33.4 Antenatal Corticosteroid Therapy

Drug	Dose and Route	Frequency/Duration
Betamethasone	12 mg IM	Every 24 h × 2
Dexamethasone	6 mg IM	Every 12 h × 4

IM, Intramuscular.

From National Institutes of Health Consensus Development Panel. Antenatal corticosteroids revisited: Repeat courses—National Institutes of Health Consensus Development Conference Statement, August 17–18, 2000. *Obstet Gynecol.* 2001;98:144–150.

noted, however, that prophylactic antibiotic administration remains appropriate in women who are positive for group B streptococcus (GBS) who are thought to be in preterm labor.[60]

In contrast, in patients with preterm PROM, randomized controlled trials and a meta-analysis have concluded that antimicrobial therapy prolongs pregnancy and reduces both maternal and neonatal morbidity.[61,62] Thus, when preterm PROM is diagnosed, the ACOG[63] recommends a 7-day course of antimicrobial therapy. The best antibiotic regimen is not known with certainty, although intravenous ampicillin and erythromycin (48 hours), followed by oral amoxicillin and erythromycin (5 days), is a commonly used regimen for women with preterm PROM who are receiving expectant management.[63] Regardless, prolonged expectant management for preterm PROM is a known risk for chorioamnionitis and maternal sepsis (see Chapter 36).

Neuroprotection

Several clinical trials have provided evidence that maternal administration of magnesium sulfate provides fetal neuroprotection when given to women at risk for preterm delivery. In 2003, Crowther et al.[64] reported the results of a multicenter randomized, placebo-controlled study of 1062 women (1255 infants) at less than 30 weeks' gestation, in whom delivery was planned or expected within 24 hours. The investigators observed no significant difference between groups in the primary outcomes, which included total pediatric mortality, cerebral palsy, or both, at a corrected age of 2 years. However, they observed a significantly reduced rate of substantial gross-motor dysfunction, as well as a reduced combined rate of death or substantial gross-motor dysfunction, in the children exposed to magnesium sulfate *in utero*.[64] Similarly, a randomized controlled trial of magnesium sulfate administration to 573 pregnant women at less than 33 weeks' gestation, and in whom delivery was planned or expected within 24 hours, found that infants exposed to magnesium sulfate had a reduced rate of total neonatal mortality, severe cerebral white matter injury (which is associated with cerebral palsy), and the combination of severe white matter injury and/or death, but the differences were not statistically significant.[65] In the largest randomized trial,[66] 2241 women at imminent risk for delivery before 32 weeks' gestation were randomized to receive magnesium sulfate or placebo. The offspring who had been exposed to magnesium sulfate *in utero* were significantly less likely to develop moderate/severe cerebral palsy (1.9% versus 3.5%; RR, 0.55; 95% CI, 0.32 to 0.95).[66]

Meta-analysis of clinical trials suggests that prenatal administration of magnesium sulfate reduces the occurrence of cerebral palsy (RR, 0.68; 95% CI, 0.54 to 0.87).[67] The ACOG has stated that, based on available evidence, magnesium sulfate—given before anticipated early preterm birth—reduces the risk for cerebral palsy in surviving infants.[68] Because the best regimen of magnesium sulfate administration remains unclear, physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimens, concurrent tocolysis, and monitoring based on the protocols of the larger published trials.[68]

Rescue Cerclage

Prophylactic cervical cerclage (see earlier discussion) is typically performed when the cervix is closed (see Chapter 16). A rescue cerclage (also known as emergency or physical exam-indicated cerclage) is typically a procedure to prolong gestation in women with cervical dilation and/or prolapsed membranes. The efficacy and safety of this procedure remain controversial. A 2014 article reviewed the contemporary evidence of this procedure.[69] Contraindications include established preterm labor with impending preterm birth, chorioamnionitis, heavy vaginal bleeding, preterm PROM, fetal compromise, major fetal anomalies, and fetal death. Data are mixed regarding mandating a waiting period before placement. Some experts advocate for immediate placement, and others recommend delaying for up to 24 hours; there is no single evidence-based standard to define best practice with regard to timing of rescue cerclage placement.

When placing the cerclage, prolapsing membranes need to be replaced in the uterine cavity to reduce the risk for iatrogenic preterm PROM. The surgical technique typically involves the lithotomy position with steep Trendelenburg tilt, overfilling the bladder and/or placing ring forceps or stay sutures around the circumference of the external os, and placing traction on these structures to ease the membranes back into the uterus. Invasive methods may also be used, including using a Foley catheter balloon to directly push the membranes back into the uterus. However, this practice may be associated with increased risk for iatrogenic preterm PROM. Amniocentesis/amnioreduction can also be performed to reduce the volume and pressure of the amniotic fluid on the prolapsed sac. For the actual cerclage, the **McDonald technique** is typically preferred; purse-string sutures are placed around the circumference of the cervix. Other techniques have been described (**Shirodkar** and **Wurm**); the ultimate decision on technique is based on surgeon preference. Some evidence suggests a course of perioperative antibiotic and tocolytic administration is beneficial in these patients.[70]

Only one small randomized controlled trial has compared rescue cerclage with bed rest compared with bed rest alone; the study population was heterogeneous and included twin gestation.[71] Improved outcomes were reported in the cerclage group, including prolongation of gestation by 4 weeks, and reductions in the rates of neonatal intensive care unit admission and neonatal death. Similarly, a small ($n = 29$) nonrandomized prospective trial found prolongation of gestation by over 8 weeks compared with bed rest alone.[72]

Cerclage removal. Cerclage removal does not routinely precipitate the labor process. When vaginal delivery is planned, it is recommended to proceed with removal at 36 to 37 weeks' gestation. By contrast, in cases of planned cesarean delivery, it is permissible to defer cerclage removal until delivery. However, labor may occur before the planned delivery date, and removal may need to be performed urgently.

There is a paucity of data to guide management of women with a cerclage who subsequently experience preterm PROM and/or preterm labor. In the case of isolated preterm labor, the decision to remove the cerclage can be a difficult one. Management of preterm labor should not be influenced by the presence of a cerclage; if the patient demonstrates cervical change, painful contractions, or vaginal bleeding, the cerclage should be removed.[37]

In some studies, cerclage retention following preterm PROM has been associated with increased incidence of infectious morbidities, both maternal and neonatal, as well as neonatal respiratory distress syndrome. However, other studies have not identified these associations. Given current evidence, it is reasonable to either remove or retain the cerclage after diagnosis of preterm PROM. However, if cerclage is retained, women should receive 7 days of antibiotic prophylaxis.[63]

Cerclage removal is usually a straightforward procedure. With the patient in the dorsal lithotomy position, a speculum is inserted. The suture is grasped with rings and the suture beneath the knot is transected with scissors. In most cases, elective removal of a cerclage in an office setting is appropriate.[37] Occasionally the entire stitch becomes embedded within the cervical mucosa (i.e., "buried"), and neuraxial anesthesia (see later discussion) may be required to facilitate cervical dissection and cerclage removal.

Tocolysis

Once the obstetrician has decided to begin tocolytic therapy, an appropriate agent must be selected (Table 33.5). (Each specific class of tocolytic agent is discussed in detail later in this chapter.) A 2003 analysis of studies that compared the four classes of tocolytic agents currently in use (i.e., beta-adrenergic receptor agonists, calcium entry–blocking agents, magnesium sulfate, and nonsteroidal antiinflammatory drugs [NSAIDs]) concluded that all are more effective than placebo in prolonging pregnancy, but the investigators found no evidence of a beneficial effect on neonatal morbidity or mortality.[73] A 2014 analysis suggested that magnesium sulfate is not efficacious and should not be used for tocolysis.[74]

Physiology of Uterine Contractions

Myometrial smooth muscle consists of thick (myosin) and thin (actin) filaments that slide past one another and thereby lead to the contractile force of uterine contractions. The myometrium also has pacemaker cells; electrical activity is spread by gap junctions between myometrial cells. A rise in intracellular calcium concentration from influx across the sarcolemma and/or release from internal calcium stores leads to contractions. Hormones and neurotransmitters also may regulate uterine activity through agonist-induced entry of calcium or other ions by means of receptor-controlled channels and the release of internally stored calcium.[75]

TABLE 33.5 Tocolytic Drugs for Preterm Labor

Drug	Contraindications	Maternal Side Effects	Fetal/Neonatal Side Effects
Calcium entry–blocking agents	Cardiac disease Renal disease (use with caution) Maternal hypotension	Transient hypotension, flushing, headache, dizziness, nausea	None identified
Cyclooxygenase inhibitors (NSAIDs)	Significant renal or hepatic impairment Active peptic ulcer disease Coagulation disorders or thrombocytopenia NSAID-sensitive asthma Other NSAID sensitivities	Nausea, heartburn	Constriction of the ductus arteriosus, pulmonary hypertension, reversible renal dysfunction (leading to oligohydramnios), IVH, hyperbilirubinemia, necrotizing enterocolitis
Beta-adrenergic receptor agonists	Cardiac dysrhythmias Poorly controlled thyroid disease Poorly controlled diabetes mellitus	*Cardiopulmonary:* dysrhythmias, pulmonary edema, myocardial ischemia, hypotension, tachycardia *Metabolic:* hyperglycemia, hyperinsulinemia, hypokalemia, antidiuresis, altered thyroid function *Other:* tremor, palpitations, nervousness, nausea/vomiting, fever, hallucinations	*Fetal:* tachycardia, hyperinsulinemia, hyperglycemia, myocardial and septal hypertrophy, myocardial ischemia *Neonatal:* tachycardia, hypoglycemia, hypocalcemia, hyperbilirubinemia, hypotension, IVH
Magnesium sulfate	Myasthenia gravis Myotonic dystrophy	Flushing, lethargy, headache, muscle weakness, diplopia, dry mouth, pulmonary edema, cardiac arrest	Lethargy, hypotonia, respiratory depression, demineralization (prolonged use)

IVH, Intraventricular hemorrhage; *NSAIDs,* nonsteroidal anti-inflammatory drugs.
Modified from Hearne AE, Nagey DA. Therapeutic agents in preterm labor: tocolytic agents. *Clin Obstet Gynecol.* 2000;43:787–801.

Calcium binds to calmodulin, which then activates myosin light-chain kinase (MLCK), leading to phosphorylation of the light-chain subunit of myosin. This phosphorylation allows actin to bind to myosin, with the subsequent activation of myosin adenosine triphosphatase. Adenosine triphosphate (ATP) is then hydrolyzed, and muscle shortening or contraction results. Increases in intracellular cyclic adenosine monophosphate (cAMP) cause muscle relaxation by (1) activation of a cAMP-dependent protein kinase, which decreases the activity of MLCK and (2) a reduction of the intracellular calcium concentration.[75]

The actual signals for the onset of contractions and labor, however, are complex and incompletely understood. Before labor, the uterus is in a state of functional quiescence as a result of various inhibitors, including progesterone, prostacyclin, relaxin, nitric oxide, parathyroid hormone–related peptide, corticotropin-releasing hormone, human placental lactogen, calcitonin gene–related peptide, adrenomedullin, and vasoactive intestinal peptide (Fig. 33.5). Before term, the uterus goes through an activation phase characterized by (1) greater expression of a series of contraction-associated proteins (including myometrial receptors for prostaglandins and oxytocin), (2) activation of certain ion channels, and (3) an increase in connexin-43 concentration. Expression of the oxytocin receptor in the human myometrium is tightly regulated during pregnancy. Its levels increase during gestation, with a relative paucity of receptors in mid-gestation, accumulation in the third trimester, and peak at labor onset. The receptors fall sharply in advanced labor and the postpartum period, when the uterus becomes refractive to oxytocin.[76]

There is evidence, albeit from animal models, that the fetus may contribute to changes in uterine activity through (1) its influence on the production of placental steroid hormones, (2) mechanical distention of the uterus, and (3) secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis. The final common pathway for labor is thought to be activation of the fetal hypothalamic-pituitary-adrenal axis. Of interest, however, is the observation that spontaneous labor occurs in women even if a fetus is anencephalic (without a functioning pituitary gland), suggesting that intact neurohypophyseal function is not a prerequisite for the onset of human labor.[77]

In recent years, the hormonal control of human parturition has been linked to progesterone signaling, and it appears that human parturition may be triggered by a functional progesterone withdrawal, mediated at least in part by changes in progesterone receptor transcriptional activity. It is also thought that parturition may be related to changes in inflammation, which itself is linked to functional progesterone withdrawal.[78]

Efficacy of Tocolytic Therapy

There is general consensus that acute tocolytic therapy (of any type) for the treatment of preterm labor offers only limited benefit and does not reduce the rate of preterm birth. According to a network meta-analysis,[79] compared with placebo, the probability of delivery being delayed by 48 hours was highest with prostaglandin synthesis inhibitors (odds ratio [OR], 5.39; 95% CI, 2.14 to 12.34) followed by magnesium sulfate (OR, 2.76; 95% CI, 1.58 to 4.94), calcium entry-blocking agents (OR, 2.71; 95% CI 1.17 to 5.91), beta-adrenergic receptor agonists (OR, 2.41; 95% CI, 1.27 to 4.55), and the oxytocin receptor blocker, atosiban (OR, 2.02; 95% CI, 1.10 to 3.80). No class of tocolytic was significantly superior to placebo in reducing neonatal respiratory distress syndrome.[79] Meta-analysis has also suggested that **calcium entry–blocking agents** (e.g., nifedipine), which block calcium inflow into cells through voltage-dependent calcium channels, have benefits over beta-adrenergic receptor agonists with respect to prolongation of pregnancy, serious neonatal morbidity, and maternal adverse effects.[80]

Although **beta-adrenergic receptor agonists** (e.g., ritodrine, terbutaline), which relax smooth muscle via

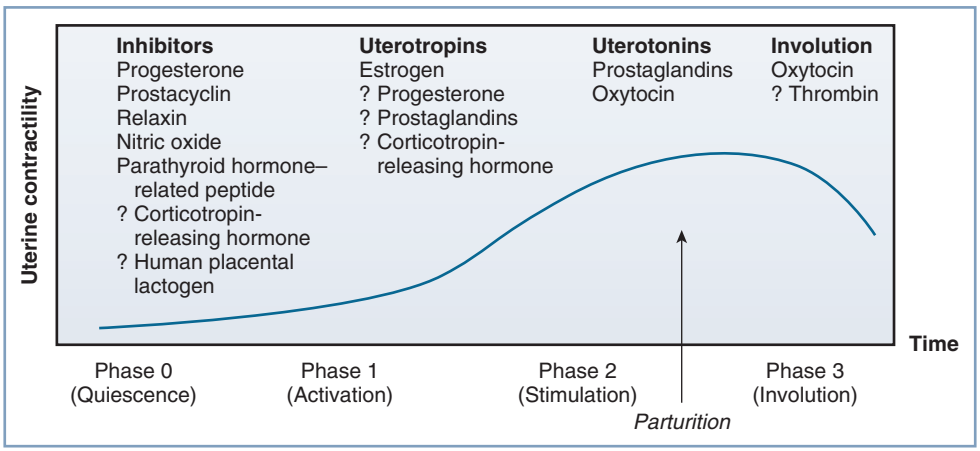

Fig. 33.5 The regulation of uterine activity during pregnancy and labor can be divided into four distinct physiologic phases—quiescence, activation, stimulation, and involution—that are, or may be, influenced by a number of stimulatory and inhibitory factors. (From Liao JB, Buhimschi CS, Norwitz ER. Normal labor: mechanism and duration. *Obstet Gynecol Clin North Am.* 2005;32:145–164; modified from Challis JRG, Gibb W. Control of parturition. *Prenat Neonat Med.* 1996;1:283.)

beta$_2$-adrenergic receptor stimulation, were used as tocolytic agents for many years, in current practice they are utilized less than other tocolytic agents (e.g., nifedipine, oxytocin antagonists) that are equally efficacious with fewer side effects.[79,80] A 2014 meta-analysis that compared beta-adrenergic receptor agonists with placebo concluded that use of beta-adrenergic receptor agonists reduced the number of women who delivered within 48 hours and decreased the number of births within 7 days.[81] However, there was no reduction in preterm birth rate or in perinatal/neonatal death or neonatal morbidity. Tocolysis was significantly associated with adverse maternal side effects (see Table 33.5). Intravenous ritodrine is no longer marketed in the United States. In 2011, the United States Food and Drug Administration (FDA) issued a warning regarding terbutaline use.[82] Specifically, it stated that *injectable* terbutaline should not be used in pregnant women for prolonged treatment (beyond 48 to 72 hours) of preterm labor in either the hospital or outpatient setting because of the potential for maternal cardiac problems and death. It also noted that oral terbutaline should not be used for prevention or treatment of preterm labor because it had not been shown to be effective and was associated with similar safety concerns.[82]

Prostaglandins are mediators in the final pathways of uterine contraction. They increase intracellular calcium concentrations, increase activation of MLCK, and promote gap junction formation. The nonselective **cyclooxygenase inhibitor** indomethacin is the agent in this class most often studied as a tocolytic agent. Serious maternal side effects are uncommon. Fetal concerns, in particular in the setting of prolonged use (greater than 48 hours), include a risk for constriction of the ductus arteriosus and oligohydramnios (caused by fetal renal dysfunction). A recent systematic review concluded no clear benefit for cyclooxygenase inhibitors was shown compared with placebo or any other tocolytic agents.[83]

The **oxytocin receptor antagonist** atosiban has also been used as a tocolytic agent. Although available in Europe, the drug was not approved by the FDA because of the finding from a randomized trial that women in the atosiban group had a higher rate of fetal death.[84] A 2014 meta-analysis did not demonstrate superiority of oxytocin receptor antagonists (largely atosiban) compared with placebo, beta-adrenergic receptor agonists, or calcium entry–blocking agents (largely nifedipine) for pregnancy prolongation or neonatal outcomes, although treatment with oxytocin receptor antagonists was associated with fewer adverse maternal effects than treatment with the other two drug classes.[80] A subsequent large randomized controlled trial comparing atosiban with nifedipine found that 48 hours of tocolysis with nifedipine or atosiban results in similar perinatal outcomes.[85]

Magnesium sulfate also has been used as a tocolytic agent. A 2014 meta-analysis of 37 heterogeneous trials that compared magnesium with placebo, no treatment, or other tocolytic drugs[74] concluded that magnesium is ineffective in delaying or preventing preterm birth and has no apparent advantages for a range of neonatal and maternal outcomes as a tocolytic agent, and its use for this indication may be associated with an increased risk for total fetal, neonatal, or infant mortality.

The **nitric oxide donor** nitroglycerin has also been evaluated for its efficacy as a tocolytic. However, findings from meta-analyses indicate that nitroglycerin does not result in significantly later gestational age at delivery or better neonatal outcome compared with placebo or other tocolytic drugs.[86]

The ACOG[48] has stated that evidence supports the use of tocolytic treatment with beta-adrenergic receptor agonist therapy, calcium entry–blocking agents, or NSAIDs for short-term prolongation of pregnancy (up to 48 hours) to allow for antenatal maternal corticosteroid administration. Multiple clinical trials have demonstrated that prolonged use of tocolytic agents (as prophylactic therapy or after completion of acute treatment) does not alter outcome. No matter which tocolytic agent is chosen, the risk for side effects appears to increase when more than one tocolytic agent is administered simultaneously.[87] It is unclear whether a combination of tocolytic drugs for preterm labor is more effective for women and/or newborns because there is a lack of large, well-designed trials that include the outcomes of interest.[87]

THE PRETERM INFANT

Physiology

Several, but not all, studies have suggested that the incidence of intrapartum acidosis is greater in the preterm fetus than in the term fetus.[88] The preterm fetus has lower hemoglobin concentration and oxygen-carrying capacity than a term fetus. Nonetheless, these characteristics do not translate into a higher risk for intrapartum fetal neurologic injury.

Preterm infants are at risk for a number of complications, including respiratory distress syndrome, hyperbilirubinemia, necrotizing enterocolitis, intraventricular hemorrhage, perinatal infection, retinopathy of prematurity, patent ductus arteriosus, pulmonary hypertension, water and electrolyte imbalances, acid-base disturbances, anemia, and hypoglycemia.[2] In the long term, preterm infants also are more likely to experience adverse outcomes such as bronchopulmonary dysplasia, reactive airway disease, failure to thrive, cerebral palsy, neurodevelopmental delay, hearing loss, blindness, pulmonary hypertension, adult hypertension, and impaired glucose regulation.[2]

Method of Delivery

For very preterm infants, especially less than 26 weeks' gestation, there is controversy regarding best mode of delivery. Although some studies have suggested survival advantage for those delivered by cesarean, these data are not consistent, and the potential for confounding (and particularly confounding by indication) is such that preterm birth at any gestational age is not considered a contraindication for trial of labor.[89]

A systematic review of six randomized controlled trials comparing elective with selective cesarean delivery for preterm infants (n = 122) found no difference in outcomes between groups, although the confidence intervals were wide

because of the small number of patients included in the analysis.[90] A retrospective analysis of 2466 VLBW preterm infants delivered in the state of Washington between 1994 and 2003 did not demonstrate any benefit of cesarean delivery for improving survival.[91] In a study published in 2012, Reddy et al.[92] examined neonatal outcomes by attempted route of delivery for singleton births that occurred between 24 0/7 and 31 6/7 weeks' gestation. Among women who delivered between 24 0/7 and 27 6/7 weeks' gestation with a vertex presentation, 77.2% attempted vaginal delivery (85% success rate) with the remainder undergoing scheduled cesarean delivery. No difference was observed in neonatal mortality or other adverse neonatal outcomes between the two groups. Similarly, when examining outcomes in women with a vertex presentation between 28 0/7 and 31 6/7 weeks' gestation, no difference in neonatal mortality was found in women who attempted vaginal delivery compared with those who underwent planned cesarean delivery.[92]

Aside from operative risks in the index pregnancy, preterm cesarean delivery may increase maternal risk in subsequent pregnancies. In an observational study that involved 26,454 women with previous cesarean delivery, the Maternal-Fetal Medicine Units Network noted that women with a prior *preterm* cesarean delivery were at higher risk for uterine rupture than women with a prior *term* cesarean delivery (OR, 1.6; 95% CI, 1.01 to 2.50).[93]

Most obstetricians perform cesarean delivery for the delivery of a VLBW singleton fetus in a breech presentation.[94,95] A systematic review of seven studies involving more than 3500 women concluded that cesarean delivery reduces neonatal morbidity when compared with vaginal delivery for breech presentation.[96] Head entrapment behind an incompletely dilated cervix is more common in preterm singleton fetuses with a breech presentation than in term infants because the head is larger than the wedge formed by the buttocks and thighs. Similarly, cesarean delivery has been recommended for preterm twins in whom the presenting fetus has a nonvertex presentation, although there are no prospective, controlled studies to support this practice.[97] The management of preterm twins when twin A is vertex and twin B is nonvertex is more controversial; there are no good data from clinical trials, and the results from observational studies suffer from potential selection and confounding bias.[9] Thus, a definitive recommendation regarding whether a breech second twin should be delivered by cesarean remains elusive; it seems reasonable that practitioners with experience can individualize care, taking into account the clinical circumstances, and offer certain patients the option of delivering preterm twins vaginally if the first twin has a vertex presentation.

The survival rate remains low for infants with a birth weight between 500 and 750 g.[10] In these cases, obstetricians must decide whether to recommend cesarean delivery for fetal indications, such as in cases of nonreassuring fetal status or breech presentation. The neonatologist is frequently asked to speak with the patient about the risk for neonatal morbidity and mortality so that the patient can make an informed decision about the method of delivery. Regardless of the mode of delivery, if resuscitation is planned, additional support personnel (ideally a neonatologist and a neonatal resuscitation team) should be prepared and present for the delivery.[9]

Ethical Issues

The antenatal maternal administration of corticosteroids, the application of advanced neonatal ventilation techniques, the use of neonatal surfactant therapy, and the use of extracorporeal membrane oxygenation (ECMO) have reduced mortality and morbidity for preterm neonates.[10] However, below a certain gestational age (i.e., less than 22 0/7 to 23 0/7 weeks), survival is not typically possible and the relationship between new treatments and reduced mortality is not relevant. Around the time when survival becomes at least possible, the chance of survival, and particularly survival without long-term major adverse outcomes, remains low and difficult to predict for any individual neonate. These uncertainties often lead to controversy about the decision to resuscitate (or not resuscitate) a preterm infant. Parents, obstetricians, and neonatologists should all be involved in the decision-making process.[9]

Anesthesia providers may find themselves in the middle of these ethical dilemmas if they are practicing at a location in which the anesthesia provider is responsible for neonatal resuscitation. Although no firm rules exist, some basic principles can be applied. First, the parents should have a critical role in the decision-making process. Second, as much data as possible should be obtained to provide a prognostic assessment. Third, discussion of these issues ideally should be held before delivery, not in the moment of crisis. The ACOG[9] has published general recommendations about the care of infants on the threshold of viability but has not made specific recommendations for neonatal resuscitation on the basis of gestational age.

Withholding and/or discontinuation of life-sustaining treatment during or following resuscitation are considered by many to be ethically equivalent, and it is considered reasonable to withdraw support when the possibility of functional survival is highly unlikely. In cases of very early gestation (gestational age less than 22 to 23 weeks), extremely low birth weight (less than 400 g), and life-limiting anomalies, resuscitation is generally not indicated. Resuscitation is nearly always indicated in conditions associated with a high survival rate and acceptable morbidity. This will generally include infants with a gestational age of 25 weeks or above. In conditions associated with uncertain prognosis, parental desires regarding resuscitation should be supported.[98]

Fetal Heart Rate Monitoring

Most obstetricians use continuous electronic fetal heart rate (FHR) monitoring once preterm labor becomes established and the gestational age and circumstances are consistent with the possibility of neonatal survival. Preterm gestation may complicate the interpretation of FHR patterns, given that the FHR pattern of preterm fetuses may have relatively decreased

variability and magnitude of accelerations compared with the FHR pattern of term fetuses.[99]

The value of continuous electronic FHR monitoring over intermittent auscultation of the FHR remains controversial. Luthy et al.[100] performed a randomized trial comparing continuous electronic FHR monitoring (with selective fetal blood gas assessment) with periodic auscultation of the FHR during preterm labor in women with fetuses weighing between 700 and 1750 g. There was no significant difference between groups in the incidence of cesarean delivery, low 5-minute Apgar scores, intrapartum acidosis, intracranial hemorrhage, or perinatal death. A meta-analysis, which added a second trial, also showed no benefit in preventing cerebral palsy (RR, 1.75; 95% CI, 0.84 to 3.63).[59] In a follow-up study at 18 months of age in the infants included in the study by Luthy et al.,[100] the incidence of cerebral palsy was significantly higher in the electronic FHR group than in the intermittent auscultation group (20% versus 8%, respectively).[101]

ANESTHETIC MANAGEMENT

Anesthesia providers often participate in the care of women with preterm delivery. Many women who deliver preterm request neuraxial analgesia for labor and vaginal delivery. These patients may also require cesarean delivery, for example, in situations of nonreassuring fetal status, and may require urgent administration of anesthesia.

Conventional wisdom holds that the preterm fetus is more vulnerable than the term fetus to the depressant effects of analgesic and anesthetic drugs, for the following reasons: (1) less protein available for drug binding, leading to a reduction in protein-drug affinity; (2) higher levels of bilirubin, which may compete with the drug for protein binding; (3) greater drug access to the central nervous system (CNS) because of the presence of an incomplete blood-brain barrier; (4) decreased ability to metabolize and excrete drugs; and (5) a higher incidence of acidosis during labor and delivery.[88,102] However, few controlled studies have documented the maternal and fetal pharmacokinetics and pharmacodynamics of anesthetic agents throughout gestation. The preterm fetus may be less vulnerable to the depressant effects of local anesthetics than originally thought. The human fetal liver cytochrome P450 system is present as early as 14 weeks' gestation and has the capability to oxidize several drugs.[103,104]

Perinatal Effects of Maternal Local Anesthetics

Teramo et al.[105] noted that the amount of lidocaine necessary to produce seizure activity in preterm fetal lambs was greater than that required in older fetal lambs. These investigators also observed that the cardiovascular response to lidocaine (i.e., increases in blood pressure and heart rate) was less severe in fetuses with a younger gestational age. Pedersen et al.[106] evaluated the effects of gestational age on the pharmacokinetics and pharmacodynamics of lidocaine in gravid ewes and fetal lambs. They studied two groups of animals, preterm (119 ± 1 days' gestation or 0.8 of term pregnancy) and near-term (138 ± 1 days' gestation or 0.95 of term pregnancy). They administered an intravenous infusion of lidocaine to obtain a maternal steady-state plasma concentration of 2 μg/mL. Transplacental transfer of lidocaine did not adversely affect fetal cardiac output, organ blood flow, or blood gas and acid-base measurements in either group. Tissue uptake of lidocaine was similar in the two groups of fetal lambs, except that it was greater in the lungs and liver of the term fetuses. The investigators concluded that there was no significant difference in the pharmacokinetics and pharmacodynamics of lidocaine between the two gestational ages studied.[106]

Smedstad et al.[107] also concluded that there was no difference in fetal blood pressure, heart rate, or blood gas measurements in response to maternal intravenous infusion of lidocaine or bupivacaine between early preterm (119 days' gestation) and late preterm (132 days' gestation) fetal lambs. In addition, the plasma concentrations of bupivacaine and lidocaine and the fetal-to-maternal ratios of both drugs were similar in the two groups of fetuses.

None of these studies evaluated the effects of anesthetic agents on the acidotic preterm fetus. Asphyxia may increase the risk for adverse effects by causing the following changes in the fetal environment: (1) reduced plasma protein-binding capacity (which increases the proportion of free drug available)[108]; (2) greater maternal-fetal hydrogen ion difference, which causes "ion trapping" of weak bases (e.g., amide local anesthetics, opioids) on the fetal side of the circulation[109]; (3) greater blood-brain barrier permeability[110]; and (4) enhanced susceptibility to the myocardial depressant effects of local anesthetics.[111,112]

Morishima et al.[111] subjected a group of preterm fetal lambs (0.8 of term gestation) to asphyxia by causing partial occlusion of the umbilical cord. They subsequently administered either lidocaine or saline-control intravenously to the gravid ewes for 180 minutes. The mean (± SD) maternal and fetal steady-state plasma lidocaine concentrations were 2.32 ± 0.12 and 1.23 ± 0.17 μg/mL, respectively. (These concentrations are similar to those that occur during administration of epidural anesthesia in humans.) Umbilical cord occlusion resulted in the typical fetal compensatory response to hypoxia (i.e., decreased FHR and increased blood flow to the fetal brain, heart, and adrenal glands). Maternal administration of saline-control did not result in additional deterioration of the fetus. However, maternal administration of lidocaine resulted in a significant increase in $Paco_2$, and decreases in pH, mean arterial pressure (MAP), and blood flow to the brain, myocardium, and adrenal glands. Thus, lidocaine attenuated the normal fetal compensatory response to asphyxia.

In an earlier study, the same investigators observed that lidocaine did not affect the fetal compensatory response to asphyxia in term fetuses.[112] They concluded that "the immature fetus loses its cardiovascular adaptation to asphyxia when exposed to clinically acceptable plasma concentrations of lidocaine obtained transplacentally from the mother."[111] Limitations of this study include (1) a failure to compare the fetal response to lidocaine with the response to other

anesthetic, analgesic, or sedative drugs and (2) consideration of only the effects of a steady-state concentration of lidocaine in the presence of asphyxia. That is, the investigators did not evaluate the potential benefits derived from epidural anesthesia, such as reduced maternal concentrations of catecholamines and the ability of epidural anesthesia to facilitate a controlled, atraumatic delivery of the preterm infant.

Bupivacaine has a low fetal-to-maternal plasma concentration ratio because of its high (96%) maternal protein binding; therefore, the potential for fetal toxicity seems minimal.[102] Studies of the effects of bupivacaine on the compensatory response to asphyxia in preterm fetal lambs have demonstrated results similar to those seen with lidocaine. Santos et al.[113] observed that bupivacaine abolished the compensatory increase in blood flow to vital organs in asphyxiated preterm fetal lambs. However, bupivacaine did not affect fetal heart rate, blood pressure, or acid-base measurements. The investigators suggested that these changes were less severe than those seen with lidocaine in their earlier study.[111,113]

Ropivacaine and bupivacaine have almost identical dissociation constants (pK_a of 8.0 and 8.2, respectively), but ropivacaine's protein binding is slightly less than that for bupivacaine (92% versus 96%, respectively), and it is substantially less lipid soluble than bupivacaine (see Chapter 13).[114] These differences may affect maternal and fetal free plasma concentrations of drug. Investigators have documented higher maternal and fetal plasma concentrations with ropivacaine than with bupivacaine.[115,116] Studies suggest that ropivacaine is less cardiotoxic than bupivacaine. However, no study has evaluated the effect of ropivacaine on the fetal compensatory response to hypoxia.

2-Chloroprocaine also is a good choice of local anesthetic to use for the mother of a preterm fetus because it is rapidly metabolized in both the maternal plasma and fetal plasma.[117] Further, placental transfer of 2-chloroprocaine is not increased by fetal acidosis.[118]

Vaginal Delivery

Neuraxial labor analgesia decreases maternal concentrations of catecholamines, ameliorates cycles of maternal hypoventilation and hyperventilation, and may thereby improve uteroplacental perfusion as long as hypotension is avoided.[119] No prospective, controlled studies have evaluated the effect of neuraxial analgesia on preterm infant outcome. The timing of the intrapartum administration of neuraxial analgesia in preterm parturients may be problematic for several reasons. First, there may be uncertainty as to whether women who have contractions are in labor. Second, even women with a clear diagnosis of preterm labor often have a prolonged latent phase of labor, with or without the use of tocolytic agents. Third, once active labor begins, patients often progress though labor very quickly. Thus, in some cases, it may be appropriate to establish neuraxial analgesia even before it is clear that a preterm delivery will soon occur. An advantage of early initiation of neuraxial analgesia is the ability to rapidly convert labor analgesia to surgical anesthesia if emergency cesarean delivery should be necessary.

Cesarean Delivery

Administration of general anesthesia for preterm cesarean delivery is similar to that for parturients at term (see Chapter 26). Most anesthetic agents that are used for induction and maintenance of general anesthesia cross the placenta. If cesarean delivery is necessary, conventional wisdom holds that it is preferable to administer either epidural or spinal anesthesia to avoid the depressant effects of agents given for general anesthesia. Rolbin et al.[120] observed that preterm infants exposed to epidural anesthesia for cesarean delivery had higher 1- and 5-minute Apgar scores than similar infants exposed to general anesthesia. Laudenbach et al.[121] performed a secondary analysis of prospectively gathered data from a population-based cohort study of all deliveries before 33 weeks' gestation in nine regions in France in 1997 ($n = 1338$). Of concern, after controlling for known confounders, infants born by cesarean delivery to mothers who received spinal anesthesia had a higher mortality rate than those born to mothers who received general or epidural anesthesia (adjusted OR, 1.7; 95% CI, 1.1 to 2.6).[121] However, the authors noted that the secondary analysis of a preexisting database did not allow them to adjust for confounders known to affect anesthetic outcome (e.g., intraoperative hypotension, choice of vasopressor, fluid management). Nonetheless, for these high-risk births, it seems reasonable that anesthesia providers should pay meticulous attention to maternal hemodynamic variables regardless of the type of anesthesia that is administered.

Data from animal studies suggest that exposure of the immature brain to anesthetic agents such as propofol, thiopental, ketamine, and inhalation agents can trigger significant brain cell apoptosis in the developing fetal/neonatal brain and cause functional learning deficits in later life.[122,123] However, in these animal studies, the duration of exposure to anesthetic agents was much longer than is typical for cesarean delivery in humans. Whether clinical exposure to anesthetic agents during general anesthesia for cesarean delivery results in clinically significant brain cell apoptosis in humans remains to be determined (see Chapter 10).

The term pregnant patient requires significantly less local anesthetic to achieve adequate surgical anesthesia than nonpregnant women (see Chapter 2). There are limited data about spinal dose requirements for cesarean delivery in preterm parturients. A retrospective study of over 5000 patients investigated the association between gestational age and the risk for inadequate spinal anesthesia for cesarean delivery.[124] The incidence of neuraxial block failure correlated inversely with gestational age, decreasing from 10.8% for women who were less than 28 weeks' gestation, to 7.7% for those between 28 and 32 weeks, and 5.3% or less for those beyond 32 weeks. In multivariable analysis, the association of gestational age with block failure was not significant; however, birth weight less than 2500 g was associated with a 2.5-fold increased odds of failed neuraxial anesthesia.[124]

In summary, at the current time there is minimal evidence to support altering the anesthetic technique for cesarean

delivery merely because the infant is preterm. Further study is necessary to determine whether one technique or medication has specific risks or benefits relative to the preterm infant.

Anesthesia for Rescue Cerclage Placement and Cerclage Removal

Cerclage placement requires a T10 level of surgical anesthesia (see Chapter 16). Frequently, rescue cerclage placement is a brief surgical procedure lasting less than 30 minutes. Occasionally, surgical complexity can extend the procedure to as long as 2 hours. Advanced cervical dilation and prolapsed membranes increase complexity. In addition, patient characteristics (e.g., morbid obesity) may extend the duration required for positioning and increase the risks associated with unplanned induction of general anesthesia. The optimal anesthetic technique depends on the obstetric plan, specifically whether the patient will be admitted for prolonged observation or will be discharged home. Shorter-acting spinal anesthetics may accelerate recovery and discharge for those going home. For those who will be admitted for postprocedural monitoring, a longer-duration spinal anesthetic or a catheter-based neuraxial technique may be appropriate.

Usually, cerclage removal does not require anesthesia, but surgical anesthesia may be necessary if the stitch is embedded under the cervical mucosa (i.e., "buried"). Spinal anesthesia for cerclage removal requires a T10 sensory level, and depending on gestational age and fetal weight, may result in excessive blockade if doses typically used for early second-trimester cerclage placement are used. The decision to utilize a catheter-based technique or single-shot spinal anesthesia depends on the obstetric plan, specifically, whether the patient will remain in hospital for delivery or will be discharged home to await spontaneous labor.

Venous Thromboembolism Prophylaxis

Obstetric venous thromboembolism (VTE) is a leading cause of maternal morbidity and mortality (see Chapter 38). Antepartum hospitalization and prolonged immobility increase the risk for VTE, particularly among obese women. Several professional societies recommend pharmacologic VTE prophylaxis for prolonged antepartum admissions, although the suggested dosing regimens are not uniform.[125] For example, the National Partnership for Maternal Safety recommends daily thromboprophylaxis with low-molecular-weight heparin, or twice-daily thromboprophylaxis with unfractionated heparin, for all antepartum patients hospitalized for more than 72 hours.[125] With wider adoption of these VTE guidelines, an increasing number of pregnant women will present for neuraxial analgesia or anesthesia in the context of pharmacologic anticoagulation. Strategies to ensure safe neuraxial blockade for women receiving anticoagulant drugs are discussed in Chapter 38 and are addressed by consensus documents from the Society for Obstetric Anesthesia and Perinatology[126] and the American Society of Regional Anesthesia.[127] Regular, ongoing communication between obstetricians and anesthesia providers to discuss women admitted to the hospital for antepartum care is required to ensure that evolving plans for delivery or surgical intervention appropriately inform optimal anticoagulation and anesthetic management.[126]

INTERACTIONS BETWEEN TOCOLYTIC THERAPY AND ANESTHESIA

Indications for Anesthesia during and after Tocolytic Therapy

There are several situations in which obstetric patients require analgesia or anesthesia during or after tocolytic therapy. First, preterm labor may progress and delivery may occur despite tocolysis. In this case, the patient may desire pain relief during labor and vaginal delivery or may require anesthesia for cesarean delivery. Second, some obstetricians give a tocolytic agent before and during the performance of therapeutic cervical cerclage. Third, some obstetricians advocate the bolus injection of a tocolytic agent when there is a tetanic uterine contraction or tachysystole in the setting of FHR abnormality. Fourth, many obstetricians administer tocolysis when attempting external cephalic version, a procedure that may also involve neuraxial analgesia.

Calcium Entry–Blocking Agents

Nifedipine is the specific drug within this class that has undergone the most extensive evaluation as a tocolytic agent; it has been proposed by some as a first-line therapy for treatment of preterm labor. Typical nifedipine dose regimens for preterm labor are listed in Table 33.6.

TABLE 33.6 Tocolytic Dose Regimens for Preterm Labor

Drug	Initiation Dose	Maintenance Dose
Nifedipine	20–30 mg PO	10–20 mg every 4–6 h
Cyclooxygenase inhibitors (NSAIDs)[a]:		
Indomethacin	50–100 mg PO or PR	25–50 mg every 4 h
Ketorolac	60 mg IM	30 mg every 6 h
Sulindac	200 mg PO	200 mg every 12 h
Terbutaline[b]	0.25 mg SQ	0.25 mg every 20 min to 3 h
Magnesium sulfate	4–6 g IV bolus over 20 min	2–4 g/h continuous IV infusion

IM, Intramuscularly; *IV,* intravenously; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PO,* per os (orally); *PR,* per rectum; *SQ,* subcutaneously.

[a]NSAID administration should be limited to 48 to 72 hours and restricted to gestations less than 32 weeks.

[b]Treatment with terbutaline administered by injection or by continuous infusion pump should not be used beyond 48 to 72 hours. In particular, injectable terbutaline should not be used in the outpatient or home setting.

Mechanism of Action

Calcium-entry blocking agents block the aqueous voltage-dependent cell membrane channels that are selective for calcium and prevent calcium release from the sarcoplasmic reticulum. The net result is a decrease in available intracellular calcium, which inhibits MLCK activity. This inhibition leads to decreased actin-myosin interaction, which results in relaxation of smooth muscle (including myometrial smooth muscle).[128]

Side Effects

Nifedipine has fewer side effects than beta-adrenergic receptor agonists. Common side effects include headache, flushing, dizziness, palpitations, and nausea.[129] Most effects are mild, but pulmonary edema[130] has been reported. Nifedipine induces significant afterload reduction. This triggers a compensatory increase in cardiac output, which is usually well tolerated,[131] but may increase the risk for demand myocardial ischemia or heart failure in women with underlying cardiac disease.

Although some initial animal studies raised concern that nifedipine and nicardipine could decrease uterine blood flow and increase fetal hypoxemia and acidosis,[132,133] clinical studies have not demonstrated these outcomes.[131,134,135]

Anesthetic Management

Although nifedipine has fewer effects on cardiac conduction than some of the other calcium entry–blocking agents, it has the potential to cause vasodilation, hypotension, myocardial depression, and conduction defects when used in combination with volatile halogenated anesthetic agents.[136] One report noted that administration of both nifedipine and magnesium sulfate was associated with neuromuscular blockade in a preeclamptic patient at 28 weeks' gestation.[137]

Cyclooxygenase Inhibitors

Indomethacin is the cyclooxygenase inhibitor most typically used for tocolysis, although other agents such as **sulindac** and **ketorolac** have been evaluated. Typical doses of this class of medication used for tocolysis are listed in Table 33.6.

Mechanism of Action

Cyclooxygenase inhibitors inhibit the enzyme cyclooxygenase, and thereby prevent the conversion of arachidonic acid to prostaglandins, which stimulate uterine contractions.

Side Effects

Maternal side effects from indomethacin are minimal when it is used for tocolytic therapy; nausea and heartburn are the most common complaints.[138] Indomethacin is often used to promote closure of the ductus arteriosus in the preterm neonate; thus, there has been concern that maternal administration may result in premature ductus closure in the fetus.[138] Moise et al.[139] used fetal echocardiography to evaluate the fetal response to short-term (less than 72 hours) indomethacin therapy. They observed evidence of transient ductal constriction in 7 of 14 fetuses between 26 and 31 weeks' gestation. Tricuspid regurgitation was also noted in three fetuses. These changes, however, were reversed within 24 hours of discontinuation of indomethacin, and are less likely at earlier gestational ages.[138,140–142] Additionally, studies suggest that clinically significant adverse neonatal effects are unlikely if indomethacin is used in short courses (e.g., 24 to 48 hours).[138,141,142]

Indomethacin administration also may result in fetal oligohydramnios secondary to decreased fetal urine output.[143-145] However, even when it occurs, amniotic fluid usually increases to normal levels within 1 week after its discontinuation. One proposed mechanism for the decrease in fetal urine output is an enhanced antidiuretic hormone effect.[146] Wurtzel[147] showed that maternal administration of indomethacin did not significantly alter neonatal renal function. There is no consistent evidence that transient prenatal administration of indomethacin results in poorer neonatal outcomes.[148]

Anesthetic Management

The effects of indomethacin on platelet function are transient. Several large studies have demonstrated the safety of epidural and spinal anesthesia in patients receiving low-dose aspirin or one of a variety of cyclooxygenase inhibitors.[126] Consensus statements from professional anesthesiology societies have concluded that such therapy is not a contraindication to administration of neuraxial anesthesia, but that additional caution is recommended for patients receiving NSAIDs in combination with other pharmacologic anticoagulation (see Chapter 38).[126]

NSAIDs and acetaminophen are key components of effective postcesarean delivery pain management. Administration of ketorolac or other NSAIDs for postoperative analgesia should consider the timing and dose of any previously administered indomethacin.

Beta-Adrenergic Receptor Agonists

The use of the beta-adrenergic receptor agonists, **ritodrine** and **terbutaline**, for tocolysis has declined substantially because of maternal side effects.[81]

Mechanism of Action

$Beta_2$-adrenergic receptors are found in smooth muscle (uterus, blood vessels, bronchi, intestine, detrusor, and spleen capsule) as well as a variety of other tissues. Ritodrine and terbutaline are relatively selective for $beta_2$-adrenergic receptors; stimulation of these receptors in the myometrium results in relaxation of uterine smooth muscle. Unfortunately, other undesired $beta_2$-adrenergic agonist effects (e.g., vasodilation) and $beta_1$-adrenergic agonist effects (e.g., increased maternal heart rate and cardiac output) still occur.[149]

Beta-adrenergic agonists interact with $beta_2$-adrenergic receptors on the outer membrane of uterine myometrial cells, activating the enzyme adenyl cyclase, which catalyzes the conversion of ATP to cAMP and causes a decrease in intracellular calcium.[143]

Treatment Regimen

Before initiation of treatment, the provider should obtain baseline maternal vital signs and weight, and exclude significant cardiovascular or pulmonary disease. There is no evidence that a continuous long-term infusion of terbutaline alters pregnancy outcome. In 2011, the FDA warned against both outpatient treatment with terbutaline and inpatient treatment beyond 48 to 72 hours.[82]

Side Effects

The administration of beta-adrenergic tocolytic therapy has resulted in the following maternal side effects: (1) hypotension; (2) tachycardia, with or without cardiac arrhythmias and myocardial ischemia; (3) pulmonary edema; (4) hyperglycemia; and (5) hypokalemia.[143] The reported frequency of these side effects varies from 0.5% to 9%.[150–152] Other uncommon maternal side effects reported with the use of beta-adrenergic receptor agonists are elevations in serum transaminase levels,[153] paralytic ileus,[154] cerebral vasospasm in patients with a previous history of migraine,[155] and respiratory arrest caused by increased muscle weakness in a patient with myasthenia gravis.[156]

Anesthetic Management

Ideally, the initiation of anesthesia would be delayed until beta-adrenergic receptor agonist–induced maternal tachycardia subsides. A delay of 15 minutes often results in slowing of the maternal heart rate. However, advanced labor, an abnormal presentation, and/or nonreassuring fetal status often require emergency administration of anesthesia. Published reports of anesthetic management after administration of a beta-adrenergic receptor agonist are scarce.[157–161] Ravindran et al.[159] reported one case each of intraoperative pulmonary edema, sinus tachycardia, and ventricular arrhythmia during general anesthesia in patients who had received terbutaline therapy immediately before or 15 minutes after the induction of anesthesia.

Theoretically, induction of epidural analgesia or anesthesia after beta-adrenergic receptor agonist therapy may cause less hemodynamic compromise than spinal anesthesia because of the slower onset of sympathetic blockade. However, this theory remains unproven. Patients receiving beta-adrenergic receptor agonist therapy are at risk for development of pulmonary edema. Therefore, aggressive hydration should be avoided before and during the induction of anesthesia in these patients.

If general anesthesia is required in a patient who has recently received tocolysis with a beta-adrenergic receptor agonist, agents that might exacerbate maternal tachycardia (e.g., atropine, glycopyrrolate, ephedrine, norepinephrine) should be avoided. Residual maternal tachycardia may make it more difficult to assess volume status and depth of anesthesia. Hyperventilation should be avoided, because it may exacerbate hypokalemia and potentiate the hyperpolarization of the cell membrane. In nonpregnant patients, Slater et al.[162] found that terbutaline pretreatment shortened the onset time and recovery of succinylcholine-induced neuromuscular blockade. It seems prudent to monitor neuromuscular function with a peripheral nerve stimulator during general anesthesia.

Oxytocin Receptor Antagonists

Atosiban (1-deamino-2-D-Tyr-[OEt]-4-Thr-8-Orn-vasotocin/oxytocin) is an oxytocin receptor antagonist. It is a competitive inhibitor of oxytocin that binds to both myometrial and decidual receptors. It does not alter the subsequent sensitivity of the myometrium to oxytocin.[163] Clinically, this feature represents a major advantage; it should reduce the risk for postpartum uterine atony and hemorrhage.

Studies have suggested that atosiban has efficacy similar to that of beta-adrenergic receptor agonists and nifedipine in obtaining and maintaining uterine quiescence. However, a meta-analysis of studies comparing atosiban with either placebo or beta-adrenergic receptor agonists did not demonstrate that atosiban resulted in a reduction in preterm birth or improved neonatal outcome, although side effects were fewer with atosiban.[164] Phase II and III studies have shown that atosiban has few maternal side effects, undergoes minimal placental transfer, and does not increase maternal blood loss at delivery.[84,85,165] The FDA has not approved atosiban for use in the United States because of a higher rate of perinatal deaths in the atosiban arm of the study that it reviewed.[84]

There are no data on the interaction between atosiban and anesthetic agents. However, given the hemodynamic profile of this agent, one would not expect significant interactions. Atosiban is widely used in Europe.

Magnesium Sulfate

Mechanism of Action

Extracellular magnesium functions as a competitive antagonist of calcium, thus reducing calcium influx into the uterine myocyte.[143]

Side Effects

Magnesium sulfate results in less frequent and less severe cardiovascular side effects than beta-adrenergic tocolytic agents.[166–168] Nonetheless, magnesium sulfate may lead to chest pain and tightness, palpitations, nausea, transient hypotension, blurred vision, sedation, and pulmonary edema.[167,168] Hypermagnesemia may attenuate the normal compensatory responses to hemorrhage in the mother and fetus.[169,170]

Magnesium is eliminated almost entirely by renal excretion. Therefore, patients with abnormal renal function should be monitored carefully if they receive magnesium sulfate, and consideration should be given to administering a lower maintenance dose (i.e., infusion rate) in women with renal dysfunction.

Anesthetic Management

It has been suggested that magnesium sulfate should be discontinued before the administration of neuraxial analgesia or anesthesia because magnesium may increase the likelihood of hypotension through its generalized vasodilating properties. Vincent et al.[171] observed that magnesium sulfate reduced

maternal mean arterial pressure but not uterine blood flow or fetal oxygenation during epidural lidocaine anesthesia in gravid ewes. This study suggests that hypermagnesemia may increase the likelihood of modest hypotension during neuraxial anesthesia in normotensive parturients. Clinical relevance in humans is debatable; any effect on hemodynamic parameters may be managed with appropriate fluid and vasopressor therapy, and thus it is not recommended to routinely discontinue magnesium at the time analgesia or anesthesia is administered.

In contrast, magnesium overdose can have serious consequences for both the mother and fetus. Magnesium sulfate administered for the purpose of fetal neuroprotection may be discontinued at the time of delivery. In the case of emergency cesarean delivery, it may be safest to discontinue the magnesium infusion before transfer to the operating room, given the risk for inadvertent magnesium bolus administration.[172]

Magnesium potentiates the action of both depolarizing and nondepolarizing muscle relaxants.[173] A defasciculating dose of a nondepolarizing muscle relaxant should not be given before administration of succinylcholine in women with hypermagnesemia. A standard intubating dose of muscle relaxant (e.g., succinylcholine 1 mg/kg) should be used because the extent of potentiation by magnesium sulfate is variable.[174] Subsequent nondepolarizing neuromuscular muscle relaxants should be administered only if necessary, at the lowest required dose to facilitate surgery.

Parturients receiving magnesium sulfate often appear sedated. Thompson et al.[175] evaluated the anesthetic effects of magnesium sulfate and ritodrine on the minimum alveolar concentration of halothane in pregnant and nonpregnant rats and reported a 20% decrease with serum magnesium levels of 7 to 11 mg/dL. A more detailed discussion of magnesium sulfate, its interactions with anesthetic agents, and management of overdose is found in Chapter 35.

KEY POINTS

- Despite improved antenatal care, the incidence of preterm delivery in the United States remains approximately 10%.
- Preterm birth is a leading cause of neonatal mortality. Survivors have an increased chance of disability.
- Spontaneous preterm labor or preterm premature rupture of membranes account for the majority of preterm births.
- Treatment with tocolytic therapy may prolong labor by up to 48 hours, and thereby facilitate transfer of the patient from a small community hospital to a tertiary care facility, maternal administration of a corticosteroid to accelerate fetal lung maturity, and maternal administration of magnesium for fetal neuroprotection. Long-term tocolytic therapy does not improve neonatal outcome.
- Nifedipine and indomethacin are used commonly to treat preterm labor in the United States; oxytocin receptor antagonists are used in Europe. Magnesium sulfate is not an effective tocolytic but is considered beneficial when used specifically for neuroprotection in reducing rates of cerebral palsy in preterm infants.
- Terbutaline is associated with a high incidence of maternal and fetal side effects, including hypotension, tachycardia (with or without cardiac arrhythmias and myocardial ischemia), pulmonary edema, hyperglycemia, and hypokalemia. Pulmonary edema is the most serious complication, and it may be life threatening.
- Cyclooxygenase inhibitors reversibly inhibit cyclooxygenase, resulting in a transient effect on platelet function. However, their use does not necessitate the assessment of platelet or coagulation function before administration of neuraxial analgesia/anesthesia in a patient whose only risk factor for bleeding is recent ingestion of a cyclooxygenase inhibitor.
- Prior administration of a tocolytic agent, regardless of drug class, does not contraindicate the administration of neuraxial anesthesia.

Abnormal Presentation and Multiple Gestation

Joy L. Hawkins, MD

CHAPTER OUTLINE

The labor and delivery of a parturient with a multiple gestation and/or fetal breech presentation represents a major challenge for the obstetrician and the anesthesia provider. Anesthetic requirements may change from moment to moment, and an obstetric emergency may necessitate immediate intervention. All members of the perinatal care team must communicate directly and clearly with each other as well as with the parturient and her family to ensure the best possible outcome for both the mother and the neonate(s).

The **presentation** denotes that portion of the fetus that overlies the pelvic inlet. In most cases, the fetal presenting part can be palpated through the cervix during a vaginal examination. The presentation may be **cephalic, breech,** or **shoulder.** Breech and shoulder presentations occur with increased frequency in patients with multiple gestation. Cephalic presentations are further subdivided into **vertex, brow,** and **face** presentations according to the degree of flexion of the neck. With an **asynclitic** presentation, the fetal head is tilted toward one shoulder and the opposite parietal eminence enters the pelvic inlet first.

The **lie** refers to the alignment of the fetal spine with the maternal spine. The fetal lie can be either longitudinal or transverse. A fetus with a vertex or breech presentation has a longitudinal lie. A persistent oblique or transverse lie typically requires cesarean delivery.

The **position** of the fetus denotes the relationship of a specific fetal bony point to the maternal pelvis. The position of the **occiput** defines the position for vertex presentations (Fig. 34.1). Other markers for position are the **sacrum** for breech presentations, the **mentum** for face presentations, and the **acromion** for shoulder presentations. The **attitude** of the fetus describes the relationship of the fetal parts with one another; the term is typically used to refer to the position of the head with regard to the trunk, as in flexed, military, or hyperextended.

ABNORMAL POSITION

During normal labor, the fetal occiput rotates to a direct **occiput anterior** position (see Fig. 34.1). In a minority of patients with a right or left occiput posterior position, the occiput rotates directly posteriorly and results in a **persistent occiput posterior** position. The occiput posterior position may lead to a prolonged labor that is associated with increased maternal discomfort. Less often, the vertex remains in the **occiput transverse** position; this condition is known as **deep transverse arrest.** Obstetricians diagnose fetal head position with ultrasonography or palpation of the sagittal suture during vaginal examination.

Obstetricians may perform manual or forceps rotation to hasten delivery and lessen perineal trauma in women with an abnormal position of the vertex. Today, many obstetricians are reluctant to perform rotational forceps delivery for fear of causing excessive maternal and/or fetal trauma; however, manual rotation of the vertex is often attempted as obstetricians work to facilitate vaginal birth.[1] Some cases of persistent occiput posterior position, and many cases of deep transverse arrest, require cesarean delivery because of dystocia.[2]

During administration of epidural analgesia to a patient with an abnormal position, the addition of a lipid-soluble opioid to a dilute solution of local anesthetic is particularly useful. This combination provides analgesia while preserving

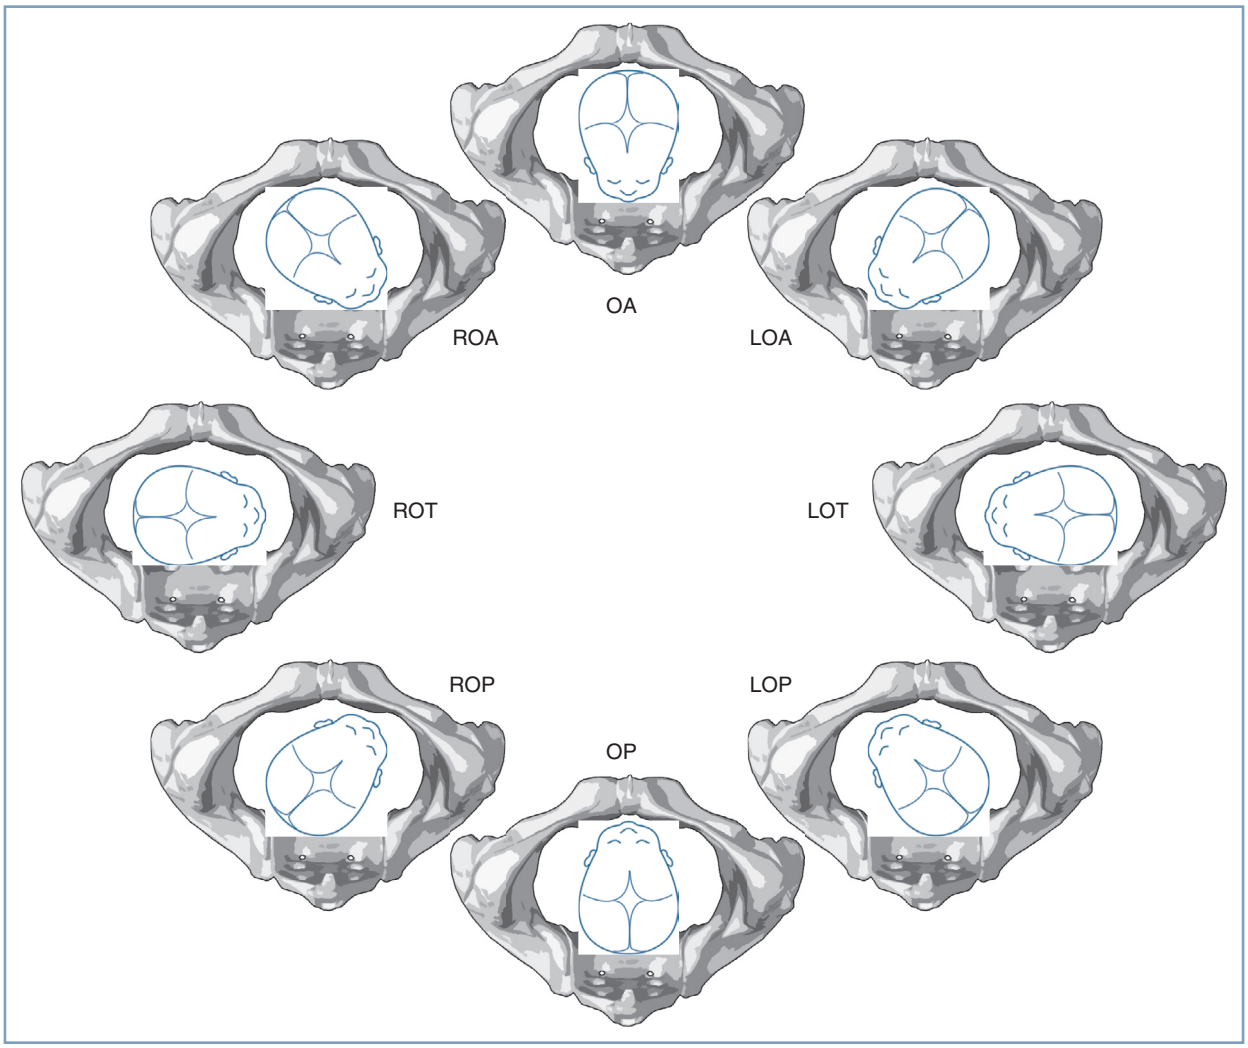

Fig. 34.1 Fetal head position in the maternal pelvis. *OA,* occiput anterior; *LOA,* left occiput anterior; *LOT,* left occiput transverse; *LOP,* left occiput posterior; *OP,* occiput posterior; *ROP,* right occiput posterior; *ROT,* right occiput transverse; *ROA,* right occiput anterior.

pelvic muscle tone. Relaxation of the pelvic floor and perineum may prevent the spontaneous rotation of the vertex during labor.[3] In contrast, profound pelvic floor relaxation is needed to facilitate instrumental vaginal delivery with forceps.

BREECH PRESENTATION

Breech presentation describes a longitudinal lie in which the fetal buttocks and/or lower extremities overlie the pelvic inlet. Fig. 34.2 shows the three varieties of breech presentation:

- **Frank breech**—lower extremities flexed at the hips and extended at the knees
- **Complete breech**—lower extremities flexed at both the hips and the knees
- **Incomplete breech**—one or both of the lower extremities extended at the hips

Ultrasonographic or radiographic examination typically allows the obstetrician to confirm the type of breech presentation and to exclude the presence of associated severe congenital anomalies (e.g., anencephaly). The type of breech presentation may influence the obstetrician's decision regarding the mode of delivery. The fetus with a frank breech presentation tends to remain in that presentation throughout labor. In contrast, a complete breech presentation may change to an incomplete breech presentation at any time before or during labor.

Epidemiology

The breech presentation is the most common of the abnormal presentations. Both the incidence and the type of breech presentation vary with gestational age (Table 34.1). Before 28 weeks' gestation, approximately 25% of fetuses are in a breech presentation.[4] Most change to a vertex presentation by 34 weeks' gestation, but 3% to 4% of fetuses remain in a breech presentation at term.[4]

Many factors predispose to breech presentation (Box 34.1).[4] Abnormalities of the fetus or the maternal pelvis or uterus may play a role. Among patients with pelvic or uterine abnormalities, a breech presentation may allow more room for fetal growth and movement. Likewise, hydrocephalic fetuses

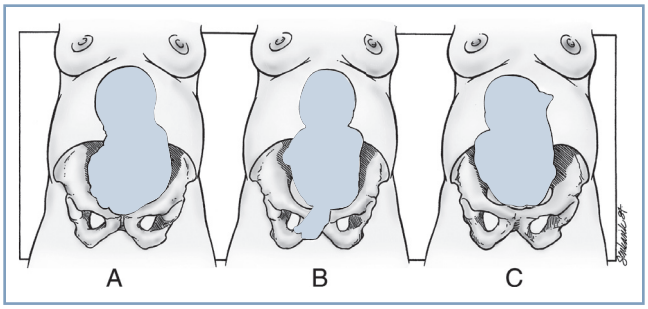

Fig. 34.2 Three possible breech presentations. (A) The *complete breech* demonstrates flexion of the hips and flexion of the knees. (B) The *incomplete breech* demonstrates intermediate deflexion of one or both hips and knees. (C) The *frank breech* shows flexion of the hips and extension of both knees. (From Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al., eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:368–394.)

TABLE 34.1 Types of Breech Presentation

Type of Breech	Percentage of All Breech Presentations	Percentage of Preterm Gestation Breech Presentations
Frank	48–73	38
Complete	5–12	12
Incomplete	12–38	50

Modified from Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:376.

are more likely to assume a breech presentation. Multiparity, multiple gestation, polyhydramnios, and anencephaly also predispose to breech presentation. These conditions may interfere with the normal process of accommodation between the fetal head and the uterine cavity and maternal pelvis.

Obstetric Complications

Obstetric complications are more likely with a breech presentation (Table 34.2). Cesarean delivery decreases the risk for some of these complications. Vaginal breech delivery entails a higher risk for neonatal trauma than delivery of an infant with a vertex presentation, but cesarean delivery does not eliminate the risk for trauma to the infant.[5] Rather, cesarean delivery of a breech presentation can be difficult and traumatic, especially if the skin and uterine incisions are insufficient or maternal muscle relaxation is inadequate.

The risk for umbilical cord prolapse varies with the type of breech presentation (Table 34.3). In the parturient with an incomplete breech presentation, the presenting part does not fill the cervix as well as the vertex or buttocks, allowing the umbilical cord to prolapse into the vagina before delivery. Umbilical cord prolapse typically necessitates emergency cesarean delivery.

TABLE 34.2 Incidence of Complications Associated With Breech Presentation

Complication	Incidence
Intrapartum fetal death	Increased 16-fold[a]
Intrapartum asphyxia	Increased 3.8-fold[a]
Umbilical cord prolapse	Increased 5- to 20-fold[a]
Birth trauma	Increased 13-fold[a]
Arrest of aftercoming head	4.6%–8.8%
Spinal cord injuries with deflexion	21%
Major congenital anomalies	6%–18%
Preterm delivery	16%–33%
Hyperextension of head	5%
Fetal heart rate abnormalities	15.2%

[a]Compared with cephalic presentation.

Modified from Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:381.

BOX 34.1 Factors Associated With Breech Presentation

Uterine Distention or Relaxation
- Multiparity
- Multiple gestation
- Polyhydramnios
- Macrosomia

Abnormalities of the Uterus or Pelvis
- Pelvic tumors
- Uterine anomalies
- Pelvic contracture

Abnormalities of the Fetus
- Hydrocephalus
- Anencephaly

Obstetric Conditions
- Previous breech delivery
- Preterm gestation
- Oligohydramnios
- Cornual-fundal placenta
- Placenta previa

Modified from Cunningham FG, Leveno KJ, Bloom SL, et al. eds. *Williams Obstetrics. 24th ed.* New York, NY: McGraw-Hill Education; 2014:558–573; Lanni SM, Gherman R, Gonik B: Malpresentations. Morbidity and Mortality

There is a higher risk for **perinatal morbidity and mortality** with a breech presentation, even when the risk is adjusted for preterm gestation. The factors that cause breech presentation are often more important than the presentation itself. For example, the severe congenital anomalies that predispose to breech presentation (e.g., hydrocephalus, anencephaly) significantly contribute to neonatal morbidity and mortality.

TABLE 34.3 Risk for Umbilical Cord Prolapse

Type of Breech	Risk for Cord Prolapse (%)
Frank	0.5
Complete	4–6
Incomplete	15–18

Modified from Lanni SM, Gherman R, Gonik B: Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:376.

Relative perinatal mortality rates (calculated from data for linked siblings from the Medical Birth Registry of Norway) confirm that breech presentation is a marker of perinatal risk, regardless of the mode of delivery.[6] Even after successful external cephalic version (ECV), women are at increased risk for cesarean delivery due to dystocia or an abnormal fetal heart rate (FHR) tracing, as compared with women presenting with a cephalic presentation.[7]

Vaginal breech delivery entails a higher risk for **maternal morbidity** (e.g., infection, perineal trauma, hemorrhage) than vertex delivery.[4] However, among women with a fetal breech presentation, maternal outcomes are similar between women who had a planned cesarean delivery and those who had a trial of labor. At 2 years postpartum, maternal morbidity assessed by questionnaire (917 responses for a 79% return) was not different for urinary incontinence, breast-feeding, pain, depression, menstrual problems, fatigue, and distressing memories of the birth experience.[8] In a single-center study of 846 singleton breech deliveries, Schiff et al.[9] also did not find a higher risk for maternal morbidity in women who underwent cesarean delivery during labor than in women who underwent planned cesarean delivery.

Obstetric Management

External Cephalic Version

The process of ECV converts a breech or shoulder presentation to a vertex presentation. The average success rate for this procedure is 58%, with a wide range reported in published studies.[10,11] ECV is most likely to be successful if (1) the presenting part has not entered the pelvis, (2) amniotic fluid volume is normal, (3) the fetal back is not positioned posteriorly, (4) the patient is not obese, (5) the patient is parous, and (6) the presentation is either frank breech or transverse.[12] Early labor does not preclude successful ECV, but ECV is rarely successful when the cervix is fully dilated or when the membranes have ruptured. No scoring system has been developed that reliably predicts which candidates will have a successful version attempt, although the variables just listed can be used when obtaining informed consent.

The optimal timing of ECV is after 36 or 37 weeks' gestation, for the following reasons.[11,13] First, if spontaneous version to a vertex presentation is going to occur, it will likely happen by 36 or 37 weeks' gestation, and successful performance of ECV after 37 weeks' gestation decreases the likelihood of reversion from a vertex to a breech presentation. Second, if complications occur during ECV performed after 37 weeks' gestation, emergency delivery will not result in delivery of a preterm infant.

Successful ECV helps reduce the risk for perinatal morbidity and mortality associated with breech delivery. The American College of Obstetricians and Gynecologists (ACOG)[10] has suggested that "because the risk for an adverse event occurring as a result of external cephalic version is small and the cesarean delivery rate is significantly lower among women who have undergone successful version, all women near term with breech presentations should be offered an ECV attempt if there are no contraindications." There is no general consensus on eligibility for ECV, and contraindications vary between published guidelines.[14] Oligohydramnios may be the most common contraindication cited. Labor and vaginal delivery occur in the majority of patients who have undergone successful ECV, but anesthesia providers should remain vigilant because of the increased risk for intrapartum cesarean delivery necessitated by dystocia or a nonreassuring FHR tracing.[7]

ECV is associated with a low rate of morbidity in contemporary obstetric practice, although placental abruption and preterm labor have been reported.[10] Safe ECV requires FHR monitoring and access to cesarean delivery services. In a systematic review of 84 studies that involved 12,955 women, complications included transient (6.1%) and persistent (0.22%) FHR abnormalities, vaginal bleeding (0.30%), placental abruption (0.08%), emergency cesarean delivery (0.35%), and stillbirth (0.19%).[11] Fetal-maternal hemorrhage is another potential complication of ECV.[11] In one study, 16 of 89 (18%) patients undergoing ECV had Kleihauer-Betke stains that signaled the occurrence of fetal-maternal hemorrhage.[15]

Obstetricians usually administer a tocolytic agent (e.g., terbutaline or nitroglycerin) before performing ECV. A randomized placebo-controlled trial found that the success rate of version was doubled when terbutaline was given rather than placebo.[15] A randomized controlled trial of intravenous nitroglycerin for tocolysis (100- to 300-μg bolus doses, up to a maximum total dose of 1000 μg) found that the success rate was 24% in nulliparous women who received nitroglycerin versus 8% in the placebo group.[16] The success rate was higher in parous women (43%), but it did not differ between the nitroglycerin and placebo groups.[16] Interestingly, the rates of hypotension were similar between groups. A Cochrane Review[17] found that tocolytic therapy with a beta-adrenergic agonist drug for ECV increases the number of women with a cephalic presentation at the onset of labor (relative risk [RR], 1.68; 95% confidence interval [CI], 1.14 to 2.48) and reduces the number of cesarean deliveries (RR, 0.77; 95% CI, 0.67 to 0.88).

Another method to improve the success rate of ECV may be use of neuraxial analgesia or anesthesia. Several studies have described the use of epidural or spinal analgesia or anesthesia for ECV.[18] For example, Weiniger et al.[19] randomly assigned 70 nulliparous women to receive either spinal anesthesia with bupivacaine 7.5 mg or no anesthesia for ECV. The success rate was 67% in those receiving spinal anesthesia,

32% in those without analgesia, and 42% in those who did not consent to enroll in the study. A randomized controlled trial in parous women using similar methodology also found an increased success rate with spinal anesthesia (87% versus 58%).[20] A meta-analysis of 9 trials and 934 women found that compared with control, neuraxial anesthesia increased ECV success rates, increased the occurrence of cephalic presentation in labor, increased vaginal delivery rates, decreased cesarean delivery rates, and decreased maternal discomfort.[21] There was no difference in the incidence of emergency cesarean delivery, transient fetal bradycardia, nonreassuring fetal testing, or placental abruption.

Maternal discomfort may be significant during ECV; greater pain during the procedure is associated with a lower chance of success.[22] Some obstetricians argue that the absence of anesthesia limits the force that the obstetrician can apply during the procedure. They contend that administration of anesthesia may encourage the obstetrician to use excessive force, possibly increasing the risk for perinatal morbidity and mortality, but that concern is not supported by published evidence. In fact, spinal anesthesia reduces the force required for successful version.[23]

Several investigators have reported successful outcomes with neuraxial analgesia or anesthesia in women in whom the first attempt at ECV without neuraxial analgesia had been unsuccessful.[19,24] These patients elected to undergo another version attempt with neuraxial analgesia. Weiniger et al.[19] found that failure of ECV was attributed to pain in 15 women in their control group. Eleven of those 15 (73%) women subsequently had successful ECV with spinal analgesia.

The optimal dose of spinal local anesthetic is controversial. A meta-analysis of seven studies using neuraxial blockade to facilitate ECV concluded that administration of an *anesthetic* dose of local anesthetic doubles the success rate of ECV (RR, 1.95; 95% CI, 1.46 to 2.60), whereas an *analgesic* dose does not have any effect (RR, 1.18; 95% CI, 0.94 to 1.49).[25] A subsequent prospective, randomized, blinded trial addressed the question of optimal intrathecal bupivacaine dose to facilitate ECV success.[26] Patients were randomized to receive intrathecal bupivacaine doses of 2.5, 5.0, 7.5 or 10.0 mg combined with fentanyl 15 μg as part of a combined spinal-epidural technique. Overall success rate of ECV was 51.5% with no difference in success rates or cesarean delivery rates between the groups, demonstrating that intrathecal bupivacaine doses greater than 2.5 mg are not necessary and may only increase the incidence of hypotension. Obstetricians did not perceive a difference in abdominal wall relaxation between the groups, even though pain scores were higher in the 2.5 mg bupivacaine group (12 versus 4 to 5 on a 0 to 100 scale). Patient satisfaction was high and not different between groups.[26] In an accompanying editorial, Carvalho and Bateman[27] suggested that the optimal dose varies according to the clinical situation. If the goal is timely discharge whether or not the version is successful, then a lower-dose spinal anesthetic will allow earlier discharge as a result of faster resolution of the block. If the patient will be admitted for delivery regardless of whether the version is successful, then a higher dose will not affect the patient's length of admission and could facilitate emergent cesarean delivery should that become necessary.[27]

In contrast to neuraxial analgesia or anesthesia, intravenous analgesia does not appear to facilitate successful ECV. Khaw et al.[24] randomized parturients to receive either spinal anesthesia with intrathecal hyperbaric bupivacaine 9 mg plus fentanyl 15 μg, intravenous analgesia using a remifentanil infusion at 0.1 μg/kg/min, or control (no anesthetic or analgesic intervention) before attempted ECV. On the first attempt, success rates were 83% in the spinal group versus 64% in the remifentanil group and 64% in the control group. Among those that failed, a second attempt was successful in 78% of the patients with spinal anesthesia versus 0% receiving remifentanil. There was no significant difference in fetal bradycardia requiring cesarean delivery.[24]

In our practice, we provide spinal or combined spinal-epidural anesthesia during ECV at patient or obstetrician request. Evidence suggests that neuraxial anesthesia may help facilitate successful version and vaginal delivery, and therefore it should be used routinely. If a neuraxial technique is used, intrathecal administration of 2.5 mg bupivacaine combined with fentanyl may provide optimal conditions. Higher local anesthetic doses may be appropriate if delivery is planned for the admission, but may increase the incidence of hypotension.[26,27]

Mode of Delivery

A substantial number of obstetricians recommend the routine performance of cesarean delivery in patients with a breech presentation. The publication of the Term Breech Trial in 2000 changed clinical practice around the world.[5] In contemporary obstetric practice in the United States, most parturients with a breech presentation are delivered by cesarean.

The Term Breech Trial Collaborative Group[5] enrolled 2088 women from 26 countries with a singleton fetus in a frank or complete breech presentation. These women were randomly assigned to undergo planned cesarean delivery or planned vaginal delivery. Using an intent-to-treat analysis, the investigators noted that perinatal and neonatal mortality rates, and serious neonatal morbidity, were significantly lower in the planned cesarean delivery group (1.6% versus 5%). This difference was greatest in those countries with a low perinatal mortality rate (e.g., Canada, United Kingdom, United States).[5] Secondary analysis of perinatal outcomes demonstrated that the lowest risk for adverse outcome occurred when a prelabor cesarean delivery was performed at term gestation.[28] The risk for adverse perinatal outcome progressively increased with cesarean delivery performed during early labor and active labor and was highest with a vaginal birth. Labor augmentation and a longer time between the start of pushing and delivery were associated with an increased risk for adverse perinatal outcome, whereas the presence of an experienced clinician at delivery was associated with a reduced risk for adverse perinatal outcome.[28]

In the Term Breech Trial,[5] maternal morbidity and mortality did not differ between the two groups for the first 6 postpartum weeks. Women who underwent planned cesarean

delivery were less likely to report urinary incontinence at 3 months[29]; however, there was no difference at 2 years.[8] As assessed by questionnaire, maternal outcomes at 2 years after delivery were similar after planned abdominal delivery and after planned vaginal delivery for singleton breech infants born at term.[8]

Despite the results of the Term Breech Trial, Canadian multicenter data from 2003 to 2011 illustrate that vaginal delivery was increasingly popular for Canadian women with breech presentation of nonanomalous singleton infants at term.[30] The vaginal delivery rate increased from 2.7% to 3.9% over that time, and the rate of cesarean deliveries in labor increased from 8.75% to 9.8%. Delivery by planned cesarean had the lowest morbidity. Composite neonatal morbidity and mortality rates were significantly higher after vaginal delivery than planned cesarean with an adjusted rate ratio of 3.6 (95% CI, 2.50 to 5.15). Cesarean delivery during labor also resulted in higher neonatal morbidity and mortality.[29] The Canadian data support the results of the Term Breech Trial.

In many other regions of the world, the number of planned vaginal breech deliveries has decreased as a result of the Term Breech Trial. For example, in Denmark, the proportion of singleton term breech infants delivered vaginally decreased abruptly from 20% before 1999 to 6% after 2001.[31] At the same time, intrapartum or early neonatal mortality among all term breech infants decreased from 0.13% to 0.05% (RR, 0.38; 95% CI, 0.15 to 0.98).[31] The downward trend in rates of vaginal breech delivery is likely to continue. As the number of practitioners with experience in performing vaginal breech delivery has decreased, the number of vaginal breech deliveries available to teach obstetric residents may no longer be adequate. Unintended results of this practice change include a generation of obstetricians who have lost the skills to practice vaginal breech deliveries and medicolegal concerns that now discourage the practice of vaginal breech delivery.[32]

Nevertheless, obstetricians in some regions of the world retain a strong tradition of offering vaginal breech delivery for selected patients. Published in 2006, the PREsentation et MODe d'Accouchement (PREMODA; presentation and mode of delivery) study[33] described birth outcomes for all term breech deliveries in 2001 through 2002 in 174 centers in France and Belgium. The study included 5579 women who planned cesarean breech delivery and 2526 women who planned vaginal breech delivery, of whom 1796 actually delivered vaginally.[33] The primary outcome captured a composite of fetal and neonatal mortality and serious morbidity and was not different between women who planned to undergo vaginal delivery (1.60%; 95% CI, 1.14 to 2.17) and women who planned to undergo cesarean delivery (1.45%; 95% CI, 1.16 to 1.81), with an overall odds ratio (OR) of 1.10 (95% CI, 0.75 to 1.61).[33] The authors suggested that rigorous adherence to protocols for patient selection, intrapartum fetal surveillance, and second-stage management contributed to improved outcomes for women attempting vaginal breech delivery.

In 2006, in recognition of results from the PREMODA study and other single-center descriptions of excellent outcomes for vaginal breech delivery, the ACOG made the following recommendations about mode of singleton breech delivery at term:[34]

- "The decision regarding the mode of delivery should depend on the experience of the health care provider. Cesarean delivery will be the preferred mode of delivery for most physicians because of the diminishing expertise in vaginal breech delivery."
- "Obstetricians should offer and perform external cephalic version whenever possible."
- "Planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines for both eligibility and labor management."
- "In those instances in which breech vaginal deliveries are pursued, great caution should be exercised, and detailed patient informed consent should be documented."
- "Before embarking on a plan for a vaginal breech delivery, women should be informed that the risk of perinatal or neonatal mortality or short-term serious neonatal morbidity may be higher than if a cesarean delivery is planned."

Although a planned trial of labor and vaginal breech delivery occurs uncommonly in most hospitals in North America and the United Kingdom because of concerns for higher rates of adverse perinatal outcomes,[35] vaginal breech delivery still occurs because some patients present in advanced labor. Selection criteria such as those listed in Box 34.2 are used by advocates of a trial of labor and vaginal delivery.[4] The availability of personnel experienced in obstetric anesthesia and neonatal resuscitation are prerequisites for a trial of labor. Hyperextension of the fetal head remains an absolute contraindication to a trial of labor in the patient with a breech presentation.[4]

Vaginal Breech Delivery

Several aspects of the conduct of breech labor differ from those for a vertex presentation. The cervix must be fully

BOX 34.2 Criteria for a Trial of Labor and Vaginal Delivery for Patients With Fetal Breech Presentation

- Frank breech presentation
- Adequate pelvis by imaging pelvimetry
- Estimated fetal weight between 2000 and 3500 g by ultrasonography or by two experienced examiners
- Flexion of the fetal head (the neutral position—the so-called military position—is also acceptable)
- Continuous electronic fetal heart rate monitoring
- Spontaneous progression of labor, with timely effacement and dilation of the cervix and timely descent of the breech
- Availability of an individual skilled in vaginal breech delivery and an assistant
- Availability of an individual skilled in the administration of obstetric anesthesia
- Spontaneous delivery to the level of the umbilicus
- Ability to perform an abdominal delivery promptly
- Availability of an individual with skills in neonatal resuscitation

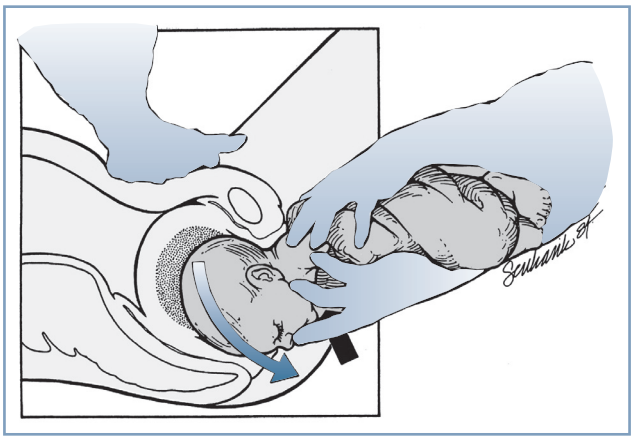

Fig. 34.3 Vaginal breech delivery. The *black arrow* indicates the direction of pressure from two fingers of the operator's right hand on the fetal maxilla (not the mandible). This maneuver assists in maintaining appropriate flexion of the fetal vertex *(direction of blue arrow),* as does moderate suprapubic pressure from an assistant. Delivery of the head may be accomplished with continued maternal expulsive forces and gentle downward traction. (From Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:368–394.)

Fig. 34.4 Vaginal breech delivery. Demonstration of ***incorrect assistance*** during the application of Piper forceps; the assistant hyperextends the fetal neck. Such positioning increases the risk for neurologic injury. (From Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:368–394.)

dilated before the patient begins to push. Indeed, some obstetricians delay maternal expulsive efforts until 30 minutes after the diagnosis of full cervical dilation. Others delay expulsive efforts until the breech is at the perineum.

There are three varieties of vaginal breech delivery. **Spontaneous breech delivery** is delivery without any traction or manipulation other than support of the infant's body. With **assisted breech delivery** (also known as partial breech extraction), the infant is delivered spontaneously as far as the umbilicus; at that time, the obstetrician assists delivery of the chest and the aftercoming head. With **total breech extraction,** the obstetrician applies traction on the feet and ankles to deliver the entire body of the infant. Except for vaginal delivery of a second twin, obstetricians almost never perform total breech extraction. Total breech extraction increases the likelihood of difficult, traumatic delivery, including entrapment of the fetal head.

During assisted breech delivery or total breech extraction, the obstetrician attempts to maintain flexion of the cervical spine during delivery of the aftercoming head. This may be accomplished manually or by the application of Piper forceps (Figs. 34.3 to 34.5). In most cases, the obstetrician performs a generous episiotomy to prevent perineal obstruction of the aftercoming head.

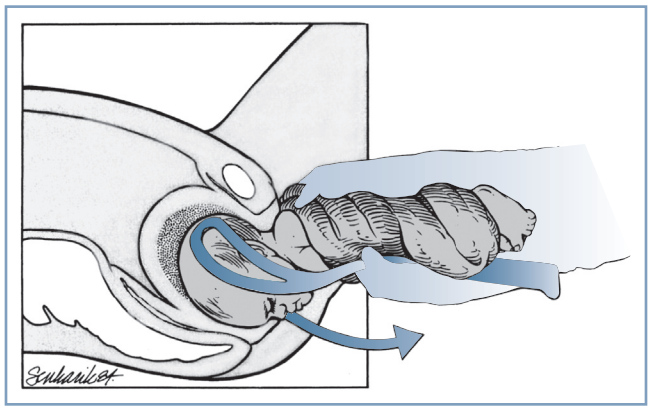

Fig. 34.5 Vaginal breech delivery. Once the Piper forceps are applied, the fetal trunk is supported by one hand, and gentle traction on the forceps *(arrow)* in the direction of the pelvic axis results in a controlled delivery. (From Lanni SM, Gherman R, Gonik B. Malpresentations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:368–394.)

Cesarean Delivery

Cesarean delivery does not guarantee an atraumatic delivery. Generous skin and uterine incisions should be made based on estimated fetal size. In preterm deliveries, a vertical uterine incision may need to be performed if the lower uterine segment is poorly developed. In such cases, the obstetrician should perform a low vertical uterine incision, which can be extended to facilitate an atraumatic delivery. Unfortunately, such incisions often extend to the body of the uterus, which does not heal as well as the lower uterine segment. It is unclear whether a low vertical uterine incision increases the risk for uterine rupture during a trial of labor in a subsequent pregnancy, but a classic uterine incision is associated with a 1% to

12% risk for uterine rupture in subsequent pregnancies (see Chapter 19).

Anesthetic Management

Benefits of neuraxial analgesia during labor include (1) pain relief, (2) inhibition of early pushing by blocking the perineal reflex, (3) ability of the parturient to push during the second stage and spontaneously deliver the infant to the level of the umbilicus, (4) a relaxed pelvic floor and perineum at delivery, and (5) the option to extend analgesia to surgical anesthesia for emergency cesarean delivery if needed.

Analgesia for Labor

Emergency cesarean delivery may be required at any time during a trial of labor. Epidural analgesia and CSE analgesia are excellent choices during a trial of labor in patients with a breech presentation. The anesthesia provider should tailor the analgesic technique to the needs of the individual patient. Patients with a breech presentation often have earlier complaints of rectal pressure than patients with a vertex presentation. It is important to provide sufficient sacral analgesia to inhibit pushing during the first stage of labor. The patient must not push before the cervix is fully dilated; otherwise, the patient might push a fetal lower extremity through her partially dilated cervix, which may result in umbilical cord prolapse or fetal head entrapment. A bolus dose of local anesthetic solution that includes a lipid-soluble opioid (e.g., fentanyl, sufentanil) may be required to block the sacral segments and the reflex urge to push during the late first stage of labor. Use of a local anesthetic alone to eliminate low back and perineal discomfort results in extensive motor blockade, which may decrease the effectiveness of maternal expulsive efforts during the second stage.

Anesthesia for vaginal breech delivery. The patient with a breech presentation should deliver in an operating room where an emergency abdominal delivery can be performed immediately. The anesthesia provider should consider administration of a nonparticulate antacid at the time of transfer to the operating room. The anesthesia provider should be prepared for emergency administration of general anesthesia at any time. Umbilical cord compression is common during the second stage of labor in a patient with a breech presentation.

Provision of effective analgesia/anesthesia for vaginal breech delivery represents a true challenge for the anesthesia provider. During the second stage of labor, the anesthesia provider is asked to provide adequate analgesia (which should include blockade of the sacral segments) while maintaining adequate maternal expulsive efforts. If a patient is unable to achieve spontaneous delivery of a *vertex* presentation, the obstetrician may perform instrumental vaginal delivery. In contrast, total breech extraction of a singleton fetus is unacceptable in modern obstetric practice. Most obstetricians insist on spontaneous delivery of the infant to the level of the umbilicus.

At any time, the anesthesia provider may be asked to quickly provide dense anesthesia for vaginal or cesarean delivery. Many obstetricians routinely apply Piper forceps to the aftercoming head. This maneuver requires adequate anesthesia and perineal muscle relaxation. Because a dilute solution of local anesthetic has been administered during the first stage of labor, it is often necessary to administer a more concentrated solution of local anesthetic at the time of delivery. Either 3% 2-chloroprocaine or 2% lidocaine with epinephrine and bicarbonate may be used to rapidly extend the epidural analgesia to anesthesia for operative delivery. To ensure adequate anesthesia for operative delivery, we begin to inject a more concentrated solution of local anesthetic at the first evidence of difficulty.

Perhaps the obstetrician's greatest fear is the risk for **fetal head entrapment.** Most cases of this complication involve entrapment of the fetal head behind a partially dilated cervix. The head may also be entrapped by the perineum. Fetal head entrapment is more likely to occur in patients at less than 32 weeks' gestation. Before 32 weeks' gestation, the fetal head is larger than the wedge formed by the fetal buttocks and thighs. The lower extremities, buttocks, and abdomen may deliver before the cervix is fully dilated, and the cervix may then entrap the head. If this complication occurs, the obstetrician may choose one of the following three options: (1) performance of Dührssen incisions in the cervix, (2) relaxation of skeletal and cervical smooth muscle, or (3) cesarean delivery.

The performance of **Dührssen incisions** involves two or three radial incisions in the cervix at the 2-, 6-, and 10-o'clock positions.[4] This procedure is associated with a high risk for maternal morbidity (e.g., genitourinary trauma, hemorrhage). The blood loss may be substantial and concealed. Bleeding within the peritoneal cavity may not be visible externally.

More often, the obstetrician requests that the anesthesia provider establish **relaxation of skeletal and cervical smooth muscle.** Smooth muscle represents less than 15% of total cervical tissue,[4] and some physicians argue that it is not possible to provide profound relaxation of the cervix through smooth muscle relaxation. Nonetheless, the provision of both skeletal and smooth muscle relaxation often facilitates vaginal delivery of the aftercoming head. In the past, the technique of choice was rapid-sequence induction of general anesthesia, followed by administration of a high concentration (2 to 3 minimum alveolar concentration [MAC]) of a volatile halogenated agent. This technique results in uterine and cervical relaxation in 2 to 3 minutes. If fetal head entrapment results from perineal obstruction by skeletal musculature, delivery may soon follow the administration of succinylcholine.

Immediately after delivery, the anesthesia provider should discontinue administration of the volatile halogenated agent and substitute nitrous oxide, with or without an opioid. Administration of a high concentration of a volatile halogenated agent increases the risk for uterine atony and hemorrhage after delivery. Prompt discontinuation of the volatile halogenated agent, along with intravenous infusion of oxytocin, should facilitate adequate uterine tone in most patients. Anesthesia should be maintained until the placenta is delivered, the episiotomy and lacerations are repaired, and hemostasis is secured.

In modern practice, intravenous or sublingual administration of nitroglycerin has nearly replaced the use of volatile halogenated agents as agents for uterine relaxation. Administration of nitroglycerin results in the release of nitric oxide, which helps mediate the relaxation of smooth muscle. Transient hypotension is common. Use of nitroglycerin for this purpose is based on case reports and small series of cases. Well-designed clinical trials of the use of nitroglycerin to provide uterine relaxation in obstetric emergencies are lacking, although the administration of nitroglycerin for this purpose appears safe for both the mother and the infant.[36]

Published case reports have described clinically apparent uterine relaxation achieved with cumulative intravenous nitroglycerin doses ranging from 50 to 1500 μg. The actual dose required for specific clinical situations is unknown. Sublingual tablets or sprays of metered-dose nitroglycerin (400 μg) may provide a more convenient means of administration, whereas intravenous administration may allow for more rigorous titration. Either sublingual or intravenous routes of administration appear to provide a rapid onset of uterine relaxation, and the effect typically is very brief. The patient should be warned about the acute onset of headache, and she should be treated with a vasopressor such as phenylephrine if hypotension occurs. The anesthesia provider should simultaneously prepare for the induction of general anesthesia should nitroglycerin not provide enough relaxation.

The use of epidural analgesia has likely lowered the incidence of fetal head entrapment during vaginal breech delivery for at least two reasons. First, epidural analgesia inhibits early pushing during the first stage of labor. Second, although epidural analgesia does not relax the cervix at delivery, it provides effective pain relief and skeletal muscle relaxation. A relaxed pelvic floor and perineum facilitates placement of Piper forceps and delivery of the aftercoming head. Moreover, effective analgesia and skeletal muscle relaxation allow an assistant to provide maternal suprapubic pressure, which helps maintain flexion of the fetal cervical spine during delivery.

Anesthesia for Cesarean Delivery

Spinal, epidural, or general anesthesia can be administered for cesarean delivery. At cesarean delivery, the obstetrician should perform a uterine incision that allows an atraumatic delivery of the infant. Rarely, the obstetrician may request provision of uterine relaxation even when a vertical uterine incision has been performed. Uterine relaxation may be necessary in cases of fetal malformations (e.g., sacral teratoma, hydrocephalus). When general anesthesia is used, the anesthesia provider may increase the concentration of the volatile halogenated agent. When neuraxial anesthesia is used, intravenous or sublingual administration of nitroglycerin, or intravenous administration of a beta-adrenergic tocolytic agent such as terbutaline, typically provides adequate relaxation. Rarely, it is necessary to perform intraoperative induction of general anesthesia followed by administration of a high concentration of a volatile halogenated agent.

Regardless of the route of delivery, all members of the obstetric care team should remember that newborn infants with a breech presentation tend to be more depressed than infants with a vertex presentation. An individual skilled in neonatal resuscitation should be immediately available.

OTHER ABNORMAL PRESENTATIONS

Face Presentation

Face presentation, in which the neck is deflexed (extended backward) occurs in 1 in 600 to 800 live births. Vaginal delivery can be achieved in 70% to 80% of infants with a face presentation if the mentum rotates to an anterior position, but FHR abnormalities are common.[4] Manual efforts to flex the fetal cervical spine or convert an unfavorable mentum posterior position to a more favorable mentum anterior position are rarely successful and may result in significant maternal complications including uterine rupture, as well as adverse neonatal complications including spinal cord injury and difficult ventilation due to tracheal and laryngeal edema.[37]

Brow Presentation

In patients with a brow presentation, the cervical spine position is intermediate between the full flexion of a normal vertex presentation and the full extension of a face presentation. On vaginal examination, the obstetrician can palpate the brow, orbits, and saddle of the nose, but not the mouth or chin. Brow presentation occurs in approximately 1 in 500 to 4000 deliveries. Persistent brow presentation typically requires cesarean delivery due to dystocia. Spontaneous flexion or extension of the neck may occur during labor, which may allow vaginal delivery.[4]

Compound Presentation

Compound presentation (an extremity is prolapsed alongside the main presenting fetal part) occurs in 1 in 300 to 1000 deliveries. Most often, an upper extremity presents with the vertex. Umbilical cord prolapse is more common (10% to 20%) in deliveries with a compound presentation, as is neurologic or musculoskeletal damage to the involved extremity.[4] Labor and delivery may occur safely, but abdominal delivery is needed in patients with cord prolapse or arrest of labor. Expectant management rather than manipulation of the prolapsed extremity is the most common practice.[4]

Shoulder Presentation

A shoulder presentation (also known as a transverse lie) mandates performance of cesarean delivery except in two circumstances. First, successful ECV will allow vaginal delivery. Second, the obstetrician may perform internal podalic version and total breech extraction of a second twin with a shoulder presentation.

Transverse lie can present back down or back up. Cesarean delivery of a fetus with a back-down transverse lie can be especially difficult with no presenting part to grasp. If intra-abdominal version cannot be accomplished before

hysterotomy, this presentation represents an indication for a classic or low vertical uterine incision.

MUTLIPLE GESTATION

Epidemiology

Monozygotic twins (which occur when a single fertilized ovum divides into two distinct individuals after a variable number of divisions) exhibit a constant incidence of approximately 4 per 1000 births. The incidence of **dizygotic twins** (which occur when two separate ova are fertilized) varies among races and by maternal age. In the United States, dizygotic twins occur most frequently among non-Hispanic black and white Americans, with an intermediate frequency among Asian Americans and Puerto Ricans, and least frequently among other Hispanic groups and Native Americans.[38] The incidence increases with parity, independent of maternal age.[39] In the United States, the twin birth rate rose 76% between 1980 and 2009, from 19 to 33 per 1000 live births.[40] Twin birth rates rose by nearly 100% among women 35 to 39 years of age and more than 200% among women 40 years of age and older. Delayed childbearing and spontaneous twinning among women older than 30 years of age appears to explain one-third of the increase in the rate of multiple gestation between 1980 and 2010, with the remainder attributed to greater use of assisted reproductive technologies.[40]

Placentation

Placentas in multiple gestation may be (1) **monochorionic monoamniotic;** (2) **monochorionic diamniotic;** or (3) **dichorionic diamniotic** (Fig. 34.6). In all occurrences of dizygotic twins, the placenta is dichorionic diamniotic. A dichorionic diamniotic placenta is also present if monozygotic twinning occurs during the first 2 to 3 days after fertilization. Twinning between 3 and 8 days commonly results in a monochorionic diamniotic placenta. Monochorionic monoamniotic placentas are found when twinning occurs at 8 to 13 days. Embryonic cleavage between 13 and 15 days results in conjoined twins with a monochorionic monoamniotic placenta. Chorionicity is best determined by ultrasonography in the first or early second trimester.[41]

It is important to know the type of placentation because it determines the likelihood of vascular communications. Vascular communications occur in nearly all monochorionic placentas and are rare in dichorionic placentas.[42] Vascular communications may result in twin-to-twin transfusion syndrome and intrauterine fetal death. Monochorionic placentation also increases the risk for intrauterine fetal death from other causes (e.g., cord accident).[42]

Physiologic Changes

Multiple gestation accelerates and may exaggerate the physiologic and anatomic changes of pregnancy. Of interest to the anesthesia provider, multiple gestation intensifies the cardiovascular and pulmonary changes of pregnancy. In contrast, the renal, hepatic, and central nervous system changes resemble those that occur in women with a singleton fetus.

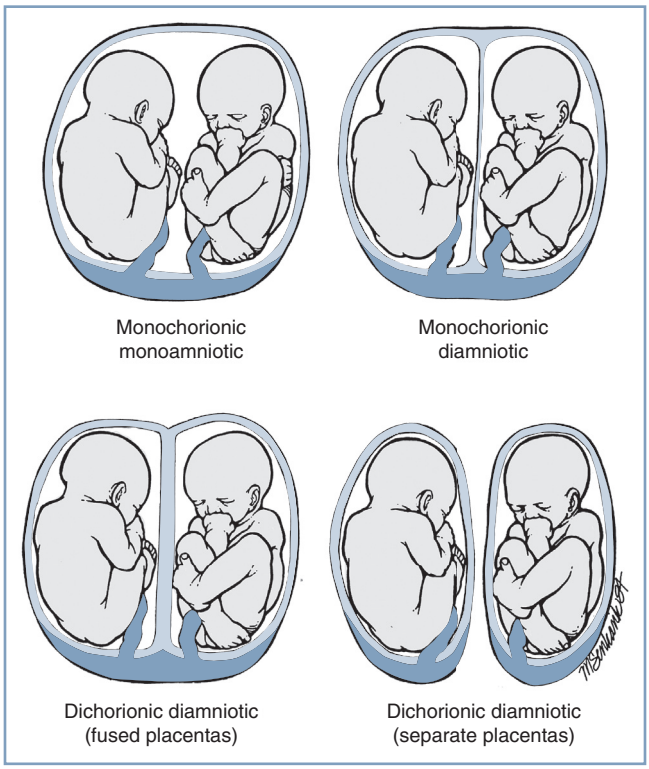

Fig. 34.6 Placentation in twin pregnancies. (From Newman RB, Unal ER. Multiple gestations. In Gabbe SG, Niebyl JR, Simpson JL, et al. eds. *Obstetrics: Normal and Problem Pregnancies. 7th ed.* Philadelphia, PA: Elsevier; 2017:706–736.)

Increased uterine size, especially near term, may result in a reduction in both total lung capacity and functional residual capacity. During periods of hypoventilation or apnea, hypoxemia develops more rapidly because of the decreased functional residual capacity and an increased maternal metabolic rate. However, one cross-sectional study demonstrated no significant difference in pulmonary function tests between 68 women with a twin pregnancy and 140 women with a singleton pregnancy.[43] Maternal weight increases at a greater rate after 30 weeks' gestation in women with multiple gestation.[44] Greater uterine size displaces the stomach cephalad, decreasing the competence of the lower esophageal sphincter and increasing the risk for passive regurgitation and potential pulmonary aspiration of gastric contents. All these physiologic and anatomic factors, plus increased breast size, combine to potentially increase the risk for difficult tracheal intubation and ventilation.

Normal plasma volume increases by an additional 750 mL with twin gestation.[45] Relative or actual anemia often occurs. Likewise, multiple gestation results in a 20% greater increase in cardiac output than occurs in women with a singleton fetus, owing to a greater stroke volume (15%) and a higher heart rate (3.5%). In a longitudinal study comparing uncomplicated twin pregnancies to singleton pregnancies, at all points cardiac output was higher with twins while total vascular resistance was lower.[46] The greater fetal weight and larger volume of amniotic fluid predispose the mother with

BOX 34.3 Fetal Complications Associated With Multiple Gestation

- Preterm delivery
- Congenital anomalies
- Polyhydramnios
- Cord entanglement
- Umbilical cord prolapse
- Fetal growth restriction
- Twin-to-twin transfusion
- Malpresentation

multiple gestation to aortocaval compression and the supine hypotension syndrome.

Obstetric Complications

Fetal Complications

Fetal complications include those related solely to multiple gestation (e.g., twin-to-twin transfusion syndrome) and those related to abnormal presentation (e.g., prolapsed umbilical cord) (Box 34.3).

Twin-to-twin transfusion. Nearly all monochorionic twin placentas have vascular anastomoses. Deep arteriovenous anastomoses create a common villous compartment in about one-half of monochorionic twin placentas. Most of these anastomoses have little fetal consequence. Those with deep arteriovenous vascular communications may result in twin-to-twin transfusion,[47] in which one twin becomes the donor and the other twin becomes the recipient. The donor twin is smaller and is at risk for fetal growth restriction (also known as intrauterine growth restriction) and anemia. The recipient twin is plethoric and is at risk for volume overload and cardiac failure. Alternative explanations for the syndrome include unequal blood volumes secondary to compression of a velamentous umbilical cord insertion and higher arterial blood pressure in the donor than in the recipient. Twin-to-twin transfusion increases both the perinatal mortality rate and the risk for adverse neurodevelopmental outcome in survivors.[48]

The therapeutic options most often considered are decompression amniocentesis, amniotic septostomy, interruption of the placental vessel communications, and selective feticide.[49] Decompression amniocentesis or serial amnioreduction to treat polyhydramnios in the recipient twin may improve circulation to a "stuck" donor twin (the term refers to such severe oligohydramnios in the donor twin that the fetus is wedged in the corner of the uterus and appears "stuck"). Amnioreduction restores normal amniotic fluid volume and improves fetal growth in the donor twin. Compared with serial amnioreduction, septostomy has the advantage of requiring only a single procedure.[50] Selective fetoscopic laser photocoagulation may be used to reduce the vascular anastomoses, and may improve perinatal outcomes.[51–53] Anesthetic management of these procedures focuses on maintaining uteroplacental circulation, achieving profound uterine relaxation, optimizing surgical conditions, monitoring fetal hemodynamics, and minimizing maternal and fetal risk.[54]

Fetal growth restriction. Twin-to-twin transfusion represents only one of the potential causes of fetal growth restriction in multiple gestation. The polyhydramnios within one fetal sac may limit the growth of the other fetus. In patients with three or more fetuses, limited intrauterine size may restrict fetal growth. Of course, factors that cause fetal growth restriction in singleton pregnancies also may cause fetal growth restriction in multiple gestation (e.g., uteroplacental insufficiency, chromosomal abnormalities).

Preterm labor. Patients with multiple gestation are at high risk for preterm labor and delivery. Preterm labor occurs in 52% of women with twins resulting from *in vitro* fertilization compared with 22% of women with spontaneous twins.[41,55] Sixty percent of women with twins deliver before 37 weeks' gestation, and only 6.4% of triplet pregnancies reach term.[38] Routine use of bed rest, prophylactic cerclage, vaginal progesterone, and/or tocolytic therapy has not been shown to improve perinatal outcome in multiple gestation pregnancies.[56] When preterm labor occurs, the patient may receive parenteral tocolytic therapy to facilitate administration of betamethasone to accelerate fetal lung maturation, or magnesium sulfate for fetal neuroprotection, or both. The side effects of magnesium and other tocolytic agents may affect the response to anesthesia (see Chapter 33) and may increase the risk for postpartum hemorrhage. Multiple gestation most likely increases the risk for pulmonary edema associated with tocolytic therapy.[57]

Abnormal presentation. Multiple gestation is associated with a higher incidence of abnormal presentation, which results in part from the need to accommodate two or more fetuses within the uterine cavity. Malpresentation increases the risk for umbilical cord prolapse, which may occur either before or after delivery of the first infant.

Morbidity and mortality. In 2013, 8.6% of fetal deaths occurred in multiple gestation.[58] The perinatal mortality rate in twin pregnancies is 2.5 times greater than that associated with singleton pregnancies (14.1 deaths per 1000 births versus 5.7 per 1000 births, respectively) and is 5-fold higher in triplet or higher-order gestations (30.5 per 1000 births).[58] Preterm delivery accounts for most of this increase, although twins and triplets also have a higher weight-specific mortality, which may be related to twin-to-twin transfusion, congenital malformations, preeclampsia, malpresentation, and/or prolapsed umbilical cord. Some maternal-fetal medicine specialists advocate selective multifetal reduction to reduce the risk for maternal morbidity and the perinatal morbidity and mortality associated with three or more fetuses; this issue is a moral and ethical dilemma for some patients and physicians. The ACOG[41] has stated:

> *Women who underwent pregnancy reduction from triplets to twins, as compared with those who continued with triplets, were observed to have lower frequencies of pregnancy loss, antenatal complications, preterm birth, low-birth-weight infants, cesarean delivery, and neonatal deaths, with rates similar to those observed in women with spontaneously conceived twin gestations.*

Intensive inpatient monitoring improves perinatal survival of *monoamniotic* twins. A literature review of studies comparing inpatient and outpatient monitoring of monoamniotic twins suggested a 10-fold reduction in fetal death with inpatient monitoring after 28 weeks' gestation.[59] In addition to the risks faced by all twins, monoamniotic twins face the unique risk for cord entanglement. Three-times daily fetal monitoring and nonstress tests are used to check for multiple deep variable decelerations that could be related to cord entanglement. Intensive surveillance may also benefit *monochorionic diamniotic* pregnancies.[60] The long-term outcome of the complications of monochorionicity remains unclear.[61]

Death of one fetus may occur well before term. Johnson and Zhang[62] evaluated outcome for 150,386 sets of twins and 5240 sets of triplets born between 1995 and 1997; fetal death at 20 weeks' gestation or later occurred in 2.6% of twin gestations and 4.3% of triplet gestations. The investigators noted that "survival of the remaining fetuses was inversely related to the time of the first fetal demise."[62] Opposite-gender twins were more likely to survive, possibly reflecting the absence of monochorionic placentation. In monochorionic twin gestations complicated by twin-to-twin transfusion and fetal death, approximately 40% of the surviving twins experience mortality or serious neurodevelopmental morbidity.[63] Obstetric management decisions are based on the cause of death and the status of both the surviving fetus and the mother. If the cause of death was an abnormality of the fetus rather than maternal or uteroplacental pathology, expectant management of the pregnancy may be warranted.[41,42] Development of maternal pulmonary edema from mirror syndrome or disseminated intravascular coagulation from dead fetal tissue are theoretical complications that occur rarely.[41]

Multiple gestation is also associated with an increased risk for neonatal morbidity and mortality. Triplet and quadruplet pregnancies have significantly higher risks than twin pregnancies for neonatal complications.[64]

Order of Delivery

Compared with first-born twins, the second-born has a higher incidence of adverse outcome due to lower birth weight, higher frequency of malpresentation, umbilical cord prolapse, and placental abruption.[41,65,66] Abruption can occur when rapid decompression of the uterus with delivery of the first twin leads to shearing forces through the basal plate of the placenta. Delivery of the second twin may require internal podalic version due to nonvertex presentation.

Administration of neuraxial anesthesia may improve the outcome for the second twin. In 1987, Crawford[67] observed that among women who received epidural analgesia, the two twins had similar umbilical cord blood pH measurements. In contrast, among women who received general anesthesia, the second twin tended to be more acidotic than the first. Likewise, Jarvis and Whitfield[68] reported no difference in outcome for first and second twins when the mother received epidural analgesia. Administration of general anesthesia is increasingly rare for cesarean delivery in women with multiple gestation.[69]

BOX 34.4 Maternal Complications Associated With Multiple Gestation

- Preterm premature rupture of membranes
- Preterm labor
- Prolonged labor
- Preeclampsia/eclampsia
- Placental abruption
- Disseminated intravascular coagulation
- Operative delivery (forceps and cesarean)
- Uterine atony
- Obstetric trauma
- Antepartum and/or postpartum hemorrhage

Maternal Complications

Multiple gestation increases the incidence of maternal morbidity and mortality (Box 34.4), even with adjustment of data for confounding factors.[70] A population-based cohort study in the Netherlands found the overall incidence of severe acute maternal morbidity was 7.0 per 1000 deliveries, but was 6.5 and 28.0 per 1000 for singletons and multiple pregnancies, respectively. The relative risk for severe acute maternal morbidity in twins compared with singleton pregnancies was 4.3 (95% CI, 3.7 to 5.0) and increased to 6.2 (95% CI, 2.5 to 15.3) in triplet pregnancies. Risk factors for morbidity included age greater than 40 years, nulliparity, use of assisted reproductive technology, and nonspontaneous onset of labor.[70] The increased incidence of cesarean delivery contributes to the higher risk for maternal morbidity and mortality associated with multiple gestation. Multiple gestation and the associated use of assisted reproductive technologies also increase both the incidence and severity of preeclampsia.[71] The ACOG has stated: "Women with multiple gestations are nearly 6 times more likely to be hospitalized with complications, including preeclampsia, preterm labor, preterm premature rupture of membranes, placental abruption, pyelonephritis, and postpartum hemorrhage."[41]

The incidence of maternal complications increases in proportion to the number of fetuses.[72] Compared with mothers of twins, mothers of triplets and quadruplets are more likely to have preterm premature rupture of membranes, hypertension, and/or excessive bleeding; require tocolysis; require cesarean delivery at less than 29 weeks' gestation; and have one or more infants die.[64] Abdominal distention and diaphragmatic elevation can cause respiratory distress and may necessitate early delivery in some patients with three or more fetuses.

Blood loss with delivery is approximately 500 mL greater in multiple gestation pregnancies than in singleton pregnancies.[42] Uterine distention increases the risk for uterine atony and postpartum hemorrhage. Most cases of atony respond to standard pharmacologic therapy (e.g., oxytocin, methylergonovine, 15-methyl prostaglandin $F_{2\alpha}$ [carboprost]). Persistent uterine atony may require the performance of interventions such as a uterine brace or B-Lynch suture or emergency hysterectomy.

Obstetric Management

Delivery at 38 weeks' gestation for twins and 35 weeks' gestation for triplets may be associated with the lowest risk for perinatal mortality, although timing of delivery also depends on chorionicity and presence of fetal growth restriction.[41] Twin gestation itself does not contraindicate labor and vaginal delivery. However, multiple gestation is associated with a higher incidence of cesarean delivery. Most obstetricians favor cesarean delivery for all patients with three or more fetuses.[42]

Several studies have investigated outcomes for twin delivery by planned cesarean or trial of labor.[73] Barrett et al.[74] randomized a total of 1398 women (2795 fetuses) to planned cesarean delivery and 1406 women (2812 fetuses) to planned vaginal delivery. The rate of cesarean delivery was 90.7% in the planned-cesarean-delivery group and 43.8% in the planned-vaginal-delivery group. The authors found that planned cesarean delivery did not significantly decrease or increase the risk for fetal or neonatal death or serious neonatal morbidity, as compared with planned vaginal delivery.[74] A 2-year neurodevelopmental follow-up of these children found no significant difference in the outcome of death or neurodevelopmental delay: 5.99% in the planned cesarean versus 5.83% in the planned vaginal delivery group (OR, 1.04; 95% CI, 0.77 to 1.41; $P = .79$).[75]

Observational data suggest that perinatal outcomes may be improved with a trial of labor when the presenting twin is in a vertex position. A large cohort study of 5915 twin deliveries in France compared planned cesarean delivery with planned vaginal delivery.[76] Of those with a cephalic presentation of the first twin at or beyond 32 weeks' gestation, 75.4% had planned vaginal deliveries, of whom 80.3% delivered both twins vaginally. They found that planned cesarean compared with planned vaginal delivery before 37 weeks' gestation was associated with increased composite neonatal mortality and morbidity, and they recommended planned vaginal rather than cesarean delivery between 32 and 37 weeks' gestation.[76] A second cohort study of 2597 twin deliveries at or after 34 weeks' gestation, with the first twin in a cephalic presentation, found that intrapartum and postpartum neonatal complications occurred in 26.5% of intended vaginal deliveries and 31.7% of scheduled cesarean deliveries ($P = 0.005$).[77] The authors concluded that their findings do not support a policy of planned cesarean delivery for twin pregnancies at or after 34 weeks' gestation.[77] A meta-analysis of 39,571 twin pregnancies found that neonatal morbidity was lower after vaginal delivery than after cesarean delivery for twin A, but there was no significant difference in neonatal morbidity between the two modes of delivery for twin B.[78] When outcomes were stratified for both presentation and mode of delivery, the mortality rate was lower after vaginal delivery than after cesarean delivery for both vertex and nonvertex twin B.[78] If twin A is in a vertex presentation, the evidence supports a planned vaginal delivery after 32 weeks' gestation. Retrospective data support a similar policy for twin delivery before 32 weeks' gestation.[79] A policy of planned vaginal delivery of very preterm twins from 26 to 32 weeks' gestation with the first twin in cephalic presentation did not increase either severe neonatal morbidity or mortality.[79]

Maternal morbidity depends on the likelihood of achieving vaginal birth for both twins. A 7-year retrospective cohort study of women delivering twins after 32 weeks' gestation compared maternal morbidity after trial of labor or elective cesarean delivery.[80] Vaginal delivery of both twins was successful in 74% of those having a trial of labor, but they found that postpartum hemorrhage was more common among women who attempted vaginal delivery compared with those electing cesarean delivery, with rates of 9.1% compared with 4.9%, respectively ($P < .01$, adjusted OR 2.2, 95% CI, 1.4 to 3.6). Hemorrhage was responsible for the difference in the composite morbidity rate between groups.[80] The authors noted that the tradeoff for a 74% chance of vaginal delivery is a 4% absolute increase in the rate of serious postpartum hemorrhage, a discussion that should occur between the patient and her obstetrician during delivery planning. The ACOG recommends a trial of labor for women with twin gestation when the first twin is in cephalic presentation as one method of safe reduction of the rate of primary cesarean deliveries.[81]

Both fetuses have a vertex presentation in 30% to 50% of cases of twin gestation, and in 25% to 40% of cases the presentation is a vertex/breech combination. The remaining patients have various combinations of vertex, breech, and transverse lie. Most obstetricians allow a trial of labor if both twins have a vertex presentation. Similarly, a majority of obstetricians opt for cesarean delivery if the first twin has a breech or shoulder presentation. Notwithstanding the results of recent studies,[73–79] there may still be variations in management when twin A has a vertex presentation and twin B has a nonvertex presentation.[41] As in decisions about mode of delivery after prior cesarean delivery, these choices reflect shared decision-making between the patient and the obstetrician, informed by the likelihood of achieving intended vaginal birth, her desire for future pregnancies, and a tailored risk assessment for each mode of delivery.

Twin A

Decisions regarding the method of delivery typically begin with the gestational age and presentation of twin A. An obstetrician who is unwilling to allow a trial of labor in a patient with a singleton breech presentation is unlikely to allow a trial of labor in a patient with a breech presentation for twin A. Moreover, if twin A has a breech presentation and twin B has a vertex presentation, the chins may become interlocked during labor and delivery. This complication occurs infrequently, but the consequences can be devastating.[42] The unanticipated case of head entrapment, deflexed head, or locked twins may necessitate emergency abdominal delivery of both twins. The obstetrician proceeds with cesarean delivery while an assistant supports the exteriorized body of twin A. The obstetrician applies gentle traction on the head while the infant's body is guided back into the uterus.[42]

When twin A has a cephalic presentation, decisions about mode of delivery must account for the relative size,

presentation, and position of twin B. Antepartum ultrasonographic examination allows the obstetrician to assess the presentation, position, head size, and weight of both fetuses. Indications for planned cesarean delivery of twins include (1) evidence of discordant growth (especially if twin B is larger than twin A); (2) twin-to-twin transfusion syndrome; (3) selected congenital anomalies; and (4) evidence of uteroplacental insufficiency.[42]

A trial of labor mandates continuous FHR monitoring of both fetuses. After amniotomy, an electrocardiography lead may be placed on the scalp of twin A and Doppler ultrasonography may be used to monitor twin B.

Twin B

If twin A is delivered vaginally, the obstetrician must make a decision about the method of delivery of twin B. Presentation and position should be verified, because these can change after delivery of twin A. If twin B has a vertex presentation and the head is well applied to the cervix, or if the amniotic membranes are still intact in a diamniotic pregnancy, the obstetrician may allow the patient to resume labor and await spontaneous vaginal delivery.

For the twin B with nonvertex presentation, options include (1) ECV followed by a resumption of labor, (2) internal podalic version and total breech extraction, and (3) performance of cesarean delivery. Real-time ultrasonography facilitates the performance of ECV. Mothers who received epidural anesthesia will be more relaxed and should tolerate the procedure better than those without neuraxial anesthesia.[41] Internal podalic version and total breech extraction may increase the likelihood of vaginal birth when compared with attempted ECV. Total breech extraction is considered appropriate if twin A is the same size or larger than twin B to ensure that the pelvis and cervical dilation are adequate for vaginal delivery of twin B, and if delivery is attempted early after delivery of twin A to ensure that the cervix has not begun to contract.[42] In a retrospective cohort study of women who labored with twin pregnancies, patients with nonvertex second twins had comparable, if not higher, rates of vaginal delivery than their vertex-presenting counterparts.[82] Vaginal birth of both twins was associated with labor induction and the physician's years in practice, leading the authors to suggest a role for provider selection and delivery planning.[82] Indications for emergency cesarean delivery of twin B include malpresentation not amenable to obstetric maneuvers, nonreassuring FHR tracing, and umbilical cord prolapse.

In the past, obstetricians favored the delivery of twin B within 15 to 30 minutes of delivery of twin A. However, most data supporting this practice were obtained before the use of intrapartum FHR monitoring. In a review of 118 twin deliveries, Leung et al.[83] demonstrated an association between the twin-twin delivery interval and the umbilical cord blood gas and pH measurements for twin B. Some 73% of the second twins not delivered by 30 minutes required operative delivery because of a nonreassuring FHR tracing. A German retrospective analysis of 4110 twin pregnancies suggested that an increasing interval between delivery of twins is an independent risk factor for adverse short-term outcomes for twin B.[84] Continuous FHR monitoring of twin B is essential.

Anesthetic Management

Labor and Vaginal Delivery

Epidural analgesia provides optimal analgesia and flexibility for subsequent anesthetic needs. The anesthesia provider must be vigilant, because obstetric conditions are dynamic and anesthetic requirements may change rapidly. Given the greater risk for cesarean delivery in patients with multiple gestation, the anesthesia provider should aim for optimal epidural analgesia. If there is any question regarding the location of the catheter or the efficacy of the block, the catheter should be removed and replaced.

Patients with multiple gestation may be at higher risk than singleton pregnancies for aortocaval compression and hypotension during the administration of neuraxial analgesia and anesthesia. Use of the full left or right lateral position after induction of epidural analgesia reduces the risk for aortocaval compression. Because these patients are at increased risk for uterine atony and postpartum hemorrhage, establishment of large-bore intravenous access is recommended before delivery.

Patients with multiple gestation should deliver in a room where an emergency abdominal delivery can be performed immediately. As the time for delivery of twin A nears, the epidural analgesia is evaluated once more and augmented if necessary, although motor block is avoided so that the patient can continue to push effectively. Effective anesthesia facilitates the performance of internal podalic version and total breech extraction of twin B if necessary, and it also enables the extension of anesthesia for cesarean delivery if necessary. We prepare a syringe of 3% 2-chloroprocaine to be used if emergency extension of epidural anesthesia is required, and we also have nitroglycerin immediately available in case uterine relaxation is needed acutely for delivery of twin B. At least one member of the anesthesia team stays with the patient until twin A is delivered and twin B is either delivered or the vertex is well applied in the pelvis.

We prefer to administer CSE anesthesia for vaginal delivery in patients with multiple gestation who do not have preexisting epidural analgesia. An analgesic spinal dose can be administered for the second stage of labor and vaginal delivery, while the epidural catheter can be used to extend the block if cesarean delivery is required. We do *not* administer single-shot spinal anesthesia for vaginal delivery in these patients because of its lack of flexibility in cases of rapidly changing conditions. If a single-shot analgesic spinal dose is administered, it will not be adequate when cesarean delivery is required, and if an anesthetic dose is administered it will cause too much motor block for effective pushing and vaginal delivery.

Vaginal Delivery of Twin A/Operative Delivery of Twin B

The flexibility associated with epidural analgesia is especially advantageous if the obstetrician delivers twin A vaginally but twin B requires operative delivery. We administer a

nonparticulate antacid at the first sign of obstetrician concern, or even before proceeding to the operating room. Once the obstetrician determines that cesarean delivery will be necessary, we inject additional local anesthetic to extend the surgical sensory level to approximately T4 using 3% 2-chloroprocaine for fastest onset. In cases of prolonged fetal bradycardia or umbilical cord prolapse, it may be necessary to administer general anesthesia if adequate neuraxial anesthesia cannot be achieved rapidly. This problem can usually be avoided if (1) both the level and density of analgesia are optimized at the time of delivery of twin A and (2) the anesthesia provider is present in the room and gives attention to both the FHR tracing and the obstetrician.

If the obstetrician opts for internal podalic version and total breech extraction of twin B, it is better to perform the procedure shortly after delivery of twin A, before the uterus and the cervix begin to contract. Pain relief and skeletal muscle relaxation (both provided by epidural anesthesia) facilitate internal version and total breech extraction of twin B. In some cases, pharmacologic uterine relaxation may be required to facilitate internal version and breech extraction of twin B. Sublingual (400 µg) or intravenous (150 to 250 µg) administration of nitroglycerin should provide adequate relaxation for internal podalic version.[85,86] Intravenous or subcutaneous terbutaline 250 µg may also be used for uterine relaxation. If this maneuver is unsuccessful, rapid-sequence induction of general anesthesia, followed by administration of a high concentration of a volatile halogenated agent may be needed.

Cesarean Delivery

Epidural, spinal, or general anesthesia can be safely administered for elective abdominal delivery. Spinal anesthesia is increasingly preferred by many anesthesia providers. A historical preference for epidural anesthesia was based on the gradual onset of sympathetic blockade, which was thought to reduce the incidence of severe hypotension. It has been long believed that women with multiple gestation are at higher risk for hemodynamic instability during administration of neuraxial anesthesia than women with a singleton gestation. Ngan Kee et al.[87] compared the incidence of hypotension and vasopressor requirements in women with multiple and singleton gestations undergoing cesarean delivery with spinal anesthesia. There were no differences between groups in maternal and neonatal outcomes.

Comparison of brachial artery (arm) and popliteal artery (leg) blood pressures could allow the detection of occult supine hypotension, which results in reduced uteroplacental perfusion in the presence of a normal brachial artery pressure. If either hypotension or occult supine hypotension is detected or suspected, additional left uterine displacement or displacement to the other side may resolve the problem. A nonreassuring FHR tracing for either infant should also prompt the administration of additional efforts to optimize uteroplacental perfusion.

Jawan et al.[88] found that women with multiple gestation had a greater cephalad spread of neuroblockade with spinal anesthesia than women with a singleton gestation, whereas Ngan Kee et al.[87] did not. Similarly, Behforouz et al.[89] found no difference in the extent of sensory blockade after administration of epidural anesthesia between women with higher-order multiple gestation pregnancies and women with a singleton gestation. Any difference that may exist is likely to be of little clinical significance. A combined spinal-epidural anesthetic allows the anesthesiologist to use a lower dose of spinal anesthetic if desired, while retaining the capability of raising the anesthetic level using epidural local anesthetic if needed.

Vallejo and Ramanathan[90] demonstrated that mean umbilical venous and umbilical arterial lidocaine concentrations were 35% to 53% higher in twin newborns than in singleton newborns exposed to epidural anesthesia for cesarean delivery. Mean fetal-to-maternal lidocaine ratios were at least 18% higher in the twin newborns than in the singleton newborns. The investigators speculated that this difference may be a result of greater maternal cardiac output and plasma volume associated with twin gestation as well as the decreased total plasma protein concentration, which leads to an increase in the free lidocaine concentration.[90] The clinical relevance of these findings is unclear.

When general anesthesia is used, greater oxygen consumption and decreased functional residual capacity associated with multiple gestation increases the risk for maternal hypoxemia during periods of apnea. Adequate denitrogenation and preoxygenation is essential.

The presence of two or more fetuses results in a prolonged uterine incision-to-delivery interval because of the longer time required to deliver multiple infants. A prolonged interval increases the risk for umbilical cord blood acidemia and neonatal depression. Neonatal depression, especially of twin B, is less likely with neuraxial anesthesia than with general anesthesia.[67,68] In any case, an individual skilled in neonatal resuscitation should be immediately available.

KEY POINTS

- A higher incidence of breech presentation occurs among patients with preterm labor.
- External cephalic version has a low rate of morbidity in contemporary obstetric practice and is recommended by the ACOG for most women with a singleton breech presentation near term. Successful external cephalic version helps reduce the risk for perinatal morbidity and mortality associated with breech delivery and lowers the cesarean delivery rate. Neuraxial anesthesia may improve the success rate of external cephalic version, including after an initial failed attempt.

- Both breech presentation and multiple gestation are associated with an increased incidence of perinatal morbidity and mortality, regardless of the method of delivery.
- Epidural analgesia offers several advantages during a trial of labor in the patient with a breech presentation. Specifically, it (1) provides effective pain relief; (2) inhibits early pushing; (3) relaxes the pelvic floor and perineum, facilitating atraumatic delivery of the aftercoming head; and (4) enables provision of anesthesia for emergency cesarean delivery.
- Multiple gestation exaggerates the physiologic and anatomic changes of pregnancy.
- Epidural analgesia is the analgesic technique of choice during labor in the patient with multiple gestation. Provision of pain relief and skeletal muscle relaxation facilitates the vaginal delivery of twin B. Provision of epidural analgesia also facilitates the administration of anesthesia for emergency cesarean delivery if it is needed.
- The obstetrician may request pharmacologic provision of uterine and/or cervical relaxation to facilitate vaginal delivery of twin B or, in cases of breech presentation, to facilitate the delivery of the aftercoming fetal head. Intravenous or sublingual nitroglycerin provides rapid uterine relaxation of short duration. Alternatively, rapid-sequence induction of general anesthesia followed by administration of a high concentration of a volatile halogenated agent is another reliable method of providing uterine and cervical relaxation.

Hypertensive Disorders

Robert A. Dyer, FCA (SA), PhD,
Justiaan L. Swanevelder, FCA (SA), FRCA, MMed (Anes), Brian T. Bateman, MD, MSc

CHAPTER OUTLINE

Hypertension is the most common medical disorder of pregnancy, affecting 6% to 10% of pregnancies.[1–3] It is a leading cause of maternal mortality; together with hemorrhage it accounts for about one-half of all maternal deaths worldwide.[4] Hypertensive disorders are an important risk factor for fetal complications, including preterm birth, fetal growth restriction, and fetal/neonatal death.[2,5] They also pose very significant anesthesia risks.[6]

Anesthesia providers play a critical role in the management of women with preeclampsia; they are well positioned to understand the pathophysiology, assist with assessment of the severity of preeclampsia, and assess the impact of the disease on the administration of anesthesia, cardiovascular monitoring, and critical care. Working as part of a multidisciplinary team that includes obstetricians, cardiologists, neonatologists, midwives, and critical care specialists, anesthesia providers play a critical role in ensuring optimal outcomes for women with preeclampsia.[7,8]

CLASSIFICATION OF HYPERTENSIVE DISORDERS

Hypertensive disorders of pregnancy encompass a range of conditions—chronic hypertension, gestational hypertension, preeclampsia, preeclampsia superimposed on chronic hypertension, and eclampsia—that can be difficult to differentiate because the clinical presentation is often similar despite complex differences in their underlying pathophysiologies and prognoses. In 2000, the National High Blood Pressure Education Program (NHBPEP) Working Group on High Blood Pressure in Pregnancy[1] published a classification scheme (Box 35.1). This classification was updated in 2013 when the American College of Obstetricians and Gynecologists (ACOG) Taskforce on Hypertension in Pregnancy reviewed available literature and published a summary of current knowledge and recommendations for the care of women with preeclampsia.[2]

Gestational hypertension is the most frequent cause of hypertension during pregnancy, affecting approximately 5% of parturients.[9,10] Gestational hypertension presents as elevated blood pressure after 20 weeks' gestation without proteinuria (in the absence of chronic hypertension or systemic manifestations of preeclampsia) that resolves by 12 weeks postpartum.[11,12] Most cases of gestational hypertension develop after 37 weeks' gestation. Approximately one-fourth of patients diagnosed with gestational hypertension will develop preeclampsia. A definitive diagnosis of gestational hypertension can be made only in retrospect after delivery when the diagnosis of chronic hypertension can be excluded based on return to a normotensive state.

Preeclampsia is defined as the new onset of hypertension and proteinuria after 20 weeks' gestation (Box 35.2). The diagnosis of preeclampsia should also be considered in the absence of proteinuria when any of the following signs or symptoms of end-organ involvement are present: (1) persistent epigastric or right upper quadrant pain, (2) persistent

BOX 35.1 Classification of Hypertensive Disorders in Pregnancy

- Gestational hypertension
- Preeclampsia
  - Preeclampsia without severe features
  - Severe preeclampsia
- Chronic hypertension
- Chronic hypertension with superimposed preeclampsia

From the American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy: *Hypertension in Pregnancy*. Washington, DC: American College of Obstetricians and Gynecologists; 2013.

BOX 35.2 Diagnostic Criteria for Preeclampsia

Preeclampsia without Severe Features

- Blood pressure greater than or equal to 140/90 mm Hg after 20 weeks' gestation
- Proteinuria (greater than or equal to 300 mg/24 h, protein-creatinine ratio greater than or equal to 0.3, or 1+ or greater on urine dipstick specimen)

Severe Preeclampsia

- Blood pressure greater than or equal to 160/110 mm Hg
- Thrombocytopenia (platelet count less than 100,000/mm^3)
- Serum creatinine concentration greater than 1.1 mg/dL or greater than 2 times the baseline serum creatinine concentration
- Pulmonary edema
- New-onset cerebral or visual disturbances
- Impaired liver function

Modified from American College of Obstetricians and Gynecologists Task Force on Hypertension in Pregnancy: *Hypertension in Pregnancy*. Washington, DC: American College of Obstetricians and Gynecologists; 2013.

cerebral symptoms, (3) fetal growth restriction, (4) thrombocytopenia, or (5) elevated serum liver enzymes.[1] The term **eclampsia** is used when central nervous system (CNS) involvement results in the new onset of seizures in a woman with preeclampsia. **HELLP syndrome** refers to the development of hemolysis, elevated liver enzymes, and low platelet count in a woman with preeclampsia. This condition may be a variant of severe preeclampsia, but this classification is controversial because the disease may represent a pathophysiologically distinct entity.

Chronic hypertension involves either (1) systolic blood pressure of 140 mm Hg or higher and/or diastolic blood pressure of 90 mm Hg or higher presenting before pregnancy or before 20 weeks' gestation or (2) elevated blood pressure that fails to resolve after delivery. Chronic hypertension develops into preeclampsia in approximately one-fifth to one-fourth of affected patients. However, even in the absence of preeclampsia, chronic hypertension is an important risk factor for unfavorable maternal and fetal pregnancy outcomes.[5,13]

Chronic hypertension with superimposed preeclampsia occurs when preeclampsia develops in a woman with chronic hypertension before pregnancy. The diagnosis is made in the presence of new onset of proteinuria or a sudden increase in proteinuria or hypertension, or both, or when other manifestations of severe preeclampsia appear. Morbidity is increased for both the mother and fetus compared with preeclampsia alone.[14]

The clinical findings in chronic hypertension, gestational hypertension, and preeclampsia are compared in Table 35.1.

PREECLAMPSIA

Preeclampsia is a multisystem disease unique to human pregnancy. It is characterized by diffuse endothelial dysfunction with maternal complications, including placental abruption, pulmonary edema, acute renal failure, liver failure, stroke, and neonatal complications, including indicated preterm

TABLE 35.1 Hypertensive Disorders of Pregnancy

Clinical Feature	Chronic Hypertension	Gestational Hypertension	Preeclampsia
Time of onset of hypertension	Before 20 weeks' gestation	After 20 weeks' gestation	After 20 weeks' gestation
Severity of hypertension	Mild or severe	Mild	Mild or severe
Proteinuria[a]	Absent	Absent	Typically present
Serum uric acid greater than 5.5 mg/dL (0.33 mmol/L)	Rare	Absent	Present in almost all cases
Hemoconcentration	Absent	Absent	Present in severe disease
Thrombocytopenia	Absent	Absent	Present in severe disease
Hepatic dysfunction	Absent	Absent	Present in severe disease

[a]Defined as 300 mg or greater in a 24-hour urine collection, urine protein-creatinine ratio 0.3 or greater, 1+ or greater result on urine dipstick testing.

From Sibai BM. Treatment of hypertension in pregnant women. *N Engl J Med*. 1996;335:257–265; American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy. *Hypertension in Pregnancy*. Washington, DC: American College of Obstetricians and Gynecologists; 2013.

TABLE 35.2 Differences between Early- and Late-Onset Preeclampsia

	Early Onset	Late Onset
Onset of clinical symptoms	Before 34 weeks' gestation	After 34 weeks' gestation
Relative frequency	20% of cases	80% of cases
Association with fetal growth restriction	Yes	No
Clear familial component[a]	Yes	No
Placental morphology	Abnormal[b]	Normal[b]
Etiology	Primarily placental[c]	Primarily maternal[d]
Risk factor (relative risk)	Family history (2.9)	Diabetes (3.56)
		Multiple pregnancy (2.93)
		Increased blood pressure at registration (1.38)
		Increased body mass index (2.47)
		Maternal age greater than or equal to 40 years (1.96)
		Cardiovascular disorders (3.84)

[a]Defined as recurrence across generations and occurrence within families.
[b]From Egbor M, Ansari T, Morris N, et al. Morphometric placental villous and vascular abnormalities in early- and late-onset preeclampsia with and without fetal growth restriction. *BJOG.* 2006;113:580–589.
[c]Reduced extravillous trophoblast invasion.
[d]Predisposed maternal constitution reflecting microvascular disease or predisposed genetic constitution with *cis*- or *trans*-acting genomic variations subject to interaction.
From Oudejans CB, van Dijk M, Oosterkamp M, et al. Genetics of preeclampsia: paradigm shifts. *Hum Genet.* 2007;120:607–612.

delivery, fetal growth restriction, hypoxic-ischemic neurologic injury, and perinatal death.[15] Although significant advances have been made in the understanding of the pathophysiology of the disease, the specific proximal cause remains unknown. Management is supportive; delivery of the infant and placenta remains the only definitive cure.

The clinical syndrome of preeclampsia is defined as the new onset of hypertension and proteinuria after 20 weeks' gestation. Previous definitions included edema, but edema is no longer part of the diagnostic criteria because it lacks specificity and occurs in many healthy pregnant women. Preeclampsia is classified as **preeclampsia with or without severe features** (see Box 35.2). The ACOG now discourages use of the term *mild* for preeclampsia without severe features because preeclampsia may be rapidly progressive, and appropriate management involves frequent reevaluation for severe features.[2]

Some authors suggest classifying preeclampsia into the **early form (type I)**, with symptom onset before 34 weeks' gestation, or the **late form (type II)**, with symptom onset after 34 weeks' gestation (Table 35.2).[16,17] Early-onset preeclampsia begins with abnormal placentation, has a high rate of recurrence, and has a strong genetic component. In contrast, late-onset preeclampsia generally occurs in women metabolically predisposed to the disease, and abnormal placentation may feature less prominently in the pathogenesis. These women, who often have long-standing hypertension, obesity, diabetes, or other forms of microvascular disease, are challenged to meet the demands of the growing fetoplacental unit and decompensate near term. Decompensation manifests as late-onset or, less frequently, postpartum preeclampsia.[16]

Epidemiology

Preeclampsia occurs in 3% to 4% of pregnancies in the United States.[10] Delivery of the infant and placenta is the only definitive treatment; thus, preeclampsia is a leading cause of indicated preterm delivery in developed countries.[18] Low-birth-weight and preterm infants born to women with preeclampsia present major medical, social, and economic burdens to families and societies.[19] Preterm delivery is the most common indication for admission to the neonatal intensive care unit.[20] Preeclampsia is also a leading indication for maternal peripartum admission to an intensive care unit.[21,22]

The clinical findings of preeclampsia can manifest as a **maternal syndrome** (e.g., hypertension and proteinuria with or without other systemic abnormalities) with or without an accompanying **fetal syndrome** (e.g., fetal growth restriction, oligohydramnios, abnormal oxygen exchange).[1,23] In approximately 75% of cases, preeclampsia occurs without severe features near term or during the intrapartum period.[23] In contrast, disease onset before 34 weeks' gestation correlates with increased disease severity and poorer outcomes for both the mother and fetus.

A significant increase in the incidence of hypertensive disorders of pregnancy has occurred, with a near doubling in the rate in the United States in the past quarter century (Fig. 35.1).[24] The increase is at least partially explained by major shifts in the demographics and clinical conditions of pregnant women in the United States and other developed countries.[25] Average maternal age is increasing; advanced maternal age is a recognized risk factor for preeclampsia. Both the growing epidemic of obesity and the increased prevalence of diabetes and chronic hypertension in the developed world may also contribute to this trend. An increase in the use of assisted reproductive techniques and the use of donated gametes is contributory; these techniques increase the risk for the disease, potentially by altering the maternal-fetal immune reaction[26] and by increasing the incidence of multiple gestation. Last, improvements in record keeping and the use of

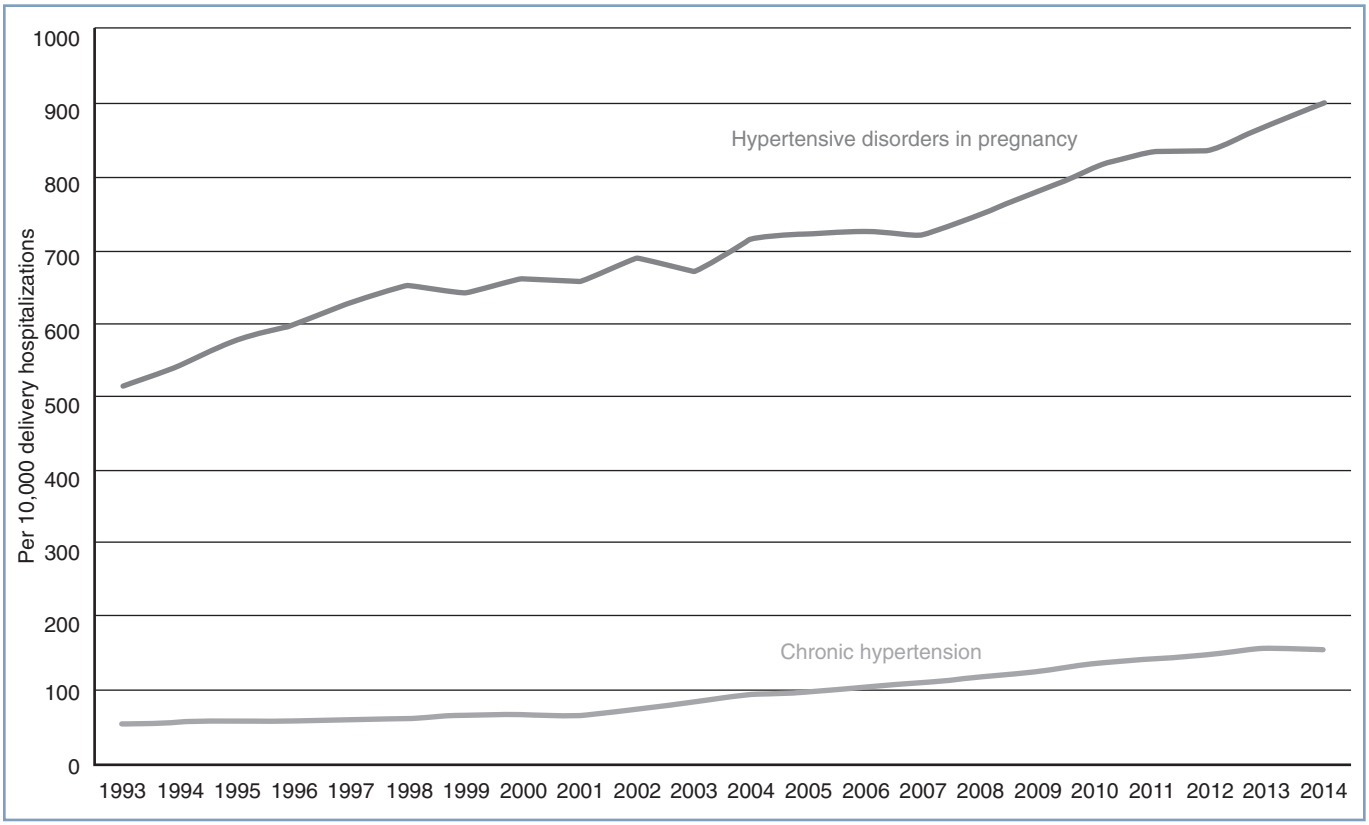

Fig. 35.1 Rate of hypertensive disorders per 10,000 delivery hospitalizations, 1993 to 2014. (From U.S. Centers for Disease Control and Prevention: Data on selected pregnancy complications in the United States. 2017. Available at https://www.cdc.gov/reproductivehealth/maternalinfanthealth/pregnancy-complications-data.htm. Accessed June 8, 2018.)

consistent disease definitions since 2000 may have contributed to the increased number of reported cases.[1]

Numerous preconception and pregnancy-related risk factors associated with the development of preeclampsia have been identified (Box 35.3). Risk factors for preeclampsia can be divided into maternal demographic factors, genetic factors, medical conditions, obstetric conditions, behavioral factors, and partner-related factors.

Risk Factors

Demographic factors. **Advanced maternal age** has consistently been shown to be a risk factor for preeclampsia, with women who are 40 years of age or older having an approximately twofold increase in risk compared with women between 20 and 29 years of age.[27,28] This risk may be independent of the increased prevalence of medical conditions and obesity that accompany advancing age.[27] Teenage pregnancy may also be a risk factor for preeclampsia,[29–31] but data are inconsistent.[32]

Black women constitute a high-risk group, with increased rates of chronic hypertension,[33,34] obesity,[34,35] and preeclampsia.[36–39] Black women with severe preeclampsia demonstrate more extreme hypertension, require more antihypertensive therapy,[40] are more likely to develop eclampsia,[41] and are more likely to die of the condition compared with women of other racial backgrounds.[42] Hispanic ethnicity may also confer increased risk for developing preeclampsia and eclampsia.[41,43,44]

Genetic factors. **Maternal genetic factors** are known to be important risk factors for the development of preeclampsia. Pregnant women with a family history of preeclampsia are approximately twice as likely to develop the disorder.[45,46] It is estimated that approximately one-third of the variance in liability to preeclampsia is caused by maternal genetic factors.[47]

In a study of 1.7 million births in the Medical Birth Registry of Norway, men who fathered one preeclamptic pregnancy were found to be nearly twice as likely to father a preeclamptic pregnancy with a different woman, irrespective of her previous obstetric history.[48] Therefore, **paternal genes** (in the fetus) contribute significantly to a pregnant woman's risk for preeclampsia. It is estimated that approximately one-fifth of the variance in liability for preeclampsia is conferred through the fetal genes.[47]

Women with a history of preeclampsia in a previous pregnancy are at increased risk for preeclampsia in a subsequent pregnancy,[28,49] particularly if the preeclampsia was of early-onset.[50] Risk for recurrence increases with multiple affected pregnancies.[50] In addition, women with a history of previous placental abruption and fetal growth restriction are at increased risk for preeclampsia in a subsequent pregnancy,[51] and women with a history of preeclampsia are

BOX 35.3 Risk Factors for Preeclampsia

Demographic Factors
- Advanced maternal age greater than 35 years
- Black race
- Hispanic ethnicity

Genetic Factors
- History of preeclampsia in previous pregnancy
- Family history of preeclampsia
- History of placental abruption, fetal growth restriction, or fetal death
- Partner who fathered a preeclamptic pregnancy in another woman (through fetal genes)

Medical Conditions
- Obesity
- Chronic hypertension
- Diabetes mellitus
- Chronic renal disease
- Antiphospholipid antibody syndrome
- Systemic lupus erythematosus

Obstetric Conditions
- Multiple gestation
- Hydatidiform mole

Behavioral Factor
- Cigarette smoking (risk reduction)

Partner-Related Factors
- Nulliparity
- Limited preconceptional exposure to paternal sperm

at risk for these outcomes even in the absence of recurrent preeclampsia.[52] These associations suggest that some women harbor a susceptibility (potentially genetically mediated) to obstetric conditions caused by placental dysfunction, which manifests differently in different pregnancies.

Medical and obstetric conditions. **Obesity** is an important risk factor for preeclampsia, and risk escalates with increasing body mass index (BMI).[53,54] A systematic review found that an increase in BMI of 5 to 7 kg/m^2 was associated with a twofold increased risk for preeclampsia.[53] Obesity is strongly associated with insulin resistance, another risk factor for preeclampsia.

Women with **chronic hypertension** are also at increased risk for preeclampsia. Primary hypertension increases the odds of developing preeclampsia 10-fold, and secondary hypertension increases the odds nearly 12-fold.[5] Chronic hypertension in association with other risk factors, including diabetes, renal disease, and collagen vascular disease, confers particularly elevated risk.[5]

Diabetes mellitus is associated with an approximately twofold increase in the risk for development of preeclampsia.[5,28] The prevalence of preeclampsia also increased with the severity of diabetes as determined by the White classification.[55]

The **metabolic syndrome,** which occurs in about one-fifth of women of childbearing age in the United States, is characterized by the presence of obesity, hyperglycemia, insulin resistance, and hypertension.[56] The metabolic syndrome increases the risk for preeclampsia.[57] The insulin resistance and microvascular dysfunction observed in this condition have been implicated as a common factor in both preeclampsia and cardiovascular disease; these conditions may partially mediate the association of preeclampsia and increased risk for cardiovascular disease later in life.[58–60]

Additional maternal medical conditions that are well-recognized risk factors for preeclampsia include **chronic renal disease,**[61,62] **antiphospholipid antibody syndrome,**[28] and **systemic lupus erythematosus.**[5,63] Pregnancy-related conditions that increase placental mass, including **multifetal gestation**[28,64] and **hydatidiform mole,**[65] are associated with higher rates of preeclampsia as well.

Behavioral factors. Paradoxically, **cigarette smoking** during pregnancy has been associated with a decreased risk for preeclampsia,[66,67] an effect consistently observed across studies in various countries. Women who smoke during pregnancy have a 30% to 40% lower risk for developing preeclampsia compared with women who do not smoke. The mechanism may include nicotine inhibition of thromboxane A_2 synthesis,[68] simulation of nitric oxide release,[69] or a combination of these factors.

Recreational physical activity. Recreational physical activity during pregnancy has been associated with a decrease in the risk for gestational hypertensive disorder,[70] particularly in nonobese women.[71] Mechanistically, this may occur through exercise promoting placental growth, decreasing oxidative stress, enhancing endothelial function, and modulating the immune and inflammatory response.[72]

Partner-related risk factors. The unifying theme among partner-related risk factors is limited maternal exposure to paternal sperm antigens before conception, which suggests an immunologic role in the pathophysiology of preeclampsia. A leading risk factor for preeclampsia is nulliparity; the incidence is approximately threefold higher compared with parous women.[28] Preeclampsia is also more common in (1) parous women who have conceived with a new partner, (2) women who have used barrier methods of contraception before conception, and (3) women who have conceived with donated sperm.[73,74] Long-term sperm exposure with the same partner appears to be protective; this protective effect is lost in a pregnancy conceived with a new partner.

Pathogenesis

The exact pathogenic mechanisms responsible for the initiation and progression of preeclampsia are not known. The placenta is the focus of hypotheses regarding disease pathogenesis; delivery of the placenta results in resolution of the disease, and the disease can occur in the absence of a fetus (e.g., a molar pregnancy).[75]

Preeclampsia as a Two-Stage Disorder

Contemporary hypotheses generally conceptualize preeclampsia as a two-stage disorder.[76] The **asymptomatic first stage** occurs early in pregnancy with impaired remodeling of

the spiral arteries (the end branches of the uterine artery that supply the placenta).[75] In normal pregnancy, embryo-derived cytotrophoblasts invade the decidual and myometrial segments of the spiral arteries, replacing endothelium and causing remodeling of vascular smooth muscle and the inner elastic lamina (Fig. 35.2).[77,78] The luminal diameter of the spiral arteries increases fourfold, resulting in the creation of flaccid tubes that provide a low-resistance vascular pathway to the intervillous space. Furthermore, the remodeled arteries are unresponsive to vasoactive stimuli. These alterations in maternal vasculature ensure adequate blood flow to nourish the growing fetus and placenta.

In contrast, in preeclamptic pregnancies, cytotrophoblast invasion is incomplete and only the decidual segments undergo change; the myometrial spiral arteries are not invaded and remodeled and thus remain small, constricted, and hyperresponsive to vasomotor stimuli.[75] This failure of normal angiogenesis results in superficial placentation. Abnormal placentation results in decreased placental perfusion and placental infarcts, predisposing the fetus to growth restriction (Fig. 35.3). Placental ischemia worsens throughout pregnancy as narrowed vessels are increasingly unable to meet the needs of the growing fetoplacental unit.

In some women, the reduced perfusion of the intervillous space in the first stage leads to the **symptomatic second stage,** which is characterized by the release of antiangiogenic factors from the intervillous space into the maternal circulation; these factors cause widespread maternal endothelial dysfunction and an accentuated systemic inflammatory response. In the absence of preeclampsia, healthy endothelium prevents platelet activation, activates circulating anticoagulants, buffers the response to vasopressors, and maintains fluid in the intravascular compartment. These normal functions are disrupted in preeclampsia. As a result, the pregnant woman develops hypertension and proteinuria, and is at risk for other manifestations of severe systemic disease (e.g., HELLP syndrome, eclampsia, other end-organ damage). By definition, these clinical manifestations manifest after 20 weeks' gestation.

Abnormal Placentation

The basis for abnormal uteroplacental development has not been fully elucidated and is likely due to a complex interaction of immunologic, vascular, environmental, and genetic factors. The hypothesis that immune maladaptation may play a central role in predisposing to abnormal placentation and subsequent preeclampsia is supported by evidence showing that long-term exposure to paternal antigens in sperm is protective. Furthermore, the importance of an intact immune system in the development of preeclampsia is demonstrated by the lower incidence of preeclampsia in women with untreated human immunodeficiency virus; the incidence returns to baseline after treatment with antiretroviral therapy.[79]

The immune cells present in the decidua—the endometrium in the nonpregnant state becomes the decidua in pregnancy—include macrophages, dendritic cells, and natural killer (NK) cells. Macrophages and dendritic cells are found in greater density in preeclamptic placentas than in control placentas.[80,81] Similarly, levels of chemokines that attract these immune cells are also elevated.[80,81] Excess macrophages in the decidua are associated with impaired trophoblast invasion, suggesting that excess inflammation may be one of the causal components of impaired placentation.[81] NK cells may also be

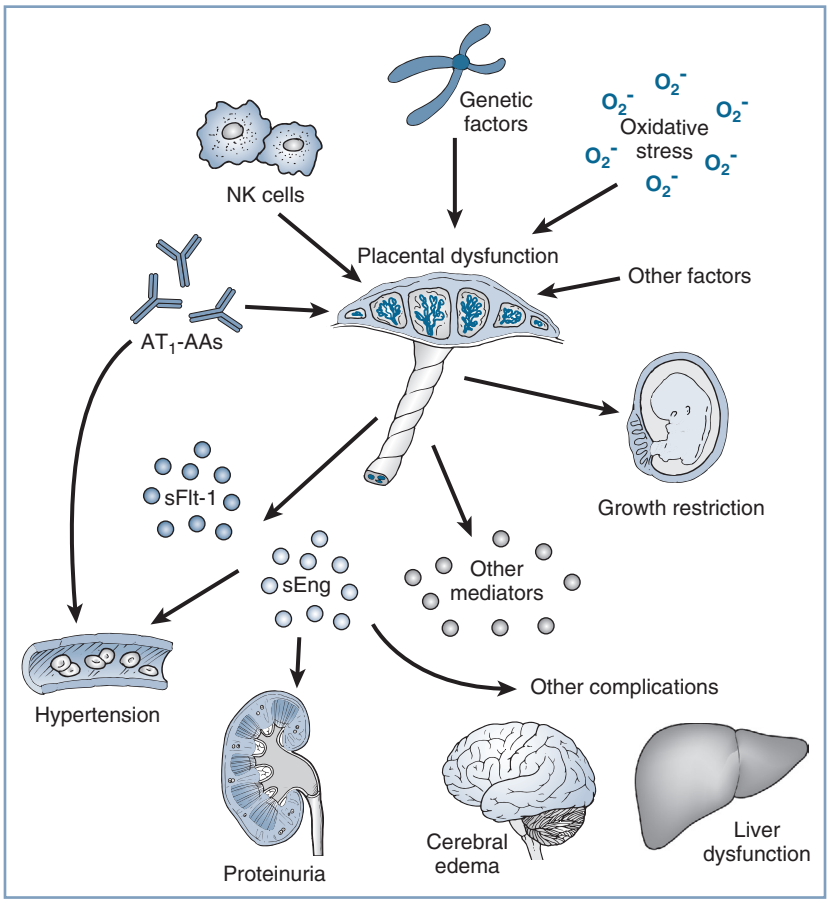

Fig. 35.4 Angiotensin receptor autoantibodies (AT_1-AAs) in preeclampsia. AT_1-AAs and other factors (e.g., oxidative stress and genetic factors) may cause placental dysfunction, which, in turn, leads to the release of antiangiogenic factors (e.g., soluble fms-like tyrosine kinase-1 [sFlt-1] and soluble endoglin [sEng]) and other inflammatory mediators to induce preeclampsia. AT_1-AAs may also act directly on the maternal vasculature to enhance angiotensin II sensitivity and hypertension. *NK,* Natural killer. (From Parikh SM, Karumanchi SA. Putting pressure on preeclampsia. *Nat Med.* 2008;14:810–812.)

important in regulating vascular development during placentation. NK cells interact with fetal trophoblast cell markers via killer immunoglobulin receptors (KIR) to influence trophoblastic invasion. Specific genotypic combinations of maternal KIR and trophoblastic human leukocyte antigen C (HLA-C) may mediate the risk for preeclampsia.[82,83]

Aberrant hemostatic activation during placental development has also been proposed to contribute to the abnormal placentation that is a hallmark of pregnancies destined to develop preeclampsia.[84] Increased tissue factor expression may cause inappropriate activation of clotting pathways, which in turn may impair trophoblast invasion of the decidua. Abnormal protease-activated receptor 1 (PAR 1) may also play a role in failure of trophoblasts to convert to an endothelial phenotype.

Agonistic autoantibodies to the angiotensin type 1 receptor (AT_1) are present in many women with preeclampsia in association with defective remodeling of the uteroplacental vasculature.[85,86] These autoantibodies activate AT_1 receptors on trophoblast cells, endothelial cells, and vascular smooth muscle cells.[87–89] They appear to block trophoblastic invasion[88] and may induce the production of reactive oxygen species[89] and thus play a significant role in the pathophysiology of preeclampsia (Fig. 35.4). Furthermore, introduction of these autoantibodies into pregnant mice increases production of **soluble fms-like tyrosine kinase-1 (sFlt-1)** and results in hypertension and proteinuria.[90] Thus, these autoantibodies may play an important role in the pathogenesis of preeclampsia at several different stages.

Oxidative stress is another mechanism that has been postulated as an important component of impaired placentation.[80] Oxidative stress and the resultant oxygen free radicals are known to contribute to atherosclerosis and thus may contribute to placental atherosis.[80] Volatile organic compounds measured in a breath test, a marker for oxidative stress, are found in greater quantity in women with preeclampsia compared with healthy pregnant controls.[91] Enthusiasm for this theory is tempered by the failure of antioxidant supplementation to decrease the risk for preeclampsia in clinical trials.[80]

Maternal Systemic Disease

The symptomatic second stage of preeclampsia is marked by signs and symptoms attributable to the manifestations of widespread endothelial dysfunction specific to each

organ system.[75] This notion is supported by studies showing increased levels of biomarkers indicating endothelial activation or injury, or both, including endothelin-1, fibronectin, von Willebrand factor, and thrombomodulin.[75] The central role of endothelial dysfunction is further evidenced by the fact that chronic conditions that cause prepregnancy endothelial injury, including chronic hypertension, preexisting diabetes, and renal disease, are risk factors for preeclampsia. A predilection for endothelial dysfunction may similarly explain the association of preeclampsia and future cardiovascular disease.[75,92]

The mechanistic link between abnormal placentation and subsequent widespread endothelial dysfunction is an area of great interest and ongoing investigation. The prevailing hypothesis is that the placenta becomes relatively hypoxic as the pregnancy progresses, and this change results in an overexpression and release into the maternal circulation of placentally derived antiangiogenic factors, including **sFlt-1** and **soluble endoglin (sEng).**[75,76]

The vascular endothelium requires proangiogenic factors for normal function. sFlt-1 antagonizes the angiogenic growth factors, vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).[93,94] Evidence for a central role of sFlt-1 in the pathogenesis of preeclampsia comes from both animal and human studies. Maynard et al.[93] demonstrated that sFlt-1 levels increase during gestation and fall after delivery and that increased circulating sFlt-1 levels reduce circulating levels of free VEGF and PlGF, causing endothelial dysfunction that can be rescued by exogenous VEGF and PlGF. Furthermore, these investigators found that the administration of sFlt-1 to pregnant rats induced hypertension, proteinuria, and glomerular endotheliosis, which is the classic renal lesion of preeclampsia.[93] When administered *in vitro*, VEGF and PlGF cause rat renal arteriolar relaxation, which is blocked by sFlt-1. In response to increased circulating levels of sFlt-1, VEGF and PlGF levels are reduced, resulting in endothelial dysfunction in maternal vessels (Fig. 35.5).[95] In a study in humans, elevated sFlt-1 levels and reduced levels of PlGF predicted the subsequent development of preeclampsia before the development of any maternal symptoms.[96] In women presenting at less than 35 weeks' gestation with a possible diagnosis of preeclampsia, a low PlGF level has a high sensitivity and negative predictive value for the development of preeclampsia within 14 days.[97] Studies have also confirmed

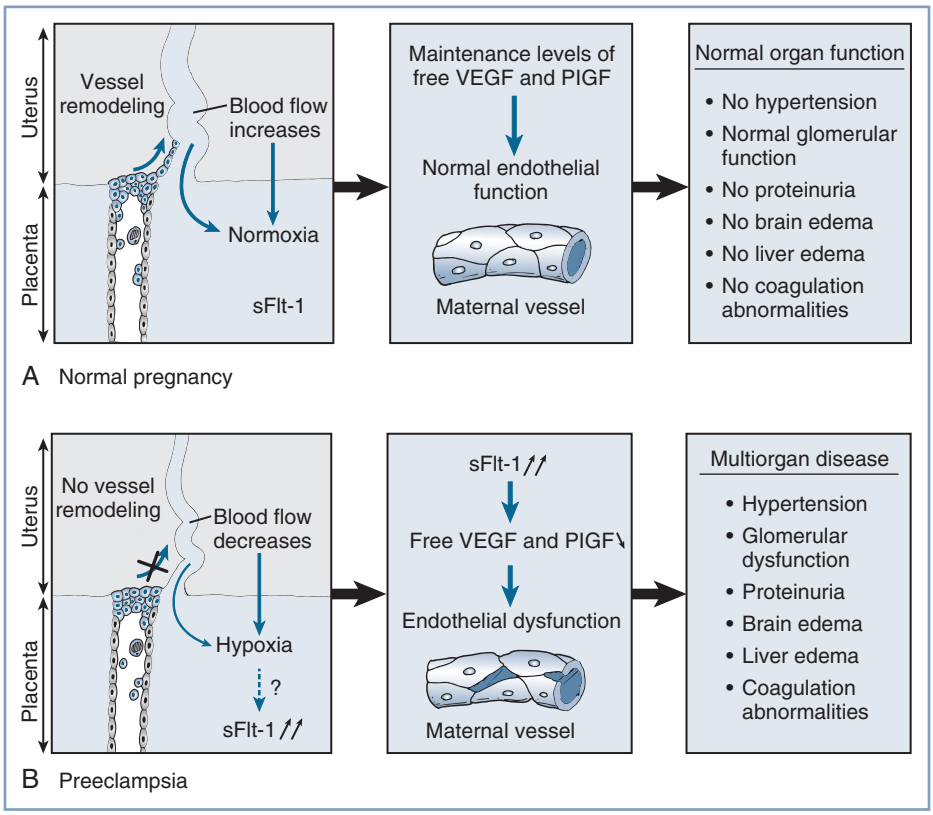

Fig. 35.5 Hypothesis on the role of soluble fms-like tyrosine kinase (sFlt-1) in preeclampsia. (A) During normal pregnancy, the uterine spiral arteries are infiltrated and remodeled by endovascular invasive trophoblasts, thereby increasing blood flow significantly to meet the oxygen and nutrient demands of the fetus. (B) In the placenta of preeclamptic women, trophoblast invasion does not occur and blood flow is reduced, resulting in placental hypoxia. In addition, increased amounts of soluble sFlt-1 are produced by the placenta and scavenge vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), thereby lowering circulating levels of unbound VEGF and PlGF. This altered balance causes generalized endothelial dysfunction, resulting in multiorgan disease. (From Luttun A, Carmeliet P: Soluble VEGF receptor Flt1: the elusive preeclampsia factor discovered? *J Clin Invest.* 2003;111:600–602.)

the importance of the sFlt-1–to–PlGF ratio as a marker of preeclampsia.[98]

sEng is another placentally derived antiangiogenic protein that appears to be important in the pathogenesis of preeclampsia.[94] Circulating levels of sEng are markedly increased in women who subsequently develop preeclampsia. Furthermore, if women have both elevated sEng and increased sFlt-1/PlGF ratios, their risk for preeclampsia is elevated approximately 30-fold compared with women who have normal levels of both factors/ratios.[99]

The study of antiangiogenic proteins is an active area of current research, and rapid progress is being made in understanding the role of these proteins in the pathogenesis of preeclampsia. However, the importance of recent findings is tempered by the knowledge that preeclampsia does not develop in all women with high sFlt-1 and low PlGF levels, and the syndrome occurs in some women with low sFlt-1 and high PlGF levels.[96,100] These observations are consistent with those from a large, longitudinal study involving 2246 singleton pregnancies that found that PlGF and sFlt-1 levels had limited sensitivity, specificity, and positive predictive value for predicting the development of preeclampsia.[101]

Kanasaki et al.[102] hypothesized that a molecular defect upstream from the soluble factors contributes to preeclampsia. The investigators demonstrated that pregnant mice deficient in **catechol-*O*-methyltransferase (COMT)** demonstrate a preeclampsia-like phenotype in response to the absence of **2-methoxyestradiol (2-ME),** a natural metabolite of estradiol that is elevated during the third trimester of normal pregnancy. Administration of 2-ME to COMT-deficient mice suppresses placental hypoxia and sFlt-1 elevation. In addition, women with severe preeclampsia have significantly lower levels of COMT and 2-ME than women with healthy pregnancies. However, a subsequent study in humans failed to find a significant difference in placental COMT expression in women with early-onset, severe preeclampsia compared with normotensive women[103]; therefore, further research is needed to determine what role, if any, COMT plays in the pathogenesis of preeclampsia.

Genetic Factors

There is a strong genetic basis underlying the risk for preeclampsia that is attributable to both maternal and fetal genetic factors. It is estimated that approximately one-fifth of the variance in disease risk is attributable to fetal genetic effects, and one-third is attributable to maternal genetic factors.[47] A recent genome-wide association study in offspring from preeclamptic pregnancies reported that variants in the fetal genome near *FLT1* are associated with risk for preeclampsia.[104] With the possible exception of thrombophilia genes, no genetic variants in the maternal genome have been robustly associated with preeclampsia.[105]

Prophylaxis

Various strategies to prevent preeclampsia have been studied. These include antiplatelet drugs, metformin, antioxidant and calcium supplementation, and dietary sodium restriction among other lifestyle modifications.[2,106] A 2014 systematic review by the U.S. Preventive Services Task Force found that low-dose aspirin use is associated with a 2% to 5% absolute reduction in the risk for preeclampsia (depending on baseline risk)[107] and a 2016 ACOG practice advisory suggests that consideration should be given for initiating prophylactic low-dose aspirin between 12 and 24 weeks' gestation in women at high risk for preeclampsia.[108]

Clinical Presentation

Preeclampsia occurs more frequently in nulliparous women and most commonly presents during the third trimester, often near term.[109] Women with early-onset disease (before 34 weeks' gestation) have poorer outcomes than women with late-onset disease. The disease typically regresses rapidly after delivery, with resolution of symptoms within 48 hours. However, preeclampsia can also manifest postpartum with hypertension, proteinuria, or the occurrence of seizures (eclampsia). Postpartum preeclampsia usually presents within 7 days of delivery.[110] Disease manifestations of severe preeclampsia occur in all body systems as the result of widespread endothelial dysfunction.

Identification of women at greatest risk for adverse maternal outcomes is potentially useful in guiding triage to high-risk centers and weighing the risks and benefits of expectant management.[109] A 2011 multicenter prospective study involving 2023 women with preeclampsia admitted to tertiary care centers described a model (fullPIERS) for predicting which women will develop fatal or life-threatening complications.[111] Unfavorable outcomes occurred in 261 patients. Predictors of unfavorable maternal outcome included early gestational age, chest pain or dyspnea, low oxygen saturation, low platelet count, and elevated creatinine and aspartate aminotransferase concentrations. The model showed excellent discrimination, with an area under the receiver operating characteristics (ROC) curve of 0.88 for adverse events within 48 hours of admission. It continued to perform well in predicting adverse events up to 7 days after admission.[111] The fullPIERS model has recently been validated in low- and middle-income countries.[112]

In further work on prediction of complications in early-onset preeclampsia, women were recruited from 53 maternity units in the United Kingdom to a large cohort study for the development of prognostic models for risk for complications.[113] These models were externally validated in two large cohorts of patients and were found to be predictive of adverse maternal outcome risk, including preterm delivery.[113] It was concluded that the models may have a role in triaging women who would benefit from referral for tertiary care.

A further advance in the prediction of disease severity relies on strong-ion analysis of maternal acid-base status.[114] Early investigation suggests that preeclampsia is associated with greater offsetting of hypoalbuminemic alkalosis with hyperchloremic acidosis, although the overall base excess in severe preeclampsia is similar to that in healthy pregnancy. The magnitude of these opposing contributors may be a better indicator of disease severity than the overall base excess.[114]

Central Nervous System

Although the term *preeclampsia* suggests that eclampsia is the end stage of preeclampsia, it is more accurate to consider eclampsia as the outward manifestation of disease progression in the brain, similar to other organ involvement. Central nervous system manifestations include severe headache, hyperexcitability, hyperreflexia, and coma.[1,115] Visual disturbances can include scotoma, amaurosis, and blurred vision.[116]

Noninvasive measurements of cerebral blood flow and resistance, along with other neuroimaging approaches, suggest that the loss of cerebral vascular autoregulation and vascular barotrauma occur with preeclampsia and eclampsia.[116,117] Hyperperfusion of the brain, particularly in the setting of the endothelial dysfunction that is present in preeclampsia, causes vasogenic edema. Failure of autoregulation occurs most commonly in the posterior circulation; these changes may result in the **posterior reversible leukoencephalopathy syndrome (PRES).**[116,118–120]

Other neurologic markers of disease severity are being examined. Optic nerve sheath diameter (ONSD) is being investigated as a marker for increased intracranial pressure. In a study that compared women with preeclampsia and healthy controls, the median ONSD was greater in women with disease.[121] Nineteen percent of women with preeclampsia had ONSD of greater than 5.8 mm, a value that had previously been associated with a 95% risk for raised intracranial pressure in nonobstetric settings. However, this study found no association between ONSD and the severity of preeclampsia. Future investigations are necessary to understand whether the increase in ONSD is associated with raised intracranial pressure in preeclampsia or higher risk for eclampsia.

Regional cerebral hemoglobin oxygen saturation ($rcSO_2$) has been measured using near-infrared spectroscopy in women with severe preeclampsia and was found to be lower in women with preeclampsia compared with healthy women.[122] The $rcSO_2$ increased after the administration of magnesium sulfate, with the percent increase indirectly correlating with blood pressure.

Airway

In pregnant women, the internal diameter of the trachea is reduced because of mucosal capillary engorgement. In women with preeclampsia, these changes can be exaggerated with upper airway narrowing as a result of **pharyngolaryngeal edema;** these changes may compromise visualization of airway landmarks during direct laryngoscopy.[123] Signs of airway obstruction include dysphonia, hoarseness, snoring, stridor, and hypoxemia.[124,125]

Obstructive sleep apnea (OSA) is a sleep-related breathing disorder characterized by recurrent episodes of upper airway collapse leading to hypoxia and sleep disturbance. A meta-analysis of available cohort studies suggests that parturients with OSA have a twofold increase in risk for developing preeclampsia.[126] This is plausibly a causal association, as recurrent nocturnal desaturations might result in placental hypoxia, hypertension, and maternal endothelial dysfunction, all of which are associated with preeclampsia.[126]

Cardiovascular

Women with preeclampsia have increased vascular tone and increased sensitivity to vasoconstrictors and circulating catecholamines, which result in the clinical manifestations of hypertension, vasospasm, and end-organ ischemia.[15] In preeclampsia without severe features, plasma volume may be normal; however, it may be reduced as much as 40% in women with severe disease.[127]

Severe preeclampsia is usually a **hyperdynamic state.** Many studies have attempted to characterize the hemodynamic characteristics of preeclampsia using invasive monitoring techniques such as pulmonary artery catheterization or echocardiography.[128–131] Interpretation and comparison of the results of these studies have been difficult because of variation in patient populations, definitions of preeclampsia, disease severity, prior treatment, and the presence or absence of concomitant comorbid disease. Hemodynamic characteristics in preeclamptic women are more complex than originally thought. This is partly because hemodynamic measurements change with treatment and disease progression. In a large prospective series of normotensive nulliparous women who were assessed with transthoracic echocardiography (TTE) at 24 weeks' gestation, 107 women developed preeclampsia (75 early- and 32 late-onset). Mean (± standard deviation) total vascular resistance was 1605 ± 248 dyne · s · cm^{-5} and 739 ± 244 dyne · s · cm^{-5}, and cardiac output was 4.49 ± 1.09 L/min and 8.96 ± 1.83 L/min in early- and late-onset preeclampsia, respectively, suggesting two different cardiovascular responses.[132]

Overall, studies have found that the majority of affected women without clinical signs of pulmonary edema exhibit normal to increased cardiac output,[131] hyperdynamic left ventricular function,[128] and mild to moderately increased systemic vascular resistance,[128,131] often associated with diastolic dysfunction. In severe preeclampsia, cardiac magnetic resonance imaging studies demonstrate that the myocardium may be edematous as well as hypertrophied.[133]

Echocardiographic speckle-tracking is a new method of quantifying myocardial strain that appears to be a more sensitive marker of systolic dysfunction than the left ventricular ejection fraction in women with preeclampsia.[134] Systolic dysfunction is more common in early- than late-onset disease[135] and in some cases may present as severe cardiac failure with a low ejection fraction.[136,137] This cardiac dysfunction is generally different from that which occurs in peripartum cardiomyopathy (see Chapter 41).[138] The hypothesis that there are shared pathways of abnormal angiogenesis in preeclampsia and peripartum cardiomyopathy is controversial.[139]

There is growing interest in the use of biomarkers such as brain natriuretic peptide (BNP) to identify cardiac dysfunction in preeclampsia. A systematic review found that serum BNP levels are higher in the third trimester in women with preeclampsia compared with healthy women.[140] Studies

included in this review found that elevated BNP levels correlated with echocardiographically demonstrated cardiac dysfunction as well as increased systemic vascular resistance, decreased cardiac output, and left ventricular diastolic dysfunction. Future studies are needed, however, to define BNP threshold values that have high sensitivity and specificity for heart failure in preeclampsia.

Pulmonary

Pulmonary edema is a severe complication that occurs in approximately 3% of women with preeclampsia.[141] It occurs infrequently in healthy, younger women; the risk increases in older multigravid women, in women with preeclampsia superimposed on chronic hypertension or renal disease, and among those whose preeclampsia leads to oliguria.

Plasma colloid osmotic pressure is reduced in normal pregnancy because of decreased plasma albumin concentration, and it is decreased even further in women with preeclampsia.[142] Women with normal pregnancies have a mean osmotic pressure of approximately 22 mm Hg in the third trimester and approximately 17 mm Hg during the early postpartum period. In contrast, a study of women with preeclampsia demonstrated a mean colloid osmotic pressure of approximately 18 mm Hg before delivery and 14 mm Hg after delivery.[143] Decreased colloid osmotic pressure, in combination with increased vascular permeability due to abnormalities of the pulmonary endothelial glycocalyx and the loss of intravascular fluid and protein into the interstitium, increases the risk for pulmonary edema.[144] In addition, increased intravascular hydrostatic pressure due to fluid overload and/or increased left ventricular end diastolic pressure, and occasional systolic heart failure, may cause pulmonary edema.[145] All of these factors may coexist in a single patient.

Lung ultrasonography may be a useful adjunct to identify lung pathology. In a study of 20 asymptomatic women with severe preeclampsia and healthy controls,[146] interstitial edema, which precedes alveolar edema, was identified by sonographic B-line artefacts in 25% of the cases. High lung "echo comet scores" were associated with increased left ventricular end-diastolic pressure. Another investigation in women with preeclampsia found echo comet scores were higher before delivery than 4 days after delivery, although tissue Doppler indices did not change after delivery.[147] The authors concluded that increased extravascular lung water before delivery may be associated with increased pulmonary capillary permeability in addition to cardiac dysfunction.

Hematologic

Thrombocytopenia is the most common hematologic abnormality in women with preeclampsia, and preeclampsia is the most common cause of severe thrombocytopenia in the second half of pregnancy (see Chapter 44). Platelet counts less than 100,000/mm^3 occur most commonly in women with severe disease or HELLP syndrome[23] and correlate with the severity of the disease process.

Studies using thromboelastography have found that women with preeclampsia without severe features are *hyper*coagulable relative to women without preeclampsia and that those with severe disease are relatively *hypo*coagulable.[148] In contrast to normal pregnancies and other hypertensive disorders, platelets are activated in preeclampsia[149]; subsequent platelet degranulation is believed to account for the decreases in platelet function, and aggregation appears to account for the decrease in platelet count.[150]

The syndrome of **disseminated intravascular coagulation (DIC)** occurs in some women with preeclampsia, generally in the setting of severe liver involvement, intrauterine fetal demise, placental abruption, or postpartum hemorrhage.[151] Activation of the coagulation system is marked by consumption of procoagulants, increased levels of fibrin degradation products, and end-organ damage secondary to microthrombi formation. In advanced DIC, procoagulants (e.g., fibrinogen, platelets) decrease to a level that may lead to spontaneous hemorrhage.

Hepatic

Hepatic manifestations of preeclampsia include periportal hemorrhage and fibrin deposition in hepatic sinusoids. Hepatic involvement frequently presents as right upper quadrant or epigastric pain. Damage ranges from mild hepatocellular necrosis to the more ominous HELLP syndrome and can be associated with subcapsular bleeding and risk for hepatic rupture. Spontaneous hepatic rupture is rare but is associated with a 32% maternal mortality rate.[152]

Renal

Renal manifestations of preeclampsia include persistent proteinuria, changes in the glomerular filtration rate, and hyperuricemia. The presence of **proteinuria** is a defining element of preeclampsia but is no longer considered essential for diagnosis if other evidence of end-organ injury is present. The characteristic renal histologic lesion of preeclampsia is glomerular capillary endotheliosis, which manifests as glomerular enlargement and endothelial and mesangial cell swelling. Increasing urinary excretion of protein likely results from changes in the pore size or charge selectivity of the glomerular filter and impaired proximal tubular reabsorption.[153]

During normal pregnancy, the **glomerular filtration rate (GFR)** *increases* by 40% to 60% during the first trimester,[154,155] with a resulting decrease in the serum markers of renal clearance, including blood urea nitrogen (BUN), creatinine, and uric acid. In preeclampsia, this increase in GFR is blunted compared with normal pregnancy.[153] Notably, women with preeclampsia may have BUN and creatinine measurements in the normal range for nonpregnant women despite significantly decreased GFR relative to healthy pregnant women.

The association between preeclampsia and **hyperuricemia** was recognized as early as 1917.[156] Most evidence suggests that decreased renal clearance is the primary mechanism for elevated uric acid levels.[157] Because levels of serum uric acid begin to increase as early as 25 weeks' gestation,[158] it has been investigated as a possible early predictor of preeclampsia.

Oliguria is a possible late manifestation of severe preeclampsia and parallels the severity of disease. Persistent

oliguria requires immediate assessment of intravascular volume status. Progression to renal failure is rare and is typically preceded by hypovolemia, placental abruption, or DIC.

Uteroplacental Perfusion

Uteroplacental perfusion can be impaired in pregnancies complicated by preeclampsia. In contrast with normal pregnancy, fetal umbilical artery flow waveforms demonstrate an increase in downstream resistance, a decrease in diastolic flow velocity, and an increase in the systolic-to-diastolic flow velocity ratio.[159] The systolic-to-diastolic ratio, calculated from Doppler ultrasonographic determination of blood flow velocities, reflects intrinsic arterial resistance in the chorionic plate of the placenta.[160] Pathophysiologic changes can result in fetal growth restriction (the fetal syndrome) in some pregnancies complicated by severe preeclampsia.

Obstetric Management

Optimal management of the woman with preeclampsia requires a team approach. There is considerable overlap in areas of concern to the obstetrician and the anesthesia provider. Obstetric management of preeclampsia centers on (1) decisions regarding the timing and route of delivery, (2) fetal and maternal surveillance, (3) treatment of hypertension, and (4) seizure prophylaxis.

Delivery remains the only cure for preeclampsia. Obstetric care of women with preeclampsia without severe features differs little from routine management of healthy pregnant women, except for careful monitoring to detect the development of severe features. Data suggest that induction of labor for pregnancies beyond 37 weeks' gestation in women with gestational hypertension or preeclampsia without severe features is associated with improved maternal outcomes compared with expectant management.[2,161] Outcomes in these pregnancies are similar to those in uncomplicated pregnancies.[2,11,76] In general, delivery is recommended for women presenting with preeclampsia with severe features at 34 weeks' gestation or later.[2,23]

For women with preeclampsia with severe features at less than 34 weeks' gestation (Fig. 35.6), expectant management may improve fetal outcomes without substantially endangering the mother,[76,162] but data are few.[163] Delay of delivery for 24 to 48 hours allows for the administration of corticosteroids to facilitate fetal lung maturity and transfer to a facility with maternal and neonatal intensive care resources. Expedited delivery, regardless of corticosteroid administration, is indicated for patients with eclampsia, pulmonary edema, DIC, placental abruption, abnormal fetal surveillance, a previable or nonviable fetus, or intrauterine fetal demise.[2,164] If a woman develops refractory severe hypertension despite maximum doses of antihypertensive agents *or* persistent cerebral symptoms while receiving magnesium sulfate, delivery should occur within 24 to 48 hours, regardless of gestational age or corticosteroid administration.[2,164] Expectant management before 34 weeks' gestation should be undertaken at facilities with neonatal and maternal intensive care resources.[2]

Maternal and Fetal Surveillance

Maternal surveillance is indicated for all preeclamptic women.[109] In women with preeclampsia without severe features, the goal is early detection of severe disease. In women with severe disease, the goal is detection of worsening organ dysfunction. All women should be evaluated for signs or symptoms indicating end-organ involvement, including (1) severe headache, (2) visual disturbances, (3) altered mentation, (4) dyspnea, (5) right upper quadrant or epigastric pain, (6) nausea and vomiting, (7) decreased urine output, and (8) CNS hyperexcitability.[1]

Initial laboratory investigations for the pregnant woman who develops hypertension after 20 weeks' gestation are listed in Table 35.3. The admission platelet count is an excellent predictor of subsequent thrombocytopenia.[165] For preeclamptic women with a platelet count exceeding 100,000/mm^3, further coagulation testing is not required because coagulopathy is rarely present in severely preeclamptic women who have a normal platelet count.[165] If the platelet count is less than 100,000/mm^3, other hemostatic abnormalities (e.g., prolonged prothrombin time [PT] and activated partial thromboplastin time [aPTT], reduced fibrinogen concentration) may be present.[165] Further coagulation studies may be useful, particularly if risk factors for DIC are present (e.g., placental abruption, liver dysfunction, HELLP syndrome). Liver

TABLE 35.3 Initial Laboratory Investigations for Women in Whom Hypertension Develops after 20 Weeks' Gestation

Test	Rationale
Hemoglobin and hematocrit	Hemoconcentration supports diagnosis of preeclampsia and is an indicator of severity. Values are decreased if hemolysis is present.
Platelet count	Thrombocytopenia suggests severe preeclampsia.
Urine protein-creatinine ratio or 24-hour urine protein excretion	Presence of proteinuria distinguishes preeclampsia from gestational hypertension.
Serum creatinine level	Abnormal or rising creatinine level suggests severe preeclampsia, especially in presence of oliguria.
Serum aminotransferase levels	Elevated serum aminotransferase levels suggest severe preeclampsia with hepatic involvement.

Modified from Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. *Am J Obstet Gynecol.* 2000;183:S1–S22; American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy: *Hypertension in Pregnancy.* Washington, DC: American College of Obstetricians and Gynecologists; 2013.

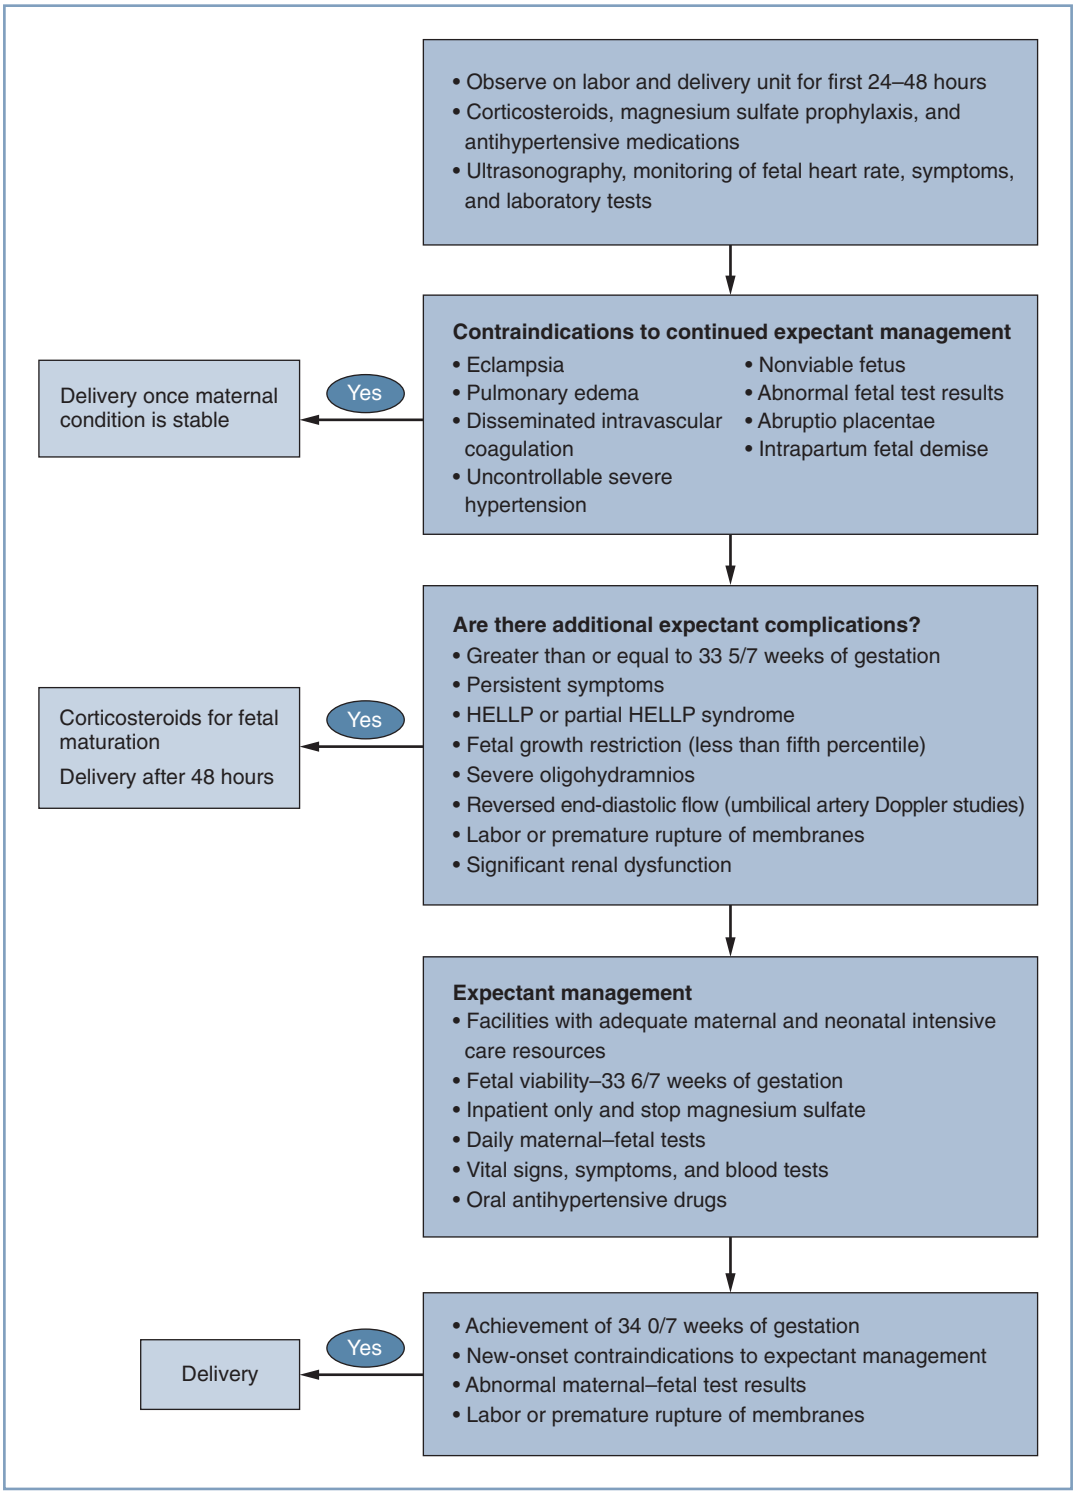

Fig. 35.6 Suggested algorithm for the management of severe preeclampsia at less than 34 weeks' gestation. *HELLP,* hemolysis, elevated liver enzymes, and low platelet count. (From American College of Obstetricians and Gynecologists Taskforce on Hypertension in Pregnancy: *Hypertension in Pregnancy.* Washington, DC: American College of Obstetricians and Gynecologists; 2013.)

function tests are obtained in all women with preeclampsia because abnormal levels indicate more severe disease and may prompt delivery. Approximately 20% of women with preeclampsia have elevated serum aminotransferase levels.[166] The value of uric acid testing is controversial, with conflicting evidence regarding its association with increased fetal or maternal risk for complications.[167–169]

In general, the frequency of subsequent laboratory evaluation will be guided by the initial findings and the severity of illness and disease progression.[164] A diagnosis

of preeclampsia without severe features should prompt at least weekly laboratory investigations, with the frequency modified based on subsequent clinical findings.[2] In the expectant management of preeclampsia with severe features, hemoglobin, platelet count, liver function tests, creatinine, and coagulation parameters should be assessed daily or every other day.[2,170] For women undergoing induction of labor for whom initial laboratory measurement or daily platelet counts demonstrate thrombocytopenia, serial platelet counts at least every 6 hours may be useful to detect declining platelet counts and to guide decision-making about the timing of delivery and analgesic or anesthetic technique. Finally, for women with indicated delivery, an active blood type and screen is indicated with consideration of type and cross-match of 2 units of packed red blood cells or more for patients with thrombocytopenia or other abnormalities in coagulation parameters.[171]

Preeclampsia is a known risk factor for perinatal death. The ACOG Taskforce on Hypertension in Pregnancy recommends daily fetal movement counts with either nonstress testing or biophysical profile testing at the time of diagnosis and at regular intervals thereafter.[2,172] Ultrasonography is used to estimate fetal weight and amniotic fluid volume. Doppler ultrasonography is used to measure fetal blood flow velocimetry if fetal growth restriction is suspected.[2,160]

Fluid Management

Although preeclampsia is associated with intravascular volume depletion, the optimal approach to fluid management remains controversial, given potential dysfunction of the pulmonary endothelial glycocalyx and renal glomeruloendotheliosis. A 2011 systematic review[173] found insufficient evidence of maternal or neonatal benefit of plasma volume expansion in preeclampsia. Given the heterogeneity of the disease, clinicians should restrict fluids in these patients unless monitoring is used (e.g., invasive blood pressure monitoring with or without noninvasive cardiac output monitoring, TTE) to assess response to fluid administration. Volume expansion is not recommended, and fluids should be limited to 80 mL/h or 1 mL/kg/h. In the case of hemorrhage, losses should be replaced appropriately. Administration of additional fluid may be considered before intravenous hydralazine, neuraxial anesthesia, or immediate delivery. Care must be taken not to overtreat oliguria with fluids; a fluid challenge is recommended in oliguric patients only if a volume deficit is suspected or can be confirmed.[174]

Treatment of Acute Hypertension

Antihypertensive medications are used to treat severe hypertension (systolic blood pressure greater than or equal to 160 mm Hg or diastolic blood pressure greater than or equal to 110 mm Hg) with the goal of preventing adverse maternal sequelae such as hypertensive encephalopathy, cerebrovascular hemorrhage, myocardial ischemia, and congestive heart failure.[175]

Although acute control of maternal blood pressure is critical, rapid changes in maternal perfusion pressure may adversely affect uteroplacental perfusion and oxygen delivery to the fetus. Antihypertensive medications should be carefully titrated to avoid abrupt changes in maternal blood pressure. The aim of therapy is to lower the mean arterial blood pressure by no more than 15% to 25%, with a target systolic blood pressure between 120 and 160 mm Hg and a diastolic blood pressure between 80 and 105 mm Hg.[2,176,177] Commonly used drugs include labetalol, hydralazine, and nifedipine. Nicardipine and esmolol may be considered second-line agents (Table 35.4). Historically, sodium nitroprusside was also considered a second-line agent. However, it is a highly potent smooth muscle vasodilator, and careful titration is required to avoid acute hypotension. Therefore, it is seldom used in the current management of preeclampsia.

Systematic review and meta-analysis of available studies show insufficient data regarding the relative efficacy of these commonly used agents and recommend selection based on clinician familiarity and adverse effects.[178] The authors of the systematic review do, however, suggest that some agents are inferior and recommend avoiding diazoxide, ketanserin, nimodipine, and magnesium sulfate for the treatment of severe hypertension in pregnancy (although magnesium is recommended for seizure prophylaxis).[178] The ACOG committee opinion on the treatment of acute hypertension recommends labetalol or hydralazine as a first-line treatment for acute-onset, severe hypertension in pregnant or postpartum patients.[175]

TABLE 35.4 Treatment of Acute Severe Hypertension[a] in Preeclampsia/Eclampsia

Medication	Onset of Action[b]	Dose
Labetalol	5–10 min	20 mg IV, then 40–80 mg every 10 min up to maximum dose of 220 mg IV
Hydralazine	10–20 min	5 mg IV every 20 min up to maximum dose of 20 mg IV
Nifedipine	10–20 min	10 mg PO every 20 min up to a maximum dose of 50 mg
Nicardipine	10–15 min	Initial infusion 5 mg/h, increase by 2.5 mg/h every 5 min to a maximum dose of 15 mg/h

IV, Intravenously; *PO,* per os.
[a]Systolic blood pressure 160 mm Hg or greater, diastolic blood pressure 110 mm Hg or greater, or both, if sustained.

Labetalol

Labetalol is a combined alpha- and beta-adrenergic receptor antagonist with a 1:7 ratio of alpha- to beta-adrenergic receptor antagonism when administered intravenously. Labetalol should be avoided in women with severe asthma or congestive heart failure.[179]

A meta-analysis concluded that intravenous labetalol has efficacy similar to intravenous hydralazine but with fewer maternal side effects, although evidence was limited to four small randomized controlled trials.[178] Neonates born to mothers exposed to beta-adrenergic receptor antagonists during delivery, including labetalol, demonstrate increased rates of neonatal hypoglycemia and bradycardia.[180]

Hydralazine

Hydralazine has been used safely in pregnant women for decades and is also considered a first-line drug for treating severe hypertension in pregnancy.[175] Hydralazine exerts a potent direct vasodilating effect. Plasma volume expansion before administration decreases the risk for maternal hypotension. Other side effects include tachycardia, palpitations, headache, and neonatal thrombocytopenia. In a randomized clinical trial, hydralazine was associated with more maternal tachycardia and palpitations and less neonatal bradycardia and hypotension than labetalol,[181] but both antihypertensive drugs are considered safe and effective for the treatment of severe hypertension in pregnant women.

Nifedipine

Nifedipine is a calcium entry–blocking agent that lowers blood pressure by relaxing arterial and arteriolar smooth muscle. It can be administered as a long-acting oral medication once the severe hypertension has stabilized. Nifedipine immediate-release capsules should not be administered to women with known coronary artery disease, long-standing diabetes mellitus or aortic stenosis, or to women older than 45 years of age because of an increased risk for sudden cardiac death.[76] In the absence of contraindications, nifedipine is now recommended as a first-line agent in women for whom intravenous access is difficult to secure.[175]

Although earlier reports suggested that the coadministration of nifedipine with magnesium sulfate causes adverse effects in both the mother and fetus, including severe maternal hypotension,[182] neuromuscular blockade,[183] and nonreassuring fetal heart rate (FHR) patterns,[182] subsequent data suggest that these drugs can be used together safely.[184] Oral nifedipine has been found to be as efficacious and safe as intravenous labetalol.[185]

Other Agents

If labetalol, hydralazine, or nifedipine are not effective in controlling blood pressure, consideration may be given to using a nicardipine or labetalol infusion or other antihypertensive agents.[175]

Nicardipine is a calcium entry–blocking agent that can be administered by intravenous infusion and has been shown to achieve rapid decreases in systolic and diastolic blood pressures in pregnant women.[186] It is an excellent option for treating severe hypertension that is not responsive to labetalol or hydralazine.[175]

Esmolol is a short-acting beta-adrenergic receptor antagonist that can be used to treat acute hypertension accompanied by maternal tachycardia. Concerns regarding the use of esmolol during pregnancy arose in 1989 after a report of dose-dependent prolonged fetal bradycardia in a study of gravid ewes receiving esmolol by stepped infusion.[187] Subsequent human case reports have reported variable responses,[188,189] but in most cases fetal bradycardia was transient and FHR returned to baseline after discontinuation of the drug. Placental transfer is rapid, and clinicians should expect to observe the effects of beta-adrenergic receptor blockade in the fetus. Maternal administration of esmolol produces a greater degree of beta-adrenergic receptor blockade in the fetal lamb than that observed after maternal administration of an equipotent dose of labetalol.[187,190]

Seizure Prophylaxis

The routine use of magnesium sulfate for seizure prophylaxis in women with preeclampsia with *severe features* is an established obstetric practice. There is clear evidence that magnesium sulfate is the best available agent for prevention of recurrent seizures in women with eclampsia[191,192]; thus, its use has been extended to seizure prophylaxis in women with preeclampsia with severe features.[2]

A meta-analysis of the available data identified six trials involving 11,444 women that compared magnesium sulfate for the treatment of preeclampsia with either placebo or no anticonvulsant.[193] Magnesium decreased the risk for developing eclampsia (relative risk [RR], 0.41; 95% confidence interval [CI], 0.29 to 0.58); there was also a trend toward lower risk for maternal death (RR, 0.54; 95% CI, 0.26 to 1.10), but no effect on serious maternal morbidity.[193] Additionally, magnesium therapy reduced the risk for placental abruption. It did not adversely affect fetal and/or neonatal outcomes, including stillbirth, perinatal death, or neurosensory disability.[193] Treatment with magnesium increased the risk for maternal respiratory depression (RR, 1.98; 95% CI, 1.24 to 3.15) and cesarean delivery (RR, 1.05; 95% CI, 1.01 to 1.10).[193] Other side effects that were significantly more common in those treated with magnesium included feeling warm or flushed, nausea/vomiting, muscle weakness, hypotension, dizziness, drowsiness/confusion, and headache.[193]

In general, magnesium sulfate is not indicated for seizure prevention in preeclampsia without severe features.[2] Studies have failed to show a difference in the number of women who progressed to severe preeclampsia.[194,195]

The mechanism of the anticonvulsant effect of magnesium is not well understood. It was previously believed that eclamptic seizures were the result of cerebral vasospasm, and it was also believed that the cerebral vasodilating properties of magnesium reduced the rate of eclamptic seizures by relieving vasospasm.[196] However, there is evidence that abrupt, sustained blood pressure elevation overwhelms

myogenic vasoconstriction and causes forced dilation of the cerebral vessels, hyperperfusion, and cerebral edema.[117,196–198] This evidence raises the question of how magnesium sulfate—a vasodilator—could be effective in seizure prophylaxis; magnesium would be expected to worsen cerebral hyperperfusion and edema. Using a rat model, Euser and Cipolla[196] demonstrated that the mesenteric vessels are more sensitive to magnesium-induced vasodilation than are cerebral vessels, suggesting that part of the effect may be mediated through decreasing peripheral vascular resistance. Further animal work suggests that magnesium may ameliorate neuroinflammation and brain edema in an eclampsia-like seizure model.[199] Magnesium may also protect the blood-brain barrier, or act centrally at *N*-methyl-D-aspartate (NMDA) receptors to raise the seizure threshold.[200]

No consensus exists regarding (1) the ideal time to initiate treatment with magnesium sulfate, (2) the best loading and maintenance doses, or (3) the optimal duration of therapy. Many obstetricians administer a loading dose of 4 to 6 g over 20 to 30 minutes, followed by a maintenance infusion of 1 to 2 g/h. The infusion is commonly initiated once the decision is made to deliver and is continued for 24 hours postpartum.[201] Expert opinion recommends that women with preeclampsia with severe features undergoing cesarean delivery should receive magnesium sulfate at least 2 hours before the procedure, during surgery, and for 24 hours postpartum.[2,194]

Magnesium sulfate is eliminated almost entirely by renal excretion,[202] and serum levels may become dangerously high in the presence of renal insufficiency. Side effects of hypermagnesemia include chest pain and tightness, palpitations, nausea, blurred vision, sedation, transient hypotension, and, rarely, pulmonary edema.[203,204] In untreated patients, the normal range for serum magnesium concentrations is 1.7 to 2.4 mg/dL. The therapeutic range lies between 5 and 9 mg/dL.[205] Reflex testing is used as a clinical screen for hypermagnesemia; when deep tendon reflexes are preserved, the more serious side effects are usually avoided. Patellar reflexes are lost at serum magnesium levels of approximately 12 mg/dL. Respiratory arrest occurs at levels between 15 and 20 mg/dL, and asystole occurs when the level exceeds 25 mg/dL.[206] Preeclamptic women with renal impairment should be monitored closely because magnesium toxicity can occur with usual dosing regimens. Serial measurement of serum magnesium levels may be helpful in the management of women with renal dysfunction.

Treatment of suspected magnesium toxicity includes immediate discontinuation of the infusion and the intravenous administration of **calcium gluconate** (1 g) over 10 minutes.[207] In the rare event of respiratory compromise, the patient may require tracheal intubation and mechanical ventilation until spontaneous ventilation returns.

Route of Delivery

Vaginal delivery should be attempted in all women with preeclampsia without severe features, assuming no other indications for cesarean delivery exist. Vaginal delivery should also be attempted in most women with severe disease, especially those beyond 34 weeks' gestation.

Cesarean delivery is appropriate when the maternal or fetal condition mandates immediate delivery or when other indications for cesarean delivery exist.

Corticosteroid Administration for Severe Preeclampsia or HELLP Syndrome

To accelerate fetal lung maturity, all women who develop preeclampsia with severe features or HELLP syndrome between 24 and 34 weeks' gestation should receive a course of corticosteroid therapy. A randomized double-blind trial of 218 women with severe preeclampsia at 26 to 34 weeks' gestation found that the infants of those receiving betamethasone, compared with the infants of those receiving placebo, exhibited a significant reduction in the rate of the neonatal respiratory distress syndrome and reduced rates of neonatal intraventricular hemorrhage, infection, and death.[208] The available data also suggest that treatment with corticosteroids results in improvement in the maternal platelet count in women with HELLP syndrome, with dexamethasone being more efficacious than betamethasone.[209] However, these studies do not show a clear benefit of corticosteroid treatment on the endpoints of severe maternal morbidity or mortality.[209]

Complications

Preeclampsia is associated with an increased risk for maternal morbidity and mortality, including HELLP syndrome, cerebrovascular accident, pulmonary edema, renal failure, placental abruption, and eclampsia. In general, these complications are more common in women with early-onset preeclampsia and in women with prepregnancy medical conditions, including diabetes mellitus, chronic renal disease, and thrombophilia.[37]

Cerebrovascular Accident

Although the absolute risk for cerebrovascular accident is low, preeclampsia confers markedly increased risk for intracerebral and subarachnoid hemorrhage[210,211] and ischemic stroke.[212,213] Stroke remains the leading cause of death in women with preeclampsia.[214] A 2017 publication used multivariable analysis to delineate the risk factors for stroke in women with preeclampsia.[215] Women with stroke were more likely to have severe preeclampsia or eclampsia, infections present on admission, prothrombotic states, coagulopathies, or chronic hypertension.

The endothelial dysfunction of preeclampsia contributes to edema, vascular tone instability, platelet activation, and local thrombosis. Reversible cerebral edema is the most common CNS feature of preeclampsia or eclampsia. The loss of cerebral autoregulation causes hyperperfusion that, compounded by endothelial disruption, leads to interstitial or vasogenic edema.[75,216,217] The presence of HELLP syndrome or DIC increases the risk for a hemorrhagic event.

In the 2006–2008 Confidential Enquiry into Maternal and Child Health (CEMACH) report from the United Kingdom,

19 deaths were attributed to eclampsia and preeclampsia; 9 resulted from intracranial hemorrhage. Failure to adequately control hypertension was noted in most of these cases. The CEMACH report emphasized the importance of urgent treatment of women with a systolic blood pressure in excess of 150 to 160 mm Hg.[214] A recent consensus bundle for the management of severe hypertension in pregnancy also emphasizes that, once confirmed, systolic blood pressure greater than or equal to 160 mm Hg, or diastolic blood pressure greater than or equal to 110 mmHg, should be treated within 30 to 60 minutes.[8]

Mean arterial blood pressure and diastolic blood pressure may not reflect the true risk for stroke. A review of 28 case histories of severely preeclamptic women who suffered a stroke revealed that (1) systolic blood pressure in excess of 160 mm Hg was a far superior predictor of stroke than diastolic hypertension or elevated mean arterial pressure, (2) the majority of strokes were hemorrhagic (93%) as opposed to thrombotic (7%), and (3) the majority of strokes (57%) occurred in the postpartum period.[177] Close attention to blood pressure control throughout the peripartum period is the mainstay of stroke prevention.[175] In keeping with this goal, ergot alkaloids should generally be avoided in hypertensive patients because their administration can result in severe hypertension.[214]

Pulmonary Edema

The clinical presentation of pulmonary edema is characterized by worsening dyspnea and orthopnea with concomitant signs of respiratory compromise, including tachypnea, rales, and hypoxemia. A large proportion of cases of pulmonary edema occur postpartum, usually within 2 to 3 days after delivery, and management is directed toward the underlying cause.[218] TTE can be helpful in the diagnosis of heart failure with low ejection fraction, and in the identification of other cardiac comorbidities contributing to pulmonary edema.[219] Initial treatment includes administration of supplemental oxygen, fluid restriction, and diuretic therapy (e.g., furosemide). A retrospective study of 86 women with peripartum pulmonary edema found that even in the presence of extensive radiographic infiltrates and severe hypoxemia, resolution was typically rapid, with a limited need for intensive care unit admission.[220] Rarely, women with severe systolic heart failure with a low ejection fraction may develop precipitous hypoxemia and require urgent tracheal intubation and ventilatory support. Notably, in mortality reports from the United Kingdom in the current millenium,[214,221] no deaths were attributed solely to cardiopulmonary causes. Presumably, this trend reflects improvements in the fluid management of women with severe preeclampsia. These results cannot be extrapolated to limited-resource environments. In the 6th Report on the Confidential Enquiries into Maternal Death in South Africa (2011–2013),[222] pulmonary edema and respiratory failure were two of the most common causes of death in women with hypertensive disease, each accounting for approximately one-fourth of these deaths.

Renal Failure

Acute renal failure is a rare but serious complication of severe preeclampsia and HELLP syndrome.[223] The true incidence remains unknown. Acute renal failure is divided into three categories: (1) **prerenal,** which refers to renal hypoperfusion; (2) **intrarenal,** which suggests intrinsic renal parenchymal damage; and (3) **postrenal,** which implies obstructive uropathy. The majority of cases (83% to 90%) of acute renal failure in preeclampsia result from prerenal and intrarenal pathologic processes (most commonly acute tubular necrosis) and resolve completely after delivery.[224,225] In contrast, bilateral renal cortical necrosis is a rare and serious condition associated with considerable maternal and perinatal morbidity and mortality. It occurs most commonly in association with known renal parenchymal disease, chronic hypertension with superimposed preeclampsia, placental abruption, DIC, HELLP syndrome, sepsis, or fetal death.[226,227]

Placental Abruption

Placental abruption occurs in approximately 2% of women with preeclampsia and results in increased perinatal morbidity and mortality. A 2006 retrospective case-control study of 161 women with placental abruption and 2000 women without abruption found a threefold increased risk for placental abruption in women with preeclampsia.[228] The incidence is also increased in women with underlying chronic hypertension. Management depends on the extent of abruption and associated hypotension, coagulopathy, or fetal compromise (see Chapter 37). Placental abruption is also associated with the development of DIC (see Chapter 44).

HELLP Syndrome

HELLP syndrome is characterized by hemolysis, elevated levels of liver enzymes, and a low platelet count. It may be a variant of severe preeclampsia, but this is controversial because a substantial fraction of women with HELLP syndrome do not have hypertension or proteinuria. It is associated with increased rates of maternal morbidities, including DIC, placental abruption, pulmonary edema, acute renal failure, liver hemorrhage or failure, acute respiratory distress syndrome, sepsis, stroke, and death (Table 35.5).[229] Additionally, 70% of women with HELLP syndrome deliver preterm,[229] contributing to prematurity-related perinatal morbidity and mortality. The onset of HELLP syndrome occurs antepartum in 70% of cases and postpartum in 30%.

Because of a lack of universally accepted diagnostic criteria for HELLP syndrome, its incidence cannot be determined accurately. The existence of a subset of preeclampsia complicated by abnormal peripheral blood smear, abnormal liver function tests, and thrombocytopenia has been recognized for decades; in 1982, Weinstein[230] described a series of 29 cases and coined the acronym HELLP. Women who do not demonstrate one or more of these clinical features are said to have "partial" HELLP syndrome.

Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the classic hallmark of HELLP syndrome;

TABLE 35.5 Serious Maternal Complications in a Series of 442 Patients with Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

Complication[a]	Number of Patients	Percent
Disseminated intravascular coagulation	92	21
Placental abruption	69	16
Acute renal failure	33	8
Severe ascites	32	8
Pulmonary edema	26	6
Pleural effusions	26	6
Cerebral edema	4	1
Retinal detachment	4	1
Laryngeal edema	4	1

TABLE 35.6 Diagnostic Criteria for Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

Criteria	Laboratory Tests
Hemolysis	Abnormal peripheral blood smear
	Increased bilirubin greater than 1.2 mg/dL
	Increased LDH greater than 600 IU/L
Elevated liver enzyme levels	Increased AST greater than or equal to 70 IU/L
	Increased LDH greater than 600 IU/L
Thrombocytopenia	Platelet count less than 100,000/mm^3

LDH, Lactic dehydrogenase; *AST,* aspartate aminotransferase.
Modified from Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol.* 1990;162:311–316.

the peripheral blood smear demonstrates schistocytes, burr cells, and echinocytes.[231] Common histopathologic findings are periportal hepatic necrosis and hemorrhage.[232] Sibai[231] proposed standardized laboratory diagnostic criteria, as outlined in Table 35.6. Maternal signs and symptoms include right upper quadrant or epigastric pain, nausea and vomiting, headache, hypertension, and proteinuria. Notably, clinical presentation varies; 12% to 18% of women may be normotensive, and proteinuria is absent in approximately 13% of affected women. Diagnosis can be especially challenging because numerous medical and surgical disorders, including acute fatty liver of pregnancy, hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, idiopathic thrombocytopenic purpura, and lupus, can mimic HELLP syndrome (Box 35.4). Pregnant women likely to have preeclampsia, but who demonstrate atypical symptoms, should be screened with a complete blood cell count, platelet count, and liver enzyme assessment.

BOX 35.4 Differential Diagnosis of Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

- Acute fatty liver of pregnancy
- Appendicitis
- Cholestasis of pregnancy
- Diabetes insipidus
- Gallbladder disease
- Gastroenteritis
- Glomerulonephritis
- Hemolytic-uremic syndrome
- Hepatic encephalopathy
- Hyperemesis gravidarum
- Idiopathic thrombocytopenia
- Nephrolithiasis
- Peptic ulcer disease
- Systemic lupus erythematosus
- Thrombotic thrombocytopenic purpura
- Viral hepatitis

From O'Brien JM, Barton JR. Controversies with the diagnosis and management of HELLP syndrome. *Clin Obstet Gynecol.* 2005;48:460–477.

In general, patients with HELLP syndrome are not considered candidates for expectant management[164]; however, deferred delivery for 24 to 48 hours to allow for corticosteroid administration to accelerate fetal lung maturity may be appropriate for women less than 34 weeks' gestation if the maternal and fetal condition remain stable.[2] Women with HELLP syndrome who have not yet reached 34 weeks' gestation should be managed in a tertiary care facility with a neonatal intensive care unit capable of caring for a compromised preterm neonate.[2] Clinical management is similar to that for severe preeclampsia and includes intravenous magnesium sulfate for seizure prophylaxis and antihypertensive medications to maintain a systolic blood pressure below 160 mm Hg and a diastolic blood pressure below 110 mm Hg.[231] The first priority is to assess and stabilize the maternal condition, with particular attention given to hypertension and coagulation abnormalities. Next, the fetal condition should be assessed with FHR monitoring, Doppler ultrasonography of fetal blood flow, a biophysical profile, or several of these options.

The platelet count can fall precipitously in the presence of HELLP syndrome, and it should be evaluated before the administration of neuraxial anesthesia. Women with a platelet count less than 50,000/mm^3 are at significantly increased risk for bleeding,[233] and general anesthesia is the method of choice for cesarean delivery. Data suggest treatment with dexamethasone may improve the platelet count in women with HELLP syndrome.[209] If treatment with dexamethasone

improves the patient's platelet count, the decision as to whether to use neuraxial anesthesia must weigh the risk for recurrent thrombocytopenia against the risk for a difficult airway and hypertension during induction of general anesthesia.

Platelet transfusions are indicated in the presence of significant bleeding and in all parturients with a platelet count less than 20,000/mm^3. For women with a platelet count less than 40,000/mm^3 who are scheduled for cesarean delivery, the preincision administration of 6 to 10 units of pooled random-donor platelets (or 1 to 2 units of apheresis platelets) has been recommended.[234] The risk for postpartum hemorrhage is significantly increased in patients with HELLP syndrome; large-bore intravenous access should be obtained, and identification of compatible red blood cell units should be considered.

Rupture of a subcapsular hematoma of the liver is a life-threatening complication of HELLP syndrome and severe preeclampsia[235] that manifests as abdominal pain, nausea and vomiting, and headache; the pain worsens over time and becomes localized to the epigastric area or right upper quadrant. Hypotension and shock typically develop, and the liver is enlarged and tender.[236] Diagnosis is confirmed with ultrasonography, computed tomography (CT), or magnetic resonance imaging of the liver (Fig. 35.7). Subcapsular hematoma rupture *with shock* is a surgical emergency that requires immediate multidisciplinary treatment that includes intravascular volume resuscitation and blood and plasma transfusions.[236] In some circumstances, selective arterial embolization by an interventional radiologist may be useful.[235,237,238] Patients with fulminant hepatic failure may require liver transplantation.[235] Prompt surgical intervention and refinements in surgical technique have substantially reduced the maternal mortality rate associated with spontaneous hepatic rupture to less than 20% in the past decade.[235] The most common causes of death are coagulopathy and exsanguination.[229,239]

Anesthetic Management

The anesthetic management of the woman with preeclampsia without severe features differs little from the management of a healthy pregnant woman. However, the potential for rapid progression to the severe form of the disease mandates careful observation of the patient. The anesthesia provider must recognize the unpredictability of the development and progression of severe preeclampsia and should be prepared at all times for immediate cesarean delivery.

Preanesthetic Evaluation

The preanesthetic assessment of women with confirmed or suspected preeclampsia should focus on the airway examination, maternal hemodynamic and coagulation status, and fluid balance.

Airway. Generalized edema can involve the airway and obscure visualization of anatomic landmarks at laryngoscopy.[123] The anesthesia provider should anticipate the possibility of difficult airway management (see Chapter 29).

Hemodynamic monitoring. Noninvasive blood pressure monitoring is appropriate in uncomplicated severe preeclampsia, although automated devices may underestimate blood pressure in preeclampsia. The most frequent indications for radial artery catheter insertion are (1) the need for continuous blood pressure monitoring during the induction of and emergence from general anesthesia in women with severe preeclampsia and poorly controlled hypertension; (2) a requirement for frequent arterial blood gas measurements, especially in the context of pulmonary edema; and (3) use of calculated systolic pressure variation[240] to estimate intravascular volume status, particularly in the setting of hemorrhage.

In the past, guidelines recommended the placement of a pulmonary artery catheter and measurement of central pressures and cardiac output to inform fluid management decisions in women with pulmonary edema or renal failure. However, the causes of pulmonary edema are often multifactorial, and left ventricular compliance varies widely. This leads to poor correlation between pulmonary capillary wedge pressure and left ventricular end-diastolic volume. The placement of a pulmonary artery catheter is not a benign procedure; well-recognized risks include pneumothorax, venous air embolism, neuropathy, and cardiac arrhythmias. Additional risks for an indwelling pulmonary artery catheter include pulmonary artery hemorrhage, thromboembolism, sepsis, and endocardial damage.[241] The 1991–1993 Report on Confidential Enquiries into Maternal Deaths in the United Kingdom described the postpartum death of a woman after several unsuccessful attempts at internal jugular vein line placement and a likely carotid artery puncture.[242] In the 2003–2005 CEMACH report, an anesthesia-related maternal death occurred in a woman with fulminant preeclampsia and HELLP syndrome who developed a large right hemothorax after subclavian vein line insertion.[221] Because both immediate and delayed[243] maternal deaths have been attributed to the use of central venous catheters, insertion of these catheters should be done only after careful consideration of risks and

benefits. A 2012 systematic review failed to identify any randomized trials evaluating the use of the pulmonary artery catheter for fluid management in women with preeclampsia.[244] Thus, in the setting of preeclampsia, the pulmonary artery catheter should probably be reserved for the rare patient with severe multiple organ failure, or underlying congenital or valvular heart disease, and critical cardiovascular instability.

Point-of-care TTE has become a useful technique for assessing cardiopulmonary status in the peridelivery period.[219,245] Valuable information about volume status, chamber size and wall thickness, and ventricular function may be gleaned in critically ill patients with preeclampsia. Indeed, clinical examination, coupled with passive leg raising and TTE, have largely supplanted central venous and pulmonary artery catheters in the assessment of volume status. Research has shown that passive leg raising combined with TTE assessment of stroke volume changes accurately predicts fluid responsiveness.[246] Pulse waveform analysis has been suggested as a minimally invasive method to measure cardiac output; cardiac output measurements using this approach have been shown to closely match those obtained from thermodilution in women with preeclampsia.[247]

In summary, indications for invasive central monitoring are similar to those in other multisystem disorders such as severe sepsis, multisystem organ dysfunction, pulmonary edema, congenital heart disease, and cardiomyopathy. TTE and arterial waveform monitoring provide less invasive means of assessing hemodynamic parameters in these patients. Some women will require transfer to an intensive care unit for specialized nursing care and management directed by a critical care medicine specialist.

Neuraxial Analgesia for Labor and Delivery

The confirmation of the safety of neuraxial anesthesia for labor and cesarean delivery in women with preeclampsia is one of the most important developments in the past 25 years in obstetric anesthesia practice. The major advantages of neuraxial anesthesia are control of hypertension and avoidance of the need for airway management.

Continuous lumbar epidural analgesia or combined-spinal epidural (CSE) analgesia are the preferred methods of pain management during labor in women with preeclampsia. Advantages include (1) provision of high-quality analgesia, which attenuates the hypertensive response to pain; (2) a reduction in levels of circulating catecholamines and stress-related hormones[248]; (3) provision of a means for rapid initiation of epidural anesthesia for emergency cesarean delivery, thus obviating the need for general anesthesia and its associated risk for airway catastrophe and critical hypertension during laryngoscopy; and (4) possible improvement in intervillous blood flow.[249] Early initiation of neuraxial labor analgesia is recommended in the absence of contraindications in all patients with preeclampsia with severe features, particularly in women with HELLP syndrome, obesity, and when there is concern for fetal status. The advantages and disadvantages of a traditional epidural compared with a CSE technique are not different for women with preeclampsia compared with healthy women (see Chapter 23).

Continuous antepartum epidural infusion of local anesthetic has been suggested as a means to optimize uteroplacental blood flow and prolong pregnancy in women with preeclampsia remote from term. In one study, women with severe preeclampsia between 28 and 32 weeks' gestation who received an epidural local anesthetic infusion had delayed delivery and improved blood pressure and platelet counts compared with women who received standard treatment.[250] A second study found a unilateral decrease in uterine artery vascular resistance (in the artery with highest baseline resistance) during the period of epidural ropivacaine infusion compared with saline infusion in women with early-onset preeclampsia.[251] Although promising, this technique for prolonging pregnancy requires further study.

For the most part, the clinical administration of neuraxial labor analgesia to women with preeclampsia does not differ from that in healthy women (see Chapter 23). However, four special considerations exist: (1) assessment of coagulation status, (2) intravenous hydration before neuraxial administration of a local anesthetic, (3) treatment of hypotension, and (4) use of epinephrine-containing local anesthetic solutions.

Coagulation status. Platelets contribute to coagulation and hemostasis in two important ways. First, their adhesive and cohesive functions lead to the formation of the hemostatic plug. Second, they activate the coagulation process by exposing a phospholipid surface and acting as a catalytic site for subsequent coagulation and consolidation of the initial platelet plug. Activated platelets release adenosine diphosphate, serotonin, thromboxane A_2, and other adhesive proteins, coagulation factors, and growth factors (see Chapter 44).

Women with preeclampsia without severe features are usually hypercoagulable relative to women with an uncomplicated pregnancy and should not be denied neuraxial labor analgesia.[148] Women with preeclampsia *with severe features* (particularly those with HELLP syndrome) may develop thrombocytopenia, which increases the risk for bleeding into the epidural or spinal space during a neuraxial procedure (see Chapter 31). Neuraxial hematoma formation can result in permanent neurologic sequelae. Therefore, documentation of the platelet count is necessary before provision of neuraxial analgesia in women with severe preeclampsia. The incidence of neuraxial hematoma cannot be precisely determined because not all cases are reported and because there is no accurate method to determine the denominator of all preeclamptic women who have received neuraxial anesthesia. That said, the incidence of epidural hematoma in contemporary obstetric anesthesia practice is exceptionally low.[252]

In the past, a platelet count greater than or equal to 100,000/mm^3 was considered necessary for the safe administration of neuraxial anesthesia. This threshold probably originated from the results of a 1972 study that correlated platelet

counts with bleeding times.[253] Critical appraisal of 1083 human studies concluded that the bleeding time is not a reliable method of assessing the risk for bleeding in individual patients.[254] Coagulopathy is rare in women with preeclampsia with a platelet count exceeding 100,000/mm^3, and in the absence of other risk factors for coagulopathy, neuraxial anesthetic procedures are considered safe without further coagulation testing.[165]

Currently, many anesthesia providers agree that neuraxial procedures may be initiated in pregnant women without other risk factors if the platelet count is higher than 80,000/mm^3.[233,252] There is general consensus among anesthesia providers that a platelet count less than 50,000/mm^3 precludes the administration of neuraxial anesthesia. For women with a platelet count between 50,000 and 80,000/mm^3, the risks and benefits of neuraxial anesthesia must be weighed against the risks associated with general anesthesia for the individual patient if emergency cesarean delivery is required, including whether anatomic features of the patient's airway are favorable. A 2017 systematic review of retrospective case series of thrombocytopenic parturients receiving neuraxial techniques estimated the risk for epidural hematoma across a range of platelet counts (15 studies, 1524 women).[252] No epidural hematoma was reported in any of the case series. The authors concluded that the risk remains poorly defined in parturients with a platelet count less than 70,000/mm^3 due to the limited number of observations and the low absolute risk.[252]

Two additional considerations in the decision to initiate neuraxial analgesia in women with preeclampsia include the platelet count trend over time and any coexisting coagulopathy. In certain cases, the platelet count decreases rapidly and the nadir in the platelet count cannot be identified prospectively. If serial platelet counts are stable and remain in the normal range, platelet count measurement every 24 to 48 hours is adequate to monitor women undergoing expectant management of severe preeclampsia remote from term.[2,170] Once a decision is made to induce labor, platelet count determination at least every 6 hours will ensure that a timely measurement has been obtained at the time of request for neuraxial analgesia. If the platelet count is low (80,000 to 100,000/mm^3), early epidural catheter insertion is recommended in anticipation of worsening thrombocytopenia.

If the platelet count is less than 100,000/mm^3, other hemostatic abnormalities, including prolonged PT and aPTT and hypofibrinogenemia, may be present.[165] Further coagulation studies may be useful, particularly if risk factors for DIC are present (e.g., placental abruption, HELLP syndrome).[165] Thus, in the presence of thrombocytopenia or abnormal results of liver function tests, the PT and aPTT should be assessed before the initiation of neuraxial anesthesia.[255]

Viscoelastic monitors of coagulation may expedite decision-making about neuraxial block administration for women with preeclampsia-related hemostatic dysfunction. Although thromboelastography (TEG) has shown some promise in the assessment of coagulation status in pregnant patients with thrombocytopenia,[148] it has been criticized for its inability to diagnose specific coagulation defects, particularly impairment in primary hemostasis.[256] Platelet function analysis (PFA-100) appears to be more sensitive to coagulation dysfunction in women with severe preeclampsia.[150] However, with both TEG and PFA, the ability to predict the risk for epidural hematoma after the administration of neuraxial anesthesia is unproven and requires further study.[257]

The risk for **epidural hematoma** formation exists not only at the time of epidural catheter placement but also at the time of its removal. In patients with thrombocytopenia, the catheter should not be withdrawn from the epidural space until there is evidence of an acceptable (and increasing) platelet count. A platelet count of 75,000 to 80,000/mm^3 seems reasonable for epidural catheter removal. The platelet count in women with HELLP syndrome usually reaches a nadir on the second or third postpartum day and then gradually returns to the patient's normal baseline.

If the decision is made to proceed with a neuraxial technique when the platelet count is less than 100,000/mm^3, the following suggestions may help reduce the risk for epidural hematoma and its sequelae:

1. The **most skilled anesthesia provider** available should perform the neuraxial procedure to minimize the number of needle passes and subsequent bleeding.
2. **A single-shot spinal technique may be preferable to an epidural technique** (when appropriate) because of the smaller needle size, although supporting data are lacking.
3. **Use of a flexible wire–embedded epidural catheter, if available,** may reduce epidural vein trauma.[258]
4. The patient should be carefully monitored after delivery for **neurologic signs that may signal bleeding into the epidural space**.
5. **The platelet count should be checked for evidence of a return toward normal measurements (at least 75,000 to 80,000/mm^3) before removal of the epidural catheter.** Epidural vein trauma at the time of catheter discontinuation can result in epidural bleeding and perhaps epidural hematoma.
6. **Imaging studies and neurologic or neurosurgical consultation should be obtained immediately if there is any question of an epidural hematoma.**

Intravenous hydration. In the past, when high concentrations of local anesthetic solution (e.g., 0.25% to 0.5% bupivacaine) were administered during labor, intravenous crystalloid hydration preceded epidural local anesthetic administration to prevent or ameliorate hypotension. In contemporary practice, lower concentrations of local anesthetic solutions are used (e.g., 0.0625% to 0.125% bupivacaine in combination with an opioid), hypotension is less common, and fluid administration at the time of analgesia initiation is of less clinical importance. Furthermore, the rapid administration of a large bolus of intravenous fluid (preload) results in only a transient increase in central venous pressure and has little impact on the risk for hypotension.[259] The risk for maternal hypotension and FHR abnormalities after initiation of neuraxial analgesia may be reduced if fluid preload is administered to individuals with a narrow pulse pressure.[260] Careful

attention to intravenous fluid infusion rates is necessary in women with severe preeclampsia because of the increased risk for pulmonary edema in these patients; vasopressors should be used in preference to large fluid boluses to treat hypotension.

Treatment of hypotension. In a landmark study in which invasive hemodynamic monitoring was used during epidural analgesia in women with severe preeclampsia in labor, remarkable hemodynamic stability was observed.[261] Although the management of neuraxial labor analgesia–induced hypotension has not been formally studied, most clinicians treat hypotension with small bolus doses of phenylephrine or ephedrine. There is an often-expressed concern that women with severe preeclampsia may have an exaggerated response to vasopressors that might result in a sharp increase in blood pressure[262,263]; however, supportive data are lacking.[262,263] The anesthesia provider should initiate treatment with phenylephrine (25 to 50 µg) or ephedrine (5 to 10 mg), and assess maternal blood pressure response before administration of a larger dose. With careful titration, increased sensitivity to vasopressors is rarely a clinical problem.

Epinephrine. It has been suggested that local anesthetic solutions containing epinephrine (including the standard epinephrine-containing epidural test dose) should be avoided during the administration of epidural analgesia in women with preeclampsia. This concern arises from observations that preeclamptic women exhibit an increased sensitivity to vasopressors, including angiotensin II,[264,265] norepinephrine and epinephrine,[266,267] and a thromboxane A_2-mimetic agent.[268] In addition, clinical studies have demonstrated that smaller doses of ephedrine and phenylephrine are required to restore maternal blood pressure during spinal anesthesia in preeclamptic women compared with healthy women.[262,263,269,270] An early study employing invasive hemodynamic monitoring in healthy human volunteers showed that epidural administration of 20 mL of 2% lidocaine containing epinephrine 5 µg/mL was followed predominantly by systemic beta-adrenergic-agonist effects (increased heart rate, decreased systemic vascular resistance and blood pressure, and increased cardiac output).[271] One case report described a hypertensive crisis in a preeclamptic woman after the incremental administration of 30 mL of freshly mixed 2% lidocaine with epinephrine 5 µg/mL for planned cesarean delivery.[272] However, the onset and duration of hypertension were atypical, and a drug error could not be excluded. In contrast, several other case series have used the same solution without adverse effects in women with preeclampsia.[273]

No randomized controlled trials have assessed the effects of epidural epinephrine in women with severe preeclampsia. In the absence of malignant hypertension, epinephrine is unlikely to pose a significant risk for hypertensive crisis, given the absence of confirmed reports after decades of its use in obstetric anesthesia practice. Although not necessarily harmful for women with preeclampsia, the use of epinephrine in epidural test doses or analgesic solutions may not be particularly helpful. Patients who have received beta-adrenergic receptor antagonists (e.g., labetalol) do not demonstrate the typical tachycardia after intravascular administration of epinephrine.[274] This lack of response decreases the sensitivity of the epinephrine test dose to detect intravascular administration of local anesthetic solution, and alternative testing strategies to detect intravascular catheter location may be preferred (see Chapter 12).[275] The addition of epinephrine to local anesthetic solutions results in a modest local anesthetic–sparing effect, at best,[276] and increases the density of motor blockade.[277] Finally, consideration should be given to the consequences of an unintentional intravascular injection of an epinephrine-containing test dose in a patient with baseline hypertension. Given the available evidence, it seems prudent to avoid epinephrine during administration of labor epidural analgesia in women with preeclampsia with severe features.

Anesthesia for Cesarean Delivery

The administration of neuraxial anesthesia for cesarean delivery in women with preeclampsia does not differ greatly from the practice in healthy pregnant women (see Chapter 26). Hepatic dysfunction can result in reduced drug clearance but has little clinical impact on choice of anesthetic or analgesic agents.

The choice of local anesthetic agent, technical aspects of neuraxial anesthesia, and maintenance of anesthesia are not affected by the presence of preeclampsia. However, there are three special considerations in women with preeclampsia undergoing cesarean delivery: (1) choice of anesthetic technique, (2) technique for induction of general anesthesia, and (3) the interaction between magnesium sulfate and nondepolarizing muscle relaxants.

Neuraxial anesthesia. In the Seventh and Eighth Reports of the Confidential Enquiries into Maternal Deaths in the United Kingdom,[214,221] the leading cause of death in women with preeclampsia was **intracranial hemorrhage.** Disadvantages of general anesthesia in the presence of preeclampsia include the risk for intracranial hemorrhage from the hypertensive response to both tracheal intubation and extubation. In a study involving more than 300,000 women in Taiwan, general anesthesia for cesarean delivery in preeclamptic women was associated with a greater than twofold increase in the risk for stroke after adjusting for confounders compared with neuraxial anesthesia.[278] However, despite attempting to statistically correct for confounding variables, it is difficult to overlook the major limitation of this study—it was not a randomized trial. It is likely that patients with more severe and complicated disease received general anesthesia. Neuraxial anesthesia does avoid the possibility of difficult tracheal intubation secondary to airway edema. Therefore, neuraxial anesthesia is preferred whenever clinical circumstances permit its use.

The traditional view was that spinal anesthesia is relatively contraindicated in severe preeclampsia because of the possibility of marked hypotension as a result of the rapid onset of spinal anesthesia–induced sympathetic blockade. However, this concern is not supported by evidence. Wallace et al.[279] randomized 80 women with severe preeclampsia who required cesarean delivery to receive general, epidural, or

CSE anesthesia. There was no significant difference between the CSE and epidural anesthesia groups in maternal mean arterial pressure over time. Notably, the initial spinal dose in the CSE group (hyperbaric bupivacaine 11.25 mg) is a dose comparable to that often used for a single-shot spinal technique. Another small prospective study randomized women with severe preeclampsia to receive either spinal or epidural anesthesia, with similar results.[280] Hood and Curry[281] retrospectively reviewed cesarean delivery records for 138 women with severe preeclampsia who received either spinal or epidural anesthesia and found that the lowest mean blood pressure measurements did not differ between groups. Because of the retrospective study design, the possibility that the groups were dissimilar cannot be excluded (i.e., the anesthesia providers may have chosen to administer epidural anesthesia to more severely ill women). Nonetheless, the expected marked hypotension after spinal anesthesia did not occur.

In two prospective cohort studies of women undergoing cesarean delivery, Aya et al.[262,269] compared women who had severe preeclampsia with healthy pregnant women (both preterm and term) and found that the risk for significant hypotension (defined as requiring the administration of ephedrine) was significantly lower in the preeclampsia groups than in the healthy control groups. The authors speculated that the known increased vascular sensitivity to vasoconstrictors may explain the infrequent incidence of hypotension after spinal anesthesia and the ease with which mean arterial blood pressure can be restored to baseline with small doses of vasopressor.

In contrast, a randomized multicenter study[282] comparing the hemodynamic effects of spinal anesthesia with epidural anesthesia for cesarean delivery in women with severe preeclampsia found that significantly *more* women in the spinal anesthesia group experienced hypotension. However, the duration of hypotension was less than 1 minute in both groups and, although more ephedrine was used in the spinal group than in the epidural group, hypotension was easily treated in both groups. In addition, there was no significant difference in neonatal outcome between infants whose mothers received spinal anesthesia compared with those whose mothers received epidural anesthesia. Another study suggested that spinal anesthesia has little effect on cardiac output in severely preeclamptic women, and reduction in afterload was modest.[263] These data, taken together, suggest that the use of spinal anesthesia for cesarean delivery in women with severe preeclampsia is appropriate.

Epidural anesthesia for cesarean delivery is often initiated with 2% lidocaine. In contrast to the lack of benefit of epinephrine for epidural labor analgesia, its addition to lidocaine for cesarean delivery likely has a more favorable risk/benefit ratio. Epinephrine enhances the quality of epidural lidocaine anesthesia for surgery, and when giving a large dose of lidocaine, the addition of epinephrine likely reduces the risk of local anesthetic systemic toxicity (LAST).

Disruption of the endothelial glycocalyx by fluid loading before spinal anesthesia occurs even in healthy parturients, which may reduce its effectiveness in expanding intravascular volume.[283] The glycocalyx structure is altered in preeclampsia[284]; fluid loading may result in exaggerated effects on the endothelium. The assumption that these changes also occur in the pulmonary endothelial glycocalyx supports a restrictive fluid management strategy and preferential use of vasopressors in managing spinal hypotension in women with preeclampsia.

Two randomized trials have shown that neonatal acid-base status is independent of the choice to use ephedrine or phenylephrine, whether administered by prophylactic infusion[285] or used as a bolus[286] to treat spinal hypotension in women with preeclampsia. Another randomized trial concluded that the maternal stroke volume response to colloid preload was variable, and phenylephrine 50 µg was more effective than ephedrine 15 mg in restoring systemic vascular resistance after spinal anesthesia.[287] Therefore, in the absence of systolic heart failure, phenylephrine is preferred for the management of spinal hypotension during cesarean delivery in women with preeclampsia.

General anesthesia. General anesthesia is less desirable than neuraxial anesthesia because of (1) the possibility of difficult tracheal intubation secondary to airway edema and (2) the transient but severe hypertension that accompanies tracheal intubation and extubation. Nonetheless, there are situations in which general anesthesia is the best anesthetic option. Clinical indications include severe ongoing maternal hemorrhage, sustained fetal bradycardia with a reassuring maternal airway examination, and severe thrombocytopenia or other coagulopathy, or a combination of these indications. The platelet count can fall dramatically with rapidly progressive severe preeclampsia or HELLP syndrome and may mandate administration of general anesthesia. Major placental abruption, intrauterine fetal demise, and preeclampsia all increase the risk for DIC. However, placental abruption without maternal hemodynamic compromise or coagulation abnormalities is not an absolute contraindication to neuraxial anesthesia. The safe administration of general anesthesia in women with preeclampsia requires an advanced state of readiness and careful preparation.

Once the decision has been made to proceed with general anesthesia, the anesthesia provider faces three specific challenges: (1) the potential difficulty of securing the airway, (2) the hypertensive response to direct laryngoscopy and tracheal intubation, and (3) the effects of magnesium sulfate on neuromuscular transmission. A suggested technique for the administration of general anesthesia is outlined in Box 35.5.

Airway considerations. Before proceeding with general anesthesia, careful airway examination is mandatory. Airway edema may be present even with a relatively reassuring airway examination; thus, many anesthesia providers try to avoid emergency administration of general anesthesia if there is any suspicion of a difficult airway. Endotracheal tubes of various sizes, and difficult airway equipment should be immediately available (see Chapter 29). One of the dangers of repeated tracheal intubation attempts in the setting of preeclampsia is the risk for traumatic bleeding, which may make ventilation difficult or even impossible.

Given the potential for a difficult airway, use of video laryngoscopy should be considered. If tracheal intubation is not rapidly achieved, a supraglottic airway (SGA) should be placed.[288] The reduction in oropharyngeal cavity dimensions due to edema, or a bitten tongue in the setting of eclampsia,

BOX 35.5 A Suggested Technique for Administration of General Anesthesia in Women with Severe Preeclampsia

1. Place a radial arterial cannula for continuous blood pressure monitoring in women with severe hypertension.
2. Verify that smaller-sized endotracheal tubes and supraglottic airway devices are immediately available. Equipment needed for difficult airway management should also be immediately available.
3. Consider the administration of an H_2-receptor antagonist and metoclopramide IV between 30 and 60 minutes before induction of anesthesia.
4. Administer 0.3 M sodium citrate 30 mL PO immediately before induction of anesthesia.
5. Denitrogenate (3 minutes of tidal-volume breathing or 8 vital capacity breaths with an F_{IO_2} of 1.0 and a tight-fitting face mask).
6. Give labetalol (10-mg bolus doses) IV to titrate systolic blood pressure between 140/90 and 160/110 mm Hg before the induction of anesthesia.
7. Continue to monitor FHR during labetalol administration.
8. Consider alternative antihypertensive agents for patients who do not respond to labetalol (or those with a contraindication to labetalol) (see Table 35.4). A remifentanil bolus (0.5 μg/kg) is an effective adjunct.
9. Perform rapid-sequence induction with propofol 2.0 to 2.8 mg/kg and succinylcholine 1.0 to 1.5 mg/kg (avoid ketamine as an induction agent given its sympathomimetic properties). For patients with severe heart failure, titrate propofol carefully or use etomidate. Consider the administration of a bolus dose of labetalol, esmolol, remifentanil, or magnesium sulfate to blunt the hemodynamic response to laryngoscopy. For patients with heart failure, carefully titrate small doses of propofol or use etomidate for induction of anesthesia, and avoid beta-adrenergic blocking agents.
10. Maintain anesthesia with a volatile halogenated agent and 40% to 50% oxygen as required, together with 50% to 60% nitrous oxide, before delivery. After delivery, decrease the concentration of the volatile halogenated agent to prevent uterine atony, and administer an opioid. Consider giving a propofol infusion and/or a benzodiazepine if there is concern for awareness and recall.
11. Avoid giving additional muscle relaxants; if absolutely required, administer a small repeat dose of succinylcholine with a small dose of anticholinergic agent, or a *low dose* of a short-acting nondepolarizing muscle relaxant because of the exaggerated effect of this class of drug when co-administered with magnesium.
12. At the end of surgery, reverse neuromuscular blockade and consider the administration of labetalol 5 to 10 mg IV bolus, titrated to effect, to prevent hypertension during emergence and tracheal extubation.

requires consideration.[289] Guidelines for airway management in obstetric anesthesia provide a useful decision matrix to assess whether to wake the patient or continue the surgery using an SGA (see Chapter 29).[288] In the setting of preeclampsia, where maternal or fetal factors lend urgency to delivery, there may be compelling reasons to proceed with surgery. An awake fiberoptic tracheal intubation may be necessary to secure the airway in rare circumstances, but thrombocytopenia and/or airway edema can make this procedure complex. In rare circumstances, it may be prudent to have a surgeon immediately available to establish a surgical airway, if needed.

Hypertensive response to laryngoscopy. The hemodynamic instability associated with rapid-sequence induction and tracheal intubation presents a serious problem in women with severe preeclampsia. The transient but severe hypertension that may accompany tracheal intubation can result in cerebral hemorrhage or pulmonary edema, both potentially fatal complications. Invasive arterial blood pressure monitoring is required for patients with poorly controlled and severe hypertension, to monitor the effects of antihypertensive drugs administered before and after tracheal intubation, and to allow rapid detection of adverse hemodynamic responses to laryngoscopy. The goal of treatment is to reduce the arterial blood pressure to less than 160/110 mm Hg before the induction of general anesthesia, and to maintain the systolic blood pressure between 140 and 160 mm Hg and the diastolic blood pressure between 90 and 100 mm Hg throughout laryngoscopy and tracheal intubation.[175]

A 2014 narrative review discussed the pharmacology, efficacy, side effects, and the therapeutic range of beta-adrenergic receptor antagonists, opioids, vasodilators (e.g., sodium nitroprusside, nitroglycerin, hydralazine), and magnesium sulfate to blunt the hemodynamic response to laryngoscopy and tracheal intubation.[290] None of these agents are problem-free: maternal beta-adrenergic receptor blockade may be associated with fetal bradycardia or hypoglycemia,[180] nitrates may cause precipitous hypotension in volume-depleted patients, hydralazine has a delayed onset and a prolonged effect, and remifentanil may be associated with respiratory depression in the neonate.[291]

Many anesthesia providers consider **labetalol** to be the drug of choice for attenuating the hypertensive response to laryngoscopy in women with severe preeclampsia and preserved systolic function. Ramanathan et al.[292] compared intravenously administered labetalol with no treatment in a randomized study of preeclamptic women who received general anesthesia for cesarean delivery. Mean arterial blood pressure increased after tracheal intubation in both study groups, but the hypertensive response was significantly less pronounced in the labetalol group. Women in the control group also developed tachycardia (in response to laryngoscopy and tracheal intubation), which did not occur in the labetalol group. Labetalol can be administered using either a bolus technique or a continuous intravenous infusion, or both.

There is also evidence of safe short-term administration of **esmolol** in this setting. A randomized double-blind study of 80 hypertensive women presenting for cesarean delivery

demonstrated that intravenous esmolol—in doses as high as 2 mg/kg, carefully titrated—can be safely used to dampen the hemodynamic response to laryngoscopy and tracheal intubation, particularly if hypertension and tachycardia are present.[293]

The short-acting opioid **remifentanil** is rapidly metabolized by both the mother and neonate by nonspecific blood and tissue esterases and has been administered to preeclamptic women. A clear advantage of remifentanil compared with other opioids is the rapid onset and short duration of the drug; the limited duration of action should not interfere with the resumption of spontaneous ventilation if tracheal intubation is unsuccessful. Ngan Kee et al.[294] randomized 40 pregnant women without preeclampsia who required general anesthesia for cesarean delivery to receive either a one-time intravenous dose of remifentanil 1 μg/kg or saline immediately before induction of anesthesia. The primary outcome was the maximum increase in systolic blood pressure (compared with a baseline measurement). Administration of remifentanil significantly blunted the systolic blood pressure response. However, remifentanil crosses the placenta, and two neonates in the remifentanil group required naloxone administration for poor respiratory effort at birth. Park et al.[295] randomized 48 patients with severe preeclampsia to receive remifentanil 0.5 μg/kg or 1 μg/kg before tracheal intubation. Both doses prevented a hypertensive response, but three patients treated with the higher dose required ephedrine to treat hypotension. Apgar scores and umbilical cord blood gas measurements were comparable in both groups, but a significant number of neonates in each group required tracheal intubation. The lower remifentanil dose, 0.5 μg/kg, is therefore likely preferable.

A bolus dose of **magnesium sulfate** 30 to 40 mg/kg administered immediately after the induction agent, with or without alfentanil, has been found to suppress maternal catecholamine release and effectively obtund the hypertensive response to tracheal intubation in women with preeclampsia.[296–299] There were no maternal or neonatal adverse effects attributable to bolus magnesium, although caution is advised in women with renal insufficiency.

Sodium nitroprusside and nitroglycerin have been used in the past, but are seldom used in contemporary practice; the former can cause precipitous hypotension, and the hemodynamic effects of the latter are dependent on intravascular volume.

Effects of magnesium sulfate. Most women with severe preeclampsia will present to the operating room while receiving magnesium sulfate for seizure prophylaxis. The magnesium infusion should continue throughout surgery to minimize the risk for eclampsia.[2] The primary anesthetic considerations for women receiving magnesium sulfate is the interaction with nondepolarizing muscle relaxants. Magnesium sulfate, when appropriately administered, is generally a safe drug, but systems should be in place to avoid inadvertent infusion of large boluses of the drug. Although magnesium sulfate has been used for tocolysis, it is relatively ineffective, and uterine tone is unlikely to be altered significantly.[300]

Magnesium inhibits the presynaptic release of acetylcholine at the neuromuscular junction, decreases the sensitivity of the postsynaptic receptor to acetylcholine, and depresses the excitability of the muscle fiber membrane. Magnesium sulfate increases the potency and duration of vecuronium, rocuronium, and mivacurium.[301–303] Several case reports have described a requirement for overnight mechanical ventilation after administration of routine doses of vecuronium in women receiving magnesium sulfate.[304] Thus, if nondepolarizing muscle relaxants are used, they should be administered in very small doses. Interpretation of responses to peripheral nerve stimulation may be difficult in this setting. Many practitioners avoid the use of nondepolarizing neuromuscular blocking agents in women with preeclampsia because of concern regarding residual postoperative neuromuscular blockade.

Airway guidelines discuss the use of sugammadex for the reversal of neuromuscular blockade when rocuronium has been used for rapid-sequence induction. Studies in nonpregnant populations showed that peri-induction administration of magnesium sulfate 40 to 60 mg/kg did not delay reversal of neuromuscular blockade with sugammadex.[305,306] No cases of recurarization were observed. Although these studies did not address the patient with preeclampsia who is receiving magnesium, several case reports of magnesium use in women with severe preeclampsia support the contention that magnesium does not influence reversal with sugammadex.[307]

Even though succinylcholine mimics acetylcholine at the nerve terminal, the onset and duration of a single intubating dose is not prolonged when administered concurrently with a magnesium sulfate infusion[308]; a routine intubating dose of 1 to 1.5 mg/kg should be used during rapid-sequence induction of anesthesia.

Although some reports have suggested that coadministration of a calcium entry–blocking agent and magnesium may cause hypotension and/or neuromuscular blockade,[182–184,309] more recent information suggests that these medications can be used safely together.[184]

Postoperative analgesia. Multimodal options for postoperative analgesia are the same as for healthy pregnancies and include acetaminophen (paracetamol), nonsteroidal antiinflammatory drugs (NSAIDs), oral or intravenous opioids, neuraxial opioids (single injection), and continuous epidural infusion of analgesic agents. Many anesthesia providers prefer neuraxial opioid administration for postcesarean analgesia (see Chapter 27). For women whose postpartum hypertension persists longer than 1 day, the ACOG has suggested that NSAIDs be replaced by alternative analgesics, as these drugs may contribute to hypertension.[2] However, more recent data have called this recommendation into question.[310] In the rare case of a woman with continuing severe refractory hypertension, continuous epidural analgesia with a local anesthetic is an attractive option because of its blood pressure–modulating properties.

Regardless of the postoperative analgesic technique, all women should be carefully monitored for signs of respiratory depression, airway obstruction, and pulmonary edema.

Postpartum Management

The risks associated with severe preeclampsia do not end with delivery. Postpartum women are at significant risk for pulmonary edema, sustained hypertension, stroke, venous thromboembolism, airway obstruction, and seizures, and should receive close monitoring of oxygenation, blood pressure, fluid intake, and urinary output. In addition, severe preeclampsia, the HELLP syndrome, and eclampsia can present for the first time in the postpartum period, with delayed presentation as late as 4 weeks after delivery.[2] A study of almost 4000 women diagnosed with preeclampsia found that the incidence of postpartum onset of disease was 5.7%,[110] and hypertension is the leading indication for postpartum hospital readmission.[311]

The risk for **pulmonary edema** is also highest in the postpartum period. The resolution of preeclampsia usually occurs within 5 days of delivery and is heralded by a marked diuresis that follows mobilization of extracellular fluid and an increase in intravascular volume. As a consequence, women with severe preeclampsia, particularly those with early-onset disease, renal insufficiency, or pulmonary capillary leak, are at increased risk for development of postpartum pulmonary edema.[172]

In contrast with women with gestational hypertension, who typically become normotensive within 1 week of delivery, women with severe preeclampsia may have a longer duration of hypertension; the risk for **cerebrovascular accident** is highest during this time.[177,210,211,312] Given the increased risk for postpartum cerebrovascular accident, the ACOG recommends antihypertensive therapy in the postpartum period when systolic blood pressure persistently exceeds 150 mm Hg or diastolic blood pressure exceeds 100 mm Hg.[2] Antihypertensive therapy should be continued, started, or resumed for these women, and blood pressure should be closely monitored. For women in the postpartum period who develop new-onset hypertension associated with headache or other neurologic symptoms, or new-onset severe hypertension, a 24-hour course of magnesium sulfate administration may help prevent eclampsia or a cerebrovascular accident.[2]

Postpartum venous thromboembolism (VTE) is a leading cause of maternal mortality in pregnancy. Both cesarean delivery[313,314] and preeclampsia[313,315] are independent risk factors for postpartum VTE. Prophylaxis and treatment of VTE are discussed in Chapter 38.

Preeclampsia has been associated with increased upper airway resistance and an increased risk for obstructive sleep apnea.[316,317] A review of anesthesia-related maternal deaths in Michigan[318] described a series of postoperative and postpartum deaths attributed to **airway obstruction** or **hypoventilation,** including the death of one woman with severe preeclampsia and sleep-disordered breathing who likely experienced opioid-related respiratory depression while receiving patient-controlled intravenous analgesia after cesarean delivery. Such findings highlight the need for close monitoring and consistent vigilance in the postoperative care of women with severe preeclampsia—particularly those with generalized edema, known airway swelling, snoring, and obesity.

Long-Term Outcomes

Although usually asymptomatic, a significant proportion of women who had preeclampsia have persistent moderate to severe abnormalities of left ventricular function as demonstrated using echocardiography 1 year postpartum.[135] Women with a history of preeclampsia are at increased risk for chronic hypertension and cardiovascular disease, including ischemic heart disease, stroke, and diabetes, later in life,[58,60] and an earlier onset of cardiovascular disease than women with healthy pregnancies.[59,319] Risks for ischemic heart disease and stroke are elevated approximately twofold.[60] There may also be an increased risk for chronic renal failure.[320] In addition, there is evidence of a dose-response relationship between preeclampsia and cardiovascular disease. Women with severe and/or early-onset preeclampsia, and those whose pregnancies are complicated by both preeclampsia (the maternal syndrome) and fetal growth restriction (the fetal syndrome), are at higher risk than women with preeclampsia without severe features or gestational hypertension.[58] Women with preeclampsia in both their first and second pregnancies are at even greater risk for future ischemic heart disease.[319]

The mechanism of increased risk for cardiovascular disease in preeclampsia is unclear. It is possible that preeclampsia causes permanent damage to the endothelium and hastens the onset of cardiovascular disease. Women with a history of preeclampsia have persistent impairment of brachial artery endothelium-dependent vascular relaxation at 1 to 3 years after delivery compared with healthy control women.[321,322] In addition, preeclampsia and cardiovascular disease probably have a common pathogenesis because of shared risk factors. Common risk factors for preeclampsia and atherosclerosis include hypertension, obesity, insulin resistance, advanced age, hypercholesterolemia, and dyslipidemia.[60,323] Cigarette smoking is the notable exception in that it is an established risk factor for cardiovascular disease but is protective against preeclampsia.[66,67] Preeclampsia may be a cardiovascular risk marker in women with an underlying predisposition to vascular disease; the hemodynamic and metabolic stress of pregnancy causes the predisposition to manifest as preeclampsia. After pregnancy, women return to a normal state until the threshold for disease development is exceeded in later life.

Regardless of the mechanism of increased risk, these observations represent a potential opportunity for primary disease prevention and risk factor modification. In a 2004 multinational study, 90% of the risk for a first myocardial infarction was attributed to potentially modifiable risk factors.[324] Possible interventions include earlier cardiovascular disease screening and individual counseling regarding the importance of smoking cessation, regular exercise, and a diet low in saturated fat and high in antioxidants. It may also be beneficial for anesthesia providers to elicit a history of preeclampsia when conducting the preanesthesia evaluation for older women scheduled for nonobstetric surgery.

In contrast with the increased risk for cardiovascular disease, a history of preeclampsia has been associated with a

decreased risk for cancer. Several earlier studies have suggested that women who have been diagnosed with preeclampsia have a slightly lower risk for breast cancer in later life compared with other parous women.[325,326] However, a 2007 systematic review and meta-analysis of almost 200,000 women with a history of preeclampsia found no association between preeclampsia and future cancer risk.[60]

Evidence indicates that preeclampsia may also result in psychological sequelae. The experience of severe preeclampsia (particularly with early-onset disease and preterm delivery) reflects a serious complication that threatens the mother's life and the life of her child. In one study, approximately one-fourth of women developed posttraumatic stress disorder (PTSD) after early-onset preeclampsia.[327] This association may be mediated by the condition of the offspring after preterm delivery.[328–330] Further research is required to characterize women at risk for PTSD and to investigate strategies for PTSD prevention and intervention.

ECLAMPSIA

Eclampsia is defined as the new onset of seizures or unexplained coma during pregnancy or the postpartum period in a woman with signs and symptoms of preeclampsia and without a preexisting neurologic disorder.[331–334]

Epidemiology

Findings from population-based studies in the past two decades suggest that the incidence of eclampsia varies from 0.1 to 5.9 per 10,000 pregnancies in developed countries.[10,37,335–339] The variation in rates of eclampsia among studies likely reflects reporting differences among countries or differences in treatment for severe preeclampsia.[336,340] On average, studies have shown a decrease in the incidence of eclampsia in developed countries over time; this decrease is likely attributable to an increase in the use of magnesium for seizure prophylaxis,[336,338,339] or early initiation of antihypertensive therapy in combination with magnesium.[341]

Eclampsia can occur suddenly at any point in the puerperium; however, most seizures occur intrapartum or within the first 48 hours after delivery. Late eclampsia is defined as seizure onset from 48 hours after delivery to 4 weeks postpartum.[332,342] The majority of eclamptic women have evidence of severe preeclampsia, but in 10% to 15% of cases, hypertension is absent or modest and/or proteinuria is not detected.[342] Reported risks include young maternal age, nulliparity, multiple gestation, molar pregnancy, triploidy, preexisting hypertension, renal or cardiac disease, previous severe preeclampsia or eclampsia, nonimmune hydrops fetalis, and systemic lupus erythematosus.[339,343] Major maternal complications of eclampsia include pulmonary aspiration, pulmonary edema, cerebrovascular accident, cardiopulmonary arrest, venous thromboembolism, acute renal failure, and death.[334–336,339] Eclampsia is associated with a high perinatal death rate and has also been associated with placental abruption, severe fetal growth restriction, and extreme prematurity.[331,335,336,339]

Clinical Presentation and Diagnosis

Any of the pathophysiologic changes of preeclampsia can be present in eclampsia. About 80% of patients will have premonitory neurologic symptoms, the most common of which are headache and visual disturbances.[344] Other premonitory signs and symptoms can include photophobia, epigastric or right upper quadrant pain, hyperreflexia, and altered mental status[331,342]; these symptoms can occur before or after the onset of seizures.[331]

Seizures have an abrupt onset, typically beginning as facial twitching that is followed by a tonic phase that persists for 15 to 20 seconds. This phase progresses to a generalized clonic phase characterized by apnea, which lasts approximately 1 minute. Breathing generally resumes with a long stertorous inspiration, and the patient enters a postictal state with a variable period of coma. Cardiorespiratory arrest and pulmonary aspiration of gastric contents can complicate a seizure. Although the definitive diagnosis for eclampsia is a sudden seizure in a pregnant woman who has signs and symptoms of preeclampsia, a woman who lapses into coma without witnessed convulsions can also be classified as eclamptic.[331]

The mechanism of eclamptic seizures remains poorly understood.[333] It may involve a loss of the normal cerebral autoregulatory mechanism, resulting in hyperperfusion and leading to interstitial or vasogenic cerebral edema and decreased cerebral blood flow.[216,217,333] Neuroradiologic studies suggest that eclampsia might be a manifestation of PRES.[119,120]

Until proven otherwise, the occurrence of seizures during pregnancy should be considered eclampsia. Conditions simulating eclampsia include seizure disorder, stroke, hypertensive encephalopathy, ischemia or hypoxia, cerebral space–occupying lesion, systemic disease (e.g., systemic lupus erythematosus, sickle cell anemia), infection (e.g., meningitis, encephalitis), electrolyte and endocrine disturbances, PRES, vasculitis or angiopathy, cerebral venous thrombosis, amniotic fluid embolism, medications (withdrawal, substance use disorder), and organ failure.[331,332]

Obstetric Management

Immediate goals are to stop convulsions, establish a patent airway, and prevent major complications (e.g., hypoxemia, aspiration). Further obstetric management includes antihypertensive therapy, induction or augmentation of labor, and expeditious (preferably vaginal) delivery. Fetal bradycardia typically begins during or immediately after a seizure but does not mandate immediate delivery unless it is persistent.

Resuscitation and Seizure Control

During the seizure, oxygenation may prove impossible, but supplemental oxygen should be delivered by means of a face mask (Box 35.6). Attempts to insert an oral airway should be withheld until the seizure abates. As soon as breathing resumes, ventilation may be gently augmented with a bag-and-mask device. Pulse oximetry should be used to assess maternal

BOX 35.6 Eclampsia: The ABCs of Eclamptic Seizure Control

Airway
- Turn patient to the left side; apply jaw thrust.
- Attempt bag-and-mask ventilation (F_{IO_2} = 1.0).
- Insert oral airway if necessary.

Breathing
- Continue bag-and-mask ventilation (F_{IO_2} = 1.0).
- Apply pulse oximeter, and monitor Sp_{O_2}.

Circulation
- Secure intravenous access.
- Check blood pressure at frequent intervals.
- Monitor electrocardiogram.

Drugs
- Magnesium sulfate
  - 4 to 6 g IV over 20 min
  - 1 to 2 g/h IV for maintenance therapy
  - 2 to 4 g IV over 10 min for recurrent seizures
- Antihypertensive agents
  - Labetalol or hydralazine as needed to treat hypertension (see Table 35.4)

IV, Intravenously.

oxygenation. Blood pressure and the electrocardiogram should be monitored to identify hypertension, arrhythmia, or cardiac arrest. While initial resuscitation is under way, an assistant should establish intravenous access, which may be difficult in a combative postictal woman. Judicious sedation may be required to allow further treatment in some patients.

Magnesium sulfate is preferred to diazepam for the prevention of further seizures in eclampsia.[191,192] The administration of magnesium sulfate in eclamptic women is associated with significantly lower maternal death rates. An initial intravenous bolus of 4 to 6 g is administered, followed by an infusion at 1 to 2 g/h, assuming the patient has adequate renal function.[345] Recurrent convulsions should prompt administration of an additional bolus of 2 to 4 g, infused over 5 to 10 minutes.[345] The patient should be carefully monitored for signs of magnesium toxicity. Should there be recurrent uncontrolled seizures, small doses of midazolam or diazepam may be used to raise the seizure threshold.

Anesthetic Management

The preanesthetic management of an eclamptic woman parallels that of a patient with severe preeclampsia. Considerations[331,346] specific to the woman with eclampsia are as follows:

1. **Assessment of seizure control and neurologic function.** The possibility of increased intracranial pressure is not a cause for concern if the patient remains conscious, alert, and free of seizures. Persistent coma and localizing signs may indicate a major intracranial pathologic process that could affect anesthetic management.
2. **Maintenance of fluid balance.** Intake should be restricted to 75 to 100 mL/h to minimize the risk for exacerbating cerebral edema.
3. **Blood pressure control.** Antihypertensive therapy should be instituted if the systolic pressure is 160 mm Hg or higher, or if the diastolic pressure is 110 mm Hg or higher.
4. **Continuous pulse oximetry monitoring of maternal oxygen saturation.**
5. **Continuous FHR monitoring.**
6. **Laboratory investigations mimic those for preeclampsia.** Additionally, coagulation studies should be obtained regardless of the platelet count.

The anesthetic plan is tailored to each individual case. In stable eclamptic women (fully conscious, no recent seizures, treated with magnesium sulfate, and no organ failure), neuraxial analgesia/anesthesia can be considered. In a retrospective review of 66 South African women with stable eclampsia, Moodley et al.[347] found no difference in maternal and neonatal outcomes in women who received epidural anesthesia compared with general anesthesia for cesarean delivery. Another series describing spinal anesthesia in 12 stable eclamptic women reported only one episode of hypotension and no major complications.[348] Eclamptic seizures are likely associated with an increase in intracranial pressure. Should operative delivery be required in a woman with ongoing seizures, a technique similar to that used for neuroanesthesia in patients with increased intracranial pressure should be considered. Intravenous induction agents such as propofol[349] and thiopental will reduce the cerebral metabolic rate and cerebral blood flow, with a consequent decrease in cerebral blood volume and intracranial pressure. These agents are also effective in terminating seizures.[350] Because hyperventilation reduces cerebral blood flow without a reduction in cerebral metabolic rate, it should be employed with caution. Conversely, hypoventilation should be avoided because hypercarbia can lower the seizure threshold. To prevent further neurologic injury, blood pressure should be carefully controlled to maintain cerebral perfusion pressure (the difference between mean arterial pressure and intracranial pressure). Avoidance of hypoxemia, hyperthermia, and hyperglycemia is also important in avoiding an exacerbation of neurologic injury.[351] Mechanical ventilation should be continued after cesarean delivery in patients who have not recovered neurologically, and these patients should be monitored in an intensive care unit. Sedation during ventilation should include a sedative with some anticonvulsant activity. Although benzodiazepine infusions have often been used in this setting, recent evidence in the nonobstetric population suggests that nonbenzodiazepine options are associated with less drug accumulation, a shorter period of mechanical ventilation, and reduced hospital stay.[352] An infusion of propofol supplemented with judicious doses of an opioid is an acceptable alternative, carefully titrated to maintain adequate cerebral perfusion pressure in view of cerebral edema and raised intracranial pressure. If unconsciousness persists after discontinuation of sedation, further neurologic evaluation with electroencephalography and brain imaging to rule out persistent seizures and/or other underlying neurologic disorders should be performed.

Long-Term Outcomes

Neurologic abnormalities occurring in patients with eclampsia (e.g., cortical blindness, focal motor deficits, coma) do not usually result in permanent neurologic deficits.[331] However, studies suggest that formerly eclamptic women had significantly poorer neurocognitive function as well as an increase in visual impairment years after the index pregnancy, both of which may be attributable to permanent white matter changes caused by eclampsia.[353–355]

KEY POINTS

- Preeclampsia is a multisystem disorder of pregnancy characterized by a maternal syndrome with or without a fetal syndrome.
- Preeclampsia is a leading cause of maternal and perinatal morbidity and mortality worldwide, particularly in developing countries.
- Disease pathophysiology involves superficial placentation related to abnormal angiogenesis, leading to placental hypoxia and the release of soluble substances toxic to vascular endothelium.
- Management of preeclampsia is supportive, and delivery of the fetus and placenta is the only definitive cure.
- Antihypertensive drugs should be used when systolic blood pressure is 160 mm Hg or higher, or the diastolic blood pressure is 110 mm Hg or higher.
- Preeclampsia likely consists of more than one disease; early-onset disease (earlier than 34 weeks' gestation) carries a poorer prognosis than late-onset disease.
- Systemic disease manifestations result from widespread maternal vascular endothelial dysfunction.
- Complications of preeclampsia with severe features include severe refractory hypertension, cerebrovascular accident, pulmonary edema, placental abruption, renal failure, and the HELLP syndrome.
- Important hematologic changes in severe preeclampsia include the potential for thrombocytopenia and disseminated intravascular coagulation.
- There are no indications for invasive central hemodynamic monitoring unique to preeclampsia; indications are similar to those in other multisystem disorders such as severe sepsis or multisystem organ dysfunction.
- Preeclamptic women are at risk for airway edema. The anesthesia provider should anticipate the possibility of difficult airway management.
- The hypertensive response to direct laryngoscopy and tracheal intubation can cause intracranial hemorrhage in women with severe preeclampsia.
- Spinal anesthesia is acceptable for women with severe preeclampsia, especially as an alternative to general anesthesia for emergency cesarean delivery.
- The risks for pulmonary edema, cerebrovascular accident, and venous thromboembolism are increased in the postpartum period.
- Preeclampsia poses considerable long-term future cardiovascular risks in many women.

Infection

Melissa E. Bauer, DO, Catherine M. Albright, MD, Scott Segal, MD, MHCM, David J. Wlody, MD

CHAPTER OUTLINE

FEVER

Definition and Pathophysiology

In 1868, Carl Wunderlich analyzed more than 1 million axillary temperature measurements from 25,000 patients.[1] He concluded that the average normal temperature of healthy adults was 37°C (98.6°F). However, he found a range of temperatures, with a nadir of 36.2°C between 2:00 and 8:00 AM and a zenith of 37.5°C between 4:00 and 9:00 PM. A 1992 study using modern oral thermometers largely confirmed Wunderlich's original data.[2]

Well-regulated temperature results from hypothalamic integration of afferent thermal information from the skin, spinal cord, and other sites within the central nervous system (CNS). Hypothermia prompts vasoconstriction in peripheral tissues to decrease skin blood flow, decrease heat loss, and retain heat in the core compartment. If vasoconstriction is not adequate to prevent hypothermia, thermoregulatory shivering is triggered to increase heat production. Increased body temperature initially prompts vasodilation. It is mediated by the sympathetic nervous system, and it is observed in unanesthetized adults exposed to a hot environment before any significant change in central temperature occurs. If vasodilation is not adequate to prevent hyperthermia, thermoregulatory sweating occurs, which increases evaporative heat loss.

An abnormal body temperature can result from drugs or diseases that either change thermoregulatory thresholds or impair thermoregulatory responses. Hypothalamic activity and fever may be triggered by endogenous pyrogens released from immune effector cells in response to invasion by microorganisms (Fig. 36.1). Although no single endogenous pyrogen has been conclusively identified as the mediator of the febrile response, tumor necrosis factor seems capable of reproducing many components of the febrile response.[3] Endogenous pyrogen activity appears to depend largely on increased endothelial cell production of prostaglandins. Of interest, many of these substances help mediate uterine activity and parturition.[4]

Clinically, temperature measurements greater than 38°C represent fever. During episodes of fever, the thermoregulatory set point is elevated, and the normal thermoregulatory mechanisms are used to maintain the elevated temperature. However, there are circumstances in which an abnormally

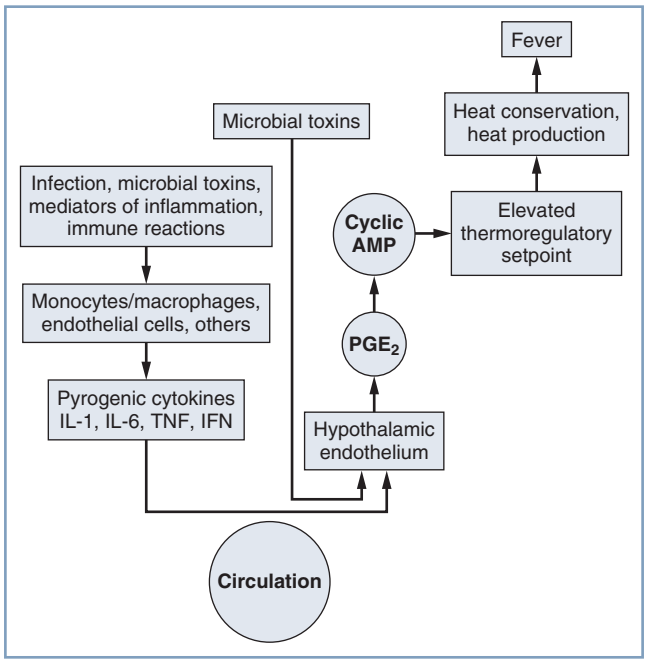

Fig. 36.1 Chronology of events required for induction of fever. *AMP,* adenosine-5′-monophosphate; *IFN,* interferon; *IL,* interleukin; *TNF,* tumor necrosis factor; *PGE_2,* prostaglandin E_2. high temperature is measured in the absence of a change in thermoregulatory set point, such as when thermoregulatory responses to hyperthermia are prevented (e.g., block of sympathetically mediated sweating) or overwhelmed (e.g., immersion in hot water, malignant hyperthermia).

The fetus, by virtue of its intraabdominal location, has a unique problem with heat elimination. The only anatomic routes for egress of heat are the fetal skin surface (through the amniotic fluid) or the uteroplacental circulation. Evidence suggests that the fetus relies on heat exchange across the uteroplacental circulation to dissipate most of its metabolic heat. The normal fetus maintains a temperature that is approximately 0.5°C to 0.75°C higher than the maternal temperature.[5,6]

Neonatal Effects of Maternal Fever

Infection is the most common cause of fever and involves liberation of inflammatory cytokines, which are implicated in the pathogenesis of many fetal and neonatal injuries (see Chapter 10).[7,8] The mechanism linking neonatal neurologic injuries to maternal fever likely involves the inflammatory cytokines.[7–9] Animal models of chorioamnionitis suggest that fetal brain lesions can be induced by infection and blocked by antiinflammatory cytokines.[10] Infants developing neonatal encephalopathy in the setting of maternal fever do not generally exhibit positive blood cultures, implying that it is neuroinflammation, rather than infection, that causes damage.[11,12] Fever alone has a limited effect, but when combined with acidosis, inflammation, and/or infection, it appears to exacerbate neurologic injury.[13]

Early studies suggested that mild maternal intrapartum fever may not be benign. These studies focused only on the presence or absence of fever, and did not specifically comment on a clinical or pathologic diagnosis of chorioamnionitis. Macaulay et al.[6] measured fetal scalp temperature *in utero* using a modified intrauterine pressure catheter. They concluded that maternal oral temperature is often an underestimation of fetal skin temperature. Lieberman et al.[14] retrospectively reviewed the records of 1218 nulliparous women with singleton, term pregnancies in spontaneous labor who were afebrile on admission. They found fever (greater than 38°C) in 10% of the patients, nearly all of whom had received epidural analgesia. One-minute Apgar scores less than 7 and hypotonia were more common in the newborns of febrile mothers. Fever higher than 38.3°C was associated with more frequent requirement for bag-and-mask ventilation in the delivery room and need for supplemental oxygen in the nursery. There was also an increase in the incidence of neonatal seizures.[14] The same group performed a case-control study of unexplained neonatal seizures in term infants and found a strong association with intrapartum fever and seizures (odds ratio [OR], 3.4).[15] Perlman[16] reported a high incidence of maternal fever among a cohort of infants with a 5-minute Apgar score less than or equal to 5 and those requiring resuscitation with chest compressions in the delivery room. Similarly, Greenwell et al.[17] found an association between low-grade fever and adverse neonatal outcomes, including hypotonia and low 1-minute Apgar scores. More extreme fever (greater than 38.3°C) was also associated with low 5-minute Apgar scores and assisted ventilation.[17] Lastly, a statistically significant association has been observed between maternal fever and neonatal encephalopathy.[11]

Hyperthermia

Hot tub and sauna use in pregnancy have been linked epidemiologically to neural tube defects in the fetus.[18] Spontaneous abortion[19] and major structural birth defects[20] have similarly been associated with the frequency of use of hot tubs and saunas. Neonatal hypoxic encephalopathy has been observed after prolonged immersion in 39.7°C water during otherwise uncomplicated labor.[21]

Noninfectious Inflammatory Fever

Neuraxial labor analgesia is associated with intrapartum fever (so-called "epidural fever"). The predominant theory is that noninfectious inflammation is responsible for epidural analgesia–associated fever (see Chapter 23). The incidence of fever in parturients with neuraxial analgesia ranges from 20% to 30% compared with 5% to 7% in parturients without neuraxial analgesia.[22] Why some women with neuraxial analgesia develop fever, but others do not, is not understood. It is not known whether epidural fever is associated with an increased risk for adverse maternal and fetal outcomes.

Fever Secondary to Infection

Maternal fever from chorioamnionitis that leads to neonatal infection is associated with both short- and long-term

neonatal morbidity. In an observational evaluation of women with clinical chorioamnionitis, there was a higher incidence of prolonged positive-pressure ventilation in the delivery room, tracheal intubation, admission to a neonatal intensive care unit, and 5-minute Apgar score less than 6 in febrile versus afebrile newborns.[23] Additional acute neonatal morbidity associated with chorioamnionitis includes neonatal pneumonia, meningitis, sepsis, and death.[24] Importantly, the use of intrapartum antibiotic therapy given in response to maternal Group B streptococcal colonization or in response to signs of chorioamnionitis has significantly decreased the incidence of neonatal infection and sepsis.[25–29] Clinical or pathologically diagnosed chorioamnionitis may also correlate with neonatal brain injury. In several large epidemiologic studies, there was an increased incidence of cerebral palsy in infants born to mothers with intrapartum fever (greater than 38°C) diagnosed with chorioamnionitis compared with those born to afebrile mothers.[9,30,31]

Maternal Effects of Fever

Fever also produces significant maternal effects. Elevated temperature is associated with increased maternal heart rate, cardiac output, oxygen consumption, and catecholamine production. Women who develop fever are more likely to shiver and experience uncomfortable rigors.[32,33] Not surprisingly, obstetricians fearing infection are more likely to treat febrile women with antibiotics.[34,35] While suspected chorioamnionitis in the setting of maternal fever is not an indication for immediate delivery,[24] low-grade fever may prompt obstetricians to choose instrumental vaginal or cesarean delivery over expectant labor management.[36]

INFECTIONS IN PREGNANT WOMEN

Chorioamnionitis (Intrauterine Inflammation and/or Infection)

In January 2015, an expert panel was convened by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) to review the criteria for diagnosis and management of chorioamnionitis.[37] They proposed that the phrase "intrauterine inflammation, infection, or both" (abbreviated "Triple I") be used instead of the term "chorioamnionitis" because of the diverse range of conditions, both infectious and inflammatory, that it was used to describe. Triple I can be diagnosed when fever (diagnosed as maternal temperature greater than or equal to 39.0°C on one reading or greater than or equal to 38.0°C on two occasions separated by 30 minutes) is present with one or more of the following: (1) fetal tachycardia (greater than 160 bpm for 10 minutes or longer), (2) maternal white blood cell count greater than $15{,}000 \times 10^6$ cells/L in the absence of corticosteroids, (3) purulent fluid from the cervical os (cloudy or yellowish thick discharge confirmed visually on speculum examination to be coming from the cervical canal), and (4) biochemical or microbiologic amniotic fluid results consistent with microbial invasion of the amniotic cavity. It is stressed that maternal fever in the absence of other criteria should be categorized as "isolated maternal fever."[37] The new nomenclature of "intrauterine inflammation, infection, or both" (Triple-I) is in the process of being incorporated into practice to replace the term "clinical chorioamnionitis."

Previously, the diagnosis of chorioamnionitis was made when any combination of the following elements was noted: maternal fever, maternal or fetal tachycardia or both, elevated maternal white blood cell count, uterine tenderness, and purulent fluid or discharge from the cervical os.[37] Using this definition, it occurs with variable frequency in the literature with reported event rates ranging from 0.5% to 10%, depending on the means of ascertainment and the demographic and obstetric characteristics of the population. It may be seen in over 90% of deliveries before 24 weeks' gestation, in almost 40% of women who deliver between 25 and 28 weeks, and in approximately 5% of deliveries at term.[38] Independent risk factors include low parity, a history of chorioamnionitis in a prior delivery, the number of vaginal examinations, duration of total labor, duration of ruptured membranes, and use of internal monitors.[39,40] Unfortunately, the laboratory diagnosis of chorioamnionitis is neither sensitive nor specific and may not correlate with the clinical presentation.[41,42] Moreover, the classic clinical signs of chorioamnionitis are often absent. Goodman et al.[41] reviewed the records of 531 women with pathologically proven chorioamnionitis. They found that only 10% of the patients had abdominal tenderness and only 1% had foul-smelling amniotic fluid.

In most cases, bacteria gain access to the amniotic cavity and the fetus by ascending through the cervix after rupture of the membranes. Alternatively, infectious agents present in the maternal circulation may undergo transplacental transport and gain access to the amniotic cavity.[43] Similar to other pelvic infections, chorioamnionitis often is polymicrobial in origin, and bacteria normally present in the genital tract most likely are responsible for infections. *Bacteroides* species, Group B streptococci, *Mycoplasma* and *Ureaplasma* species, and *Escherichia coli* are organisms commonly isolated from the amniotic fluid of parturients with chorioamnionitis.[43,44] Maternal bacteremia occurs in 5% to 12% of women with the clinical diagnosis of chorioamnionitis.[41,45–47]

Maternal complications of chorioamnionitis include preterm labor,[48] placental abruption,[49] postpartum infection,[50] uterine atony,[51] postpartum hemorrhage,[52] peripartum hysterectomy,[53] adult respiratory distress syndrome, sepsis, intensive care unit (ICU) admission, and death.[37] In addition, several studies have noted an increased incidence of cesarean delivery for dystocia in women with chorioamnionitis.[52,54,55] Some investigators have suggested that infection adversely affects uterine contractility and contributes to an increased risk for cesarean delivery.[56] However, in some cases, chorioamnionitis may represent an ascending infection developing late in a labor that is already prolonged and dysfunctional.[54]

Neonatal complications of chorioamnionitis include pneumonia, meningitis, sepsis, and death.[43,45] An association between chorioamnionitis and cerebral palsy has been identified.[9,30,31,57,58] A recent meta-analysis also found an association with chorioamnionitis and cerebral palsy, but the association

was much weaker than in previous meta-analyses. Once the studies were separated for analysis by gestational age, exclusion of studies without evaluation of postnatal causes of cerebral palsy, and potential sources of bias and confounding, the relative risk was much lower than in previous analyses.[31,59,60] The link between maternal infection and neurologic injury in the neonate appears related to intra-amniotic infection or inflammation, particularly when there is evidence of fetal systemic inflammation or inflammation of the umbilical cord (funisitis).[9,57]

Historically, prompt delivery was the cornerstone of obstetric management of patients with chorioamnionitis. However, Gibbs et al.[45] did not identify a correlation between poor maternal or neonatal outcome and the time interval from diagnosis of chorioamnionitis to delivery. They performed cesarean delivery only for standard obstetric indications and not for the diagnosis of chorioamnionitis alone.[45] Similarly, a large prospective observational study found no relationship between the duration of infection and most measures of adverse neonatal outcome among 1965 gestations complicated by chorioamnionitis, although low 5-minute Apgar scores and neonatal mechanical ventilation were correlated with duration of chorioamnionitis.[55] No recent studies have reinvestigated this practice as it relates to neonatal neurologic injuries. Many fetuses will exhibit tachycardia during maternal fever and infection, but this pattern is not highly predictive of neonatal acidemia and, therefore, by itself, is not an indication for immediate delivery.[61]

Early antepartum treatment for chorioamnionitis results in decreased maternal and neonatal morbidity compared with delayed postpartum treatment.[24,62,63] With chorioamnionitis, a combination of **ampicillin** and **gentamicin** should cover most relevant pathogens and is the recommended primary antibiotic regimen.[24] The early use of antibiotics also may affect the anesthesia provider's decision regarding the administration of neuraxial labor analgesia or anesthesia (see later discussion). If a cesarean delivery is performed, additional anaerobic coverage with **clindamycin** or **metronidazole** may decrease the risk for endometritis.[24] Continuation of antimicrobial agents postpartum should not be automatic, but rather based on risk factors for postpartum endometritis. In general, women who have a vaginal delivery are less likely to develop postpartum endometritis, and therefore may be candidates for discontinuing antimicrobial therapy after delivery. Even in women undergoing cesarean delivery, studies have shown only preoperative or one single postoperative dose appears to have the same efficacy as continuing antibiotics for a longer duration.[24,64–66]

Urologic Infection

Urinary tract infections are common during pregnancy, although the incidence of asymptomatic bacteriuria may not be higher than in nonpregnant women. Increased concentrations of progesterone cause the relaxation of ureteral smooth muscle. In addition, the gravid uterus causes partial ureteral obstruction. Both factors cause urinary stasis, which increases the risk for urinary tract infection.[43,67,68] Furthermore, these physiologic changes increase the likelihood that asymptomatic bladder infection will ascend into the kidneys and produce pyelonephritis. Approximately 1.3% of pregnant women will develop symptomatic cystitis,[69] and up to 25% of women with untreated bacteriuria in pregnancy may develop pyelonephritis.[70]

Acute pyelonephritis is a serious threat to maternal and fetal well-being and complicates approximately 1% to 2.5% of pregnancies.[43] Symptoms of acute pyelonephritis include fever, chills, flank pain, and other symptoms of lower urinary tract infection. Approximately 14% to 17% of pregnant women with pyelonephritis will develop bacteremia during the course of this infection.[71,72] Complications may also include anemia, renal insufficiency, and respiratory insufficiency.[72] The most common causative organisms are *E. coli,* gram-positive organisms, *Klebsiella, Enterobacter,* and *Proteus* species.[72]

Hospitalization is indicated to initiate aggressive parenteral antibiotic treatment of this serious maternal infection, although limited data support outpatient treatment for carefully selected patients in the first and second trimester.[73] Nevertheless, treatment failures and septic complications have been reported in patients randomized to outpatient therapy in clinical trials.[74]

Pyelonephritis may be associated with organ dysfunction. Nearly 20% of affected women have transient renal dysfunction,[75] and the disease may also be complicated by pulmonary injury. Cunningham et al.[76] suggested that "this syndrome was probably caused by permeability pulmonary edema, likely mediated by endotoxin-induced alveolar-capillary membrane injury."[76] Towers et al.[77] compared 11 pregnant women who had pyelonephritis and pulmonary injury with 119 women who had pyelonephritis only. They observed that fluid overload and the use of tocolytic therapy were the most significant predictive factors associated with pulmonary injury. The authors suggested that "strict management of fluids should occur so that patients do not have fluid overload."[77] Contemporary authors, however, have questioned fluid restriction in pyelonephritis and instead suggest fluid administration sufficient to generate urine output of 30 to 50 mL/h, while observing respiratory rate, oxygen saturation, and symptoms of dyspnea to identify impending respiratory compromise. Respiratory failure should be investigated with chest radiography and arterial blood gas analysis and managed with appropriate respiratory support.[43]

Respiratory Tract Infection

Pregnancy results in a number of changes that may predispose the pregnant woman to the development of serious respiratory tract infection. Hyperemia and hypersecretion are characteristic of the respiratory tract mucosa during pregnancy, and these changes may intensify the effect of the initial infection.[78] In the case of a viral infection, the excess secretions may predispose the patient to bacterial superinfection. Immunologic modulation during pregnancy may also predispose to pulmonary infection.[79] Furthermore, the increased oxygen consumption, elevation of the diaphragm, and decreased functional residual capacity characteristic of

pregnancy may increase the likelihood that infection will result in maternal hypoxemia.

Fortunately, most respiratory tract infections during pregnancy are upper respiratory tract viral infections that do not pose a serious threat to the mother or fetus. Most lower respiratory tract infections are also viral and self-limiting; pneumonia occurs during pregnancy with an incidence approximating that of the nonpregnant population.[80]

Benedetti et al.[81] emphasized the importance of early diagnosis and treatment as well as the direct measurement of maternal oxygenation in cases of pneumonia during pregnancy. Most community-acquired pneumonias in healthy young women are bacterial in origin. *Streptococcus pneumoniae* is the most common pathogen.[81] *Mycoplasma pneumoniae* and influenza are other common pathogens. *Legionella pneumophila, Chlamydia,* and varicella are less common pathogens in this population. Varicella pneumonia has been associated with maternal and fetal morbidity and up to 40% maternal mortality. **Acyclovir** has been used successfully to treat varicella pneumonia during pregnancy.[82]

Because morbidity and mortality from influenza are increased in pregnancy, influenza vaccination is strongly recommended for pregnant women or those who will be pregnant during influenza season.[83] Notably, pregnant women are disproportionately represented when evaluating mortality from influenza, and a significant number of women were treated with extracorporeal membrane oxygenation (ECMO).[84,85] In the Confidential Enquiries into Maternal Deaths and Morbidity in the United Kingdom and Ireland 2009 to 2012 report, of the women who died, one in eleven died from influenza and more than one-half of the deaths could have been prevented by vaccination.[86] The risk for fetal death is increased by maternal influenza infection and is reduced by vaccination.[87] The infant is also passively protected for up to 20 weeks after birth.[88] Aggressive treatment with antiviral drugs **(oseltamivir, zanamivir)** reduces the severity of the ensuing illness; in the 2009 to 2010 H1N1 influenza pandemic, initiation of therapy in the first 2 days of the infection reduced hospitalization and ICU admission; however, benefits have also been seen if antiviral drugs were started up to 4 days after onset of symptoms.[84,89] Antiviral drugs appear to be safe in pregnancy, with no reported increase in adverse pregnancy or neonatal outcomes.[90,91]

The Centers for Disease Control and Prevention (CDC) recommends the following: "droplet precautions should be implemented for patients with suspected or confirmed influenza for 7 days after illness onset or until 24 hours after the resolution of fever and respiratory symptoms, whichever is longer, while a patient is in a healthcare facility." It is also recommended that health care providers wear a fitted N95 respirator or its equivalent when performing aerosol-generating procedures (e.g., tracheal intubation and extubation).[92]

Postpartum and Surgical Site Infection

The most common source of postpartum infection is the **genital tract.** The urinary tract and less often the breasts or the lungs may also be infected.[43] Postpartum uterine infection typically presents with a combination of fever, malaise, abdominal pain, and/or purulent discharge or lochia. Although obstetricians typically refer to postpartum uterine infection as *endometritis,* this infection involves the decidua, myometrium, and parametrial tissues. Bacteria that colonize the cervix and vagina gain access to the amniotic fluid during labor, and they may invade devitalized uterine tissue postpartum. Surgical site infection (SSI), defined by the CDC as infection related to an operative procedure that occurs at or near the surgical incision within 30 days of the procedure,[93] is another increasingly common postpartum infection.

Cesarean delivery, prolonged rupture of membranes, and prolonged duration of labor are risk factors for postpartum endometritis.[43] Similarly, risk factors for surgical site infection following cesarean delivery include patient-level factors such as obesity, prior cesarean delivery, hypertension, diabetes, and tobacco use; pregnancy-related factors such as emergency delivery, labor or rupture of membranes, and chorioamnionitis; and surgical factors such as operative time and surgeon experience.[94] Prophylactic administration of antibiotics decreases the incidence of postpartum uterine infection and wound infection after cesarean delivery in all women, whether performed electively or emergently.[95]

Antibiotic prophylaxis should be administered 15 to 60 minutes before skin incision for cesarean delivery[96] unless the patient is already receiving appropriate antibiotic coverage (e.g., for chorioamnionitis). A first-generation cephalosporin is effective against gram-positive bacteria, gram-negative bacteria, and some anaerobic bacteria, and is the first-line antibiotic for cesarean delivery prophylaxis. In women with a history of a significant penicillin or cephalosporin allergy, clindamycin with an aminoglycoside is an appropriate alternative.[97] Extended-spectrum antibiotics, such as azithromycin, used in addition to first-generation cephalosporins for cesarean delivery prophylaxis, have been shown to reduce rates of endometritis and wound infection in women undergoing nonelective cesarean delivery during labor or after membrane rupture.[98]

A single intravenous dose of **cefazolin** is appropriate for most women undergoing cesarean delivery, as a therapeutic level is maintained for 3 to 4 hours. However, obese women may require a higher dose, although the specific appropriate dose has yet to be identified.[97,99–101] Consistent with surgical prophylaxis principles, patients with prolonged surgical procedures or those with significant blood loss should receive an additional intraoperative dose of the antibiotic used for preincision prophylaxis.[102]

No important differences have been identified among various skin preparation solutions used before cesarean delivery.[103] Vaginal preparation before cesarean delivery has been evaluated in a meta-analysis of 16 trials.[104] These trials demonstrate an overall reduction in postcesarean endometritis, especially for women in labor or with ruptured membranes. More data are needed to evaluate the effect of this intervention on women not in labor or with intact membranes. A meta-analysis evaluating the effect of bundles of at least three evidence-based interventions (such as antibiotic prophylaxis

selection or dose, hair removal with clippers, and chlorhexidine skin preparation) showed a significant reduction in surgical site infection rates with a reduction in risk of 67%.[105]

Systematic reviews have found insufficient evidence to recommend prophylactic antibiotics for operative vaginal delivery or for manual removal of the placenta after vaginal delivery; however, consideration may be given to prophylactic antibiotics in the setting of complex perineal repairs.[96,106–108]

Parenteral, broad-spectrum antibiotic therapy with a combination of **gentamicin** and **clindamycin** is recommended to treat postpartum endometritis. Ampicillin is added in refractory cases and often in cases in which the patient was colonized with Group B streptococcus before delivery.[109]

Endometritis typically responds to the above antibiotic therapy, and outcomes are generally excellent. However, serious complications (e.g., peritonitis, abscess, septic thrombophlebitis) may rarely occur.[110,111]

SEPSIS AND SEPTIC SHOCK

Definition

In 2016, the definitions for sepsis and septic shock were updated. Sepsis is defined by the Society of Critical Care Medicine and the European Society of Intensive Care Medicine as life-threatening organ dysfunction caused by a dysregulated host response to infection.[112] The term "severe sepsis" is no longer used because of redundancy. **Septic shock** is defined as a subset of sepsis in which profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk for mortality than with sepsis alone.[112]

Sepsis remains an important cause of maternal mortality and morbidity. In the United States between 2006 and 2013, infection accounted for 13% of all maternal deaths, with a cause-specific mortality ratio of 2.2 deaths per 100,000 live births.[113,114] In a population-based study of sepsis in delivery hospitalizations, Bauer et al.[110] reported the most common infections were pneumonia, genitourinary infection, and chorioamnionitis. Although only 40.4% reported a specific organism, the most common organisms were *E. coli,* staphylococcus, streptococcus, and gram-negative organisms. Independent risk factors of congestive heart failure, chronic liver disease, chronic renal disease, cerclage, and retained products of conception were identified; however, the authors noted that sepsis often occurs in the absence of risk factors, and screening tools should be developed to enhance detection in pregnant women.[110]

In the United Kingdom and Ireland, sepsis was the reported cause of death in almost 25% of all maternal deaths in the Confidential Enquiries into Maternal Deaths and Morbidity 2009 to 2012 report owing to the large increase in maternal deaths from an H1N1 influenza epidemic.[86] The most recent 2013 to 2015 report demonstrated a cause-specific mortality ratio of 0.6 per 100,000.[115] In a United Kingdom case-control study, Acosta et al.[116] reported the most common sources of infection were genital tract infection in 31.0% of cases, followed by urinary tract infection in 19.7% of cases. The most common organisms identified were *E. coli,* Group A streptococcus, and Group B streptococcus. No organism was identified in 36.2% of cases. Most cases of a Group A streptococcal infection were diagnosed with severe sepsis (using the previous definition) less than 9 hours from the first sign of the systemic inflammatory response syndrome (SIRS); one-half had less than 2 hours between first signs and diagnosis.[116]

Screening and Diagnosis

Given the importance of early identification and treatment, prompt recognition is key. Clinically, sepsis is now defined as the combination of infection with end-organ injury. If end-organ injury is suspected, it is essential to screen for infection. If a patient has a suspected infection, it is essential to monitor closely for end-organ injury. Serial bedside evaluation is desirable to detect trends in vital signs and clinical status and to more rapidly assess and reassess for signs of sepsis.[112]

Several **screening tools** exist to help in the identification of end-organ injury. Organ dysfunction is characterized by a score of greater than or equal to 2 points on the Sequential (Sepsis-related) Organ Failure Assessment (SOFA) score (Table 36.1).[112] Bedside screening for end-organ injury can be accomplished using an abbreviated set of criteria called quick SOFA (qSOFA). A nonobstetric patient screens positive with two or more of the following criteria: respiratory rate greater than or equal to 22 breaths/min, altered mentation, and systolic blood pressure less than or equal to 100 mm Hg.[112] Previous diagnostic criteria using two or more abnormal values of the SIRS criteria were nonspecific; patients with noninfectious inflammatory processes exhibit these signs, including healthy pregnant women.[117]

It is not known how either SOFA or qSOFA will perform in the identification of sepsis in pregnant women. Parameters have not been adjusted for pregnancy; many healthy pregnant women have a systolic blood pressure less than or equal to 100 mm Hg and a respiratory rate greater than or equal to 22 breaths/min, especially during labor. Altered mentation is rare in pregnant women, even in the setting of severe disease, and can be considered a more specific sign of end-organ injury and sepsis in the presence of infection. Maternal Early Warning (MEW) criteria were proposed by the National Partnership for Maternal Safety as a set of criteria to identify impending maternal morbidity from a variety of causes (Table 36.2).[118] In a case series study of maternal deaths caused by sepsis in Michigan by Bauer et al.,[119] 75% of patients met MEW criteria at the time of admission. The authors found that deaths were preceded by delays in recognition, administration of appropriate antibiotics, and escalation of care.[119] Future research will help to determine the best screening tool to identify sepsis. Given the rarity of maternal sepsis, it seems prudent to use a screening tool to assess multiple types of morbidity at once rather than using a separate tool for each. It is recommended that if a patient meets any of the MEW criteria, she should receive prompt evaluation by a physician or other practitioner with ability to escalate care. A diagnosis of pulmonary, genital tract, or other systemic infection should prompt close monitoring for end-organ injury, and therefore sepsis.

TABLE 36.1 Sepsis-Related Organ Failure Assessment Score (SOFA)

SOFA Score	1	2	3	4
Respiration				
PaO_2/FiO_2, mm Hg	< 400	< 300	< 200 with respiratory support	< 100 with respiratory support
Coagulation				
Platelets, $\times 10^3/mm^3$	< 150	< 100	< 50	< 20
Liver				
Bilirubin, mg/dL (μmol/L)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	> 12.0 (> 204)
Cardiovascular				
Hypotension	MAP < 70 mm Hg	Dopamine ≤ 5 or dobutamine (any dose)[a]	Dopamine 6–15, epinephrine ≤ 0.1, or norepinephrine ≤ 0.1[a]	Dopamine > 15 or epinephrine > 0.1 or norepinephrine > 0.1[a]

The Sepsis in Obstetrics Score (SOS) may be useful for assessing the severity of illness, and to identify women requiring ICU admission (Table 36.3). In a retrospective cohort of 850 women with clinical suspicion of sepsis, an SOS score of greater than or equal to 6 was independently associated with ICU admission.[120] A prospective validation study confirmed the threshold score of 6, making it the first score derived and validated in an obstetric population. The specificity of the score was 88%, but the sensitivity was only 64%. Additionally, given the low incidence of ICU admission, the negative predictive value of the score was excellent (98.6%), but the positive predictive value was poor (15%). It did not perform statistically better than other validated sepsis scoring systems.[121] A screening tool that consistently facilitates rapid diagnosis of sepsis in pregnancy is therefore still an unmet need.

Initial Treatment

Once diagnosis has been established, prompt **treatment** is paramount. There is an increase in mortality of 7.6% for each hour delay in appropriate antibiotic administration in nonobstetric patients.[122] Care should be escalated to accommodate the resources and requirements to treat critically ill patients. Surviving Sepsis Campaign (SSC) Guidelines[123] were created to provide best practice guidelines in the management of sepsis based on available evidence, with strong recommendations worded as "recommended" and weak recommendations as "suggested." SSC *recommends* IV antibiotic administration as soon as possible, within 1 hour, for sepsis and septic shock. Microbiologic cultures are *recommended* before antibiotic administration as long as there is no substantial delay in antibiotic administration.[123] In a review of sepsis and septic shock in pregnancy by Barton and Sibai, the antibiotic regimen chosen should provide empiric coverage for the common obstetric infections and should include either a combination of **gentamycin, clindamycin,** and **penicillin** or a combination of **vancomycin** and **pipercillin/tazobactam**.[111] Within the first 3 hours it is *recommended* to give 30 mL/kg of IV crystalloid fluid to treat sepsis-induced hypotension. It is *recommended* to use an initial target mean arterial blood pressure (MAP) of 65 mm Hg with norepinephrine used as the first-line vasopressor, and it is *suggested* to add either vasopressin or epinephrine as a second agent (if needed) to achieve hemodynamic goals. It is *suggested* to provide active resuscitation to normalize lactate.[123] In the Confidential Enquiries into Maternal Deaths and Morbidity in the United Kingdom and Ireland 2009 to 2012 report, it was also recommended to consult with an infectious disease

specialist.[86] For a further discussion beyond initial management, see Chapter 54.

Although the effects of maternal therapy on the fetus should be considered, treatment of the mother has first priority. Fetal status is best optimized by meeting maternal treatment goals. For nonreassuring fetal heart rate patterns in the setting of maternal sepsis, fetal resuscitation *in utero* and maternal medical therapy are frequently successful in delaying delivery.[124] Nevertheless, in some cases, maternal sepsis may require delivery, even before the age of viability, particularly if chorioamnionitis is present. In a 2013 series of maternal admissions for sepsis, 40% of women diagnosed with severe sepsis and all with septic shock required delivery during the same hospitalization, most requiring emergent delivery for worsening maternal respiratory status.[125] Maternal sepsis also increases the risk for perinatal mortality, with stillbirth approaching 33% when maternal sepsis requires ICU admission.[125–128] A multidisciplinary team should consider the mother's response to initial therapeutic interventions; vasopressor, oxygen, and ventilatory requirements; and the gestational age and fetal well-being when considering the optimal timing and route of delivery.

NEURAXIAL ANESTHESIA IN THE FEBRILE OR INFECTED PATIENT

Clinicians have long suspected an association between the performance of dural puncture during a period of bacteremia and the subsequent development of meningitis. Some clinicians have feared that diagnostic lumbar puncture may cause meningitis rather than aid in its diagnosis. They reasoned that lumbar puncture may disrupt the rich venous plexus surrounding the spinal cord and allow the direct introduction of infected blood into the CNS by the needle. Alternatively, others have speculated that disruption of the dural barrier may permit hematogenous spread of infection into the CNS without direct vessel trauma. Administration of continuous epidural analgesia often results in blood vessel trauma, and it includes the introduction of a foreign body. Theoretically, this technique could produce a nidus for subsequent infection.

This section focuses on the additional risk for CNS infection in the setting of bacteremia. The epidemiology of iatrogenic meningitis or epidural abscess as well as the discussion of lapses in sterile technique contributing to CNS infection are discussed in Chapter 31.

Laboratory Studies

Carp and Bailey[129] performed a study to assess the risk for meningitis after the performance of dural puncture in bacteremic rodents. In this study, rats were made bacteremic by producing a flank abscess using *E. coli* bacteria. The bacteremia was similar in magnitude to that which occurs during the early phase of sepsis in humans. Cisternal dural puncture was performed after the onset of bacteremia. After 24 hours, the cisterna magna was drained surgically, and the cerebrospinal fluid (CSF) was cultured for evidence of meningitis. Of the 40 animals that underwent dural puncture during *E. coli* bacteremia, 12 developed meningitis. None of the 40 bacteremic animals *not* subjected to dural puncture developed meningitis. Furthermore, dural puncture did not result in infection in the 30 animals without bacteremia. Importantly, *none* of the 30 bacteremic animals given a dose of gentamicin 15 minutes before dural puncture developed meningitis.[129]

This study is consistent with earlier laboratory studies that observed the development of meningitis after the performance of dural puncture in bacteremic laboratory animals.[130,131] Although animal models of disease permit careful control of experimental conditions, these studies do not duplicate clinical conditions. Thus, there are limitations in the application of the rat study[129] to clinical practice. First, the level of bacteremia produced in the rats exceeded the transient, low-grade bacteremia that often occurs clinically. Second, although *E. coli* is a common cause of bacteremia in surgical and obstetric patients, it is an uncommon cause of meningitis. Third, the relative size of the dural tear produced by the 26-gauge needle used in this study is greater in rats than in humans. Fourth, the cisternal site of dural puncture is not used clinically. Fifth, spinal and epidural anesthesia involves the injection of local anesthetics, and these drugs appear to be bacteriostatic.[132] Finally, the investigators knew

the identity of the organism *(E. coli)* and also knew that it was susceptible to gentamicin.

In summary, this study suggests that high-grade bacteremia may increase the risk for meningitis after dural puncture. However, antibiotic therapy before dural puncture appears to reduce, if not eliminate, this risk.

Clinical Studies

At least six retrospective clinical studies have evaluated *diagnostic lumbar puncture* and the risk for meningitis.[133–138] (These studies did not evaluate the risk associated with neuraxial anesthesia or analgesia.) These reports provided conflicting conclusions regarding the risk for meningitis after the performance of dural puncture in bacteremic patients. Two studies suggested an association between dural puncture and meningitis.[133,136] However both studies had serious methodologic flaws. A study performed during an epidemic of meningitis reported five cases of meningitis with initial negative CSF cultures (with positive blood cultures) and subsequent bacterial meningitis after lumbar puncture. However, they did not evaluate a comparable control group who did not undergo lumbar puncture.[133] Teele et al.[136] reported an association between lumbar puncture and meningitis only in bacteremic children younger than 1 year of age. Although there is a theoretical risk that a lumbar puncture seeded the meninges at the time of placement, it is also possible in both studies that diagnostic lumbar puncture was performed early in the progression of the disease before the CSF provided diagnostic evidence of infection. The remaining four studies clearly did not support an association between dural puncture and meningitis.[134,135,137,138]

Undoubtedly some parturients are bacteremic during the administration of epidural or spinal anesthesia, given the frequency with which parturients develop fever and infection during labor. For example, Blanco et al.[139] found a 1% incidence of bacteremia in a random sample of patients on the labor ward. Other studies have noted an incidence of bacteremia ranging from 5% to 12% in parturients with chorioamnionitis.[41,45–47] Although bacteremia is common, epidural abscess and meningitis rarely present after neuraxial blockade, and no epidemiologic study has clearly established a causal relationship between the performance of dural puncture during bacteremia and the subsequent development of meningitis or an epidural abscess.[140]

Bader et al.[141] retrospectively observed no cases of CNS infection after the administration of epidural or spinal anesthesia for labor or cesarean delivery in 279 patients with chorioamnionitis. Only 43 of these 279 women received antibiotic therapy before the administration of neuraxial anesthesia. At least three women had positive blood cultures consistent with bacteremia, and none of these three women received antibiotics before the administration of anesthesia. Similarly, Goodman et al.[41] found no cases of meningitis or epidural abscess among 531 patients with chorioamnionitis (proven by culture or pathologic examination) who received epidural ($n = 517$) or spinal ($n = 14$) anesthesia. Eleven of 45 patients with fever before initiation of the neuraxial procedure, and 174 of 229 patients with preexisting leukocytosis, received no antibiotics before instrumentation of the epidural or subarachnoid space.

Together, these clinical studies (combined with evidence in nonfebrile women, presented in Chapter 31) suggest that meningitis and epidural abscess are rare complications of epidural or spinal anesthesia. Furthermore, bacteremia itself does not appear to increase the risk for CNS infection after the administration of neuraxial anesthesia. However, published studies of neuraxial anesthesia in patients with chorioamnionitis were small and retrospective. Given the infrequent occurrence of CNS infection among noninfected patients undergoing neuraxial anesthesia, none of these studies was sufficiently large to exclude the possibility that chorioamnionitis increases the risk for meningitis or epidural abscess. Moreover, the retrospective study design introduces the possibility of selection bias; anesthesia providers may have avoided neuraxial anesthesia in the sickest patients with chorioamnionitis.

Recommendations

The 2017 American Society of Anesthesiologists Practice Advisory for the Prevention, Diagnosis, and Management of Infectious Complications Associated with Neuraxial Techniques recommends performing a complete history, physical examination (including vital signs), and review of laboratory studies to identify patients at risk for infectious complications.[142] There is no specific laboratory parameter that precludes the use of neuraxial techniques. In pregnancy, C-reactive protein and erythrocyte sedimentation rate are elevated.[143,144] In a meta-analysis of more than 4500 healthy pregnant women, many women had a white blood cell count of greater than $12{,}000 \times 10^6$ cells/L in the absence of infection (Fig. 36.2).[117] These tests are unreliable to determine infection or severity of infection in pregnant women. We recommend evaluation of the patient's entire clinical picture to weigh the risks and benefits for performing a neuraxial technique. In our judgment, the anesthesia provider may safely administer spinal or epidural anesthesia to healthy patients at risk for low-grade bacteremia. Appropriate antibiotic therapy may lessen the risk for meningitis or epidural abscess in patients with established infection. Thus, it often is appropriate for the anesthesia provider to request the initiation of antibiotic therapy before administration of neuraxial blockade in accordance with the American Society of Anesthesiologists practice advisory.[142] Finally, although the choice of anesthesia must be individualized, it seems prudent to avoid spinal or epidural anesthesia in untreated patients with overt clinical signs of sepsis.

GENITAL HERPES INFECTION

Primary and Secondary Infection

Herpes simplex virus type 2 (HSV-2) causes locally recurring disease that is characterized by asymptomatic periods interrupted by episodes of viral reactivation from sites in the sensory ganglia, resulting in painful vesicular lesions on the

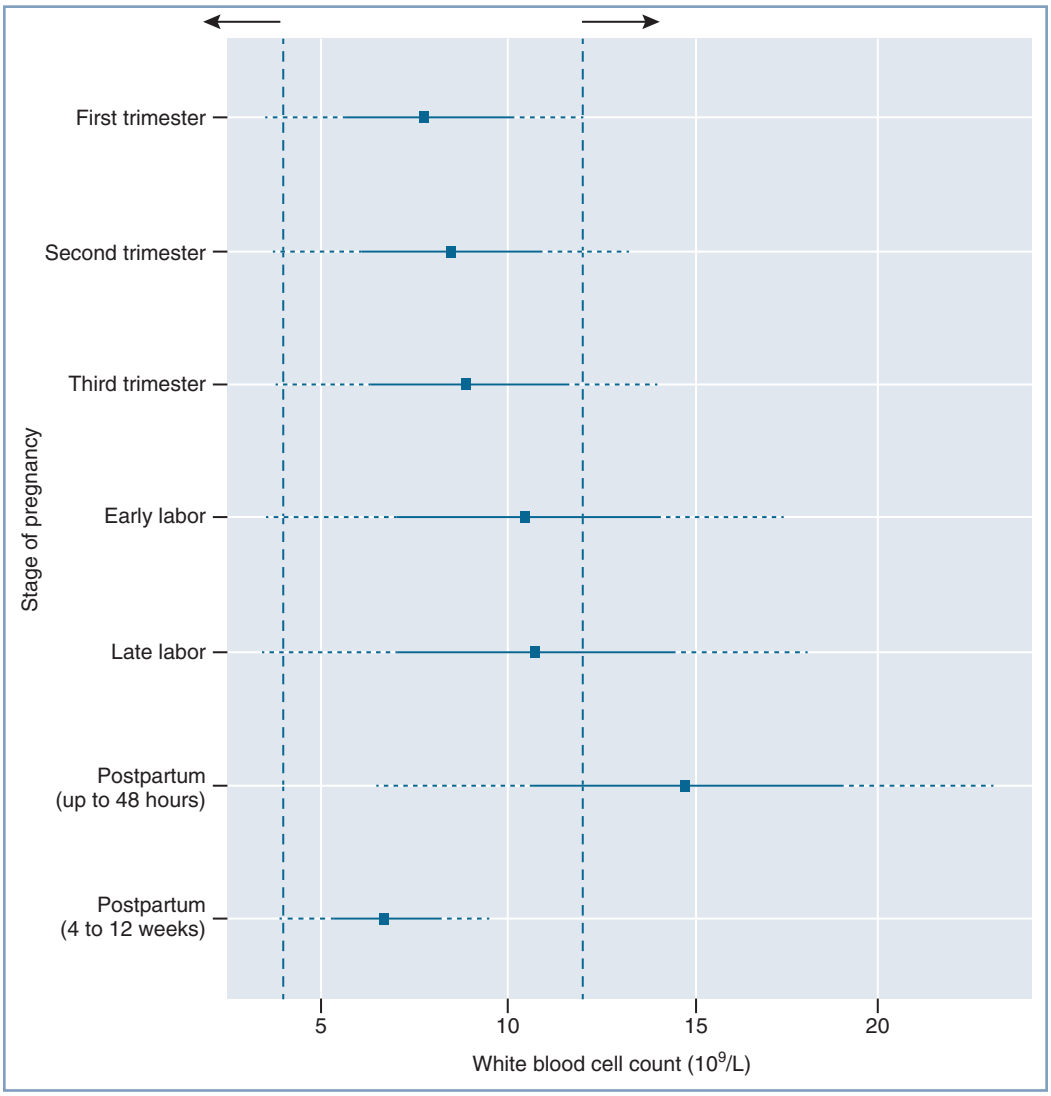

Fig. 36.2 Normal white blood cell count variation during pregnancy and postpartum. Mean is indicated by the center of each forest plot, 1 standard deviation (SD) is indicated by a solid line, and a dotted line indicates 2 SDs from the mean. Vertical dotted lines indicate systemic inflammatory response syndrome criteria. (From Bauer ME, Bauer ST, Rajala B, et al. Maternal physiologic parameters in relationship to systemic inflammatory response syndrome criteria. *Obstet Gynecol.* 2014;124:535–541.)

skin or mucous membranes of the genital tract or mouth.[145] **Primary maternal HSV-2 infection** is associated with transient viremia,[146] and up to 2% of pregnant women will be primarily infected during gestation.[145] Additionally, 10% of HSV-2 seronegative women are at risk for acquiring HSV-2 during pregnancy from a seropositive partner.[145] Epidemiologic evidence suggests that HSV-1, formerly associated only with perioral lesions (herpes labialis), is the predominant cause of new genital herpes infections in some populations.[147] Patients with primary infection may have systemic symptoms, including fever, headache, and lymphadenopathy, although asymptomatic primary infection is common. Hepatitis, aseptic meningitis, encephalitis, and cauda equina syndrome are uncommon complications of primary genital herpes infection. During **recurrent (i.e., secondary) infection,** maternal antibodies prevent the recurrence of viremia. Thus systemic symptoms are less severe—or do not occur at all—during episodes of recurrent infection. However, recurrent infection may result in severe symptoms localized to the site of the lesions on the external genitalia. Prodromal symptoms, including vulvar pain or burning, often precede development of recurrent lesions. Unfortunately, asymptomatic shedding of the virus also may occur in the genital tract.[145,146]

Interaction with Pregnancy

During the first 20 weeks of pregnancy, primary genital herpes infection may be associated with an increased risk for pregnancy loss,[148] although cohort studies have disputed the risk for fetal death.[149,150] The major obstetric concern is the potential for transmission of the virus to the infant at the time of birth. The infant may become infected in one of two ways: intrauterine infection can occur by ascent of the organism after rupture of membranes, or neonatal infection can occur as the fetus comes in direct contact with the virus during vaginal

delivery.[146] Neonatal HSV is a life-threatening infection with the potential for permanent CNS sequelae.[145,146,148,151]

Meta-analysis of seven randomized trials of antepartum antiviral therapy with **acyclovir** or **valacyclovir** demonstrated a reduction in the presence of active genital lesions at delivery (RR, 0.28) and requirement for cesarean delivery (RR, 0.30).[152] However, these trials could not demonstrate a reduction in neonatal herpes infection (there were no cases in any trial), and failure of suppressive therapy to prevent such transmission has been reported.[151]

Retrospective studies suggest that the risk for neonatal HSV infection associated with a primary maternal infection is much greater than that associated with recurrent maternal infection or asymptomatic viral shedding.[148,153–155] The risk for transmission is 30–60% in the setting of a primary HSV outbreak, 3% in the setting of active recurrent HSV, and 0.02% without genital lesions at the time of delivery.[145] Most likely there is a greater risk that the infant will be exposed to the virus during episodes of primary maternal infection; the lower incidence in cases of recurrent herpes is likely caused by passive transfer of antibodies to HSV from the mother to the fetus.[153]

Obstetric Management

A large epidemiologic study of 58,362 women provided direct evidence that cesarean delivery dramatically reduces the overall risk for HSV transmission to the neonate when HSV cultures of the cervix and external genitalia taken at the time of labor were positive (OR, 0.14).[153] Other risk factors for neonatal transmission included primary maternal HSV infection, use of invasive obstetric monitoring, and HSV-1 (compared with HSV-2) infection.[153]

The American College of Obstetricians and Gynecologists (ACOG) has reviewed the obstetric management of parturients with HSV infection and has concluded that cesarean delivery is indicated in women with active lesions or prodromal symptoms regardless of whether it is a primary or recurrent infection.[145] In the setting of an active HSV lesion and rupture of membranes near term, a cesarean delivery should be performed as soon as logistically feasible. There is no consensus regarding when the risk for HSV outweighs the risk for preterm delivery in the setting of preterm premature rupture of membranes[145]; however, in general, expectant management has become standard.

Anesthetic Management

There are at least five published retrospective studies of the use of neuraxial anesthesia in patients with genital HSV infection. These studies reported no serious neurologic sequelae related to the use of neuraxial anesthesia.[156–160] However, most of the patients in these studies had recurrent (secondary) infection. Two studies[157,158] were limited to patients with recurrent infection, a third report had a recurrent infection,[160] and a fourth report[156] did not indicate whether the patients had primary or recurrent infection. Bader et al.[159] reported outcomes for 169 women with genital herpes infection who underwent cesarean delivery. Five of the 169 women in this study had primary infections, and three of these women received spinal anesthesia. Of the three women, one had transient, postoperative weakness of the left leg. The authors[159] stated, "None of the cases of primary infection had associated systemic symptoms; it is therefore possible that some of these cases were actually misdiagnosed recurrent infections. The safety of regional anesthesia in patients with primary HSV infection remains unclear."

Viremia may accompany primary episodes of genital herpes infection. However, viremia rarely complicates recurrent episodes of genital herpes infection. It is unlikely that a spinal or epidural needle could introduce virus into the CNS in patients with recurrent genital herpes infection. Thus, a consensus exists that it is safe to administer spinal or epidural anesthesia to women with recurrent genital herpes infection and no systemic symptoms. There are insufficient data to allow a definitive recommendation regarding the safety of neuraxial anesthesia in patients with primary infection who may be viremic. If the anesthesia provider is confronted with a patient with primary infection, the theoretical risk for CNS infection should be weighed against the risks associated with alternative methods of analgesia and anesthesia.

Finally, several studies have suggested that spinal or epidural administration of morphine, commonly administered for postcesarean delivery analgesia, increases the incidence of **recurrence of oral HSV infection.** This phenomenon was confirmed in prospective randomized trials for both epidural[161] and intrathecal[162] morphine. The cause is unknown, but some investigators have speculated that pruritus and scratching play a role in reactivation of oral lesions. Boyle[163] concluded that facial pruritus is a marker of the migration of morphine to the trigeminal nucleus but not the cause of HSV recrudescence. He suggested that immunologic modulation by the opioid within this ganglion is the primary cause of the viral reactivation. Substantial evidence now supports this mechanism.[164] A case of HSV-1 meningitis after unintentional dural puncture and passage of an intrathecal catheter has been reported.[165] The patient underwent cesarean delivery with spinal bupivacaine, fentanyl, and morphine; the authors suggested that reactivation of HSV-1 caused by morphine, and the presence of the intrathecal catheter, may have contributed to the infection.[165] To our knowledge, there are no reports suggesting that epidural or intrathecal administration of opioids increases the risk for recurrent *genital* herpes infection. However, a possible case of postnatal transmission secondary to maternal reactivation of oral HSV from intrathecal morphine has been reported.[166]

HUMAN IMMUNODEFICIENCY VIRUS

Pathophysiology

Human immunodeficiency virus (HIV) is a member of the lentivirus subfamily of human retroviruses (i.e., it carries the enzyme reverse transcriptase). This enzyme converts the single-stranded viral RNA into double-stranded DNA, which subsequently can be integrated into the DNA of the infected

cell. This process is error prone, leading to rapid mutation of the virus, which significantly complicates drug therapy. Immune suppression is mainly caused by infection of helper T cells, $CD4^+$ monocytes, and macrophages.[167] Abnormalities of these elements of the immune system render the HIV patient vulnerable to bacterial, viral, fungal, parasitic, and mycobacterial infection. In addition, for reasons that are not entirely clear, patients infected with HIV are susceptible to several malignancies (e.g., Kaposi's sarcoma, B-cell lymphoma, invasive cervical carcinoma). Clinical manifestations can result from the HIV infection itself, opportunistic infection, secondary malignancy, or long-term exposure to antiretroviral therapy.

Clinical Manifestations

Neurologic involvement can occur at any time during HIV infection. Viral particles can be isolated from the cerebrospinal fluid (CSF) at the time of primary infection.[168] Patients with HIV infection typically have CSF abnormalities, including the local synthesis of HIV antibody and the presence of HIV particles or viral nucleic acid.[169] This is an important consideration when one is determining the risk for introducing virus into the CNS during the performance of neuraxial anesthesia in an asymptomatic patient. It is almost certain that CNS infection has already occurred.

The manifestations of nervous system involvement vary with the stage of the disease. During **initial systemic HIV infection,** a variety of CNS disorders may occur. Headache, photophobia, and retro-orbital pain are common, while more severe disorders such as cranial and peripheral neuropathies, demyelinating polyneuropathy, and aseptic meningoencephalitis have been reported.[170] The **late stages of HIV infection** are marked by significant neurologic deterioration in almost all patients caused by meningitis, encephalopathy, the AIDS dementia complex, or focal brain disorders. Underlying diagnoses include tuberculosis, *Cryptococcus,* metastatic lymphoma, cytomegalovirus (CMV), herpes simplex virus, toxoplasmosis, primary CNS lymphoma, and progressive multifocal leukoencephalopathy, an opportunistic viral infection that causes selective destruction of white matter tracts. Myelopathy, peripheral neuropathy, chronic pain, and autonomic neuropathy may also occur.[171] Finally, neurologic side effects such as headache and peripheral neuropathy of antiretroviral therapies also may occur. A baseline neurologic exam should be assessed and documented before performing neuraxial techniques.

Pulmonary Abnormalities

The pulmonary manifestations of HIV disease are caused not by a direct effect of the virus but, rather, by the opportunistic infections associated with the disease. The most prominent of these is *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii)*, a fungal organism.[172] Despite widespread exposure to the organism, symptomatic *Pneumocystis* pneumonia (PCP) is typically seen only in patients with severe immune suppression. Pneumonia is a leading cause of cause of death in HIV-infected pregnant women, with mortality as high as 50% for *Pneumocystis jiroveci* pneumonia.[173,174] The impairment of humoral immunity is responsible for a higher incidence of bacterial pneumonia caused by encapsulated organisms (e.g., *Streptococcus pneumoniae, Haemophilus influenzae*).[175] Finally, although less common than PCP, pneumonia secondary to other fungal organisms (e.g., *Aspergillus, Cryptococcus, Coccidioides*) is more common in patients infected with HIV than in the general population.[175] Reactivation of latent tuberculosis is common in patients with HIV infection; immunosuppression may also increase susceptibility to acquiring tuberculosis from an infectious individual.[176]

Gastrointestinal Abnormalities

Gastrointestinal disturbances occur at some time in almost all patients with HIV infection. Nausea and vomiting are common side effects of most antiretroviral medications. Painful or difficult swallowing is typically caused by herpetic, CMV, or candidal esophagitis; the contribution of these disorders to gastroesophageal reflux is unclear.[177] Severe diarrhea resulting from infection with CMV, HSV, *Shigella, Salmonella, Candida, Cryptosporidia, Giardia*, *Mycobacterium avium* complex (MAC), or HIV itself can lead to significant cachexia and electrolyte abnormalities. Finally, hepatobiliary disease may also occur. Causes of parenchymal liver disease include hepatitis B and C, CMV, mycobacterial infection (both *Mycobacterium tuberculosis* and MAC), and *Cryptococcus*.

Hematologic Abnormalities

HIV infection is associated with hematologic abnormalities that affect each of the peripheral cell lines.[178] **Leukopenia** is a hallmark of the disease, especially the depletion of $CD4^+$ lymphocytes; qualitative alterations in the functions of neutrophils and macrophages also occur. **Anemia** is also quite common. Causes include direct HIV infection of erythroid precursors, suppression of erythropoiesis caused by inappropriate release of tumor necrosis factor, infiltration of bone marrow with MAC or malignancy, and occult gastrointestinal blood loss.

Additionally, **coagulation disturbances** are often seen in patients with HIV. **Immune thrombocytopenia** is common and typically is only mildly symptomatic. The activated partial thromboplastin time may be prolonged because of the presence of the lupus anticoagulant; this finding is linked to a higher incidence of major thromboembolic events in HIV-infected patients. Finally, many of the antiretroviral agents and other drugs used in these patients have hematologic toxicity.

Cardiovascular Abnormalities

Clinically significant cardiovascular disease is rare in patients with HIV. Pericarditis or pericardial effusion have been reported to be the most prevalent cardiovascular disorders seen in HIV-infected patients.[179] The most common etiology appears to be mycobacterial infection; CMV, HSV, Kaposi's sarcoma, malignant lymphoma, and HIV itself have also been implicated.[180] Pulmonary hypertension can develop secondary

to repeated episodes of PCP and can also be a consequence of cytokine-mediated endothelial injury.[179] Direct myocardial involvement—typically, focal myocarditis—is identified in 15% to 50% of autopsy studies, but clinical myocarditis or cardiomyopathy is rare.[179] Infective endocarditis among patients with HIV occurs almost exclusively in intravenous drug users. Finally, the elevations in serum cholesterol and triglyceride concentrations produced by antiretroviral agents appear to increase the risk for coronary artery disease in patients receiving these drugs.[181]

Endocrine Abnormalities

Patients with AIDS frequently have abnormal thyroid function test results, similar to the findings in patients with other chronic illnesses, yet clinical hypothyroidism is unusual. Insulin resistance and diabetes are increasingly recognized as consequences of HIV infection and antiretroviral treatment.[182] There is a relatively high incidence of pathologic findings in the adrenal gland at autopsy, yet clinical evidence of glucocorticoid insufficiency is rare.

Renal Abnormalities

Patients with HIV are at risk for acute renal failure secondary to sepsis, dehydration, and drug toxicity.[183] A common cause of chronic renal insufficiency is proliferative glomerulonephritis secondary to deposition of immune complexes containing HIV antigen within the glomeruli. Renal failure may also occur because of HIV-associated nephropathy.[184] This entity, seen almost exclusively in patients of African descent, is characterized by a focal segmental glomerulosclerosis. Hypertension is uncommon, deterioration of renal function is extremely rapid, and the long-term prognosis is worse than that seen in renal failure from other causes. The underlying cause appears to be direct infection of renal cells by HIV. Antiretroviral therapy appears to modify the course of the disease.[184]

Interaction with Pregnancy

With the improvement in screening and treatment for HIV, the number of pregnancies in HIV-infected women is increasing.[185] The estimated number of births to all women living with HIV (diagnosed or undiagnosed) in the United States in 2006 was 8700 (95% CI, 8400 to 8800).[185] In the setting of opt-out HIV screening in pregnancy as well as risk-reducing strategies such as antiretroviral therapy (ART), scheduled cesarean delivery, and avoidance of breast-feeding, the number of perinatal transmissions of HIV in the United States has decreased from 216 (95% CI, 206 to 230) in 2002 to 69 (95 % CI, 60 to 83) in 2013, with perinatal HIV infections now estimated at 1.75 per 100,000 live births.[186,187]

Available data are mixed whether HIV infection increases the risk for adverse pregnancy outcomes (e.g., low birth weight, small for gestational age, and preterm delivery).[188,189] ART, especially protease inhibitor–based ART, may increase the risk for preterm delivery,[190–192] but does not appear to lead to low birth weight, small for gestational age, or stillbirth.[192,193] Likewise, no evidence suggests that pregnancy accelerates clinical deterioration in the HIV-infected patient or that the viral RNA load changes significantly during pregnancy.[188,194,195]

Obstetric Management

Antenatal testing for HIV is part of routine prenatal screening, ideally completed in the first trimester of pregnancy, or as early as possible during the pregnancy, using an opt-out approach.[196] Repeat HIV testing is recommended in the third trimester for patients at high risk for acquiring HIV infection. Women with undocumented HIV status should have rapid HIV testing upon presentation for delivery to guide appropriate treatment to prevent vertical transmission (Fig. 36.3).[196] For those diagnosed with HIV, serial plasma HIV RNA levels, $CD4^+$ T lymphocyte cell counts, and HIV drug-resistance assays are used to optimize antiretroviral therapy throughout pregnancy, and plasma HIV RNA levels repeated at 34 to 36 weeks' gestation are used to guide decisions about mode of delivery and treatment in the newborn.

Intrapartum Antiretroviral Therapy/Prophylaxis

Women should continue their antepartum ART drug regimen without interruption during labor and delivery to provide maximal virologic suppression and to minimize the chance of development of drug resistance.[192]

To minimize vertical transmission, IV **zidovudine** (AZT) should be administered as soon as possible upon arrival for delivery to HIV-infected women with a viral load that is high (HIV RNA greater than 1000 copies/mL) or unknown, with a goal of at least 3 hours of administration before delivery.[192,197] For women with an HIV RNA less than or equal to 1000 copies/mL but still with a detectable viral load (50 to 1000 copies/mL), IV AZT is not necessary, but may be considered, especially in cases of unclear compliance with medications or a recent increase in viral load.[192] Multiple studies have demonstrated that in the setting of virologic suppression (i.e., HIV RNA below 50 copies/mL), the addition of IV AZT did not provide additional protection against vertical transmission and therefore is not recommended.[198–201] Irrespective of viral load, the clinician may use intrapartum IV AZT based on clinical judgment.[192]

Mode of Delivery

For women with plasma HIV RNA greater than 1000 copies/mL near term, the ACOG recommends scheduled cesarean delivery at 38 weeks' gestation to reduce the risk for labor or rupture of membranes before delivery.[197] IV AZT administration (loading dose followed by infusion) should be started 3 hours before the scheduled cesarean delivery, allowing adequate time to reach equilibrium across the placenta, although cord blood zidovudine levels required to prevent perinatal transmission of HIV are currently unknown.[202] Similar to women delivering vaginally, if the viral load is less than or equal to 1000 copies/mL at the time of cesarean delivery (i.e., the cesarean is not for the indication of maternal HIV), IV AZT is not necessary, but may be considered[192] (see Fig. 36.3).

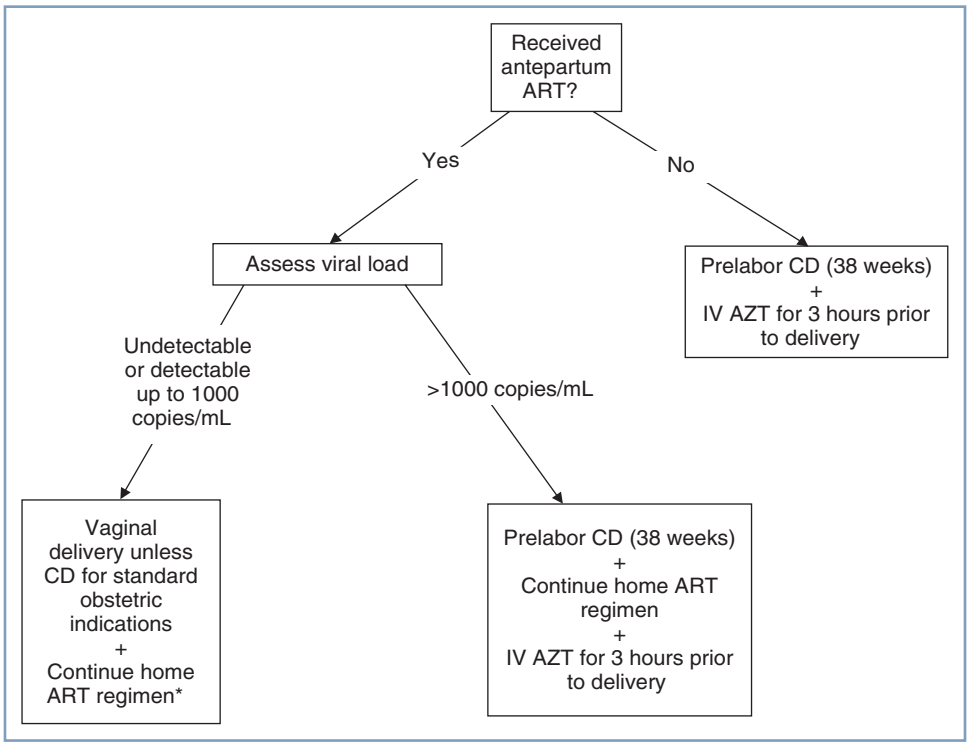

Fig. 36.3 Intrapartum management for HIV-infected pregnant women. *ART,* Antiretroviral therapy; *CD,* cesarean delivery; *IV,* intravenous; *AZT,* azidothymidine, also known as zidovudine. *IV AZT may be considered at the discretion of the provider.

After membrane rupture or onset of labor in women with a detectable viral load, the optimal strategies for zidovudine administration and mode of delivery are not established. There have been similar rates of vertical transmission reported for cesarean delivery performed for obstetric indications after labor and membrane rupture as for vaginal delivery; however, there appear to be increasing rates of transmission for every additional hour after membrane rupture.[203,204] It is unclear at what duration after onset of labor or the rupture of membranes that there is no longer a benefit to performing cesarean delivery.[199,205–207]

Additional Intrapartum and Postpartum Management Considerations

In the setting of antiretroviral therapy and an undetectable viral load, artificial rupture of membranes (AROM) is not associated with increased risk for perinatal transmission.[199,206] AROM should be avoided in women with detectable viral loads unless there is a strong clinical indication.

Invasive obstetric procedures (e.g. fetal scalp electrode, intrauterine pressure catheter, operative vaginal delivery, episiotomy) that increase the chance of fetal exposure to maternal blood may increase the risk for vertical transmission. While this risk has not been well studied in women receiving suppressive ART, obstetricians should avoid routine use of these procedures in women with HIV.[208–211]

Medical management of postpartum hemorrhage in the setting of uterine atony may need to be modified based on the ART regimen. Based on manufacturer recommendations, the use of methylergonovine maleate, which is a major substrate of cytochrome P (CYP) 450 3A4, should be avoided, if possible, in women receiving CYP450 3A4 enzyme inhibitors. CYP450 3A4 enzyme inhibitors include protease inhibitors (e.g., ritonavir, indinavir, nelfinavir), certain nonnucleoside reverse transcriptase inhibitors (e.g., delavirdine), and cobicistat. There have been reports of severe vasospasm leading to cerebral and extremity ischemia with concurrent use of ergot alkaloid drugs and CYP450 3A4 inhibitors.[212] Conversely, in women taking a CYP450 3A4 enzyme inducer (e.g., nevirapine, efavirenz, or etravirine), the efficacy of methylergonovine may be decreased.[212]

Finally, there is considerable evidence that breast-feeding may double the rate of perinatal transmission in women with established HIV infection.[213] Thus, breast-feeding should be discouraged unless bottle-feeding is not a safe alternative, as is true in many developing countries (see Chapter 14).

Anesthetic Management

Neuraxial Anesthesia

Whether HIV-infected pregnant women are prone to the occurrence of infection after administration of neuraxial anesthesia is an important concern. Hughes et al.[214] performed a study of 30 HIV-positive parturients, of whom 18 received neuraxial anesthesia and 12 did not. There was no evidence of accelerated disease progression in either group, and there were no neurologic or infectious complications in either group immediately after delivery and at 4 to 6 months postpartum.[214] A later study demonstrated no postoperative

changes in viral load or $CD4^+/CD8^+$ lymphocyte ratio and no increased hemodynamic instability or blood loss in HIV-infected patients undergoing elective cesarean delivery with spinal anesthesia.[215] The prevention of infectious complications of neuraxial anesthesia depends on strict aseptic technique, which should include handwashing with an alcohol-based antiseptic solution, removal of jewelry (e.g., rings, watches), and wearing sterile gloves, facemask, and hat (see Chapters 12 and 31). The CDC recommends that "universal blood and body-fluid precautions" should be used in the care of all patients including goggles when anticipating contact with blood or bodily fluids.[216,217] For cases of occupational exposure, please refer to the CDC guidelines for the management of health care worker exposures to HIV and recommendations for postexposure prophylaxis.[217,218]

Some physicians may question whether it is prudent to administer neuraxial anesthesia to a patient who could develop neurologic deficits at some time in the future and whether these deficits might be ascribed to the neuraxial anesthetic technique. Because such deficits are unlikely to be temporally related to the anesthesia, this does not seem to be a significant concern. Further, it seems cruel to deny the most effective intrapartum analgesic techniques to HIV-positive women simply because of fear of future litigation.

Despite the use of small-gauge, pencil-point spinal needles, and despite careful technique during administration of epidural anesthesia, post–dural puncture headache (PDPH) remains a problem in pregnant patients (see Chapter 30). Clearly, the onset of headache and photophobia in an immunosuppressed patient who has recently received a major neuraxial anesthetic can be worrisome, but the typical postural nature of a PDPH should allay fears of bacterial meningitis. Once the diagnosis of PDPH is made, conservative therapy and pharmacologic interventions may be used. However, the "gold standard" for treatment of PDPH is an autologous epidural blood patch. Some physicians have expressed concern that the introduction of HIV-infected blood into the neuraxis might lead to the introduction of HIV into a previously uninfected CNS.[219] Demonstration of subarachnoid extension of an epidural blood patch on magnetic resonance imaging heightens these concerns.[220] Even though CNS infection occurs quite early in the course of HIV disease, even in asymptomatic patients, it seems prudent to acknowledge the possibility that an epidural blood patch could accelerate the CNS manifestations of the disease. This question was addressed in a study of six seropositive patients who experienced PDPH after diagnostic lumbar puncture and who subsequently received an epidural blood patch.[221] These patients subsequently underwent serial neuropsychological testing for as long as 2 years. The investigators stated that "none of these six subjects had a decline in neurocognitive performance or other adverse neurologic or infectious sequelae" during the period of the study. Although these numbers are small and this study has never been repeated, it provides the best evidence to date of the safety of epidural blood patch in an HIV-infected patient.

General Anesthesia

As with neuraxial anesthesia, it is appropriate to ask whether patients with HIV might be more susceptible to the infectious (e.g., pulmonary) complications of general anesthesia. No published study has addressed this question. However, it seems appropriate to handle the endotracheal tube in as sterile a manner as possible and to minimize the duration of postoperative ventilation. Care should also be taken to maintain sterility of intravenous lines by using a stopcock for injections, placing caps when the stopcock is not in use, and not allowing the IV line to touch the floor.

Another question involves the effect of general anesthesia on immune function. Several published studies suggest that general anesthesia can transiently depress immune function, but this depression appears to be clinically insignificant in healthy patients.[222] It is appropriate to ask whether this effect might be exaggerated to the point of clinical significance in patients with HIV disease. Studies on this issue are lacking. At present, it would be inappropriate to recommend one anesthetic technique over another on the basis of their effects on immune function.[223]

EMERGING GLOBAL ILLNESS

Outbreaks such as the H1N1 influenza virus pandemic, the Zika virus in Brazil and surrounding areas, and the Ebola virus in West Africa have highlighted the vulnerability of pregnant women to epidemics of infectious disease.

Pregnant women have altered immunity, which leads to increased susceptibility for infectious diseases as well as increased risk for poor outcomes in the setting of infection. This was highlighted in the H1N1 pandemic, as noted earlier in this chapter. Additionally, infection or treatment or both can have teratogenetic effects. The possible teratogenic effect of infection itself was highlighted by the Zika virus pandemic and the association with fetal microcephaly.[224,225] And unfortunately, a review by Beigi[226] noted that in the recent Ebola outbreak, the high mortality rate in pregnancy may have been due in part to reluctance to care for pregnant women with Ebola. This reluctance may in part be from the knowledge that Ebola RNA has been isolated from amniotic fluid, cord blood, and the placenta, increasing the risk for health care worker infection at the time of delivery.[226,227] In times of infectious disease epidemics, pregnant women are frequently among the most vulnerable populations.

KEY POINTS

- Fever may be produced by endogenous pyrogens released from immune effector cells in response to infection.
- Maternal fever, with or without infection, may cause fetal neurologic injury.

- Pyelonephritis and chorioamnionitis are the antepartum infections most likely to result in maternal and perinatal morbidity and mortality.
- Normal physiologic changes in pregnancy make it challenging to diagnose sepsis.
- Septic shock is an uncommon but devastating complication of maternal infection that demands broad-spectrum antibiotic therapy, aggressive hemodynamic support, and in some cases, surgical intervention.
- The anesthesia provider may safely administer epidural or spinal analgesia or anesthesia to patients at risk for transient bacteremia or with an established infection, provided there is no evidence of frank sepsis. However, it seems prudent to begin antibiotic therapy before the administration of anesthesia in patients with established infection.
- Recurrent genital herpes infection does not contraindicate the administration of neuraxial anesthesia.
- Spinal and epidural morphine administration is associated with reactivation of oral herpes simplex virus.
- HIV infection eventually can be expected to involve every organ system. Central nervous system involvement occurs as early as the period of initial infection and seroconversion.
- Highly active antiretroviral therapy during pregnancy can significantly reduce the rate of vertical transmission of HIV infection to the fetus.
- Utilization of AZT as well as scheduled cesarean delivery can provide further protection against vertical transmission in women with greater than 1000 copies of viral RNA per mL of plasma, and AZT may be of benefit in women with lower viral loads as well.
- Neuraxial anesthesia and autologous blood patch are safe in the HIV-infected parturient.

Antepartum and Postpartum Hemorrhage

Jennifer M. Banayan, MD, Jennifer E. Hofer, MD, Barbara M. Scavone, MD

CHAPTER OUTLINE

Obstetric hemorrhage is the most common cause of maternal mortality worldwide, accounting for roughly 15% of maternal deaths.[1] The World Health Organization estimates that severe hemorrhage complicates 10.5% of live births globally and carries with it a case-fatality rate of 1%.[1] The rates of maternal death and death caused by hemorrhage vary widely throughout various regions of the world (see Chapter 39).[1] In the United States, hemorrhage accounts for 11.4% of pregnancy-related deaths (approximately 1.9 pregnancy-related deaths caused by hemorrhage per 100,000 live births).[2] Hemorrhage is the most common cause for admission of an obstetric patient to an intensive care unit and is a risk factor for myocardial ischemia and infarction, and stroke.[3-5] Organ dysfunction complicates 16% of cases of obstetric hemorrhage accompanied by transfusion of 5 or more units of packed red blood cells (PRBCs).[6]

Hemorrhage and severe morbidity caused by hemorrhage are increasing in the United States and other high-resource countries, primarily caused by increases in postpartum, rather than antepartum, hemorrhage.[7-10] The explanation for this acceleration is not entirely clear but appears to be related to rising rates of postpartum uterine atony as well as increases in abnormal placentation coincident with the rise in cesarean delivery rates.[7,8,11] The majority of hemorrhage-related adverse outcomes are considered preventable.[12]

MECHANISMS OF HEMOSTASIS

Uterine contraction, stimulated by endogenous oxytocic substances released after delivery, represents the primary mechanism for controlling blood loss at parturition. Uterine tetany creates shearing forces that cleave the placenta from the uterine wall through the layer of the uterine decidua (see Fig. 4.3). In addition, uterine contraction constricts the spiral arteries and placental veins spanning the myometrium and supplying the placental bed.

After disruption of vascular integrity, mechanisms of coagulation include (1) platelet aggregation and plug formation, (2) local vasoconstriction, (3) clot polymerization, and (4) fibrous tissue fortification of the clot. Platelet activation and aggregation occur rapidly after endothelial damage. Activated platelets release adenosine diphosphate, serotonin, catecholamines, and other factors that promote local vasoconstriction and hemostasis. These factors also activate the coagulation cascade. The end result of the cascade is conversion of fibrinogen to fibrin and stabilization of the blood clot (see Chapter 44).

ANTEPARTUM HEMORRHAGE

Antepartum vaginal bleeding may occur in as many as 25% of pregnant women; fortunately, only a fraction of these patients experience life-threatening hemorrhage.[13] The majority of cases occur during the first trimester. The causes of antepartum hemorrhage range from cervicitis to abnormalities in placentation, including placenta previa and placental abruption. The greatest threat of antepartum hemorrhage is not to the mother but to her fetus. Several decades ago, vaginal bleeding during the second and third trimesters was associated with perinatal mortality rates as high as 80%. More

recent data suggest that antepartum bleeding secondary to placenta previa and placental abruption results in far fewer neonatal deaths than previously reported.[14,15]

Placenta Previa

Placenta previa occurs when the placenta covers the cervix. In the past, classification was made on the basis of the relationship between the placenta and the cervical os, using terms such as *total, partial,* and *marginal.* With advances in transvaginal ultrasonography allowing for precise localization of the placental edge relative to the cervical os, these terms are being used less often. Instead, if any portion of the placenta overlies the os, it is referred to as a *previa,* and any placenta near the os is termed *low-lying.*[16,17]

Epidemiology

The incidence of placenta previa varies throughout the world but is estimated to be 1 in 200 pregnancies at term, corresponding to a prevalence of 4.0 per 1000 births.[18] The exact cause is unclear, but prior uterine trauma (e.g., scar from prior cesarean delivery) is a common finding. The placenta may implant in the scarred area, which typically includes the lower uterine segment. Conditions associated with placenta previa include multiparity, advanced maternal age, smoking history, male fetus, previous cesarean delivery or other uterine surgery, and previous placenta previa.[18,19] Asian-American women are at increased risk for placenta previa compared with white women in the United States.[20] The presence of placenta previa increases the likelihood of fetal anomalies, neurodevelopmental delay, sudden infant death syndrome, and the risk that the mother will require a peripartum hysterectomy.[14,21,22]

Diagnosis

Transvaginal ultrasonography is the "gold standard" for diagnosis of placenta previa. Routine assessment of the relationship between the placenta and cervix has nearly eliminated the need for double setup examination (i.e., vaginal examination with all clinicians prepared for immediate cesarean delivery).[17] Measuring the distance from the placental edge to the internal os predicts the likelihood of antepartum hemorrhage and need for cesarean delivery.[23,24] Magnetic resonance imaging (MRI) is also useful for the diagnosis of placenta previa, but its use is not practical in most cases of antepartum hemorrhage.

The classic clinical sign of placenta previa is painless vaginal bleeding during the second or third trimester. All parturients with painless vaginal bleeding after 20 weeks' gestation should be assumed to have placenta previa until proven otherwise. Digital or speculum examination should be avoided until ultrasonography excludes abnormal placentation. Placenta previa diagnosed in asymptomatic patients before the third trimester frequently resolves as pregnancy progresses. In fact, ninety percent of placentas identified as low lying in early pregnancy will normalize by the third trimester.[25] The lack of abdominal pain and/or absence of abnormal uterine tone helps distinguish placenta previa from placental abruption. The absence of these factors does not exclude abruption, however, and patients with placenta previa are at risk for coexisting placental abruption.

Obstetric Management

Obstetric management is based on the severity of vaginal bleeding and the maturity and status of the fetus. Active labor, persistent bleeding, a mature fetus (gestational age 36 weeks or greater), or nonreassuring fetal status should prompt delivery.[26] The fetus is at risk from two distinct pathophysiologic processes: (1) progressive or sudden placental separation that causes uteroplacental insufficiency and (2) preterm delivery and its sequelae. The first episode of bleeding characteristically stops spontaneously and rarely causes maternal shock or fetal compromise. Expectant management in the hospital has been shown to prolong pregnancy by an average of 4 weeks after the initial bleeding episode.[26] Maternal vital signs are assessed frequently, and the hemoglobin concentration is checked at regular intervals. Fetal evaluation involves frequent performance of a nonstress test or biophysical profile, and ultrasonographic assessment of fetal growth. Hemorrhage may be prevented by limitations on physical activity and avoidance of vaginal examinations and coitus, although the evidence supporting these measures is limited.

Outpatient management has resulted in good outcomes in carefully selected patients.[27] Outpatient management is reserved for stable patients without bleeding in the previous 48 hours who have both telephone access and the ability to be transported quickly to the hospital. Expectant management requires immediate access to a medical center with 24-hour obstetric and anesthesia coverage and a neonatal intensive care unit.[26]

In most cases of placenta previa diagnosed between 24 and 34 weeks' gestation, a corticosteroid (e.g., betamethasone) is administered to accelerate fetal lung maturity.[26] A significant number of patients with placenta previa have preterm labor, which may provoke bleeding. The use of tocolysis in women with placenta previa is controversial. Some obstetricians may administer tocolytic therapy to decrease preterm uterine contractions with the goal to stabilize antepartum bleeding. Ritodrine has been shown to prolong pregnancy in women with placenta previa, but no studies have confirmed any decrease in the frequency or severity of vaginal bleeding.[26,28] Obstetricians must balance the potential cardiovascular consequences of tocolytic therapy in the event of maternal hemorrhage against the consequences of preterm delivery. Tocolytic therapy is not recommended for patients with uncontrolled hemorrhage or those in whom placental abruption is suspected. Although expectant management reduces the risk for prematurity, it does not eliminate it from occurring.

Fetuses of women with placenta previa may be at risk for other complications, including fetal growth restriction (previously known as intrauterine growth restriction).[29] Several factors may account for the association between placenta previa and fetal growth restriction. First, the lower uterine segment may be less vascular than normal sites of placental

implantation. Second, the placenta often is adherent to an area of fibrosis tissue. Third, patients with placenta previa have a higher incidence of first-trimester bleeding, which may promote a partial placental separation, reducing the surface area for placental exchange. Fourth, although the blood loss from placenta previa is almost entirely maternal, trauma to the placenta with vaginal examination or coitus may result in some fetal blood loss, which could restrict fetal growth.[29] Additionally, a higher incidence of congenital anomalies in the fetuses of women with placenta previa may occur.[14]

Experts recommend that women with a placental edge–to–internal os distance greater than 1 cm be offered a trial of labor because the risk for antepartum hemorrhage and need for cesarean delivery during labor are low in this setting.[23] Parturients with a total previa, placental edge–to–internal os distance less than 1 cm, and/or significant bleeding will require abdominal delivery, as will some patients with nonreassuring fetal status.

Anesthetic Management

All patients admitted with vaginal bleeding should be evaluated by an anesthesia provider on arrival. Special consideration should be given to the airway examination, intravascular volume assessment, and history of previous cesarean delivery or other procedures that create a uterine scar. Volume resuscitation should be initiated using a non–dextrose-containing balanced salt solution (e.g., lactated Ringer's, normal saline). Women with placenta previa may remain hospitalized for some time before delivery, and at least one intravenous catheter should be maintained if bleeding is recurrent or imminent delivery is anticipated. Hemoglobin concentration measurement may be indicated after a bleeding episode. Availability of cross-matched blood should be ensured. The American Association of Blood Banks (AABB) recommends repeating such tests every 3 days in pregnant women because of the small but finite risk for developing a new alloantibody during pregnancy.[30] The use of lower-extremity sequential compression devices may decrease the risk for venous thromboembolism in patients on bed rest. Pharmacologic prophylaxis may be withheld because of the risk for bleeding.

The choice of anesthetic technique depends on the indication and urgency for delivery, the severity of maternal hypovolemia, and the obstetric history (e.g., prior cesarean delivery and risk for placenta accreta). Few reliable data exist to guide anesthetic choice in the context of abnormal placentation. Survey data reveal that obstetric anesthesia providers prefer neuraxial anesthesia in patients with placenta previa without active bleeding or intravascular volume deficit.[31] A randomized controlled trial comparing epidural with general anesthesia for cesarean delivery in women with placenta previa in the absence of active bleeding demonstrated that epidural anesthesia was associated with (1) more stable blood pressure after delivery and (2) lower transfusion rates and transfusion volumes with similar hematocrit measurements the day after surgery.[32] Operative times, estimated blood loss, urine output, and Apgar scores were similar in the two groups. Combined spinal-epidural anesthesia, or even single-shot spinal anesthesia, is considered acceptable for patients without active bleeding.

Patients who have placenta previa—even without active preoperative bleeding—remain at risk for increased intraoperative blood loss for at least three reasons. First, the obstetrician may injure an anteriorly located placenta during uterine incision. Second, after delivery, the lower uterine segment implantation site, lacking uterine muscle compared with the fundus, does not contract as well as the normal fundal implantation site. Third, a patient with placenta previa is at increased risk for placenta accreta, especially if there is a history of previous cesarean delivery (see later discussion) (Table 37.1).[19] For these reasons, it may be advisable to place two large-bore intravenous catheters before the start of either elective or emergent cesarean delivery. No consensus exists on the need for blood product availability in these patients, but it seems prudent to order a blood type and screen and ensure blood product availability. If preoperative imaging indicates the possibility of a placenta accreta, preparation for massive blood loss should be undertaken.

Patients with placenta previa and active preoperative bleeding represent a significant challenge for the anesthesia care team. Frequently, such patients have just presented to the hospital and there is minimal time for evaluation. In these cases, patient evaluation, resuscitation, and preparation for operative delivery all proceed simultaneously. Because the placental site is the source of hemorrhage, the bleeding may continue unabated until the placenta is removed and the uterus contracts. Preoperative evaluation requires careful assessment of the parturient's airway and intravascular volume. Two large-bore intravenous catheters should be placed, and blood products should be ordered as necessary. Blood administration sets, fluid warmers, and equipment for invasive monitoring should be immediately available. Initially, non–dextrose-containing crystalloid or colloid is infused rapidly. In some cases, the patient requires transfusion before cross-matched blood is available, and type-specific blood or type O, Rh-negative blood must be administered.

Rapid-sequence induction of general anesthesia is the preferred technique for bleeding patients. The choice of intravenous induction agent depends on the degree of cardiovascular instability. In patients with severe hypovolemic

shock, tracheal intubation may be accomplished without an induction agent, although this situation is rare. A low dose of propofol should be administered in women with ongoing hemorrhage. Ketamine and etomidate are useful alternative induction agents for hemodynamically unstable patients. Ketamine 0.5 to 1.0 mg/kg has an excellent record of safety and efficacy in obstetric anesthesia practice. Emergence phenomena such as hallucinations and nightmares are uncommon when the dose does not exceed 1 mg/kg. Ketamine may cause direct myocardial depression, which can result in hypotension in patients with severe hypovolemia. Etomidate 0.3 mg/kg causes minimal cardiac depression and is safe for use in obstetric patients.[33] A low dose is appropriate in patients with severe hemorrhage. Disadvantages of etomidate include pain on administration, myoclonus, and possible adrenocortical suppression.[34]

The agent(s) chosen for maintenance of anesthesia depends on maternal cardiovascular stability. In patients with modest bleeding and no fetal compromise, 50% nitrous oxide in oxygen can be administered with a low concentration of a volatile halogenated agent before delivery to prevent maternal awareness. The concentration of nitrous oxide or halogenated agent can be reduced or omitted in cases of severe maternal hemorrhage or fetal compromise. In these cases, a benzodiazepine such as midazolam may be administered to provide amnesia.

Oxytocin should be administered by intravenous infusion immediately after delivery. The relatively amuscular lower uterine segment implantation site does not contract as efficiently as the uterine fundus. If bleeding continues, it may be best to discontinue the volatile halogenated agent completely after delivery and to substitute 70% nitrous oxide and an intravenous opioid or ketamine. These drugs, along with small doses of midazolam, can be administered without causing significant uterine relaxation or cardiovascular depression. A low-dose infusion of propofol and/or ketamine may be considered, with the caution that propofol causes decreased uterine contractility in a dose-dependent manner.[35,36] Some anesthesia providers contend that bispectral index (BIS) monitoring may be useful in lowering the risk for intraoperative awareness in cases in which the volatile anesthetic agent has been discontinued, although this issue is a matter of some dispute.

If the placenta does not separate easily, placenta accreta may exist. In such cases, massive blood loss and the need for cesarean hysterectomy should be anticipated (see later discussion). The need for invasive hemodynamic monitoring varies among patients. An indwelling arterial catheter is useful for patients with hemodynamic instability or for those who require frequent determination of hematocrit and blood gas measurements.

Placental Abruption

Placental abruption is defined as complete or partial separation of the placenta from the decidua basalis before delivery of the fetus. Maternal hemorrhage may be revealed by vaginal bleeding or may be concealed behind the placenta. Fetal compromise occurs because of the loss of placental surface area for maternal-fetal exchange of oxygen and nutrients.

Epidemiology

Placental abruption complicates 0.4% to 1.0% of pregnancies. The United States incidence increased through the 1990s, particularly among African-American women, and then stabilized after 2000.[15,37] The causes of abruption are not well understood, but several conditions are known risk factors for abruption (Box 37.1).[38,39]

Diagnosis

The classic presentation of abruption consists of vaginal bleeding, uterine tenderness, and increased uterine activity, but not all symptoms are always present. In cases of concealed abruption, vaginal bleeding may be absent, and gross underestimation of maternal hypovolemia can occur. Bleeding may be painless. In some cases, abruption may manifest as idiopathic preterm labor. Patients may have a variety of nonreassuring fetal heart rate (FHR) patterns, including bradycardia, late or variable decelerations, and loss of variability. The diagnosis of placental abruption is primarily clinical, but in a subset of cases, ultrasonography may help confirm it. Ultrasonography is highly specific for placental abruption (96%), but it is not very sensitive (24%).[40] It is also useful for determining placental location, which can exclude placenta previa as a cause of vaginal bleeding. The ultrasonographic examination can ascertain whether a retroplacental or subchorionic hematoma is present. Normal findings do not exclude the diagnosis of placental abruption.

Pathophysiology

Complications of placental abruption include hemorrhagic shock, coagulopathy, and fetal compromise or demise. One-third of coagulopathies in pregnancy are attributable to abruption, and coagulopathy is associated with fetal demise.[41] Placental tissue displays tissue factor and other procoagulant

BOX 37.1 Conditions Associated with Placental Abruption

Obstetric Conditions
- Advanced maternal age
- Multiparity
- Preeclampsia
- Premature rupture of membranes
- Chorioamnionitis

Maternal Comorbidities
- Hypertension
- Acute or chronic respiratory illness
- Substance abuse
- Maternal cocaine use
- Maternal or paternal tobacco use

Trauma
- Direct (i.e., blunt abdominal)
- Indirect (e.g., acceleration/deceleration injury)

substances on cell membranes,[42] and it is surmised that when bleeding at the decidual-placental interface (i.e., abruption) occurs, these thromboplastic substances are released into the central circulation, resulting in consumptive coagulopathy and disseminated intravascular coagulation (DIC).[43]

Although some cases of abruption occur acutely (e.g., in the setting of trauma), many abruptions complicate chronic, long-standing placental abnormalities. Investigators have noted strong associations between abruption, fetal growth restriction, and preeclampsia, and all three conditions share similar risk factors.[44] Histologic evidence of shallow trophoblastic invasion of the spiral arteries supports the conclusion that "ischemic placental disease" may underlie chronic placental hypoxia, leading to preeclampsia, fetal growth restriction, and abruption.[44] Decidual necrosis at the placental margin and large placental infarcts are the most common abnormalities among patients who suffer placental abruption and fetal demise.[45] Infants who die typically have 14% less placental weight, 8% less body weight, and 3% shorter body length than surviving control infants of the same gestational age.[45] The major risks for the fetus are hypoxia and prematurity. Separation of all or part of the placenta reduces gas exchange surface area and can lead to fetal death. The risk for intrauterine fetal demise increases as the detachment area increases, particularly when the location of bleeding is retroplacental rather than subchorionic.[46] Inadequate transplacental oxygen exchange is exacerbated by maternal hypotension, which decreases uteroplacental blood flow. The increased perinatal mortality rate associated with placental abruption reflects both a high risk for fetal death and the consequences of preterm birth.

Obstetric Management

The definitive treatment is delivery of the infant and placenta, but the degree of maternal and fetal compromise and estimated gestational age determine the timing and route of delivery. If the fetus is at or near term and both maternal and fetal status are reassuring, vaginal delivery may be appropriate. If the patient is preterm, the extent of abruption is minimal, and the mother and fetus show no signs of compromise, the patient may be hospitalized and the pregnancy allowed to continue to optimize fetal maturation. The obstetrician may administer a corticosteroid to promote fetal lung maturity. If the mother develops hemodynamic instability or coagulopathy, or the fetal status becomes nonreassuring, urgent cesarean delivery may become necessary. Vaginal delivery is preferred for patients with intrauterine fetal demise.

Anesthetic Management

If abruption is suspected, the anesthesia provider should insert a large-bore intravenous catheter and assess hemoglobin, coagulation status, and blood product preparation. When gauging volume status, the clinician must remain aware of the possibility of hemorrhage concealed behind the placenta. Placement of a urethral catheter to monitor urine output may help the physician assess adequacy of renal perfusion.

Labor and vaginal delivery. Neuraxial labor analgesia may be offered in the setting of abruption provided that hypovolemia has been treated and coagulation status is normal. The appropriateness of neuraxial analgesia with its accompanying sympathectomy in patients at risk for extension of abruption and further hemorrhage has been questioned; however, the risk that neuraxial analgesia will worsen hemorrhage-associated tachycardia and hypotension can be mitigated by appropriate intravascular volume replacement and use of vasopressors. A patient with abruption presenting for vaginal delivery may have a severe coagulopathy, particularly in the setting of fetal demise. In this case, intravenous patient-controlled opioid analgesia should be offered.

Cesarean delivery. Spinal, combined spinal-epidural, or epidural anesthesia may be administered in stable patients in whom intravascular volume status is adequate and coagulation studies are normal. General anesthesia is preferred for most cases of urgent cesarean delivery accompanied by unstable maternal status, a nonreassuring FHR pattern, or both. Propofol may precipitate severe hypotension in patients with unrecognized hypovolemia; ketamine and etomidate represent alternatives for the patient with decreased intravascular volume.

Aggressive volume resuscitation is critical. In cases of severe hemorrhage, insertion of an intra-arterial catheter may aid prompt recognition of hypotension and allow for frequent blood sampling and assessment of anemia and coagulation status. Patients with abruption are at risk for postpartum hemorrhage from uterine atony and coagulopathy; after delivery, oxytocin should be infused promptly. Persistent uterine atony requires the administration of other uterotonic drugs (see later discussion). Red blood cells (RBCs) and coagulation factors should be replaced as indicated by laboratory studies. Experts recommend aggressive monitoring and early replacement of coagulation factors, especially fibrinogen, to minimize the risk for developing a coagulopathy.[47]

Most parturients recover quickly and completely after delivery. A minority of postpartum patients, notably those who have prolonged hypotension or coagulopathy, and who need massive blood volume and blood product replacement, are best monitored in a multidisciplinary intensive care unit.

Uterine Rupture

Rupture of the gravid uterus can be disastrous for both the mother and the fetus. Because of variation in nomenclature and severity, accurate determination of maternal and fetal morbidity secondary to uterine rupture is difficult. The most common variety of uterine scar disruption is separation or dehiscence; some cases are asymptomatic. **Uterine scar dehiscence** is defined as a uterine wall defect that does not result in excessive hemorrhage or FHR abnormalities and does not require emergency cesarean delivery or postpartum laparotomy. In contrast, **uterine rupture,** less common than dehiscence, refers to a uterine wall defect with maternal hemorrhage and/or fetal compromise sufficient to require emergency cesarean delivery or postpartum laparotomy.

BOX 37.2 Conditions Associated with Uterine Rupture

Obstetric Conditions
- Prior uterine surgery
- Induction of labor
- High-dose oxytocin induction
- Prostaglandin induction
- Grand multiparity (> 5)
- Morbidly adherent placenta
- Congenital uterine anomaly (e.g., bicornuate uterus)

Maternal Comorbidities
- Connective tissue disorder (e.g., Ehlers-Danlos syndrome)

Trauma

Obstetric
- Forceps application/rotation
- Internal podalic version
- Excessive fundal pressure

Nonobstetric
- Blunt
- Penetrating

Epidemiology

Fortunately, uterine rupture occurs very rarely in the woman with an unscarred uterus, but it does occur.[48] Previous uterine surgery (e.g., cesarean delivery or myomectomy) increases the risk, but the incidence of true uterine rupture after cesarean delivery is still low, occurring at a rate of less than 1%.[49] Box 37.2 lists additional conditions that have been associated with uterine rupture.[48,49]

Although rupture of a previous uterine scar may occur in the absence of labor, it occurs more commonly during labor (see Chapter 19). A population-based retrospective analysis of more than 20,000 women who had undergone one previous cesarean delivery demonstrated the risk for uterine rupture among nonlaboring women was 1.6 per 1000, whereas among women in spontaneous labor the risk increased approximately threefold to 5.2 per 1000.[50] Among women undergoing induction of labor, the risk increased nearly fivefold to 7.7 per 1000, and among women undergoing prostaglandin induction the risk increased almost 16-fold to 24.5 per 1000.[50] This apparent risk escalation may not result from the induction/augmentation process *per se,* but may reflect the fact that prolonged labor increases rupture risk, and induced/augmented labors are longer than those not induced/augmented.[51] Additional risk factors for uterine rupture during a trial of labor after cesarean (TOLAC) include an interdelivery interval of less than 12 to 16 months, multiple previous cesarean deliveries, postterm gestation, birth weight greater than 4000 g, maternal age older than 35 years, and previous delivery with severe postpartum hemorrhage.[52,53] Previous vaginal delivery and prior successful vaginal delivery after cesarean confer decreased rupture risk.[54] Evidence of decreased lower uterine segment thickness on ultrasound examination increases rupture risk, but a precise clinically applicable threshold value below which a TOLAC should not be offered has not been determined.[55]

The rupture of a classical uterine incision scar (a vertical incision involving the muscular uterine fundus) is associated with greater morbidity and mortality than rupture of a low transverse uterine incision scar because the anterior uterine wall is highly vascular and may include the area of placental implantation. Lateral extension of the rupture can involve the major uterine vessels and is typically associated with massive bleeding. Maternal death secondary to uterine rupture is rare, although there were three deaths attributed to uterine rupture in the 2006 to 2008 triennial report from the United Kingdom.[56] Rupture-associated neonatal hypoxic-ischemic encephalopathy or mortality occurs at rates of less than one per 1000 trials of labor after cesarean delivery in the United States.[49]

Diagnosis

The variable presentation of uterine rupture may cause diagnostic difficulty. An FHR abnormality is the first sign of uterine rupture in more than 80% of patients (see Chapter 19).[57] The triad of abdominal pain, abnormal FHR pattern, and vaginal bleeding is seen less frequently (9% of patients with rupture).[57] Other presenting signs include vaginal bleeding, uterine hypertonia, cessation of labor, maternal hypotension, loss of the fetal station, decrease in cervical dilation, or a change in fetal presentation. Breakthrough pain and need for frequent redosing during neuraxial labor analgesia may also indicate impending or evolving uterine rupture.[58]

Obstetric Management

Treatment options for uterine rupture include repair of the uterus, arterial ligation, and hysterectomy. Uterine repair is appropriate for most cases of separation of a prior low transverse uterine scar and for some cases of rupture of a classical incision. However, the risk for rupture in a future pregnancy remains. A disadvantage of arterial ligation is that it may not control the bleeding and may delay definitive treatment. Hysterectomy may become necessary, albeit rarely.[49]

Anesthetic Management

Patient evaluation and resuscitation are initiated while the patient is being prepared for emergency laparotomy. If rupture has occurred antepartum, fetal compromise is likely. General anesthesia may be necessary, but surgery can proceed under neuraxial anesthesia in stable patients with preexisting epidural labor analgesia. Aggressive volume replacement is essential, and transfusion may be necessary. Urine output should be monitored. Focused cardiac ultrasound monitoring may be appropriate whenever there is uncertainty about the intravascular volume status.

Vasa Previa

Vasa previa occurs when the fetal blood vessels traverse the fetal membranes covering the internal cervical os. Consequently, the fetal vessels are not protected by the placenta or the umbilical cord, and rupture of membranes can be accompanied by tearing of a fetal vessel and exsanguination of the fetus.

Two types of vasa previa exist: type 1, when the vessels are associated with a velamentous umbilical cord, and type 2, when the vessels connect the lobes of a multilobed placenta or the placenta and a succenturiate lobe.[59] Although no universal definition exists regarding the exact distance between fetal vessels and internal os that constitutes vasa previa, many clinicians use a threshold of 2 cm.[60] This cutoff is based on a case series that demonstrated that all emergent deliveries caused by vasa previa had a fetal vessel within 2 cm of the cervical os.[61]

Epidemiology

Vasa previa occurs rarely (1 in 2500 to 1 in 5000 deliveries).[26] Because it involves the loss of fetal blood, vasa previa is associated with a high fetal mortality rate (nearly 60% if vasa previa is unrecognized).[62] The blood volume of the fetus at term is approximately 80 to 100 mL/kg. Therefore, the amount of blood that can be lost without leading to fetal death is small. In addition, the presence of vasa previa exposes the vulnerable fetal vessels to compression by the fetal presenting part, resulting in fetal hypoxia and death. Risk factors for vasa previa include the presence of velamentous cord insertion, placenta previa or low-lying placenta in the second trimester, placental accessory lobes, *in vitro* fertilization, and multiple gestation.[26]

Diagnosis

Ultrasonography can be used to visualize the velamentous insertion of the vessels,[26,62] but vasa previa should be suspected whenever bleeding occurs with rupture of membranes, particularly if the rupture is accompanied by FHR decelerations or fetal bradycardia. Hemorrhage can also occur without rupture of membranes, making the diagnosis more difficult.

Obstetric Management

Prenatal diagnosis confers a neonatal survival benefit: neonatal mortality is 3% when vasa previa is diagnosed antenatally but increases to 56% when it is not.[62] Any woman at risk for vasa previa should have an ultrasonographic examination with transvaginal color Doppler.[62] The management of vasa previa is directed toward ensuring fetal survival.

Timing of delivery reflects a balance between the risks associated with preterm delivery and the risk for vessel rupture if the pregnancy is allowed to continue. Experts advocate antenatal steroid administration between 30 and 32 weeks' gestation to promote fetal lung maturity, and hospitalization of the patient between 30 and 34 weeks' gestation to ensure prompt delivery should rupture of membranes occur.[63] Mathematical modeling comparing delivery timing strategies for women with vasa previa reveals that the best fetal outcomes will occur with elective delivery between 34 and 35 weeks' gestation.[64] Amniocentesis to evaluate fetal lung maturity is not recommended because delaying delivery is typically not an option.[59]

Ruptured vasa previa is a true obstetric emergency that requires immediate delivery of the fetus by cesarean delivery. Neonatal resuscitation requires attention to neonatal volume status.

Anesthetic Management

The choice of anesthetic technique depends on the urgency of the cesarean delivery. In many cases, general anesthesia is necessary for prompt delivery.

POSTPARTUM HEMORRHAGE

Conflicting definitions of postpartum hemorrhage exist; however, the most commonly accepted definition is blood loss more than 500 mL after vaginal delivery or more than 1000 mL after cesarean delivery. The American College of Obstetricians and Gynecologists (ACOG) defines hemorrhage as blood loss greater than or equal to 1000 mL, or blood loss accompanied by signs or symptoms of hypovolemia within 24 hours of birth.[65] Primary postpartum hemorrhage occurs during the first 24 hours, and secondary postpartum hemorrhage occurs between 24 hours and 6 weeks after delivery.[65] Primary postpartum hemorrhage is more likely to result in maternal morbidity or mortality. Fig. 37.1 provides an overview of the obstetric management of postpartum hemorrhage.

Postpartum hemorrhage is the most common cause of maternal mortality worldwide and an important contributor to maternal death in the United States.[2] The incidence of postpartum hemorrhage varies widely throughout different regions of the world[1]; in the United States the current rate of postpartum hemorrhage is approximately 3%.[7,8] Postpartum hemorrhage increased in incidence between 1994 and 2006[7,8]; during this period, the transfusion rate for postpartum hemorrhage more than doubled, indicating hemorrhage also became more severe.[7] The explanation for this acceleration in incidence and severity is not entirely clear but appears to be related to rising rates of postpartum uterine atony as well as increases in the incidence of abnormal placentation, both coincident with the rise in cesarean delivery rates.[7,8,11] Other factors may include the rising rates of obstetric interventions, such as induction and augmentation of labor,[66–68] and the increasing prevalence of obesity,[69,70] multiple gestation,[67,71] hypertensive diseases of pregnancy,[72] and advanced maternal age.[9] However, the rising prevalence of these risk factors does not entirely explain the upward trend in postpartum hemorrhage that has been observed.[7,8]

Uterine Atony

Epidemiology

Uterine atony is the most common cause of severe postpartum hemorrhage, accounting for approximately 80% of cases; the incidence is increasing in the United States.[7,8] Box 37.3 lists conditions associated with uterine atony. In addition to normal hemostatic mechanisms, postpartum hemostasis involves the release of endogenous uterotonic agents—primarily oxytocin and prostaglandins—that contract the uterus and constrict uterine vessels. Uterine atony represents a failure of this process. In addition, parturients with obstetric

BOX 37.3 Conditions Associated with Uterine Atony

Obstetric Management
- Cesarean delivery
- Induced labor
- Augmented labor

Obstetric Conditions
- Multiple gestation
- Macrosomia
- Polyhydramnios
- High parity
- Prolonged labor
- Precipitous labor
- Chorioamnionitis

Maternal Comorbidities
- Advanced maternal age
- Hypertensive disease
- Diabetes

Other
- Tocolytic drugs[a]
- High concentration of volatile halogenated anesthetic agent

[a]Beta-adrenergic receptor agonists, magnesium sulfate.

hemorrhage may have uterine arteries that are relatively unresponsive to vasoconstrictor substances.[73]

Diagnosis

An atonic, poorly contractile uterus and vaginal bleeding are the most common findings in patients with uterine atony. The absence of vaginal bleeding does not exclude this disorder because the atonic, engorged uterus may contain more than 1000 mL of blood. Unrecognized bleeding may manifest initially as tachycardia; worsening hypovolemia eventually leads to hypotension (Table 37.2).[74]

Obstetric and Anesthetic Management

Prophylaxis. The ACOG recommends **active management of the third stage of labor,** including uterine massage and prophylactic oxytocin administration to decrease blood loss and transfusion requirements compared with expectant management.[65,75,76] **Oxytocin** is the first-line drug for prophylaxis of uterine atony after delivery of a third-trimester pregnancy. (The number of high-affinity receptors for oxytocin increases greatly near term; alternative uterotonics are more effective in the first and second trimesters of pregnancy.) Endogenous oxytocin is a nine–amino acid polypeptide produced in the posterior pituitary gland. The exogenous form

TABLE 37.2 Advanced Trauma Life Support (ATLS) Classification of Shock

	Class 1	Class 2	Class 3	Class 4
Blood loss (%)[a]	< 15	15–30	30–40	> 40
Heart rate (bpm)	< 100	100–120	> 120	> 140
Systolic blood pressure (mm Hg)	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	> 35
Mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic

of the drug (Pitocin, Syntocinon) is a synthetic preparation with a rapid onset and short half-life.

Unfortunately, exogenous oxytocin can be associated with serious side effects, including vasodilation, tachycardia, hypotension, coronary vasoconstriction, myocardial ischemia, and, rarely, even death, especially in hypovolemic or other hemodynamically compromised women.[77–81] Many of these adverse effects are directly related to the dose of oxytocin.[82,83] Administration of phenylephrine with oxytocin can mitigate the adverse hemodynamic consequences of oxytocin,[84] but phenylephrine may not be necessary as long as an oxytocin bolus dose is avoided and the infusion rate is maintained below 1 IU/min, the threshold at which hemodynamic consequences become apparent.[82] High doses of oxytocin administered concomitantly with large volumes of intravenous fluids, especially those containing free water, can lead to hyponatremia, seizures, and coma because of oxytocin's structural similarity to vasopressin.[85]

Oxytocin is rapidly metabolized by hepatic oxytocinases and cleared in the urine and bile, resulting in a half-life of less than 6 minutes. Consequently, a prolonged intravenous infusion is more effective than bolus administration in preventing uterine atony.[86] Administering a 5-IU bolus of oxytocin before an infusion does not provide benefit compared with an infusion without a bolus,[87] and may cause more hemodynamic perturbations. The dose of oxytocin required to generate satisfactory uterine tone after delivery is lower than previously thought (see Chapter 26). The ED_{90} of bolus-dose oxytocin for satisfactory uterine tone within 3 minutes of cesarean delivery in nonlaboring women is 0.35 IU[88]; the ED_{90} is almost ten times higher, approximately 3 IU, in women undergoing cesarean delivery for labor arrest after labor augmentation or induction with oxytocin.[89] Similarly, the ED_{90} of oxytocin administered via infusion without a bolus dose is approximately 0.3 IU/min in nonlaboring women,[90,91] but approximately 0.7 IU/min in women exposed to oxytocin during labor before cesarean delivery.[91]

Munn et al.[92] randomized women undergoing intrapartum cesarean delivery to receive a prophylactic infusion of oxytocin at 2.67 IU/min or 0.33 IU/min for 30 minutes after delivery. The higher dose was associated with less need for secondary uterotonics (19% versus 39%, respectively; $P < .001$); however, this high dose of oxytocin may be associated with clinically significant tachycardia and hypotension, and other authors have not demonstrated any differences in bleeding-related outcomes after introducing protocols that employ oxytocin doses in the lower range.[93] Awareness of the dangers of high-dose administration and data demonstrating the effectiveness of lower oxytocin doses than used historically call into question the safety of the practice of injecting 10 to 40 IU of oxytocin into a 1-liter crystalloid solution and infusing the solution at an unspecified rate, often "wide open" (i.e., gravity-dependent flow). The doses administered with this method may approach those achieved with bolus administration. Box 37.4 contains a suggested protocol for third-stage oxytocin administration.[94]

BOX 37.4 University of Chicago Family Birth Center Postpartum Oxytocin Protocol

Use standard infusion preparation: oxytocin 30 IU in 500 mL of normal saline

Cesarean Delivery without Previous Oxytocin Exposure or Vaginal Delivery

- Start infusion: 300 mL/h = 0.3 IU/min = 18 IU/h
- If uterine atony: increase to 600 mL/h = 0.6 IU/min = 36 IU/h
- If continued atony: increase to 900 mL/h = 0.9 IU/min = 54 IU/h

Cesarean Delivery with Previous Intrapartum Oxytocin Exposure

- Start infusion: 600 mL/h = 0.6 IU/min = 36 IU/h
- If uterine atony: increase to 900 mL/h = 0.9 IU/min = 54 IU/h

For Continued Atony, Consider:

- Methylergonovine 0.2 mg IM × 1
- 15-methylprostaglandin $F_{2\alpha}$ 0.25 mg IM (may repeat every 15 min for 8 doses)

After Atony Is Resolved:

- Decrease oxytocin to 60 mL/h = 0.06 IU/min = 3.6 IU/h

IM, Intramuscular.
Modified from Foley A, Gunter A, Nunes KJ, et al. Patients undergoing cesarean delivery after exposure to oxytocin during labor require higher postpartum oxytocin doses. *Anesth Analg.* 2018;126:920–924.

Carbetocin is an alternative synthetic oxytocin-receptor agonist available in Canada, the United Kingdom, and other countries, but not the United States. A large multinational randomized noninferiority trial (N = 29,645) found that carbetocin was noninferior to oxytocin for prevention of postpartum hemorrhage and need for additional uterotonic agents after vaginal delivery.[95] Carbetocin has a longer duration of action than oxytocin, eliminating the need for prolonged infusion.

Treatment. Despite preventive measures, postpartum uterine atony may occur. A multidisciplinary response to atony is imperative. General resuscitative measures include (1) additional large-bore intravenous access, (2) intravenous administration of crystalloid and colloid solutions and vasopressors, (3) laboratory determination of hemoglobin concentration or hematocrit and assessment of coagulation status, and (4) blood bank preparation of blood products for transfusion. Bimanual compression and massage of the uterus and continued infusion of oxytocin may help restore uterine tone. Unfortunately, few high-quality data exist to guide therapy if these management strategies fail, and current practice relies on expert opinion and clinical judgment. In the case of inadequate response to oxytocin, additional uterotonic agents should be employed. Three classes of drugs are currently available for the treatment of uterine atony: oxytocin, ergot alkaloids, and prostaglandins (Table 37.3).

The natural **ergot alkaloids** are produced by a fungus that commonly infests rye and other grains. Ergonovine and methylergonovine (a semisynthetic preparation with an identical pharmacologic profile) are the two ergot alkaloids currently available for use. Both drugs are dispensed in ampules containing 0.2 mg. When administered via the intramuscular route, they have a rapid onset, and the uterotonic effect usually lasts for 2 to 4 hours. Ergot alkaloids are stable at room temperature for prolonged periods.[96]

Because ergot alkaloids rapidly produce tetanic uterine contractions, their use is restricted to the postpartum period. The mechanism of action is poorly understood, but the uterotonic effect is most likely mediated by serotonergic agonism; the ergot alkaloids are also weak dopamine and alpha-adrenergic receptor agonists.[97] Parenteral administration of an ergot alkaloid is associated with a high incidence of nausea and vomiting.[97] Bolus intravenous administration is **not** recommended because of the propensity to cause serious cardiovascular system derangements; even intramuscular administration may cause vasoconstriction, hypertension, myocardial ischemia and infarction caused by coronary vasospasm,[98,99] cerebrovascular accident,[100] seizures,[100] and death.[98,101] Fortunately, these serious adverse effects occur rarely.[102] Patients at greatest risk are those with preexisting hypertension; however, sudden and marked hypertension may also occur in previously normotensive patients. The combination of an ergot alkaloid followed by a vasopressor may lead to exaggerated hypertension. Relative contraindications to the use of ergot alkaloids include hypertension, preeclampsia, peripheral vascular disease, and ischemic heart disease. Treatment of ergot-induced vasoconstriction and hypertension may require administration of a potent vasodilator such as nitroglycerin or sodium nitroprusside; blood pressure and the electrocardiogram should be monitored closely after administration, especially in the setting of hemorrhage.

Prostaglandins of the E and F families have gained wide acceptance as escalation therapy when high-dose oxytocin is inadequate. Concentrations of endogenous prostaglandins increase during labor, and levels peak at the time of placental separation. It is hypothesized that uterine atony may represent a failure of prostaglandin concentrations to increase during the third stage of labor in some women.[103,104]

TABLE 37.3 Drug Therapy for Uterine Atony

Agent	Dose and Route	Relative Contraindications	Side Effects	Notes
Oxytocin	0.3–0.9 IU/min IV infusion	None	Tachycardia Hypotension Myocardial ischemia Free water retention	Short duration of effect
Ergonovine or methylergonovine	0.2 mg IM	Hypertension Preeclampsia Coronary artery disease	Nausea and vomiting Arteriolar constriction Hypertension	Long duration of action May be repeated once after 30 minutes
15-Methylprostaglandin $F_{2\alpha}$	0.25 mg IM	Reactive airway disease Pulmonary hypertension Hypoxemia	Fever Chills Nausea and vomiting Diarrhea Bronchoconstriction	May be repeated every 15 minutes up to 2 mg
Misoprostol[a]	600–1000 μg PR, sublingual, or buccal	None	Fever Chills Nausea and vomiting Diarrhea	Off-label use

IM, Intramuscular; *IV,* intravenous; *PR,* per rectum.
[a]Meta-analysis indicates that misoprostol does not provide benefit and increases adverse effects when administered to women with postpartum hemorrhage who are already being treated with high-dose oxytocin.[111]

Prostaglandins increase myometrial intracellular free calcium concentration, ultimately leading to an increase in myosin light-chain kinase activity. Common side effects noted after prostaglandin administration include fever, chills, diarrhea, nausea, and vomiting.[97]

15-methyl prostaglandin $F_{2\alpha}$, or carboprost, is commonly employed. Its administration may succeed in controlling hemorrhage when all other pharmacologic treatments have failed. The recommended dose is 0.25 mg (250 µg) administered intramuscularly, which may be repeated every 15 to 30 minutes; the total dose should not exceed 2 mg (eight doses). Unfortunately, this valuable agent requires refrigeration and may rarely cause bronchospasm, abnormal ventilation-perfusion ratio, increased intrapulmonary shunt fraction, and hypoxemia in susceptible patients.[105,106] Methylergonovine may be a more effective second-line agent than carboprost. Retrospective data from the Maternal-Fetal Medicine Units Network demonstrated that women treated with methylergonovine were less likely to suffer hemorrhage-related morbidity than those given carboprost.[107]

Misoprostol is a prostaglandin E_1 analogue that has been used successfully for cervical ripening and induction of labor. Although it is not as effective as oxytocin, prophylactic misoprostol administration reduces the incidence of postpartum hemorrhage compared with placebo.[108] Furthermore, misoprostol is thermostable in tropical conditions and does not require intravenous access for administration. These characteristics make it an attractive alternative to oxytocin and ergot alkaloids in low-resource areas, where the rate of maternal mortality from hemorrhage is high.[109]

A large multinational randomized controlled trial and a subsequent meta-analysis indicate that misoprostol does not provide benefit and increases adverse effects when administered to women with postpartum hemorrhage who are already being treated with high-dose oxytocin.[110,111] Like other prostaglandins, misoprostol may be associated with fever, chills, nausea, vomiting, and diarrhea.[108,110] Misoprostol's prolonged half-life may make it an attractive choice for patients who experience late postpartum hemorrhage. A dose of 600 to 1000 µg per rectum is commonly administered; administration via the oral, buccal, and sublingual routes has been described.[65,108]

If hemorrhage and atony persist despite aggressive administration of multiple classes of uterotonic drugs, invasive techniques must be considered. Invasive techniques include intrauterine balloon tamponade, uterine compression sutures, embolization of the arteries supplying the uterus, surgical ligation of arteries, and cesarean hysterectomy (see later discussion).

Genital Trauma

The most common childbirth injuries are lacerations and hematomas of the perineum, vagina, and cervix. Most injuries have minimal consequence, but some puerperal lacerations and hematomas are associated with significant hemorrhage, either immediate or delayed.[112] Prompt recognition and treatment can minimize morbidity and mortality.[112] Genital tract lacerations should be suspected in all patients who have vaginal bleeding despite a firm, contracted uterus. The cervix and vagina must be inspected carefully in these patients. Computed tomography (CT) and/or MRI may be useful in detecting the presence, location, and extent of suspected hematoma.[113]

Pelvic hematomas may be divided into four types: vaginal, vulvar, vulvovaginal, and retroperitoneal.[112] **Vaginal hematomas** result from soft tissue injury during delivery, and they may involve bleeding from the descending branch of the uterine artery.[112,114] The use of forceps or vacuum extraction increases the risk.[114] A study in Sweden of all cases of vaginal hematomas from 1987 to 2000 found a prevalence of approximately 1 in 1240 deliveries.[115] The investigators identified nulliparity, advanced maternal age, and neonatal birth weight exceeding 4000 g as risk factors for vaginal hematoma. Other risk factors may include prolonged second stage of labor, multiple gestation, preeclampsia, and vulvovaginal varicosities.[112]

Vulvar hematomas commonly involve branches of the pudendal artery.[112] Injury is usually suggested by extreme pain or clinical manifestations of hypovolemia secondary to blood loss.[112] Small vaginal or vulvar hematomas that are not enlarging may be observed and treated conservatively with ice packs and oral analgesics. Large hematomas should be incised and evacuated. Bleeding vessels should be ligated. Often no specific bleeding source can be identified. The successful use of arterial embolization to decrease bleeding and aid in surgical management of genital tract hematomas has recently been reported.[114] Volume resuscitation and transfusion may be necessary.

Retroperitoneal hematomas are the least common and most dangerous hematomas associated with childbirth. A retroperitoneal hemorrhage occurs after laceration of one of the branches of the hypogastric artery. Injury typically occurs during cesarean delivery or rarely after rupture of a low transverse uterine scar during labor. A hematoma that originates in the broad ligament may dissect into the retroperitoneal space along the lateral pelvic sidewalls and may extend as far as the kidneys.

The symptoms of concealed bleeding depend on the size of the hematoma and the rate at which it forms. In some instances, progressive tachycardia or abrupt hypotension may be the first sign of bleeding. The diagnosis of a retroperitoneal hematoma must be considered whenever a postpartum patient has an unexpected decrease in hematocrit or unexplained tachycardia and hypotension. Other signs and symptoms are restlessness, lower abdominal pain, a tender mass above the inguinal ligament that displaces a firm uterus to the contralateral side, and vaginal bleeding with hypotension out of proportion to the external blood loss. Ileus, unilateral leg edema, urinary retention, and hematuria also may occur.[112] A high index of suspicion is needed; in obese women it may be especially difficult to examine the abdomen for signs of retroperitoneal hematoma.

Occasionally, a retroperitoneal hematoma may be self-limiting and need no surgical intervention. Life-threatening

hematomas require exploratory laparotomy and ligation of the hypogastric vessels. Fliegner[116] reported that 38 of 39 patients with a broad ligament hematoma received a blood transfusion. Eight (21%) of the patients required a hysterectomy.

Anesthetic Management

Choice of anesthetic technique for the repair of genital lacerations and evacuation of pelvic hematomas depends on the affected area, surgical requirements, volume/hemodynamic status of the patient, and urgency of the procedure. Local infiltration and a small dose of intravenous opioid suffice for drainage of some vulvar hematomas; however, repair of extensive lacerations and drainage of vaginal hematomas require significant levels of analgesia or anesthesia. A pudendal nerve block may not be technically feasible because of anatomic distortion or severe pain from the hematoma. Spinal or epidural anesthesia may be necessary, although the clinician should exercise caution initiating (or extending) a neuraxial block in a hypovolemic patient. In some cases, general anesthesia with tracheal intubation may be necessary. Exploratory laparotomy for a retroperitoneal hematoma typically requires the administration of general anesthesia.

Retained Placenta

Retained placenta is defined as failure to deliver the placenta completely within 30 minutes of delivery of the infant and occurs in approximately 3% of vaginal deliveries.[117-119] Retained placenta typically results from one of three causes: (1) the placenta may be blocked behind a contracted lower uterus/cervix (incarcerated placenta), (2) the placenta may be adhered to the uterine wall (placenta adherens), or (3) it may be invading the myometrium (placenta accreta). The severity of bleeding ranges from minimal to severe and can be life-threatening and require transfusion.[118] The risk for postpartum hemorrhage increases significantly if the interval between delivery of the infant and the placenta exceeds 30 minutes.[117,119] Prophylactic oxytocin facilitates placental separation from the uterine wall, and, on balance, prophylactic oxytocin administered before delivery of the placenta is not associated with retained placenta after vaginal birth.[120,121] Risk factors for retained placenta include history of retained placenta, preterm delivery, oxytocin use during labor, preeclampsia, and nulliparity.[117,118]

Obstetric Management

Treatment of retained placenta during the early postpartum period often involves gentle cord traction, uterine massage, manual removal, and inspection of the placenta. If manual extraction is not successful, curettage may be required. The clinician may need to discontinue oxytocin during curettage and then, once the placenta has fully delivered, restart it to augment uterine tone. The eventual removal of the placenta typically promotes uterine contraction and a reduction in bleeding, but close observation for evidence of recurrent hemorrhage is warranted. Because manual extraction of the placenta increases the risk for endometritis, the World Health Organization recommends prophylactic antibiotic administration,[122] but published studies neither support nor refute this recommendation.[123]

Anesthetic Management

Manual extraction of the placenta can be painful, requiring analgesia. In some cases, the administration of small amounts of sedatives and analgesics is adequate to allow examination and manual placental extraction by a skilled obstetrician. Administration of local anesthetic through an indwelling epidural catheter may prove helpful.[124] In the absence of an indwelling catheter, *de novo* neuraxial anesthesia may be considered in patients who are not bleeding severely and are hemodynamically stable. General anesthesia sometimes becomes necessary, particularly in patients who are hemodynamically unstable.

In cases in which lower uterine or cervical contraction prevents placental passage, manual removal requires uterine relaxation. Historically, anesthesia providers performed rapid-sequence induction of general anesthesia, followed by the administration of a high dose of a volatile halogenated agent to relax the uterus. However, induction of general anesthesia in a parturient entails risk for failed tracheal intubation, failed ventilation, and/or aspiration of gastric contents.

Alternatively, **nitroglycerin** may be administered for uterine relaxation. Nitroglycerin provides a rapid onset of reliable smooth muscle relaxation and a short plasma half-life (2 to 3 minutes).[125] Nitroglycerin has been administered for various obstetric emergencies without clinically significant side effects.[125] Peng et al.[126] described successful removal of retained placenta in 15 parturients after administration of intravenous nitroglycerin 500 µg. Others have used a substantially lower dose of nitroglycerin (50 to 100 µg) with similar results.[127] Nitroglycerin may also be administered sublingually via spray or tablet. A double-blind, randomized controlled study compared sublingual nitroglycerin with placebo for management of retained placenta; the placenta was delivered successfully within 5 minutes in all 12 of the parturients who received nitroglycerin compared with only 1 of the 12 who received placebo.[128] Nitroglycerin most likely produces uterine smooth muscle relaxation by releasing nitric oxide, which temporarily decreases the patient's systemic blood pressure. Because of nitroglycerin's short plasma half-life, boluses rarely lead to sustained hypotension. Nevertheless, administration of nitroglycerin necessitates vigilant blood pressure monitoring.

Uterine Inversion

Uterine inversion, or the turning inside-out of all or part of the uterus, is a rare but potentially disastrous event. It is associated with severe postpartum hemorrhage, and hemodynamic instability may be worsened by concurrent vagal reflex–mediated bradycardia. The reported incidence of this disorder varies widely; recent reports suggest an incidence of approximately 1 in 3400 deliveries.[129]

Risk factors for uterine inversion include uterine atony, a short umbilical cord, uterine anomalies, and overly aggressive management of the third stage of labor, including inappropriate fundal pressure or excessive umbilical cord traction.[129] Uterotonic therapy can convert a partial inversion to a complete inversion. An abnormally implanted placenta (i.e., placenta accreta) may be first recognized when uterine inversion occurs.

Diagnosis

Many cases of uterine inversion are obvious because of hemorrhage and a mass in the vagina, but others may not be readily apparent. Inversion should be suspected in all cases of postpartum hemorrhage. Ultrasonographic examination may show characteristic findings, such as an echolucent zone within an echogenic mass filling the uterine cavity on transverse view.[130] Historically, obstetricians have stated that the shock is out of proportion to the blood loss, but an underestimation of obstetric hemorrhage is more likely. An incomplete inversion not protruding through the introitus is more likely to result in missed or delayed diagnosis.[112]

Obstetric Management

Immediate replacement of the uterus, even before removal of the placenta, is the treatment goal, but it may be difficult to achieve. All uterotonic drugs should be discontinued immediately. The obstetrician should attempt to right the inversion by applying pressure through the vagina to the uterine fundus; ring forceps may be used on the cervix to apply countertraction. Insertion of an intrauterine balloon may prove useful during treatment of uterine inversion, preventing reinversion.[131]

Anesthetic Management

Often, uterine tone precludes replacement of the uterus, and uterine relaxation is necessary for successful uterine reduction. The use of nitroglycerin to facilitate relaxation and replacement of the uterus has been reported.[132,133] Fairly large intravenous doses (200 to 250 μg) may be required, and the anesthesia provider typically will need to support the circulation with intravenous fluids and vasopressors. Administration of general anesthesia with a volatile halogenated agent may become necessary, not only for uterine relaxation but also to prepare for laparotomy should it become necessary to correct the inversion. Once the uterus has been replaced, a firm, well-contracted uterus is desired. Oxytocin should be infused, and additional uterotonic drugs may be needed.

Placenta Accreta Spectrum

Placenta accreta is defined as a placenta that in whole or in part invades the uterine wall and is inseparable from it.[134] Three types of placenta accreta (together referred to as **placenta accreta spectrum**) occur (Fig. 37.2). **Placenta accreta vera** is defined as adherence of the basal plate of the placenta directly to uterine myometrium without an intervening decidual layer. **Placenta increta** refers to a placenta in which chorionic villi invade the myometrium. **Placenta percreta** represents invasion through the myometrium into serosa and sometimes into adjacent organs, most often the bladder.[134]

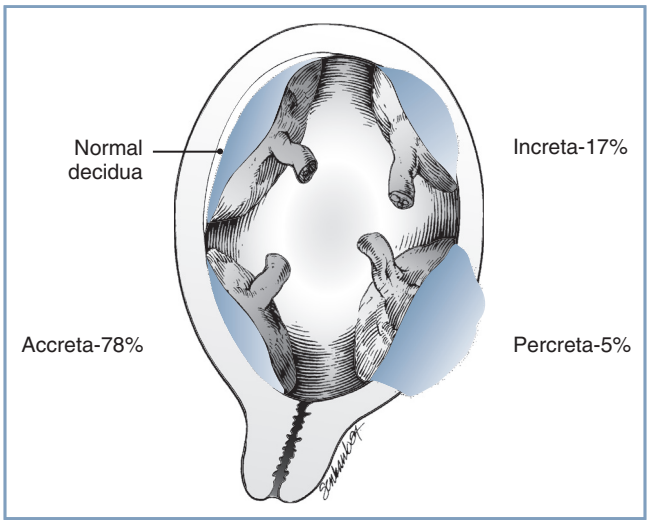

Fig. 37.2 Uteroplacental relationships found in abnormal placentation. (From Francois KE, Foley MR. Antepartum and postpartum hemorrhage. In: Gabbe SG, Niebyl JR, Simpson JL, et al., eds. *Obstetrics: Normal and Problem Pregnancies.* 6th ed. Philadelphia, PA: Elsevier; 2012:424.)

Epidemiology

The increased incidence of placenta accreta mirrors the increased cesarean delivery rate, with a lag time of approximately 6 years.[135] Between 1994 and 2007, the rate of peripartum hysterectomy for abnormal placentation increased by 20% in the United States, an increase entirely explained by adjustment for the rising prevalence of previous cesarean delivery among childbearing women.[11] The percentage of U.S. cesarean deliveries increased from 20.7% in 1997 to 32.9% in 2009, as a result of an increase in both primary and repeat cesarean deliveries and a decrease in the TOLAC rate.[136,137] Fortunately, the cesarean delivery rate stabilized after 2009 and declined to 31.9% in 2016.[138]

Previous cesarean delivery or other uterine surgery increases the risk for both placenta previa and placenta accreta. The combination of placenta previa with previous cesarean delivery synergistically increases the risk for coexisting placenta accreta, particularly if the placenta is anterior and overlies the uterine scar. A prospective multicenter observational study determined the relationship between placenta previa, previous cesarean delivery, and placenta accreta.[19] Placenta previa with no prior uterine surgery conferred a 3% risk for placenta accreta. In women with placenta previa and one previous cesarean delivery, the risk for placenta accreta was 11%. In patients with placenta previa and a history of two previous cesarean deliveries, the incidence of placenta accreta increased to 40%. The incidence of placenta accreta was more than 60% in women with placenta previa and a history of three or more previous cesarean deliveries (see Table 37.1). Another study documented a positive relationship between the extent of uterine wall invasion and the number of previous cesarean deliveries.[139]

Diagnosis

In some cases of placenta accreta the condition is first suspected at vaginal delivery, when the obstetrician notes difficulty in separating the placenta from the uterine wall.[140] The definitive diagnosis is then made at laparotomy. Antenatal diagnosis of placenta accreta facilitates effective planning. Antenatal diagnosis is associated with less maternal and neonatal morbidity, including decreased blood loss at delivery and transfusion of fewer units of blood products.[141] Ultrasonography is a useful screening tool in patients with placenta previa and/or previous cesarean delivery and is the primary imaging modality used for making the diagnosis of placenta accreta. However, among women at risk for placenta accreta, ultrasonography has imperfect sensitivity and specificity.[134] MRI may help confirm the diagnosis in at-risk patients with inconclusive ultrasonographic examinations.[134] Mathematical modeling using the presence or absence of placenta previa, number of previous cesarean deliveries, and strength of ultrasound evidence of placenta accreta can increase the sensitivity and specificity of accreta diagnosis.[142]

Obstetric Management

The ACOG advises that clinicians working at small hospitals without adequate blood bank supplies transfer patients with placenta accreta to a tertiary care facility because there is a predictable need for massive transfusion.[134,143] Patients treated at institutions with a 24-hour in-house obstetrician and anesthesia provider, immediate availability of a gynecologic oncologist, a fully stocked blood bank, and interventional radiology services suffer less morbidity than those treated at hospitals without these services.[144] Planned delivery with all of the necessary multidisciplinary collaborators present compared with emergency delivery is associated with less maternal morbidity, including fewer transfusions, complications, and intensive care unit admissions. However, circumstances may dictate emergency delivery, and institutions that manage women with suspected placenta accreta expectantly must have the capacity to mobilize the entire perioperative team at any time. Some cases of vaginal bleeding remote from term resolve spontaneously, and expectant management may prolong the duration of pregnancy, at least into the third trimester. However, the risk for severe antenatal bleeding increases as gestational age increases.[144] Timing of delivery, therefore, involves balancing this risk against the neonatal risks associated with preterm delivery. Decision analysis indicates that 34 weeks' gestational age is the preferred time for planned delivery in most clinical circumstances involving placenta previa and evidence of placenta accreta.[145]

Most patients with known placenta accreta should undergo planned preterm cesarean delivery and hysterectomy with the placenta left *in situ* because attempts to remove the placenta are likely to initiate hemorrhage. Because the positive predictive value of ultrasonography may be low, it is reasonable to await spontaneous placental delivery or even attempt manual extraction in cases in which the diagnosis is unclear, although manual extraction may increase the risk for bladder injury.[134,146] Preoperative placement of ureteral stents may minimize urinary tract injury.[134] A midline vertical skin incision may provide optimal surgical exposure, and it may be necessary to modify the uterine incision to avoid cutting through the placenta.

The preoperative insertion of **internal iliac artery balloon catheters** is controversial. Optimally, the balloons are inflated after delivery as a means to minimize blood in the surgical field and decrease blood loss and transfusion requirements. Retrospective cohort studies have reported conflicting data regarding the effects of balloon catheter placement on blood loss, transfusion requirements, and duration of the surgical procedure.[147–150]

Multiple complications can arise from the placement of these devices, some of them involving serious disruptions of the vasculature and lower extremity ischemia.[148,150–152] Introduction of the arterial catheters, even without inflation, can cause fetal bradycardia, necessitating emergency delivery.[153] If employed, therefore, internal iliac artery balloon catheters should be placed in the operating room to avoid dislodgement during transport and to allow for rapid delivery should fetal compromise occur. Authors of a 2012 review article opined that current evidence, confined to case reports, case series, and small retrospective studies, is inadequate to guide clinical decision-making.[154] The Society for Maternal-Fetal Medicine (SMFM) recommends reserving the use of prophylactic intra-arterial balloon catheters for well-counseled women with a strong desire for fertility preservation, those who decline blood products, and those with unresectable placenta percreta.[155] Prophylactic use of **resuscitative endovascular balloon occlusion of the aorta (REBOA)** reduces blood loss during placenta accreta surgery, based on meta-analysis of observational studies.[156]

Two forms of conservative therapy for placenta accreta have been described. In selected patients with a partial placenta accreta, small focal areas of placental invasion may be managed by curettage and oversewing. Alternatively, it may be possible to leave the intact placenta *in situ,* close the uterus and abdomen, and await spontaneous placental involution.[157–159] However, conservatively managed patients often require additional therapies such as internal iliac artery balloon inflation, embolization, or methotrexate. Some patients treated in this way have subsequently had successful pregnancies[157]; however, complications have been reported, including secondary hemorrhage, development of coagulopathy, subsequent need for hysterectomy, and sepsis.[157,159,160] The ACOG considers planned peripartum hysterectomy to be the management of choice for patients with placenta accreta and cautions the obstetrician to reserve uterine conservation strategies for hemodynamically stable patients who strongly desire future fertility.[134]

Anesthetic Management

Anesthetic management is similar to other cases of severe postpartum hemorrhage and peripartum hysterectomy (see later discussion). Preoperative suspicion for placental implantation abnormalities should alert the anesthesia provider to the potential for massive blood loss and transfusion.[161]

Initial blood loss may be minimal but can rapidly become torrential if the placental bed is disturbed or if the surgeons encounter unavoidable placental tissue during the course of the hysterectomy.

Invasive Treatment Options

Regardless of the cause of obstetric hemorrhage, first-line conservative measures may fail to control bleeding. In these cases, invasive procedures must be performed promptly once delivery has occurred to avoid severe morbidity and mortality. Second-line options, including intrauterine balloon tamponade, uterine compression sutures, angiographic arterial embolization, and uterine artery and/or internal iliac artery ligation, may help to avoid hysterectomy.[162] Unfortunately, no randomized controlled trials assessing relative efficacy and safety of these options exist to guide management. In cases of intractable hemorrhage, hysterectomy may become necessary.

Intrauterine balloon tamponade is a conservative method for controlling postpartum hemorrhage, especially when uterine atony or lower uterine segment bleeding is suspected.[65] The technique can reduce rates of hysterectomy.[163] An intrauterine balloon can be deployed quickly, requires minimal analgesia for both insertion and removal, and preserves fertility. Continued bleeding may be concealed behind the balloon. Failure may also be attributed to prolapse through a partially open cervix. In such cases, the balloon may be replaced and secured by applying bilateral ring forceps to the cervix or by placing a cervical cerclage. Few complications have been reported, although concerns for infection exist.[164]

Uterine compression sutures (e.g., B-Lynch suture[165]) are most useful in cases of refractory uterine atony but have also been used in cases of retained placenta and accreta.[166] A systematic review—based mostly on case reports and case series and therefore subject to reporting bias—estimated a 92% success rate for this procedure,[166] but the success rate (avoidance of hysterectomy) in a prospective population-based trial was more modest (75%).[167] The suture may slip off of the uterine fundus and fail to provide compression. Placement of compression sutures may preserve fertility, but data on the long-term effects on fertility and pregnancy outcomes are lacking. Complications include infection, uterine necrosis, and suture erosion.[166] A case report describes placenta accreta and uterine rupture presumably caused by a uterine compression suture that had been placed after a previous delivery.[168]

Angiographic arterial embolization may be appropriate if moderate blood loss continues and if the patient is stable for transport to the interventional radiology suite. The uterine arteries, which are branches of the anterior trunk of the internal iliac arteries, provide the primary blood supply to the uterus. The ovarian and vaginal arteries also make a sizable contribution to uterine blood flow during pregnancy. During angiography, the radiologist can identify the vessels responsible for bleeding and embolize these vessels with gelatin sponge pledgets (Gelfoam). A small percentage of cases may require placement of a metallic coil in addition to gelatin sponges. The gelatin sponge is a temporary occlusive agent, and flow through these vessels returns over time, preserving both the uterus and fertility.[169] Published success rates in emergently controlling postpartum hemorrhage with this approach vary between 70% and 100%.[166] Successful treatment of acute postpartum hemorrhage with this modality requires rapid access to an angiography facility and a skilled interventional radiologist. The patient must be observed and monitored carefully while undergoing the procedure. Ischemic complications of embolization therapy have been reported, but the risk is reduced with the use of selective techniques.[166,170,171]

Bilateral surgical ligation of the uterine arteries (O'Leary sutures) may be used to control bleeding at laparotomy.[172] In the case of failure to control bleeding, the surgeon may proceed with a more complex procedure that involves ligation of the tubo-ovarian and ascending and descending uterine arteries. Internal iliac artery ligation may also be considered, although it is more difficult to perform. Reported success rates are highly variable, and it appears that arterial ligation is being used less often than in the past.[65] The rich collateral circulation of the uterus at term most likely contributes to failure to control bleeding, as does the challenging nature of the procedure itself. Engorgement of pelvic viscera, variability in vascular anatomy, and the increased blood flow during pregnancy contribute to the risk for complications when this approach is used. Successful surgical ligation permits preservation of fertility. Ischemic complications and neuropathy have been reported.[166]

Peripartum hysterectomy is the definitive treatment for postpartum hemorrhage unresponsive to medical and other invasive therapies. The two most common indications for this procedure are uterine atony and placenta accreta.[11] Between 1994 and 2007, the overall rate of peripartum hysterectomy increased by 15% in the United States, because of a 130% increase in hysterectomy for atony and a 20% increase in hysterectomy for placental implantation abnormalities.[11] The increase in hysterectomy for placental abnormalities is entirely explained by an increase in the cesarean delivery rate.[11] Parturients with a history of previous cesarean delivery are more than five times as likely to require a peripartum hysterectomy as those without this history, and the risk for hysterectomy rises progressively with an increasing number of previous cesarean deliveries.[11,19] The incidence of peripartum hysterectomy caused by uterine rupture has declined in the United States because the rate of TOLAC has declined.[11] Elective peripartum hysterectomy may also be undertaken for concurrent gynecologic abnormalities, especially malignancies.

Peripartum hysterectomy is a technically challenging operation; the uterus is enlarged, exposure may be difficult, the vessels are engorged, and the pregnant uterus receives a rich collateral blood supply. The presence of dense adhesions from previous surgeries can further complicate the procedure. Compared with nonobstetric hysterectomy, patients undergoing obstetric hysterectomy are more likely to suffer postoperative hemorrhage and require blood transfusion, have intraoperative urinary tract injury, and experience

perioperative complications such as wound infection, venous thromboembolism, and cardiovascular and other medical complications.[173] Mortality is more than 25 times higher in peripartum than in nonperipartum hysterectomy.[173]

Emergency peripartum hysterectomy is associated with increased blood loss, worse coagulopathy, and increased transfusion rates compared with planned peripartum hysterectomy.[174] A 2010 systematic review of emergency postpartum hysterectomy for hemorrhage revealed a perioperative morbidity rate of 56% and a mortality rate of 2.6%.[175] Transfusion is required in 44% or more of patients.[175] A multicenter review showed that the mean blood loss for emergency obstetric hysterectomy was 2526 mL, with a mean transfusion requirement of 6.6 units of PRBCs; in elective procedures, the mean blood loss was 1319 mL and the average replacement was 1.6 units of PRBCs (Table 37.4).[174]

Because of the challenging technical aspects of the procedure, the obstetrician may elect to perform a subtotal hysterectomy, wherein the cervix is left *in situ.* Subtotal approaches are associated with fewer urinary tract and other operative injuries and a shorter length of stay,[173,175] but greater mean transfusion requirements and more frequent rates of reoperation than total hysterectomy.[173] Subtotal hysterectomy is not appropriate for patients with bleeding from the cervix, lower uterine segment, or both (e.g., implantation of the placenta on the lower uterine segment).

Manual compression of the aorta can be a lifesaving procedure in the event of catastrophic obstetric hemorrhage.[176] Effective aortic compression against a vertebral body in the upper abdomen should decrease blood flow to the pelvis, thereby allowing hemodynamic and hemostatic resuscitation and surgical control. An aortic cross-clamp requires vascular surgery expertise and retroperitoneal dissection but may be necessary to achieve hemostasis. Mild cardiac and renal dysfunction have been noted in nonobstetric patients if the aortic cross-clamp time exceeds 50 minutes.[177] If a prolonged clamp time is required, the anesthesia provider should prepare for lactic acidosis and hypotension at the time the clamp is released. An endovascular aortic balloon may be inserted emergently via the femoral artery, and partial inflation just below the renal arteries may be sufficient to facilitate surgical visualization while preserving distal blood flow.[178] Advanced surgical techniques to control friable, engorged blood vessels include felt or Teflon pledgets to buttress sutures, the rapid application of straight clamps, and the application of high-pressure surgical sealants.[179,180]

Anesthesia for peripartum hysterectomy is frequently challenging because massive blood loss may occur unpredictably.[161] An experienced, skilled team is invaluable and critical to a successful outcome (see later discussion). Anesthesia providers may elect neuraxial anesthesia in a properly prepared patient. Intraperitoneal manipulation, dissection, and traction exceed similar maneuvers required with cesarean delivery alone. Maintenance of a T4 sensory level of anesthesia and judicious sedation may reduce the need for intraoperative conversion to general anesthesia. In a multicenter

study of peripartum hysterectomy, none of the 12 patients who received continuous epidural anesthesia for elective or emergency hysterectomy required intraoperative induction of general anesthesia.[174] In a single-center retrospective review, 79 patients underwent cesarean hysterectomy with neuraxial anesthesia, of whom 21% required conversion to general anesthesia.[181] Longer surgical duration and a history of three or more prior cesarean deliveries increased the odds of requiring conversion to general anesthesia.

Single-shot spinal anesthesia is unlikely to provide anesthesia of sufficient duration for an unanticipated hysterectomy. Patients who have delivered vaginally with preexisting epidural labor analgesia may be managed successfully with extension of epidural blockade, but careful consideration of hemodynamic status should precede the administration of local anesthetics into the epidural space. Animal models suggest that sympatholysis established before the onset of hemorrhage reduces excessive catecholamine response to blood loss and may improve survival.[182] However, the induction of sympatholysis during hemorrhage may compromise end-organ perfusion and even precipitate cardiopulmonary arrest.[182]

As the magnitude of blood loss increases, general anesthesia becomes the anesthetic technique of choice. First, severely hypotensive patients may require tracheal intubation for airway protection. Second, large fluid shifts and massive transfusion may adversely affect oxygenation so that control of ventilation via an endotracheal tube becomes necessary. Third, these same fluid shifts increase airway edema, potentially making failed ventilation/failed tracheal intubation more likely as the surgery proceeds. Fourth, the massive transfusion of blood products often results in the need for co-administration of potent vasopressors and calcium chloride and, thus, central venous access; the placement of a central venous catheter may be more easily accomplished after the induction of general anesthesia. In all cases, patients at risk for peripartum hysterectomy managed with neuraxial anesthesia should be informed in advance that intraoperative discomfort or severe hemorrhage may mandate the intraoperative induction of general anesthesia.

The induction of general anesthesia in the setting of severe hemorrhage may require careful use of small doses of noncardiodepressant induction agents such as ketamine or etomidate. The circulation should be supported with replacement of intravascular volume and vasopressors as needed. A review of maternal deaths from postpartum hemorrhage in France revealed that 5 of 38 deaths followed cardiac arrest on induction of general anesthesia.[183]

Regardless of the anesthetic technique used, two or more large-bore intravenous catheters should be inserted. Invasive blood pressure monitoring may aid in the prompt recognition of hypotension and provide access for frequent blood draws. The blood bank should be alerted to the possible need for massive transfusion. At least 4 units of PRBCs should be immediately available, with additional blood products, including plasma and cryoprecipitate, readily available without delay. The ACOG recommends consideration of intraoperative blood salvage in cases with massive transfusion potential (see later discussion).[65,134] Vasoactive drugs (e.g., phenylephrine, epinephrine), fluid warmers, a forced-air body warmer, and equipment for rapid infusion of fluids and blood products should be accessible if the care team is anticipating and managing significant blood loss.

TEAM RESPONSE TO HEMORRHAGE

Prevention of Mortality

Data from the UK Confidential Enquiry into Maternal and Child Health and the French Confidential Enquiry into Maternal Death reveal that maternal deaths from hemorrhage in high-resource settings are often preventable and associated with substandard care.[56,184] In one state-level study, 93% of hemorrhage-related deaths were found to be preventable, compared with 40% of all-cause pregnancy-related deaths.[12]

Delays in diagnosis and treatment of postpartum hemorrhage increase the severity of hemorrhage.[124,184] Among women who develop postpartum hemorrhage from uterine atony after vaginal birth, risk factors for progressing to severe hemorrhage (defined as a decrease in hemoglobin concentration greater than 4 g/dL) include delaying the administration of oxytocin and delaying manual exploration of the uterus.[124] Delays of more than 10 minutes in summoning either an obstetrician or an anesthesia provider to help manage hemorrhage also increase the odds of severity, presumably by delaying treatment. Interestingly, epidural labor analgesia protects against severe hemorrhage, in all likelihood by allowing for more rapid and thorough uterine exploration.[124]

Delays in care most likely result from several factors, including difficulties in accurately estimating blood loss and in diagnosing maternal hypovolemia and shock, lack of aggressive monitoring and treatment of coagulopathy, and poor coordination of team responses. Practitioners often underestimate the amount of hemorrhage, with the degree of underestimation increasing as volume of blood loss increases (Fig. 37.3).[185–188] Accuracy of blood loss estimation can be improved with the use of calibrated collection drapes.[188,189] Clinician education using simulated scenarios with known blood volumes enhances estimation accuracy.[186,190,191] Separation of nonblood fluids (i.e., switching the suction canister after evacuation of amniotic fluid) and weighing pads and bedding improves assessment.[192] It is imperative that clinicians have a low threshold for the diagnosis of postpartum hemorrhage.

A second potential explanation for delays in diagnosis and treatment relates to difficulties in diagnosing hypovolemic shock in healthy young patients. The American College of Surgeons' Trauma Committee's Advanced Trauma Life Support (ATLS) system defines four stages of hypovolemic shock based on degree of blood loss (see Table 37.2).[74] Obstetric patients are often mildly tachycardic, and worrisome rates of tachycardia (greater than 120 bpm) may not develop until the patient has lost 30% to 40% of her total blood volume. Similarly, hypotension and mental status changes are late signs. Findings such as these have led to the

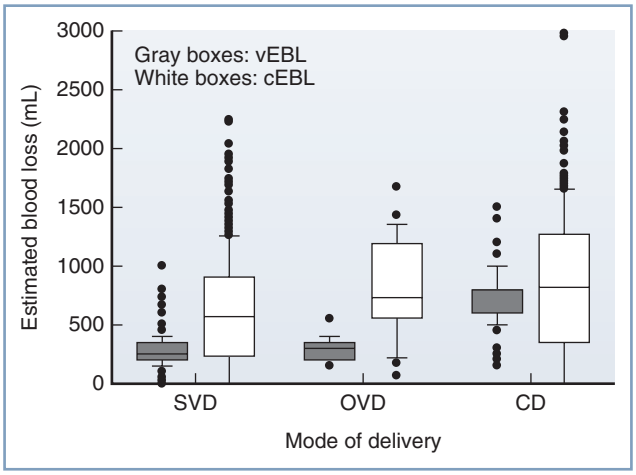

Fig. 37.3 The visually estimated blood loss *(vEBL)* and calculated estimated blood loss *(cEBL)* by mode of delivery. The boxes illustrate the 25th, 50th, and 75th percentiles, and the whiskers illustrate the 10th and 95th percentiles. Calculated estimated blood loss was derived by multiplying the calculated maternal blood volume by the percent of blood volume lost, where calculated maternal blood volume = 0.75 × {[maternal height in inches × 50] + [maternal weight in pounds × 25]} and percent of blood volume lost = [predelivery hematocrit – postdelivery hematocrit]/predelivery hematocrit. vEBL was statistically different from cEBL for all modes of delivery, demonstrating an underestimation of vEBL with increasing cEBL. *SVD,* Spontaneous vaginal delivery; *OVD,* operative vaginal delivery; *CD,* cesarean delivery. (From Stafford I, Dildy GA, Clark SL, Belfort MA. Visually estimated and calculated blood loss in vaginal and cesarean delivery. *Am J Obstet Gynecol.* 2008;199:519.e1–e7.)

The Council on Patient Safety in Women's Healthcare/National Partnership for Maternal Safety Maternal Early Warning Criteria. Abnormal blood pressure, heart rate, respiratory rate, and/or oxygen saturation triggers should be confirmed within 10 minutes, and if the abnormality is confirmed, the physician should be called to evaluate the patient at the bedside; oliguria and patient symptomatic triggers should prompt immediate action. Bedside nurses should always feel comfortable to escalate their concerns at any time. From Mhyre JM, D'Oria R, Hameed AB, et al. The maternal early warning criteria: A proposal from the National Partnership for Maternal Safety. *Obstet Gynecol.* 2014;124:782–786.

development of early warning systems to detect impending adverse events (Table 37.5).[193,194] Physiologic variables such as vital signs, oxygenation, and mental status are monitored regularly, and thresholds that trigger bedside physician evaluation are defined. Maternal early warning systems are not specific to hemorrhage. Such systems typically have low positive predictive values and high negative predictive values in predicting maternal morbidity.[193] However, when used as part of a systematic approach to maternal safety, maternal early warning systems may reduce severe maternal morbidity.[195]

Another factor that may lead to delays in care is the speed with which coagulopathy develops in the setting of obstetric hemorrhage. The rapid consumption of coagulation factors, especially fibrinogen, during obstetric hemorrhage has prompted experts to recommend aggressive monitoring and treatment of coagulopathy, especially hypofibrinogenemia.[47,196] Postpartum hemorrhage and other placental bed bleeding such as abruption appear to trigger a coagulopathy disproportionate to the amount of blood loss or dilution of coagulation factors (see later discussion). Once coagulopathy develops, the requirement for additional resources (e.g., blood products) accelerates. The institutional system(s) by which personnel and resources are rapidly activated must be clearly defined in advance.

Protocols and Team Approach

Because delays in care during postpartum hemorrhage result in unfavorable outcomes, efforts focus on early recognition and rapid treatment of hemorrhage. The National Partnership for Maternal Safety, sponsored by the ACOG Council on Patient Safety in Women's Healthcare, has published a patient safety bundle, a collection of evidence-based practices designed to enhance early detection of, and response to, hemorrhage and decrease hemorrhage-related morbidity and mortality.[197] It emphasizes team approaches; employment of multidisciplinary protocols, education, and drills; and review of cases of severe hemorrhage. The bundle also calls for quantification of blood loss, recognition of early signs of hypovolemia, early monitoring for anemia and coagulopathy, and appropriate transfusion of blood products.

The obstetric hemorrhage bundle is divided into four sections: readiness, recognition and prevention, response, and reporting and systems learning (Fig. 37.4).[197] It recommends that every maternity unit maintain a hemorrhage cart with access to important supplies, surgical instruments, and medications. It advises partnering with the local blood bank to ensure rapid availability of blood products and encourages creation of a massive transfusion protocol. Clinicians are advised to assess hemorrhage risk at multiple time points, including prenatally, on admission to the delivery unit, at the beginning of the second stage of labor, and postpartum. The bundle emphasizes quantitative cumulative blood loss measurement rather than visual estimation, and recommends that each obstetric unit develop a protocol to manage all stages of obstetric hemorrhage. Finally, it encourages the use of huddles, debriefing sessions, multidisciplinary reviews, and quality improvement committees.

The effectiveness of such approaches has been evaluated. Investigators examined outcomes before and after introduction of a comprehensive hemorrhage program, and

READINESS

Every unit

- Hemorrhage cart with supplies, checklist, and instruction cards for intrauterine balloons and compressions stitches
- Immediate access to hemorrhage medications (kit or equivalent)
- Establish a response team - who to call when help is needed (blood bank, advanced gynecologic surgery, other support and tertiary services)
- Establish massive and emergency release transfusion protocols (type-O negative/uncrossmatched)
- Unit education on protocols, unit-based drills (with post-drill debriefs)

RECOGNITION & PREVENTION

Every patient

- Assessment of hemorrhage risk (prenatal, on admission, and at other appropriate times)
- Measurement of cumulative blood loss (formal, as quantitative as possible)
- Active management of the 3rd stage of labor (department-wide protocol)

RESPONSE

Every hemorrhage

- Unit-standard, stage-based, obstetric hemorrhage emergency management plan with checklists
- Support program for patients, families, and staff for all significant hemorrhages

REPORTING/SYSTEMS LEARNING

Every unit

- Establish a culture of huddles for high risk patients and post-event debriefs to identify successes and opportunities
- Multidisciplinary review of serious hemorrhages for systems issues
- Monitor outcomes and process metrics in perinatal quality improvement (QI) committee

Standardization of health care processes and reduced variation has been shown to improve outcomes and quality of care. The Council on Patient Safety in Women's Health Care disseminates patient safety bundles to help facilitate the standardization process. This bundle reflects emerging clinical, scientific, and patient safety advances as of the date issued and is subject to change. The information should not be construed as dictating an exclusive course of treatment or procedure to be followed. Although the components of a particular bundle may be adapted to local resources, standardization within an institution is strongly encouraged.

The Council on Patient Safety in Women's Health Care is a broad consortium of organizations across the spectrum of women's health for the promotion of safe health care for every woman.

May 2015

observed a reduction in hemorrhage severity, fewer cases of coagulopathy, a decrease in blood products transfused, and a nonsignificant reduction in the number of puerperal hysterectomies performed in the postprotocol period.[198,199] The state of California witnessed a dramatic decrease in the rate of hemorrhage-related severe maternal morbidity after implementation of a hemorrhage bundle.[200] These types of programs have positive effects on sentinel events and malpractice payments.[201]

TRANSFUSION THERAPY

Despite advances in the prevention, diagnosis, and treatment of the hemorrhagic complications of pregnancy, the potential for significant blood loss remains. All physicians who provide care for pregnant women should understand the indications, risks, and benefits of transfusion. Transfusion may be indicated for treatment of severe anemia after moderate obstetric hemorrhage or to preserve life during massive hemorrhage.[202]

Risks and Benefits

Risk for Anemia

Anemia is common during pregnancy and carries many adverse effects (see Chapter 44). Blood oxygen content and oxygen delivery to the tissues depend on hemoglobin concentration. Several compensatory physiologic responses can offset the negative effect of anemia on oxygen transport, especially if euvolemia is maintained with intravascular volume expansion after moderate hemorrhage. Tachycardia and increased stroke volume combine to increase cardiac output, augmenting oxygen delivery. Anemia decreases blood viscosity and systemic vascular resistance, enhancing blood flow to the tissues. Tissue oxygen extraction increases during anemic states. Three lines of evidence support the safety of normovolemic, normotensive anemia. Weiskopf et al.[203] studied the effects of acute normovolemic hemodilution on oxygen delivery and extraction. As hemoglobin concentration fell, systemic vascular resistance decreased and heart rate, stroke volume, and cardiac index increased. Oxygen transport rate and mixed venous oxyhemoglobin saturation did not decrease, and plasma lactate did not accumulate until hemoglobin concentration reached 5.0 g/dL. Second, experience with patients who refuse blood transfusion confirms that rates of morbidity and mortality are comparable to the general surgical population until hemoglobin concentrations fall below 5.0 g/dL. Finally, postoperative wound tissue oxygenation and wound collagen deposition are preserved with mild anemia, showing no impairment until the postoperative hemoglobin concentration falls below 5.0 g/dL.[204] These data have been observed in healthy, nonpregnant patients and volunteers who were at rest. Extrapolation of these results to sick or pregnant patients may not be warranted, as anemia carries increased risks in patients with cardiovascular disease.[205]

Moderate levels of postpartum anemia are associated with fatigue. However, fatigue is transient, and within 1 week fatigue and health-related quality of life scores are similar between postpartum patients who were anemic at discharge and those who were not.[206] Transfusion of 1 or 2 units of PRBCs to hemodynamically stable, moderately anemic parturients has no effect on length of hospital stay.[207] The effect of moderate anemia on breast-feeding is unknown.

Risks Associated with Transfusion

Blood product transfusion is associated with known risks including transfusion-associated circulatory overload (TACO), transfusion-related acute lung injury (TRALI), immunologic reactions, infectious complications, and clerical error resulting in ABO incompatibility (see Table 54.2).

Transfusion-associated circulatory overload (TACO) occurs in approximately 1% of transfused patients.[208] It may follow the transfusion of as little as 1 unit of PRBCs,[209] but the likelihood of TACO increases as the volume of transfused plasma increases.[208]

Transfusion-related acute lung injury (TRALI) is defined as a new acute lung injury (ALI) that occurs within 6 hours of transfusion in a patient without an alternative risk factor for ALI.[210] It is usually accompanied by hypoxemia, transient leukopenia, and radiographic evidence of pulmonary edema in the absence of circulatory overload (Box 37.5).[210] TRALI results when human leukocyte antigen (HLA) class I and II neutrophil or possibly monocyte antibodies in donor plasma react with recipient white blood cells, leading to increased pulmonary microvascular permeability, interstitial and alveolar edema, and extravasated neutrophils in the alveolar

BOX 37.5 Recommended Criteria for TRALI and Possible TRALI

TRALI Criteria

- Acute lung injury
  - Acute onset
  - Hypoxemia
    - Research setting: $PaO_2/FIO_2 \leq 300$ or $SpO_2 < 90\%$ on room air
    - Nonresearch setting: $PaO_2/FIO_2 \leq 300$ or $SpO_2 < 90\%$ on room air or other clinical evidence of hypoxemia
  - Bilateral infiltrates on frontal chest radiograph
- No evidence of left atrial hypertension (i.e., circulatory overload)
- No preexisting acute lung injury before transfusion
- Occurs during or within 6 h of transfusion
- No temporal relationship to an alternative risk factor for acute lung injury

Possible TRALI Criteria

- Acute lung injury
- No preexisting acute lung injury before transfusion
- Occurs during or within 6 h of transfusion
- A clear temporal relationship to an alternative risk factor for acute lung injury

TRALI, Transfusion-related acute lung injury.
From Kleinman S, Caulfield T, Chan P, et al. Toward an understanding of transfusion-related acute lung injury: statement of a consensus panel. *Transfusion.* 2004;44:1774–1789.

spaces.[211] Multiparous female donors are more likely to carry the offending antibodies.[212] Consequently, in 2006, U.S. blood-collection agencies instituted male-only donor plasma transfusion policies, and the TRALI rate has fallen to approximately one-third of its prior level (approximately 1 case per 12,000 transfused units).[212] Multicomponent apheresis collection techniques also decrease the risk for TRALI.[211]

Allogeneic RBC administration also increases the risk for **transfusion-related immunomodulation (TRIM).** The mechanisms for development of TRIM are incompletely understood, but subsequent to RBC transfusion the host develops immune tolerance and a period of generalized immune suppression. Consequences of immune tolerance and suppression include an increased incidence of nosocomial infection, postoperative infection, and cancer recurrence.[213] In addition, microchimerism, whereby donor cells/DNA persist in the host for several years, occurs and predisposes the recipient to autoimmune illnesses.[213] There is some suggestion that TRIM increases the lifetime risk for nonsolid cell malignancies.[214] These consequences are more likely to manifest as time passes and therefore may be more likely to affect young obstetric patients than older patients. Leukoreduction may have a modest role in mitigating TRIM.[211]

The risk for **viral transmission** because of allogeneic blood transfusion continues to decrease with thorough donor screening and use of nucleic acid amplification testing (nucleic acid technology [NAT]).[215] The residual risk for transmission after both NAT and serologic testing of donor blood is approximately 1 in 2 million for both human immunodeficiency virus (HIV) and hepatitis C virus (HCV).[216,217] NAT is not routinely used to test for hepatitis B virus (HBV). Instead, donor screening for hepatitis B surface antigen (HBsAg) and anti-core (HBc) antibody has greatly reduced the risk for transmission of HBV, with the current risk for transmission with a blood transfusion being 1 in 350,000.[215,217] The transfusion transmission of Creutzfeldt-Jakob disease also has been reported. Levels of infectivity are very low,[215] but because of the long incubation period of this prion, symptoms may not be evident for several years after transfusion.[218] The first case of West Nile virus transmitted via a blood transfusion was identified in 2002; since 2003, routine blood screening has been implemented, virtually eliminating this risk.[215] Cytomegalovirus (CMV) is carried in the monocytes of asymptomatic donors and may be transmitted to uninfected recipients of blood transfusions. Most of the subsequent infections are asymptomatic or mild, but CMV infection of an immunocompromised patient and/or fetus or neonate can lead to serious sequelae. The transmission rate may be as high as 30% without preventive techniques. Transmission of CMV is reduced by administering seronegative or leukodepleted PRBCs.[219]

Bacterial contamination occasionally occurs, most often during platelet transfusion. Because platelets may undergo conformational changes at temperatures below 18° C, they are typically stored at 20° C to 24° C. This warmer storage temperature (compared with that used for PRBCs) increases the risk for bacterial proliferation. In 2004, the AABB mandated testing of all platelets for bacterial contamination. Use of culture-negative platelets has resulted in a reduction in the risk for septic transfusion to 1 in 75,000.[220]

Hemolytic transfusion reaction is a rare complication; it occurs most commonly as a result of accidental administration of ABO-incompatible blood.[217] Acute intravascular hemolysis typically results in fever, chills, nausea, flushing, and chest and flank pain. Signs that may manifest during general anesthesia include hypotension, tachycardia, DIC, and hemoglobinuria. Immediate supportive care consists of discontinuation of the transfusion, treatment of hypotension and hyperkalemia, administration of a diuretic, and alkalinization of the urine. Assays for urine and plasma hemoglobin concentration and antibody screening confirm the diagnosis. A second cross-match must be performed.

The biochemical and additional changes that occur during blood storage can lead to complications in the recipient, particularly when blood products are infused rapidly, as during massive transfusion for severe hemorrhage. The anticoagulant used for blood collection and storage contains citrate, which binds ionized calcium. Citrate is rapidly metabolized in the liver and typically does *not* lead to significant **hypocalcemia.** However, in patients who are hypothermic, have liver disease, or require rapid infusion of multiple units of blood products, citrate may accumulate and cause a decrease in ionized calcium. Hypocalcemia results in reduced cardiac contractility, hypotension, and elevated central venous pressure. The concentration of citrate is seven times higher in fresh frozen plasma (FFP) and platelets than in PRBCs.

Transfusion of stored blood may lead to **acidosis, hyperkalemia,** and **hypothermia.** Stored blood develops low pH caused by the addition of acidic citrate-phosphate-dextrose and the accumulation of lactic and pyruvic acids that result from RBC metabolism and glycolysis. Despite the lower pH, transfusion of blood rarely causes significant acidosis as long as tissue perfusion remains adequate. Potassium concentration increases in stored blood. Typically, transfused potassium moves intracellularly or is excreted in the urine and does not accumulate in the recipient, but hyperkalemia may develop as blood is transfused rapidly to a hypothermic and acidotic patient. PRBCs and plasma are maintained at 4° C and should be administered through a warming device to prevent development of hypothermia.

Transfusion Strategies

Several randomized controlled trials have compared the use of restrictive and liberal transfusion practices, based on lower or higher hemoglobin triggers, mostly in nonpregnant patients; these trials uniformly failed to demonstrate benefit to a liberal strategy and suggested that using higher hemoglobin triggers may cause harm.[221–224] In fact, the use of lower hemoglobin triggers reduces the risk for receiving an RBC transfusion (relative risk [RR], 0.61; 95% confidence interval [CI], 0.52 to 0.72), reduces the volume of RBC transfused, and does not affect the rate of adverse events such as myocardial infarction, other cardiac events, or stroke.[225] Furthermore, restrictive strategies are associated with a reduction of in-hospital

mortality (RR, 0.77; 95% CI, 0.62 to 0.95) and a trend toward lower 30-day mortality (RR, 0.85; 95% CI, 0.70 to 1.03).[225] In a 2014 multicenter randomized trial, stable obstetric patients who suffered postpartum hemorrhage and developed acute anemia (4.8 to 7.9 g/dL) were randomized to receive RBC transfusion or no intervention.[226] No differences were apparent between the two groups, other than a slight difference in fatigue scores at 1 week. Both the AABB and the American Society of Anesthesiologists (ASA) recommend restrictive transfusion strategies.[202,217]

The AABB further advises that transfusion not be guided by hemoglobin concentration triggers alone.[217] Physicians should consider the patient's symptoms and physiologic triggers such as mentation, blood pH, lactate concentration, urine output, and, if central access is present, central venous oxygen saturation, to guide transfusion. Every patient will have a different critical oxygen threshold, the point at which metabolism shifts from aerobic to anaerobic. Utilizing symptomatic and physiologic transfusion triggers rather than an absolute hemoglobin level can target blood transfusion to the needs of the individual patient.

Transfusion practices vary widely[227] and often deviate from both national and institutional guidelines.[228–231] Given current evidence, it seems reasonable that transfusion should be considered in obstetric patients with a hemoglobin concentration less than 7 g/dL and those with clinical evidence of inadequate oxygen-carrying capacity. Active hemorrhage may prompt transfusion in some patients with a hemoglobin concentration greater than 7 g/dL.[65]

The optimal preparation for possible transfusion in the peripartum period is controversial. Many anesthesia providers believe that the potential need for transfusion, and the occasional patient who develops an antibody from fetal antigen exposure during pregnancy, warrant the routine performance of a blood type and screen on admission to the hospital for childbirth. Others suggest that this test is unnecessary in healthy women without risk factors for peripartum hemorrhage and negative antibody screens throughout the pregnancy. Given the low rate of transfusion in this group, the number-needed-to-treat is high. The ASA Practice Guidelines for Obstetric Anesthesia state that the decision to perform a type and screen should be based on maternal history, anticipated hemorrhagic complications, and local institutional policies.[232] Patients with a positive antibody screen should have a cross-match performed to avoid a delay in obtaining blood products should the need arise.

If blood is required quickly and the results of antibody screening are not available, the safest option is to administer ABO- and Rh-specific blood. If the blood type is unknown and blood products are required immediately, type O Rh-negative RBCs and type AB plasma can be administered.

Blood Conservation Techniques

Iron deficiency anemia is the most common cause of anemia during pregnancy because fetal erythropoiesis occurs at the expense of maternal iron stores (see Chapter 44). Oral iron therapy is a mainstay of anemia prevention and treatment in pregnant women, but unfortunately, oral therapy is not well-tolerated and iron may be poorly absorbed through the gastrointestinal tract. Intravenous therapy corrects anemia more quickly and reliably than oral iron therapy.[233–235]

The potential advantages of **autologous blood transfusion** include avoiding the risk for some transfusion-related adverse events and reducing demands on the blood supply. The three methods of autologous transfusion are (1) preoperative (antepartum) donation, (2) normovolemic hemodilution, and (3) intraoperative blood salvage. The first two options are not recommended in pregnancy. Preoperative autologous donation causes anemia, may not reduce the risk for allogeneic transfusion, cannot be used in emergencies, and is not cost-effective because of difficulties in predicting transfusion need in obstetric patients, even those with traditional risk factors for hemorrhage.[236] Normovolemic hemodilution may also induce anemia and may not reduce the risk for allogeneic transfusion.[237] The third option, **intraoperative blood salvage,** is a technique whereby blood shed during surgery is scavenged, processed by centrifugation, washed, and filtered before transfusion to the patient. RBCs processed in this way have an excellent survival rate.

Historically, there was concern that the processing of salvaged blood collected from the surgical field did not adequately remove amniotic fluid, fetal debris, or fetal cells, and that reinfusion might precipitate amniotic fluid embolism. However, these concerns are unfounded, as modern salvaging processes efficiently remove these contaminants.[238,239] Washing and filtration remove tissue factor, which is implicated in the pathophysiology of amniotic fluid embolism.[240] Combining these processes with the use of a leukocyte-depletion filter greatly reduces fetal debris.[241,242] Fetal squamous cell concentration in postfiltration scavenged blood is equal to that in maternal venous blood.[242] In all cases of potential contamination, a double suction setup is recommended, although this increases the volume of unprocessed blood, and decreases the cost-effectiveness of the technique.[243] One suction line is connected to the general suction system and is used to remove grossly contaminated fluid immediately after amniotomy and delivery; a second suction line is used after delivery to transfer shed blood to the salvaging system.

Reports of clinical experience with cell salvage in obstetric patients have accumulated over recent years; no reports of acute respiratory distress syndrome, DIC, or other complications have been described.[244–251] The authors of one case report attributed maternal death to cell salvage–induced amniotic fluid embolism,[252] but many authorities do not accept the cause of death in this case as amniotic fluid embolism because the patient was quite ill with preeclampsia with severe features—hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome—and coagulopathy, and the postmortem examination was inconclusive concerning the diagnosis of amniotic fluid embolism.[241]

Some minimal maternal risks exist. The cell scavenging system does not distinguish between maternal and fetal RBCs, and the transfusion of washed blood is likely to expose the

mother to a greater amount of fetal RBCs than commonly occurs during delivery.[241,242] Isoimmunization of the mother is possible, and anti-D immune globulin should be administered as guided by Kleihauer-Betke testing in the postpartum period.[238,239,244]

Despite the potential risks, intraoperative blood salvage during cesarean delivery is widely regarded as safe. The ACOG has stated that in cases of suspected placenta accreta, "cell saver technology should be considered if available."[65] The ASA Practice Guidelines for Obstetric Anesthesia recommend: "In cases of intractable hemorrhage, when banked blood is not available or the patient refuses banked blood, consider intraoperative cell salvage if available."[232] Many authorities advocate this technique as a potential solution to the worsening shortage of banked blood, increased cost of allogeneic blood transfusion, and concern about transfusion-related infections and clerical errors.[238,239,241] An economic analysis of the use of cell salvage in obstetrics demonstrates that its cost-effectiveness may depend, in part, on an institution's case volume and the anticipated volume of blood loss. This procedure may therefore prove useful in cases of massive transfusion. Furthermore, transfusion of salvaged blood is acceptable to many Jehovah's Witness patients.[253]

Treatment of Massive Blood Loss

During initial resuscitation of the hemorrhaging patient, warmed non–dextrose-containing crystalloid (e.g., lactated Ringer's, normal saline) and/or colloid (e.g., 5% albumin) solutions are acceptable choices for volume replacement. During massive hemorrhage, blood replacement therapy becomes necessary. Coagulopathy can develop rapidly in the bleeding patient because of dilution from replacement of blood with crystalloid and PRBCs, and hemostatic factor consumption. Furthermore, obstetric hemorrhage may be associated with accelerated factor consumption, especially during bleeding from the placental bed.[43,254] Fibrinolysis may also play a role during uterine bleeding.[255] DIC further worsens hemorrhage (see later discussion). Pregnancy-related pathologic processes commonly associated with DIC include amniotic fluid embolism, placental abruption, uterine infection, intrauterine fetal demise, and severe postpartum hemorrhage.[43] Transfusion endpoints include cessation of bleeding, hemodynamic stability, urine output of 0.5 mL to 1 mL/kg/h, decreasing serum lactate, demonstrating improved end-organ perfusion, and stabilization of laboratory measures of coagulation.

Standardized laboratory tests such as the prothrombin time (PT), partial thromboplastin time (aPTT), international normalized ratio (INR), and Clauss fibrinogen assay require relatively long turnaround times, rendering them impractical to guide transfusion therapy during massive hemorrhage. Viscoelastic monitoring with thromboelastography (TEG) and rotational thromboelastometry (ROTEM) graphically displays the kinetics of clot formation and fibrinolysis in real time.[256] In some studies, transfusion therapy guided by viscoelastic monitoring, rather than transfusion using a fixed ratio of blood products, reduced the administration of blood products, specifically plasma and platelets, without increasing blood loss or coagulation abnormalities.[257–259]

Blood Products

Either whole blood or component products are transfused. Whole blood is an ideal choice for maintaining intravascular volume in the setting of massive hemorrhage. A population-based observational study of 1540 obstetric patients who required transfusion compared outcomes among patients who received only whole blood (43%), only PRBCs (39%), or multicomponent therapy (19%).[260] Whole blood was associated with lower rates of acute tubular necrosis than the two other transfusion practices. However, few donor units are stored as whole blood in the modern blood bank. The high demand for blood components such as platelets, plasma, and cryoprecipitate requires fractionation of more than 90% of donor blood into blood components. Blood component therapy provides the patient with only those products that are required and helps extend the shelf-life of each unit of donor blood because derivatives from one unit of blood can be used to treat several patients. Characteristics of commonly administered blood products are summarized in Table 37.6. During massive resuscitation, care must be taken to avoid hypothermia, acidosis, and hypocalcemia, because these conditions contribute to coagulopathy.

Packed red blood cells. PRBC units are prepared by removing plasma from whole blood and replacing it with additives to improve RBC survival. These units are packaged with preservatives and anticoagulant (citrate, phosphate, dextrose, adenine) and have a 42-day shelf-life. Each unit has a volume of approximately 300 mL with a hematocrit of 70%. Transfusion of 1 unit of PRBCs increases the hemoglobin concentration by approximately 1 mg/dL in the absence of ongoing bleeding.

Plasma. A unit of plasma has a volume of approximately 250 mL and contains coagulation factors. Components of plasma replace coagulation factors when they are depleted, as may occur during massive transfusion or in the presence of DIC. Administration of plasma may be considered for correction of microvascular bleeding if the PT is more than 1.5 times normal, the INR is greater than 2.0, or the aPTT is more than two times normal. Plasma should not be used to treat hypovolemia or as a protein supplement. One unit of plasma per 20 kg of body weight is an appropriate initial dose. The prophylactic use of plasma is not effective for decreasing blood loss in patients at risk for massive blood loss.[261]

Cryoprecipitate. Cryoprecipitate is prepared from thawed plasma and contains fibrinogen, factor VIII, von Willebrand factor, fibronectin, and factor XIII. In the setting of postpartum hemorrhage, cryoprecipitate is used to replace fibrinogen, which is rapidly consumed during obstetric hemorrhage. Normal pregnancy is a hypercoagulable state, and coagulation activity peaks at the time of parturition,[260,262] possibly because of an increase in circulating tissue factor concentration and enhancement of the tissue factor–dependent coagulation pathway.[263] It is postulated that tissue factor and other procoagulant substances are released

TABLE 37.6 Characteristics of Blood Components

Component	Dose	Volume Per Dose	Shelf Life	Storage Conditions	Expected Response
Packed red blood cells	1 unit	250–325 mL	21–42 days	1° C to 6° C	1 g/dL increase in hemoglobin concentration
Plasma	10–15 mL/kg	200 mL	Frozen: 1 year Thawed: 24 h	Frozen: ≤ –18° C Thawed 1° C to 10° C	Correction of PT, aPTT, INR by replacement of coagulation factors
Platelets	4–6 units of pooled whole blood–derived platelets or 1 unit of apheresis platelets	200–250 mL	5 days	20° C to 24° C with continuous and gentle agitation	Increase in platelet count of 30,000–60,000/mm^3
Cryoprecipitate	10 pooled units	100 mL	Frozen: 1 year Thawed/pooled: 4 h	Frozen: ≤ –18° C Thawed: 1° C to 10° C	Increase in levels of fibrinogen, von Willebrand factor, factor VIII, factor XIII

aPTT, Activated partial thromboplastin time; *INR,* international normalized ratio; *PT,* prothrombin time.
Modified from Sanford K, Roseff S. A surgeon's guide to blood banking and transfusion medicine. In: Spiess BD, Spence RK, Shander A, eds. *Perioperative Transfusion Medicine.* 2nd ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2006:179–198.

from the placental implantation site at the time of placental separation, augmenting thrombin formation and serving an important hemostatic function after delivery.[42,43] In the setting of continued bleeding from the placental bed, these thromboplastic substances may continue to enter the circulation and, in severe cases, may lead to a consumptive coagulopathy and DIC.[254]

The consumption of fibrinogen appears to play a central role in the pathophysiology of peripartum hemorrhage. Charbit et al.[196] prospectively identified 128 patients who had postpartum hemorrhage and classified the hemorrhage as severe (decrease in hemoglobin concentration more than 4 g/dL, transfusion of 4 units PRBCs or more, or invasive hemostatic intervention required) or nonsevere. Patients who developed severe hemorrhage had lower fibrinogen, prothrombin, factor V, and antithrombin levels compared with patients without severe hemorrhage. These early differences were most striking for fibrinogen; a fibrinogen concentration less than 200 mg/dL at the time hemorrhage was diagnosed had a 100% positive predictive value for severe hemorrhage, whereas a fibrinogen concentration greater than 400 mg/dL had a 79% negative predictive value for subsequent severe hemorrhage. The coagulation changes were consistent with a consumptive coagulopathy because they were accompanied by increases in thrombin-antithrombin complexes and D-dimer levels, both markers of excessive coagulation. Furthermore, because the fall in fibrinogen concentration was twice the fall in hemoglobin concentration, dilution did not account for the difference in fibrinogen levels between the two groups. Other investigators have confirmed that decreases in fibrinogen correlate better than other hemostatic measures with the severity of hemorrhage.[264,265]

The rapid consumption of fibrinogen during obstetric hemorrhage calls for early monitoring for, and aggressive treatment of, hypofibrinogenemia. During active hemorrhage, clinicians should attempt to maintain the fibrinogen concentration greater than 150 to 200 mg/dL.[196] Each *dose* of cryoprecipitate supplied by most blood banks contains 5 to 10 single-donor units of cryoprecipitate, and each unit of cryoprecipitate contains approximately twice the fibrinogen of 1 unit of plasma. Therefore, the most efficient method to replace fibrinogen during obstetric hemorrhage may be to administer cryoprecipitate.[266] In a multicenter prospective cohort study of trauma victims (n = 1175), administration of cryoprecipitate compared with large doses of plasma was associated with a decreased risk for multiorgan failure.[267]

Fibrinogen concentrate is an alternative source of fibrinogen, and has been used to restore fibrinogen levels in patients with postpartum hemorrhage.[268] Fibrinogen concentrate does not appear to improve hemostasis unless fibrinogen levels have fallen below 200 mg/dL.[257] This product is currently approved in the United States for the treatment of acute bleeding in individuals with congenital hypofibrinogenemia, but in some countries it has replaced the use of cryoprecipitate for the treatment of acquired hypofibrinogenemia.

Platelets. Thrombocytopenia may develop after massive transfusion secondary to dilution, and platelet transfusion may become necessary when hemorrhage is accompanied by a platelet count less than 50,000/mm^3. This degree of thrombocytopenia is unusual unless blood loss exceeds 5000 mL or consumptive coagulopathy is present.[269] Thrombocytopenia may also occur in association with obstetric comorbidities such as HELLP syndrome. In nonbleeding patients, a transfusion trigger of 20,000/mm^3 has traditionally been suggested, although many clinicians prefer to administer platelets before the platelet count decreases to this value. Platelet dysfunction associated with bleeding may also necessitate platelet administration. One unit of donor platelets increases the platelet count by 5000 to 10,000/mm^3 in the average adult. The blood bank typically provides pooled random-donor platelets or

single-donor apheresis platelets obtained from an ABO- and Rh-compatible donor, although ABO compatibility is not essential. One unit of apheresis platelets is equivalent to 4 to 6 units of pooled platelets.

Fixed-Ratio Transfusion

The optimal plasma:PRBC transfusion ratio remains a topic of research and debate. Borgman et al.[270] sought to characterize the relationship between this ratio and survival in a retrospective review of combat victims in Iraq between 2003 and 2005. The investigators identified 246 patients who required massive transfusion and separated them into low (median ratio 1:8), medium (median ratio 1:2.5), and high (median ratio 1:1.4) plasma:PRBC ratio groups. A high ratio was independently associated with increased odds of survival after correcting for confounders (OR, 8.6; 95%, CI, 2.1 to 35.2). After publication of these data, some experts recommended a 1:1 plasma:PRBC ratio during massive hemorrhage. However, many authors,[271] including Borgman et al.,[270] point out the well-known limitations of retrospective data, which include the potential existence of unidentified confounders. These authors articulated that deaths in the low-ratio group occurred much earlier than deaths in the high-ratio group, raising the possibility that those in the low-ratio group had more severe injuries and died before plasma could be thawed and administered (e.g., survivor bias). Indeed, if the analysis is adjusted for survivor bias, the survival benefit associated with the high plasma:PRBC ratio disappears.[271,272] Furthermore, a study in civilian trauma victims identified a plasma:PRBC ratio of 1:2 to 1:3 as optimal for survival.[273]

The extrapolation of data from young male trauma victims to bleeding parturients seems fraught with potential for error. A 2013 publication described the retrospective review of records from 142 women who had postpartum hemorrhage and required transfusion within 6 hours of delivery.[274] Patients were divided into two groups based on their response to sulprostone therapy: those in whom bleeding was controlled with sulprostone alone and those who required advanced interventional procedures. Propensity score analysis revealed that a high plasma:PRBC ratio (greater than 1:2) was associated with fewer requirements for interventional procedures. Retrospective studies such as these can only demonstrate an association between the plasma:PRBC ratio and outcome and cannot determine causation. Investigators have uniformly called for high-quality randomized trials to adequately define the optimal plasma:PRBC ratio during resuscitation for massive hemorrhage.[270,272–275]

Many blood banks and hospitals have **massive transfusion protocols** whereby blood products are delivered to the operating room in fixed ratios. Such protocols allow the blood bank to more quickly provide component products and may encourage clinicians to more effectively prevent and/or treat coagulopathy(Fig. 37.5).[276,277] Routine blood loss quantification, early uterotonic therapy, timely physician evaluation, and early fixed-ratio transfusion may reduce the transfusion requirement by ensuring treatment at an earlier stage of bleeding.[195,198,199] Viscoelastic monitoring may accelerate the transition from fixed-ratio to goal-directed transfusion, and thereby avoid unnecessary transfusion of plasma and platelets.[259]

Pharmacologic Treatment

Recombinant activated factor VII. Factor VIIa binds not only to tissue factor, but also with low affinity to the thrombin-activated platelet. This low-affinity binding to the activated platelet allows direct activation of factor X to Xa on the surface of the activated platelet, bypassing the normal need for factors VIIIa and IXa. Activation of factor X leads to a small thrombin burst. This thrombin, in turn, activates more platelets. Additionally, factor VIIa enhances platelet aggregation and adhesion. Recombinant activated factor VII (rFVIIa) is currently approved in the United States for the treatment and prophylaxis of bleeding in patients with hemophilia A and B with inhibitors to factors VIII and IX, acquired hemophilia, and congenital factor VII deficiency. However, its off-label use has been reported in multiple clinical scenarios, including postpartum hemorrhage.[278]

Most recommendations regarding rFVIIa are based on case report or case series data, which are difficult to interpret because there is a lack of standardized administration and adequate control groups against which to judge the therapeutic response.[279,280] There is concern that rFVIIa may increase the likelihood of thromboembolic events, especially because severe obstetric hemorrhage and peripartum hysterectomy increase the risk for thrombotic complications. The incidence of such events is not known. Arterial events (e.g., myocardial infarction, cerebral thrombosis) are more likely than venous events[281,282] and are dose[281] and age[282] dependent. Leighton et al.[283] advise against rFVIIa administration in the setting of amniotic fluid embolism because tissue factor may play a role in its pathophysiology and thrombotic complications may be increased.

Given the unknown efficacy and safety of rFVIIa, as well as its high cost, rFVIIa is not recommended for routine use in obstetric practice. In 2005, an American expert consensus panel judged the use of rFVIIa for treatment of postpartum hemorrhage as appropriate only when bleeding continues despite clotting factor replacement.[284] The ASA guidelines recommend consideration of rFVIIa therapy "when traditional options for treating excessive bleeding due to coagulopathy have been exhausted."[202] Importantly, maintenance of normothermia and correction of acidosis are necessary for optimal rFVIIa activity; optimization of platelet count, fibrinogen, and serum calcium are also advisable as rFVIIa requires these substances to be effective. Several authors have called for randomized placebo-controlled trials of rFVIIa use for postpartum hemorrhage, but such a trial will be difficult to undertake given the unpredictability of massive obstetric hemorrhage.

Antifibrinolytic therapy. Tranexamic acid binds to plasminogen, blocking its activation, thus inhibiting fibrinolysis. Administration of tranexamic acid decreases blood loss and transfusion risk and does not increase rates of thromboembolic

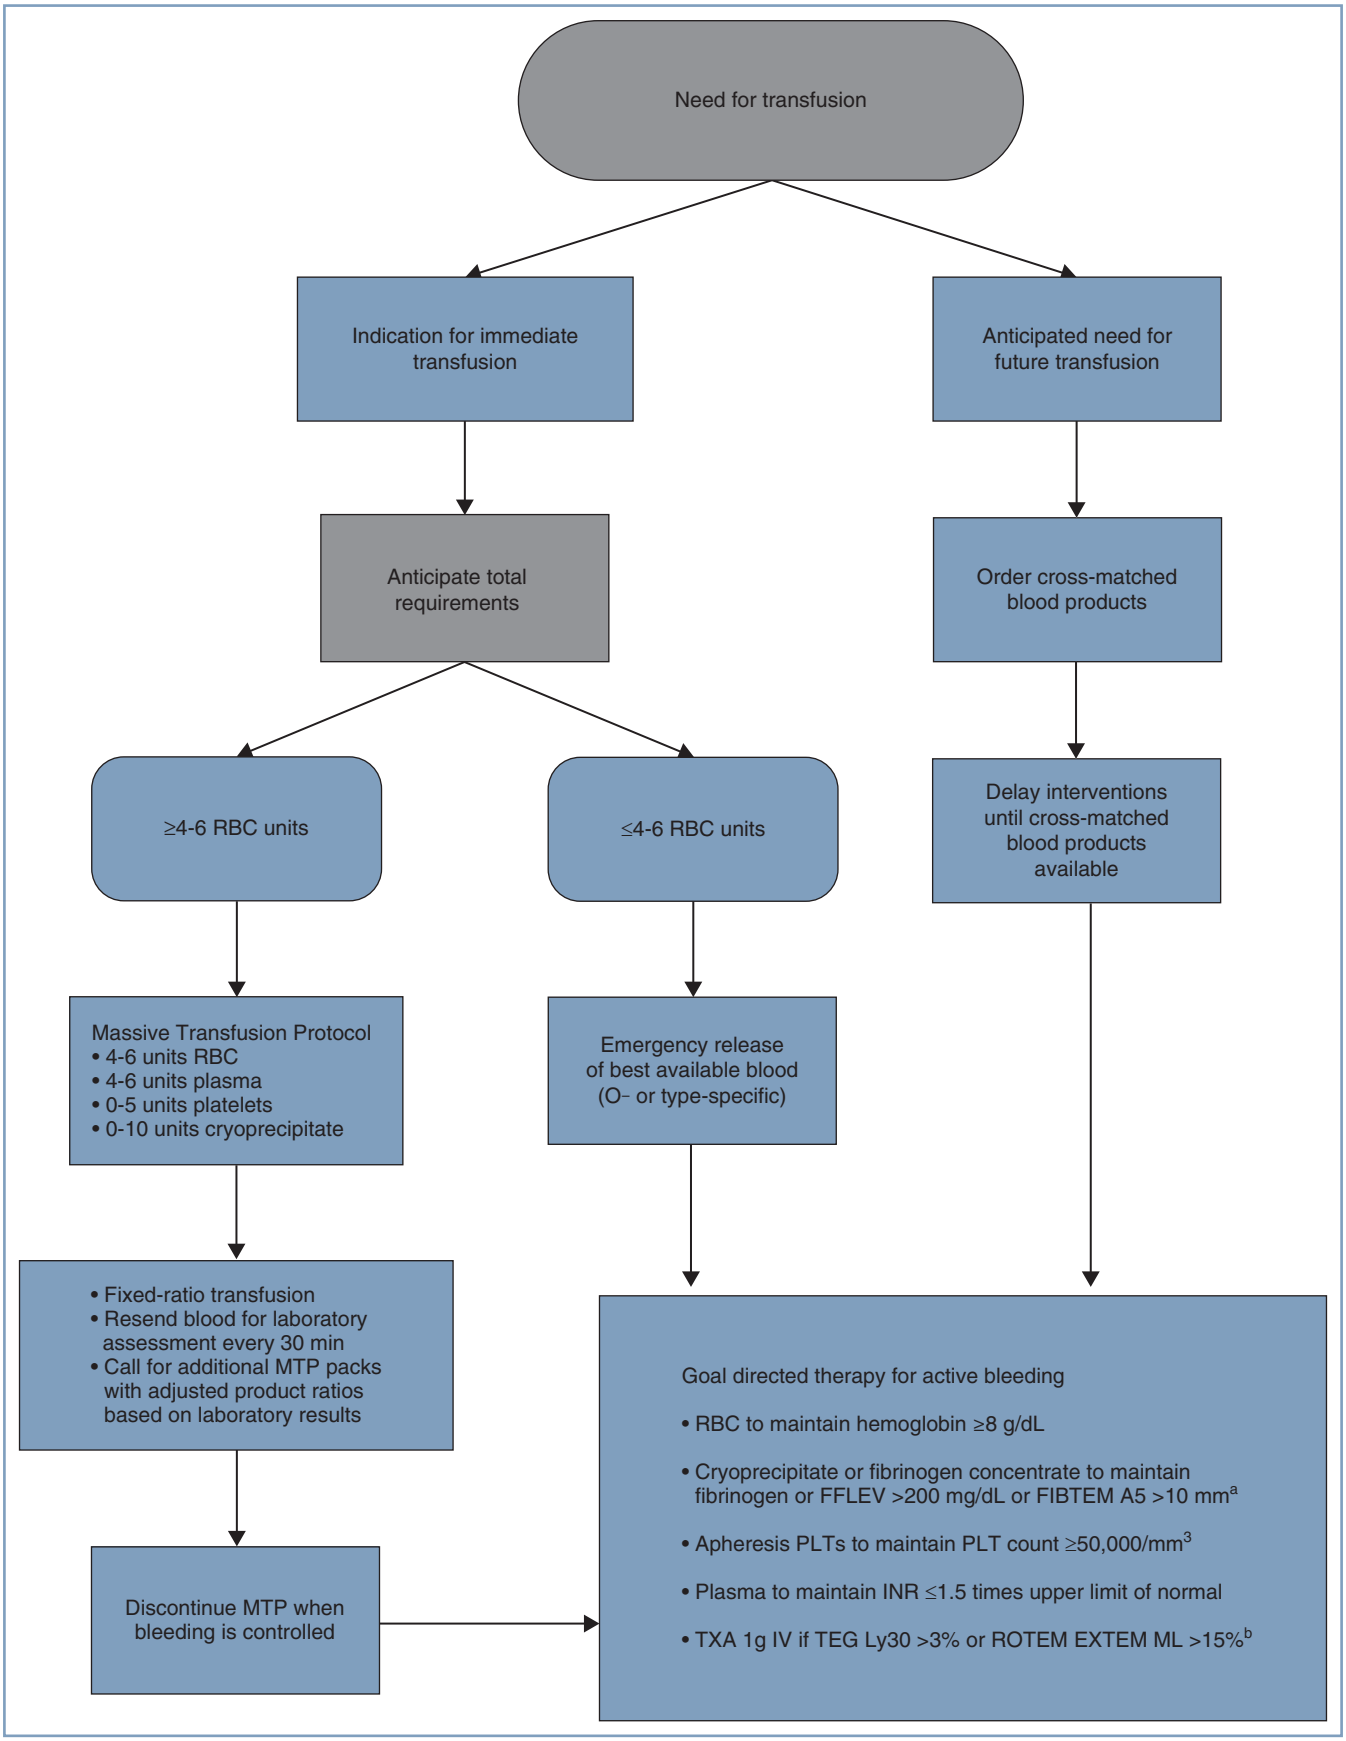

Fig. 37.5 Sample transfusion algorithm for obstetric hemorrhage that integrates a massive transfusion protocol with goal-directed therapy. [a]FFLEV and FIBTEM A5: TEG and ROTEM tests, respectively, that evaluate contribution of fibrin to clot formation by eliminating platelet contribution during testing. [b]TEG Ly30 and ROTEM EXTEM ML are tests that evaluate clot fibrinolysis. *INR,* International normalized ratio; *IV,* intravenous; *MTP,* massive transfusion protocol; *PLT,* platelet; *RBC,* red blood cells; *ROTEM,* rotational thromboelastometry; *TEG,* thromboelastography; *TXA,* tranexamic acid.

events in high–blood loss surgical patients.[285] In trauma patients, it lowers the risk for death from bleeding without increasing the risk for thromboembolic events or deaths.[286]

In low-risk obstetric patients, prophylactic use of tranexamic acid very modestly decreases blood loss,[287] but fibrinolysis may play a larger role during postpartum hemorrhage. Bleeding postpartum patients display elevated levels of D-dimer and plasmin-antiplasmin complexes, both markers of fibrinolysis, compared with nonbleeding patients, and administration of tranexamic acid attenuates these increases.[255] The results of a large multinational placebo-controlled trial of tranexamic acid therapy in the setting of postpartum hemorrhage, the WOMAN trial, were published in 2017.[288] Hemorrhaging patients who received tranexamic acid therapy within 3 hours of the diagnosis of hemorrhage suffered fewer deaths caused by bleeding than those given placebo. No differences in adverse events (including venous and arterial thromboembolic events) between the two groups were apparent. However, most patients included in the WOMAN trial were from low- and middle-resource countries; extrapolation of these results to high-resource settings such as U.S. hospitals may not be valid. More than 7% of those who died from hemorrhage in the study did so without having received any blood products. Uterine tamponade was used in only 7% of study subjects, and uterine brace sutures in just 3%.[288] Furthermore, the overall case fatality ratio (deaths per hemorrhage) in the control group was 2.6%, which greatly exceeds the ratio in high-resource countries (most likely less than 1 : 10,000). These factors make it extremely unlikely that the United States will witness similar survival benefits from tranexamic acid. The effect of tranexamic acid on hysterectomy rates and preservation of fertility among hemorrhaging women remains unknown. Nevertheless, tranexamic acid administration likely decreases blood loss and transfusion rates, similar to its effects in other nonobstetric, high–blood loss circumstances.[285,286]

Against these potential benefits, one must weigh the potential risks associated with administration of tranexamic acid. Although data on thromboembolic events from nonobstetric[285,286] and obstetric patients[288] are reassuring, parturients are hypercoagulable, and caution may be warranted. A case cluster of renal cortical thrombosis and irreversible kidney damage developed among 18 women treated with tranexamic acid for postpartum hemorrhage in France.[289] The doses of tranexamic acid used in these cases were higher than those employed in the WOMAN trial and included prolonged infusion of the drug. Practitioners are cautioned not to exceed doses of 1 g administered slowly over 10 minutes; this dose may be repeated once if bleeding continues after 30 minutes.[288] Continuous infusion is not recommended. Aortoiliac thrombosis was reported after the concomitant use of tranexamic acid and an intra-arterial balloon catheter during urgent cesarean hysterectomy.[290] Dose-dependent seizures may occur.[291] Tranexamic acid crosses the placenta.[292] Lastly, multiple reports exist of accidental injection of tranexamic acid into the intrathecal space, leading to uncontrollable seizures and death within 24 hours.[293]

The role of tranexamic acid in hemorrhage protocols in high-resource settings remains to be determined. It seems plausible that tranexamic acid may benefit women who demonstrate hyperfibrinolysis on viscoelastic monitoring. The ACOG states that "tranexamic acid should be considered in the setting of obstetric hemorrhage when initial medical therapy fails. Earlier use is likely to be superior to delayed treatment.…"[65]

KEY POINTS

- Obstetric hemorrhage is the most common cause of maternal mortality worldwide and a leading contributor to maternal mortality in developed nations.
- Most severe morbidity and mortality that occurs secondary to obstetric hemorrhage is considered preventable and is caused by delays in recognition and treatment.
- The visual estimate of vaginal bleeding often underestimates true blood loss; training clinicians, separation of amniotic fluid, use of calibrated drapes, and weighing pads and bedding improves estimation accuracy.
- Hypotension and tachycardia are late signs in hypovolemic shock.
- Antepartum hemorrhage usually represents a greater threat to the fetus than to the mother.
- Postpartum hemorrhage is increasing in both rate and severity in the developed world, mostly resulting from an increase in the incidence of uterine atony.
- Uterine atony is the most common cause of postpartum hemorrhage.
- The incidence of placenta accreta is increasing because of the higher cesarean delivery rate.
- Peripartum hysterectomy is increasing in frequency because of an increase in the incidence of both uterine atony and placenta accreta.
- Patients with placenta accreta are at high risk for massive hemorrhage and should be managed only in facilities with multidisciplinary specialists, including interventional radiologists and a well-staffed blood bank.
- Multidisciplinary team responses that emphasize the accurate estimation of blood loss, early warning signs of shock, and rapid response to blood loss and coagulopathy are associated with less maternal morbidity.
- Coagulopathy develops quickly during bleeding from the placental bed, and may be out of proportion to blood

loss or dilution because of the rapid consumption of fibrinogen.
- Intraoperative blood salvage may be lifesaving in cases of intractable hemorrhage if allogeneic blood is not available, or if the patient refuses allogeneic blood.
- Administration of tranexamic acid during postpartum hemorrhage decreases deaths caused by bleeding in low-resource settings. Its effect in high-resource settings is unknown, but it may decrease blood loss and transfusion risk.

Embolic Disorders

Paloma Toledo, MD, MPH

CHAPTER OUTLINE

Embolic disease during pregnancy includes venous thromboembolism, amniotic fluid embolism, and venous air embolism. Each of these entities varies in its incidence, clinical course, and consequences. Embolic events account for almost one-sixth of all maternal deaths in the United States.[1] Early recognition, diagnosis, and treatment are necessary to reduce associated morbidity and to avoid mortality.

THROMBOEMBOLIC DISORDERS

Incidence

Venous thromboembolic events (VTE) in pregnancy refer to deep vein thrombosis (DVT) and pulmonary thromboembolism (PTE). Analysis of administrative data from a nationally representative sample of U.S. hospital admissions that included 64,413,973 pregnancy-related hospitalizations (1994 to 2009) suggests a VTE event rate of 1.99 events per 1000 pregnancies.[2] Among these events, the DVT event rate (1.26 per 1000 deliveries) is higher than the PTE event rate (0.73 per 1000 deliveries).[2]

Compared with nonpregnant patients, pregnant women are at fivefold greater odds of thromboembolic events during pregnancy (odds ratio [OR], 4.6; 95% CI, 2.7 to 7.8) and at 60-fold greater odds during the postpartum period (OR 60.1, 95% CI, 26.5 to 135.9).[3] The highest risk occurs immediately postpartum. Analysis from a 30-year population-based cohort ($n = 50{,}080$ births) revealed the risk for both DVT and PTE was highest in the first week postpartum (incidence rate, 3573 per 100,000 woman-years; 95% CI, 2475 to 4993 per 100,000), with a progressive decline thereafter.[4] Compared with 1 year postpartum, the odds of a thrombotic event in the first 6 weeks postpartum are tenfold higher (OR, 10.8; 95% CI, 7.8 to 15.1); the period of elevated risk persists until at least 12 weeks after delivery.[5]

Multiple studies have demonstrated an increasing trend in VTE-associated hospitalizations.[2,6,7] According to data from the Nationwide Inpatient Sample (a stratified sample of inpatients from hospitals in the United States representing approximately 20% of discharges), the incidence increased by 72% between 1998 and 2009.[7] Although VTE-related mortality, as reported by the Confidential Enquiries into Maternal Deaths and Morbidity in the United Kingdom and Ireland, appeared to have been decreasing (0.85 deaths per 100,000 births in 2012 to 2014, compared with 1.26 per 100,000 births in 2009 to 2011),[8] in the most recent report (2013 to 2015), the incidence of VTE-related mortality was 1.13 deaths per 100,000 births,[9] making VTE the leading cause of direct maternal deaths. VTE-related maternal mortality appears to be stable in the United States, at 1.49 deaths per 100,000 births.[1]

Risk Factors

The two most important risk factors for thromboembolic events in pregnancy and the postpartum period are a previous history of thromboembolism and a diagnosis of thrombophilia.[10-13] Essentially all known thrombophilias increase the risk for VTE in pregnancy, with the greatest risk increase noted in women homozygous for the factor V Leiden

mutation.[13] Other common risk factors include advanced maternal age, race/ethnicity, obesity, hypertensive disorders, and smoking status.[2,6,14] Obstetric complications, such as postpartum hemorrhage and postpartum infections, are also associated with increased risk; this is likely mediated through their effects on maternal coagulation and inflammation.[2,14] Cesarean delivery increases the risk for postpartum venous thromboembolism. In a meta-analysis of 28 studies (pooled *n* greater than 53,000 postpartum VTE events), the odds ratio of postpartum VTE after a cesarean delivery compared with a vaginal delivery was 3.7 (95% CI, 3.0 to 4.6).[15] Greater increases were noted after emergency compared with elective cesarean deliveries.[2,15] The American College of Chest Physicians has defined major and minor risk factors for postcesarean VTE (Box 38.1).[16] The American College of Obstetricians and Gynecologists (ACOG) recommends that all pregnant women should be screened for risk factors for VTE early in pregnancy.[13]

BOX 38.1 Risk Factors for Venous Thromboembolism in the Postpartum Period

Major Risk Factors[a]

- Immobility (strict bed rest for greater than or equal to 1 week in the antepartum period)
- Previous venous thromboembolism
- Preeclampsia with fetal growth restriction
- Thrombophilia
  - Antithrombin III deficiency
  - Factor V Leiden (homozygous or heterozygous)
  - Prothrombin G20210A (homozygous or heterozygous)
- Medical conditions
  - Systematic lupus erythematous
  - Heart disease
  - Sickle cell disease
- Postpartum hemorrhage greater than or equal to 1000 mL *and* surgery
- Blood transfusion
- Postpartum infection

Minor Risk Factors[a]

- Body mass index greater than 30 kg/m^2
- Emergency cesarean delivery
- Multiple pregnancy
- Postpartum hemorrhage greater than 1000 mL
- Smoking greater than 10 cigarettes/day
- Fetal growth restriction
- Thrombophilia
  - Protein C deficiency
  - Protein S deficiency
- Preeclampsia

[a]The presence of at least one major risk factor or two minor risk factors is an indication for prophylactic therapy for venous thromboembolism (see text).
Modified from Bates SM, Greer IA, Middeldorp S, et al. VTE, thrombophilia, antithrombotic therapy, and pregnancy: Antithrombotic therapy and prevention of thrombosis. 9th ed. American College of Chest Physicians evidence-based clinical practice guidelines. *Chest*. 2012;141(2 Suppl):e691S–e736S.

Pathophysiology

Virchow's triad describes three factors that contribute to an increased risk for thromboembolism: (1) **venous stasis**, (2) **vascular damage**, and (3) **hypercoagulability.** The incidence of each factor is increased during pregnancy or in the postpartum period. Venous stasis occurs as a result of venocaval compression and possibly decreased mobility later in pregnancy. Separation of the placenta from the uterine wall traumatizes the endometrium, which accelerates the coagulation cascade. Additionally, pregnancy is a relatively hypercoagulable state, associated with enhanced platelet turnover, coagulation, and fibrinolysis.[17,18] Thrombin generation and the concentration of clotting factors increase during pregnancy, including factors I (fibrinogen), V, VII, VIII, IX, X, and XII.[17] Platelet count typically remains unchanged or is decreased during pregnancy. Fibrinolytic activity decreases during the 48 hours after delivery and enhances clot stability in the early postpartum period.[17]

The prognosis of PTE depends on the following factors: (1) the size and number of emboli, (2) concurrent cardiopulmonary function, (3) the rate of clot fragmentation and lysis, (4) the presence or absence of a source for recurrent emboli, and (5) the location of the embolism (proximal or main pulmonary artery embolism is more symptomatic than segmental embolization).[19] Massive PTE can occlude the pulmonary vasculature and precipitate cardiopulmonary arrest; smaller emboli may also lead to cardiopulmonary failure by triggering pulmonary arterial vasospasm and secondary pulmonary edema.[20] Local platelets embedded in the clot release serotonin, adenosine diphosphate, and thrombin, factors that promote both vasoconstriction and bronchoconstriction.[21] Redistribution in pulmonary blood flow leads to "hyperperfusion" of otherwise low $\dot{V}/\dot{Q}$ zones in unaffected areas of the lung; the resulting intrapulmonary shunts cause hypoxemia disproportionate to the cross-sectional area occluded by clot.[22] At the same time, regional hypoxic pulmonary vasoconstriction exacerbates pulmonary hypertension initiated by mechanical and humoral factors. Intracardiac shunting may develop when elevated right ventricular pressure forces blood across a probe-patent foramen ovale. The increase in right ventricular pressure leads to right ventricular dilation, with increased wall tension and oxygen demand, and a leftward shift of the interventricular septum.[23] Compression of the left ventricle combined with a decrease in preload impairs left ventricular function, cardiac output, and coronary arterial perfusion, with eventual myocardial ischemia and cardiopulmonary failure.

Deep Vein Thrombosis

Clinical Presentation

The signs and symptoms of DVT are nonspecific and often mimic normal symptoms of pregnancy, specifically lower leg edema and pain. A systematic review of the anatomic distribution of DVT in symptomatic pregnant patients (six studies, pooled $n = 124$) identified left leg thrombus in 88% of pregnant women in whom the side of the DVT was

reported.[24] Most thrombi were proximally located in the iliac or femoral veins, or both. This distribution is different from the anatomic distribution in nonpregnant patients, who are more likely to have thrombi in the distal calf vessels.[24] A prospective observational study of serial ultrasonographic examinations in pregnant women ($n = 24$) found an increase in vessel diameter and a decrease in flow velocity in the proximal deep leg veins with increasing gestation; this finding was most notable in the common femoral vein.[25] The flow velocity was slower in the left leg than in the right leg, presumably caused by uterine compression of the left iliac vein where it crosses the right iliac artery.[25]

Diagnosis

For patients with new-onset signs or symptoms suggestive of DVT, the ACOG recommends compression ultrasonography of proximal veins as the initial diagnostic test.[13] If the test is negative, and involvement of the iliac vessels is not suspected, no further action other than routine surveillance is necessary. A positive result warrants treatment (see later discussion). If the results are negative or equivocal, and iliac vein thrombosis is suspected, clinicians may opt for Doppler ultrasonography of the iliac vein, venography, or magnetic resonance imaging or presumptive anticoagulation.[13]

The D-dimer test is useful in nonpregnant patients because it has a high sensitivity and a high negative predictive value. Unfortunately, D-dimer levels are increased in pregnancy, making interpretation of elevated levels difficult in pregnant women. In one prospective, longitudinal study, serial D-dimer levels were evaluated in 89 healthy pregnant women; values exceeded the normal nonpregnant reference range in all but one woman in the third trimester.[26] Therefore, the D-dimer test is not currently recommended for diagnosis of DVT in pregnancy,[27,28] although future work may delineate pregnancy-specific thresholds.

Pulmonary Thromboembolism

Clinical Presentation

Clinical suspicion for PTE is critical to ensure timely diagnosis and treatment. Physical signs and symptoms may be subtle and limited to symptoms (e.g., shortness of breath) that mimic normal pregnancy (Table 38.1). Palpitations, anxiety, pleuritic chest pain, cyanosis, diaphoresis, and cough with or without hemoptysis may all indicate PTE. Physical examination of the patient commonly reveals tachypnea, crackles, decreased breath sounds, and tachycardia. Signs of right ventricular failure, including an accentuated or split-second heart sound, jugular venous distention, a parasternal heave, and hepatic enlargement, may be apparent. Although the Pao_2 is generally low (less than 80 mm Hg), as many as 30% of all patients with a pulmonary embolus have an arterial Pao_2 greater than 80 mm Hg; thus, the diagnosis of PTE cannot be excluded on the basis of an apparently normal Pao_2.[19,29] Left ventricular failure may occur secondary to poor left ventricular filling and arterial hypoxemia. One or more signs of DVT (calf or thigh edema, erythema, tenderness, palpable cord) generally accompanies the pulmonary or cardiovascular findings.[19] The electrocardiogram may show signs of right ventricular strain, including a right-axis shift, P pulmonale, ST-segment abnormalities, and T-wave inversion, as well as supraventricular arrhythmias. Transthoracic echocardiography may reveal signs of right ventricular dysfunction or other findings consistent with acute pulmonary embolism, such as hypokinesis of the right ventricular free wall with normal contraction of the apical segment (McConnell's sign).[30]

TABLE 38.1 Symptoms and Signs of Pulmonary Embolism

Finding	Patients Affected (%)
Dyspnea	79
Pleuritic chest pain	47
Cough	43
Calf or thigh pain	42
Tachypnea	57
Tachycardia	26
Localized rales	21
Accentuated second heart sound	15

Data from Stein PD, Beemath A, Matta F, et al. Clinical characteristics of patients with acute pulmonary embolism: data from PIOPED II. *Am J Med.* 2007;120:871–879.

Diagnosis

Diagnosing PTE in pregnancy is challenging given the lack of validated criteria specific for the peripartum period. The American Thoracic Society developed an evidence-based guideline for the evaluation of suspected PTE in pregnancy,[28] which has been endorsed by the ACOG.[27] A diagnostic algorithm for suspected PTE is shown in Fig. 38.1. If the pregnant patient has signs or symptoms suggestive of DVT, in addition to the signs or symptoms of PTE, compression ultrasonography should be done. If the results are positive, treatment should ensue. However, if the results are negative, further imaging is necessary. If there are no signs or symptoms of DVT, a chest radiograph should be performed, both to exclude alternative diagnoses, and to guide decision-making for the next most appropriate test. If the chest radiograph is normal, V/Q scanning should be performed.[13] A retrospective study of 304 women who underwent computed tomographic angiography (CTA) or V/Q scanning at a single institution between 2001 and 2006 demonstrated that pregnant women with a normal chest radiograph have a fivefold higher rate of a nondiagnostic result from a CTA compared with a V/Q scan (relative risk [RR], 5.3; 95% CI, 2.1 to 13.8).[31] The use of chest radiography as a screening procedure may also minimize the amount of radiation to which a pregnant woman and her fetus are exposed if the pregnant patient is a candidate for V/Q scanning.[28] If the chest radiograph is abnormal, CTA is the next appropriate test because the proportion of nondiagnostic V/Q scans in the presence of an abnormal chest radiograph has been reported to be as high as 48%.[32] If either the V/Q scan or CTA is positive, anticoagulation should ensue.

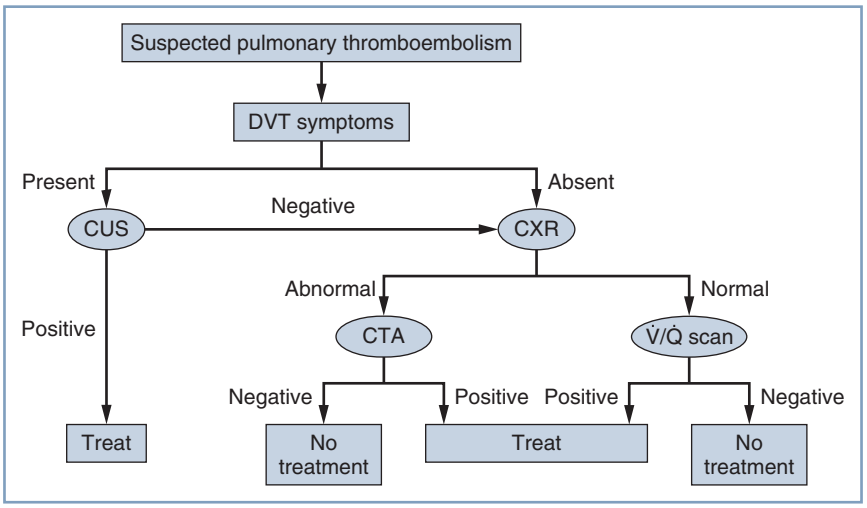

Fig. 38.1 Diagnostic algorithm for workup of suspected pulmonary thromboembolism during pregnancy. *CTA,* Computed tomography pulmonary angiography; *CUS,* compression ultrasonography; *CXR,* chest radiograph; *DVT,* deep vein thrombosis; *V/Q scan,* ventilation-perfusion scan.

The use of magnetic resonance pulmonary angiography has not been validated in the pregnant population.

Single-photon emission computed tomography (SPECT) is another diagnostic modality that has been evaluated in pregnant women.[33,34] In a nonpregnant patient population, the V/Q SPECT demonstrated 100% sensitivity and 94% specificity compared with CTA as the "gold standard."[35] A retrospective analysis of 127 women who underwent evaluation for PTE with V/Q SPECT identified PTE in 11 women (9%).[36] The negative predictive value was 100%, and the calculated fetal and breast absorbed radiation doses were low (less than 0.014 mGy and 0.25 mGy, respectively).[36]

Perhaps the greatest concern with diagnostic imaging for PTE is maternal and fetal exposure to ionizing radiation.[37] The teratogenic effects of ionizing radiation are discussed in Chapter 17. Both V/Q scanning and CTA are associated with low doses of fetal radiation exposure (less than 1 mGy). V/Q scanning delivers a higher *fetal* dose of radiation than CTA; however, the *maternal* radiation exposure is higher with CTA, particularly radiation to the breast tissue.[37] A patient's lifetime breast cancer risk may increase as much as 14% after CTA.[38] Maternal radiation exposure is lower with V/Q SPECT than with CTA.[36,39]

Management of Thromboembolic Disorders

Anticoagulation

All women with a new-onset thromboembolic event in pregnancy should be therapeutically anticoagulated.[27] Patients with a previous history of thrombosis, certain high-risk populations (e.g., patients with acquired or inherited thrombophilias), or patients with a mechanical heart valve should be anticoagulated during pregnancy as well as the postpartum period. The ACOG practice bulletin on thromboembolism in pregnancy summarizes which patients should receive prophylactic versus therapeutic anticoagulation.[27] Given the significant morbidity and mortality associated with VTE, the National Partnership for Maternal Safety, a multidisciplinary body that develops evidence-based safety bundles, published a consensus bundle on VTE in 2016.[40] This bundle broadens the indications for antepartum and postpartum pharmacologic anticoagulation beyond the ACOG practice guidelines,[13] including recommending daily thromboprophylaxis for antepartum patients hospitalized for greater than 72 hours.[13,40] This expanded use of pharmacologic thromboprophylaxis has anesthetic implications (see later discussion).

Although the exact dose and regimen for anticoagulation remain controversial, two classes of drugs are typically used to initiate anticoagulation: **unfractionated heparin (UFH)** and **low-molecular-weight heparin (LMWH).** Table 38.2 lists anticoagulation regimens commonly used in pregnancy. Both the ACOG and the American College of Chest Physicians recommend LMWH rather than UFH for prophylactic and therapeutic anticoagulation for pregnant women.[16] No differences in symptomatic thrombotic events (RR 0.47; 95% CI, 0.09 to 2.49) were identified in a 2014 Cochrane review that compared antenatal prophylaxis with UFH or LMWH (four trials, pooled $n = 404$).[41]

LMWH has an enhanced ratio of antithrombotic (anti–factor Xa) to anticoagulant (anti–factor IIa) activity compared with UFH and does not affect activated partial thromboplastin time (aPTT) measurement.[42] A 2005 systematic review (64 studies, pooled $n = 2777$) evaluated the efficacy and safety of LMWH in pregnancy.[42] The rate of VTE in women receiving LMWH for thromboprophylaxis, prevention of adverse pregnancy outcome, or for unspecified indications was 0.9% (95% CI, 0.6% to 1.3%), and the rate of significant maternal bleeding was 2.0% (95% CI, 1.5% to 2.6%). There were no reported cases of heparin-induced thrombocytopenia when LMWH was used for any indication in pregnancy.[42] An older systematic review (1999) did not identify any increase in osteoporosis in pregnant women treated with LMWH compared with nonpregnant controls.[43]

The pharmacokinetics of LMWH are altered during pregnancy.[44] When LMWH is used for therapeutic anticoagulation,

TABLE 38.2 Commonly Used Anticoagulation Regimens during Pregnancy

Drug	Dose
Prophylactic LMWH	Enoxaparin 40 mg SC once daily Dalteparin 5000 units SC once daily Tinzaparin 4500 units SC once daily Nadroparin 2850 units SC once daily
Intermediate-dose LMWH	Enoxaparin 40 mg SC every 12 hours Dalteparin 5000 units SC every 12 hours
Therapeutic LMWH (weight-adjusted treatment dose)[a]	Enoxaparin 1 mg/kg q12h Dalteparin 200 units/kg once daily Tinzaparin 175 units/kg once daily Dalteparin 100 units/kg q12h
Prophylactic UFH in the first trimester	UFH 5000–7500 units SC every 12 hours
Prophylactic UFH in the second trimester	UFH 7500–10,000 units SC every 12 hours
Prophylactic UFH in the third trimester	UFH 10,000 units SC every 12 hours (unless aPTT is elevated)
Therapeutic (adjusted-dose) UFH[b]	UFH 10,000 units or more SC every 12 hours
Postpartum anticoagulation[c]	Prophylactic LMWH for 6–8 weeks

aPTT, Activated partial thromboplastin time; *LMWH,* low-molecular-weight heparin; *SC,* subcutaneously; *UFH,* unfractionated heparin.
[a]Target anti-Xa level 4 hours after last injection for twice-daily regimen: 0.6–1.0 unit/mL. Slightly higher doses may be necessary for once-daily dosing.
[b]Adjust dose to target aPTT (1.5–2.5 times the normal range 6 h after injection).
[c]Oral anticoagulants may be considered based on planned duration of therapy, lactation, and patient preference.
Modified from American College of Obstetricians and Gynecologists. Practice Bulletin No. 196. Thromboembolism in pregnancy. *Obstet Gynecol.* 2018;132:e1–e17.)

dosing can be adjusted based on anti–factor Xa activity. The desired peak level is 0.6 to 1.0 U/mL measured 4 hours after injection[27]; however, because of the cost of the assays, routine monitoring of anti–factor Xa activity is not recommended during therapy in pregnancy.[16] Viscoelastic monitoring provides an alternative method to assess LMWH activity. Carroll et al.[45] demonstrated that the delta reaction time (ΔR) measured by thromboelastography correlates with anti–factor Xa levels in the pregnant woman and allows LMWH doses to be adjusted to ensure anticoagulation or, conversely, confirms the absence of anticoagulation. LMWH is cleared by the kidney; therefore, dose reduction may be required in patients with renal failure.

UFH therapy may be used to initiate anticoagulation or to maintain therapy as the patient nears delivery (see later discussion). UFH exerts its anticoagulant activity by binding to antithrombin III and potentiates inactivation of other coagulation factors, including thrombin (factor IIa); factors IXa, Xa, XIa, and XIIa; and kallikrein. Typically, UFH is administered as a subcutaneous injection for both prophylactic and therapeutic therapy. The aPTT measured 6 hours after an injection or dose adjustment should be maintained at 1.5 to 2.5 times the normal range.[27] In pregnancy, the bioavailability of UFH decreases as a result of an increase in heparin-binding proteins, increased plasma volume, increased renal clearance, and increased degradation by plasma heparinases.[46] Based on pharmacodynamic studies, even a twice-daily dose of subcutaneous UFH is often inadequate to achieve *prophylactic* plasma heparin concentrations in the second half of pregnancy, possibly because of the presence of a heparin-neutralizing protein or the presence of increased factor VIII and fibrinogen levels in pregnancy.[47] For *therapeutic* anticoagulation, the ACOG currently recommends a subcutaneous, twice-daily UFH dose of 10,000 units or greater, with aPTT monitoring and dose adjustment.[13] In the event of an antepartum massive PTE resulting in hemodynamic instability, thrombolytic therapy should be considered as it is associated with high maternal and fetal survival.[48] However, in the postpartum period, other options, including thrombectomy, should be considered because thrombolysis is associated with a significant risk for hemorrhage.[48]

In patients who develop heparin-induced thrombocytopenia, or severe cutaneous reactions to heparin, fondaparinux is the preferred anticoagulant because it has minimal cross-reactivity with UFH.[13] Anticoagulation with other classes of drugs such as vitamin K antagonists, thienopyridines, direct factor Xa inhibitors, and direct thrombin inhibitors is possible in pregnancy, but the use of these medications is less common. Animal studies with rivaroxaban, a direct factor Xa inhibitor, and dabigatran, a direct thrombin inhibitor, have found teratogenic effects, reduced fetal viability, hemorrhagic changes, and placental abnormalities; thus, their use in pregnancy is not recommended.[49]

Antithrombotic Therapy and Anesthetic Implications

In 2018, the American Society of Regional Anesthesia and Pain Medicine (ASRA) published updated guidelines for regional anesthesia in patients receiving antithrombotic or thrombolytic therapy.[50] Owing to the relative paucity of outcome data in pregnant women, the ASRA suggests following the guidelines for surgical patients when developing clinical policy for obstetric patients with regard to initiation of neuraxial procedures and postpartum thromboprophylaxis.[50] The ASRA-recommended time intervals between anticoagulant administration and the initiation of neuraxial anesthesia are summarized in Table 38.3.

Before the ASRA guideline release, the Society for Obstetric Anesthesia and Perinatology (SOAP) released a consensus statement with *pregnancy-specific* recommendations regarding neuraxial procedures in obstetric patients receiving thromboprophylaxis or therapeutic anticoagulation.[51] The SOAP consensus statement integrates the ASRA guidelines, pharmacokinetic parameters of anticoagulants in pregnancy, and the risks associated with maternal airway management into decision-making algorithms intended to guide clinicians. The consensus statement emphasizes the importance of

TABLE 38.3 Recommended Time Intervals for Administration of Neuraxial Anesthesia after Anticoagulation and Initiation of Postpartum Anticoagulation

	TIME INTERVAL	
Therapy	**Administration of Neuraxial Anesthesia after Anticoagulation**	**Initiation of Postpartum Anticoagulation**
SC UFH, low-dose prophylactic[a]	Greater than 4–6 h or assessment of coagulation status[b]	Greater than or equal to 1 h after neuraxial block or epidural catheter removal
SC UFH, intermediate dose[c]	Greater than or equal to 12 h, and verify normal coagulation status[b,d]	Greater than or equal to 1 h after neuraxial block or epidural catheter removal
SC UFH, therapeutic[e]	Greater than or equal to 24 h, and verify normal coagulation status[b]	Greater than or equal to 1 h after neuraxial block or epidural catheter removal
IV UFH	4–6 h, and verify normal coagulation status[b]	Greater than or equal to 1 h after neuraxial block or epidural catheter removal
LMWH, prophylactic	Greater than or equal to 12 h[b]	Greater than or equal to 12 h after neuraxial block *and* greater than or equal to 4 h after catheter removal
LMWH, therapeutic	Greater than or equal to 24 h[b]	Greater than or equal to 24 h after neuraxial block *and* greater than or equal to 4 h after catheter removal

IV, Intravenous*; LMWH,* low-molecular weight heparin; *SC,* subcutaneous; *UFH,* unfractionated heparin.
[a]UFH regimens of 5000 units SC two or three times a day.
[b]Check platelet count if either UFH or LMWH therapy for more than 4 days.
[c]UFH regimens of 7500 to 10,000 units twice a day.
[d]If less than 12 hours and aPTT is within normal range, may consider neuraxial procedure based on assessment of risks and benefits.
[e]UFH individual dose greater than 10,000 units SC or greater than 20,000 total units per day.

clinicians weighing the risk associated with potential spinal or epidural hematoma against the risk associated with general anesthesia in decision-making.

The following anticoagulation strategies will help to facilitate safe and timely neuraxial analgesia/anesthesia for parturients[40,50]:

1. Consider transitioning women taking LMWH to UFH at 36 weeks' gestation, particularly if they are at risk for urgent delivery.
2. LMWH should be discontinued before planned delivery; the interval depends on the dose (see Table 38.3). LMWH therapy should be converted to UFH if necessary.
3. Intravenous UFH should be discontinued 4 to 6 hours before planned neuraxial procedure/delivery.
4. For patients being treated with either UFH or LMWH for more than 4 days, a platelet count should be assessed before initiation of neuraxial anesthesia procedures.
5. Aspirin should be discontinued at 35 to 36 weeks' gestation in patients receiving pharmacologic thromboembolism prophylaxis.

Other anticoagulant medications sometimes administered to pregnant women include aspirin, warfarin, and newer anticoagulant medications. In patients receiving warfarin therapy, the ASRA recommends discontinuing warfarin therapy for 5 days and waiting for normalization of the international normalized ratio (INR).[50] Neuraxial catheters are *not* recommended in patients receiving fondaparinux, and neuraxial techniques are *not* recommended in patients anticoagulated with direct thrombin inhibitors. Treatment with thrombolytics is an absolute contraindication to neuraxial anesthesia.[50] By contrast, there is no contraindication to neuraxial anesthesia in patients who have received nonsteroidal antiinflammatory drugs or aspirin, if these drugs are used alone.[50]

If a patient is not a candidate for neuraxial anesthesia, noninvasive analgesic methods (e.g., intravenous opioid analgesia) should be offered for labor, and general anesthesia should be performed for operative procedures, including cesarean delivery. Risks associated with general anesthesia in the anticoagulated patient include airway bleeding. Laryngoscopy and tracheal intubation should be as atraumatic as possible. The anesthesia provider should be aware that placement of nasopharyngeal and oropharyngeal airways, gastric tubes, and other devices (e.g., temperature probes, stethoscopes) carries a tangible risk for traumatic hemorrhage. Emergency surgery may necessitate the administration of protamine or the transfusion of blood products (e.g., plasma, platelets) to reverse anticoagulation and reduce the risk for hemorrhage during and after surgery.

The timing of initiation of pharmacologic prophylaxis postpartum varies according to which drug is chosen and the dose. Both the ASRA and the SOAP consensus statements recommend at least a 1-hour delay after neuraxial blockade or epidural catheter removal before starting or restarting UFH, regardless of dose; at least a 12-hour delay after neuraxial blockade before the initiation of low-dose LWMH; and at least a 24-hour delay after neuraxial blockade before initiating therapeutic LMWH doses (see Table 38.3).[50,51]

The greatest concern with neuraxial procedures in anticoagulated patients is spinal or epidural hematoma. A meta-analysis estimated the incidence of epidural hematoma in obstetric patients (8 studies, pooled $n = 1.1$ million) to be 1:183,000.[52] An incidence of 1:251,643 (95% CI, 1:46,090 to 1:10,142,861) was identified in the SOAP Serious Complication Repository Project (SCORE).[53] Notwithstanding the very low incidence, the consequences of a spinal-epidural hematoma can be devastating. The ASRA guidelines include a summary of 15 cases of spinal hematoma after neuraxial anesthesia in obstetric patients; approximately one-third of the cases had some form of permanent motor or sensory dysfunction.[50] A systematic review of published reports (1952 to 2016) and review of the American Society of Anesthesiologists Closed Claims Project Database (1990 to 2013) identified no cases of spinal or epidural hematoma in obstetric patients who received thromboprophylaxis consistent with the 2018 ASRA guidelines.[54] However, two case reports describe women who developed an epidural hematoma following neuraxial anesthesia for cesarean delivery and administration of LMWH. In the first case, the initial dose of LMWH followed the onset of lower extremity weakness and sensory changes, and in the second case, symptoms began only after the initiation of therapeutic anticoagulation on postpartum day three.[50] Multiple cases of spontaneous epidural hematoma in pregnancy have been reported.[55]

Because of the risk for epidural hematoma—even in the absence of neuraxial procedures—anesthesia providers, obstetricians, and nursing staff must remain vigilant for signs and symptoms of epidural hematoma (see Chapter 31). These include (1) severe, unremitting backache; (2) neurologic deficit, including bowel or bladder dysfunction or radiculopathy; (3) tenderness over the spinous or paraspinous area; and (4) unexplained fever.[56] Suspicion of epidural hematoma should lead to immediate diagnostic imaging of the spinal cord and neurosurgical consultation for possible spinal cord decompression. Neurologic recovery is a function of the severity of preoperative deficits, the duration of maximum deficit, and the interval between symptom onset and surgery; better outcomes are associated with a shorter symptom onset-to-surgery interval.[57] A high index of suspicion is necessary because neurologic dysfunction may mimic local anesthetic–induced effects.[58]

Prevention of Thromboembolic Events

Anesthesia providers should work with obstetricians to develop and implement strategies to reduce VTE. Systems should be developed to identify at-risk women for whom peripartum mechanical or pharmacologic thromboprophylaxis is indicated. Given the recent expansion of indications for pharmacologic thromboprophylaxis,[40] it is imperative that communication occur between anesthesia providers and obstetricians with regard to the timing of delivery, plans for the use of neuraxial analgesia and/or anesthesia, and plans for postpartum anticoagulation. Mechanical thromboprophylaxis should be initiated in women with contraindications to pharmacologic anticoagulation, and after all cesarean births.[16,27] The use of intermittent pneumatic compression stockings have been shown to be cost-effective when compared with no thromboprophylaxis after cesarean delivery[59]; however, compliance with their use has been shown to be suboptimal.[60] For women in whom significant risk factors persist after delivery, extended prophylaxis (6 to 8 weeks postpartum) is recommended.[16,27,40] Women are at the highest risk for thrombotic events in the first week postpartum[4]; therefore, careful postdischarge planning and evaluation of VTE risk are equally as important as inpatient management.

AMNIOTIC FLUID EMBOLISM

Death attributable to an amniotic fluid embolism (AFE) was first reported by Meyer in 1926.[61] Early reports described a syndrome of fatal peripartum shock attributed to emboli of amniotic fluid mechanically obstructing the maternal pulmonary circulation.[62] Although the pathophysiology of this disease remains poorly understood, current evidence suggests that emboli alone are insufficient to precipitate this infrequent, idiosyncratic, and devastating condition. Rather, fetal material in the maternal circulation has the potential to trigger a massive cascade of inflammatory and hemostatic reactions that culminate in cardiopulmonary collapse and disseminated intravascular coagulation (DIC).

Epidemiology

The incidence of amniotic fluid embolism is difficult to establish because (1) there is no universally accepted definition for identifying cases of AFE, (2) differing ascertainment methods yield divergent rates of AFE, and (3) AFE is ultimately a diagnosis of exclusion. The lack of uniform diagnostic criteria is a significant barrier to furthering our understanding of AFE. A Japanese retrospective observational study[66] reviewed 26 registered AFE cases and compared diagnosis agreement using three commonly used diagnostic criteria for AFE (the U.S. AFE Registry entry criteria,[63] the UK Obstetric Surveillance System [UKOSS] entry criteria,[64] and the Japanese consensus criteria[65]). Table 38.4 summarizes the diagnostic criteria used for identifying AFE. Only 10 of the 26 cases were given a diagnosis of AFE by all three criteria.[66] In 2016, the Society for Maternal-Fetal Medicine (SMFM) and the Amniotic Fluid Foundation convened a task force to develop uniform diagnostic criteria for research reporting of AFE.[67] The newly published definition requires *documentation* of coagulopathy to confirm the diagnosis of AFE.[67] When this definition was applied to maternal deaths caused by AFE from the French Confidential Enquiry into Maternal Deaths (2007 to 2011), documentation of coagulopathy was missing for 14 of the 39 deaths.[68] It is important for clinicians to recognize that clinical variants of AFE exist and treatment should not be withheld if a patient is missing any of the required elements of the definition.[69,70]

Currently, the UKOSS provides the most comprehensive prospective surveillance for amniotic fluid embolism in the world. All hospitals in the United Kingdom with a consultant-led maternity unit report all suspected cases of AFE, along

TABLE 38.4 Commonly Used Amniotic Fluid Embolism Diagnostic Criteria

United States Amniotic Fluid Embolism Registry Entry Criteria[63]	United Kingdom Obstetric Surveillance System Criteria[72]	Society for Maternal-Fetal Medicine and the Amniotic Fluid Foundation Criteria[67]
1. Acute hypotension or cardiac arrest 2. Acute hypoxia (dyspnea, cyanosis, respiratory arrest) 3. Coagulopathy (laboratory evidence or hemorrhage without an alternative explanation) 4. Onset of the above during labor, cesarean delivery, dilation and evacuation, or within 30 minutes postpartum 5. Absence of an alternative explanation for the observed signs/symptoms	In the absence of any other clear cause, either: 1. Acute maternal collapse with one or more of the following features: acute fetal compromise, cardiac arrest, cardiac arrhythmias, coagulopathy, hypotension, maternal hemorrhage, premonitory symptoms, seizures, shortness of breath OR: 2. Pathologic diagnosis of fetal squames or hair in the maternal lungs	1. Sudden onset of cardiorespiratory arrest, or both hypotension and respiratory compromise 2. Documentation of overt DIC, after the appearance of initial signs or symptoms, using the scoring system of Scientific and Standardization Committee on DIC of the International Society on Thrombosis and Hemostasis (ISTH), modified for pregnancy. The coagulopathy must be detected before sufficient blood is lost to account for dilutional or shock-related consumptive coagulopathy. 3. Clinical onset during labor or within 30 minutes of delivery of the placenta 4. No fever (greater than or equal to 38.0°C) during labor

DIC, Disseminated intravascular coagulation.

Criteria from Clark SL, Hankins GD, Dudley DA, et al. with monthly delivery volume data, for central review and reporting.[71,72] Cases of AFE are defined using either *clinical criteria* that include acute hypotension, cardiac arrest, acute hypoxemia, and/or coagulopathy in the absence of any other potential explanation for the symptoms and signs observed, or *pathologic evidence* indicating the presence of fetal squames or hair in the maternal lungs. Registry data from the UKOSS suggest an event rate of 1.7 per 100,000 deliveries (95% CI, 1.4 to 2.1).[72] Cross-sectional analyses of administrative data in the United States, as well as from Australia and New Zealand, suggest higher rates—3.2 and 5.4 per 100,000 deliveries, respectively.[73,74] Although geographic differences in the incidence of AFE have been reported,[75] the wide variability likely reflects variations in the definition of AFE, differences in ascertainment procedures, and the use of case validation, as opposed to true differences by country of origin. One regional surveillance system in Australia has developed the capacity to systematically review records for all cases identified from administrative data. By only counting women using a validated case identification system (i.e., women must have experienced one of the cardinal symptoms of AFE, with no other potential explanation), the reported incidence of AFE decreased from 6.3 to 3.3 cases per 100,000 pregnancies.[76]

Despite these limitations in reporting the incidence of AFE, there do not appear to be any temporal trends.[72,74]

Risk Factors

Maternal demographic factors such as older age and race or ethnicity have been associated with AFE in population-based studies.[72,77] Other obstetric factors such as abnormal placentation, placental abruption, eclampsia, multiple gestation, induction of labor, artificial or spontaneous rupture of membranes, and operative delivery have also been associated with AFE.[63,72,76,78–80] Because nonreassuring fetal heart rate (FHR) tracings can complicate AFE in labor, cesarean delivery may be a consequence, rather than a cause, of intrapartum AFE. Nonetheless, a strong association between cesarean birth and postpartum AFE persists among women in the UKOSS dataset. Of the 55 women who presented postpartum, 71% delivered via cesarean.[72] The adjusted odds ratio of postpartum AFE after cesarean delivery compared with other modes of delivery was 16.15 (95% CI, 6.20 to 42.05).[72]

Pathophysiology

In 1941, Drs. Steiner and Lushbaugh, two pathologists from the University of Chicago, described a case series of eight autopsies after fatal intrapartum shock.[62] Examination of lung tissue from these cases revealed embolic material of squamous cells, mucin, meconium, and amorphous eosinophilic material.[62] Because all of these patients were described as having tumultuous labors with stronger than usual uterine contractions, it was presumed that the forceful contractions loosened or tore the placenta and forced the emboli into the maternal circulation.[62] Yet, periods of uterine tachysystole are the least likely times for maternoplacental exchange of embolic material to occur as uterine blood flow ceases.[81] The tachysystole is probably a result of endogenous norepinephrine release and, therefore, is likely temporally related to, but not causative for, embolic material transfer.[81]

Large intravenous boluses of human meconium suspended in human amniotic fluid can precipitate cardiovascular collapse in rabbits and dogs,[62] but injection of autologous amniotic fluid fails to reproduce the AFE syndrome in many animal models.[82] The passage of fetal squames, lanugo hair, and mucin into the maternal pelvic vasculature appears to be a common event at term,[83] and fetal material has been identified in pulmonary arterial samples aspirated from critically ill women who did not have AFE.[84,85]

The exact trigger for the reaction in women with AFE is not known but may be a rare pathologic fetal antigen or a common antigen presented in an unusual way—in amount, timing, or frequency of entry into the maternal circulation.[86] AFE appears to be a systemic inflammatory response associated with the inappropriate release of endogenous inflammatory mediators.[70] Whatever the trigger, several maternal endogenous mediators appear to play an important role in the initial reaction, including arachidonic acid metabolites (thromboxane, prostaglandins, leukotrienes, endothelins).[70]

Approximately 40% of women in a U.S. national AFE registry had a history of allergy or atopy, leading some authors to suggest an anaphylactoid mechanism.[63] In support of this theory, the symptoms of AFE could be blocked by the administration of a leukotriene inhibitor in a rabbit model.[87] However, a series of case reports now suggests that levels of tryptase and histamine are not dramatically or universally elevated among women experiencing the AFE syndrome.[88,89] Although mast cell degranulation may contribute to the pathophysiology of AFE, this effect may be a secondary product of the inflammatory cascade, rather than causal, and thus the term *anaphylactoid syndrome of pregnancy* may be a misnomer.[89]

Other immune-mediated mechanisms have also been implicated in AFE. A case-control study demonstrated low levels of the complement components C3 and C4 among women diagnosed with AFE compared with controls, suggesting that complement activation may also contribute to the inflammatory cascade.[88] Whether complement plays a primary[86] or secondary[90] role in the AFE syndrome is unknown. A heat-stable pressor agent in meconium has been suggested as another possible mediator of AFE; in a goat model, this agent caused a circulatory response similar to that seen in human AFE.[91]

Alternatively, the hemodynamic consequences of AFE could derive from activation of the coagulation system, mediated through platelet activation. Fetal squamous cells and syncytiotrophoblasts display high concentrations of tissue factor and phosphatidylserine.[92-94] Tissue factor irreversibly aggregates platelets,[95] leading to platelet degranulation, which releases thromboxane, serotonin, and additional mediators that amplify the immunologic systems. Serotonin is a potent pulmonary vasoconstrictor that produces vasodilation in the systemic vasculature and may lead to early right-sided heart failure in the AFE syndrome.[93,96,97]

Coagulopathy develops in the majority of women who survive the initial cardiovascular collapse.[63,72] One proposed mechanism involves tissue factor. As pregnancy progresses, increasing amounts of tissue factor, a potent procoagulant, accumulates in the amniotic fluid.[93,94] Tissue factor binds factor VII, thus activating the extrinsic pathway and triggering clotting by activating factor X, with the subsequent development of a consumptive coagulopathy.[93] A second possible mechanism is that amniotic fluid has a thromboplastin-like effect, which induces platelet aggregation, releases platelet factor III, and activates the clotting cascade.[98] Other components of amniotic fluid, the amniochorion, and the placenta have also been implicated in contributing to the coagulopathy. Uterine atony, whether resulting from a specific myometrial depressant or from uterine hypoperfusion, may exacerbate hemorrhage and the consumptive coagulopathy seen in AFE.[99] There is conflicting evidence regarding whether the bleeding seen in AFE is due primarily to a consumptive coagulopathy or massive fibrinolysis. A rapid and severe hypofibrinogenemia has been observed during AFE.[100,101] Future work is necessary to further refine our understanding of the coagulopathy that accompanies AFE.

Clinical Presentation

Whereas the classic presentation of AFE includes acute respiratory distress, cardiovascular collapse, and coagulopathy near the time of delivery, a broad range of AFE syndromes have been described in situations in which other diagnoses were excluded.[63,70,102]

AFE most often occurs during labor; intrapartum events comprise 53% of cases in the UKOSS registry[72] and 70% in the U.S. registry.[63] In the U.S. registry, seizure and dyspnea were the two most common presenting symptoms in women who collapsed before delivery.[63] In a more recent multicenter retrospective cohort study, loss of consciousness was the most common presenting symptom.[103] Maternal symptoms may precede FHR changes. Fetal bradycardia, or the abrupt onset of variable decelerations that progress to fetal bradycardia, may also herald AFE in labor (Fig. 38.2).[63]

AFE can present after abdominal trauma,[104] after first-trimester abortion,[105] in the second trimester,[106] at the time of delivery,[63] and in the postpartum period.[107] Although acknowledging that AFE has been reported up to 48 hours postpartum,[108] the newly published criteria by the SMFM and the Amniotic Fluid Foundation require the diagnosis of AFE to be made within 30 minutes of placental delivery.[67]

Close inspection of hemodynamic data reveals a biphasic cardiovascular response during AFE. During the initial phase, acute pulmonary hypertension results in right ventricular dilation, a decrease in cardiac output, and ventilation-perfusion (V/Q) mismatch resulting in oxygen desaturation.[63] In the U.S. registry, 11 of 17 patients with an arterial blood gas sample drawn within 30 minutes of the acute event demonstrated an initial Pao_2 less than 30 mm Hg while breathing an FIo_2 of 100%.[63] Release of endogenous catecholamines may produce a brief period of systemic hypertension and uterine tachysystole that precedes hypotension or cardiac arrest.[63] In a minority of cases, there is massive hemorrhage and DIC without preceding cardiopulmonary collapse.[102]

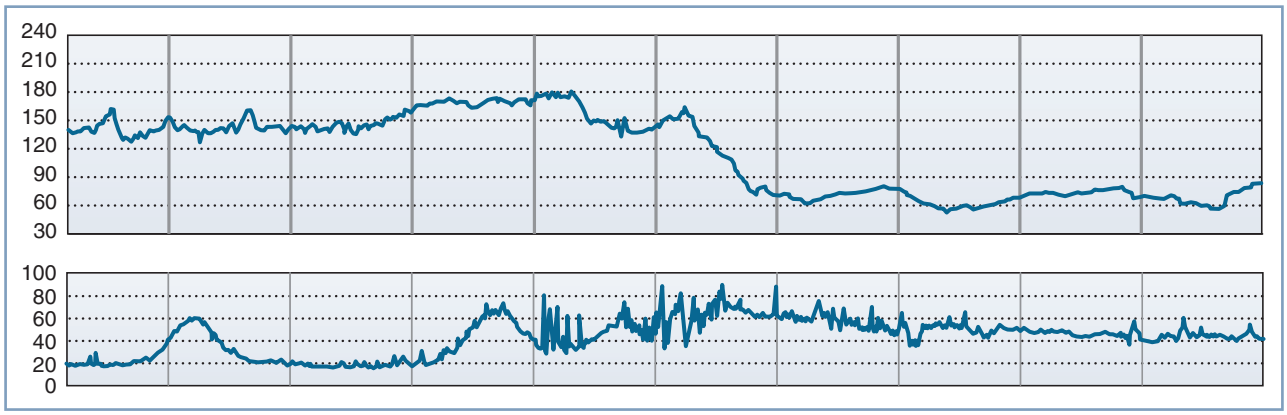

Fig. 38.2 Fetal heart rate tracing in a patient with amniotic fluid embolism. Maternal symptoms began just before the onset of spontaneous uterine tachysystole and fetal bradycardia. (Modified from Clark SL, Hankins GDV, Dudley DA, et al. Amniotic fluid embolism: analysis of the national registry. *Am J Obstet Gynecol.* 1995;172:1158–1167.)

Electrocardiographic findings are nonspecific and vary from ST-segment and T-wave abnormalities to arrhythmias or asystole. A chest radiograph may show diffuse bilateral heterogeneous or homogenous areas of opacity. Echocardiography typically demonstrates a dilated, akinetic right ventricle, pulmonary hypertension, and a normally contracting left ventricle with a nearly obliterated cavity.[109,110] Initially, right ventricular failure leads to right ventricular dilation, which compresses the left ventricle and impedes left ventricular filling and cardiac output.[109,110] A second phase commences when right ventricular function improves,[110] typically 15 to 30 minutes after the initial event. At this point, left ventricular failure may persist as a result of ischemic injury to the left ventricle[111] or direct myocardial depression,[108] and it is accompanied by decreased systemic ventricular resistance, decreased left ventricular stroke index, and pulmonary edema.[112,113] Women who survive to the second phase may also experience hemorrhage and DIC. Laboratory analysis may reveal anemia, thrombocytopenia, prolonged prothrombin time or aPTT or both, and significant hypofibrinogenemia.[63,101,108] Viscoelastic blood testing may demonstrate early hyperfibrinolysis and hypofibrinogenemia.[114]

Because many of the signs and symptoms are nonspecific, the differential diagnosis for AFE is extensive and should include nonobstetric, obstetric, and anesthetic causes (Box 38.2). Even though the time course and clinical presentation of many of these competing diagnoses are similar, only amniotic fluid embolism and placental abruption result in a relatively sudden onset of coagulopathy after maternal collapse.

Confirmatory Tests

To date, there is no definitive test to confirm the diagnosis of AFE, although the UKOSS considers the finding of fetal material in the maternal pulmonary vasculature at autopsy to be pathognomonic for AFE.[72] However, fetal squamous cells and trophoblasts are commonly found in the maternal circulation of healthy parturients. Furthermore, differentiating between maternal and fetal cells histologically is challenging.[115] Clinicians should therefore not place invasive monitors solely for the purpose of aspirating cells of fetal origin.

Several biochemical markers have been suggested.[116] Although some of these may be promising based on preliminary data and the proposed pathophysiology of AFE, studies of test performance are limited by delayed sample acquisition and small sample size because of the rarity and unpredictability of the AFE syndrome.

Several markers suggest an anaphylactic/anaphylactoid mechanism. Mast cells release tryptase and histamine during degranulation; tryptase has been used as a marker for anaphylaxis because its half-life is longer than that of histamine. Elevations in serum tryptase have been reported in some parturients with AFE.[89] However, a case series found normal tryptase and urinary histamine levels in nine women with

- Obstetric hemorrhage

Anesthetic
- High neuraxial blockade ("total spinal")
- Local anesthetic systemic toxicity
- Medication error

presumed AFE.[88] Pulmonary mast cell counts have also been suggested; however, this measurement can only be obtained using immunohistochemistry at autopsy and therefore is not useful for guiding resuscitation. In one observational study, the mean pulmonary mast cell count per fixed area for parturients who died of AFE was similar to that of parturients who died of anaphylactic shock but was higher than the mean counts in both pregnant and nonpregnant control patients.[117] These data, together with the finding of minimal to no elevation in serum tryptase, suggest that pulmonary mast cell degranulation may be a secondary process in AFE.[89]

Complement activation may cause mast cell degranulation, and there is some evidence supporting widespread complement activation, and depressed C3 and C4 levels in AFE.[88] However, because complement is activated during acute respiratory distress syndrome and other inflammatory states, results are not specific for AFE. C1 esterase inhibitor (C1INH), which inhibits C1 as well as kallikrein and factors XIa and XIIa, has been suggested as a possible biomarker to support the clinical diagnosis of AFE.[118] C1INH levels were lower in women who were diagnosed with AFE compared with healthy pregnant controls (30% versus 62%, $P < .001$). C1INH levels were further decreased in fatal AFE cases compared with nonfatal cases (23% versus 32%, $P < .05$).

Zinc coproporphyrin[119] and sialyl Tn antigen[88] are two biomarkers that are components of meconium and have been associated with the AFE syndrome. Sialyl Tn is a mucinous glycoprotein that originates in the fetal gastrointestinal tract and is also associated with mucinous gastrointestinal tumors.[88] Insulin-like growth factor–binding protein-1 (IGFBP-1) has been identified as a sensitive and specific biomarker for AFE in a case-control study conducted in 13 delivery centers in France.[120] IGFBP-1 levels exceeded 104.5 µg/L in 23 of 25 women with AFE and remained below 95 µg/L in all patients with postpartum hemorrhage caused by atony, thrombotic pulmonary embolism, or uncomplicated labor. Finally, squamous cell carcinoma (SCC) antigen, a gene product present only in the amniotic fluid and not in the maternal serum, has been suggested as a potential candidate marker for diagnosing AFE.[121] Serum SCC antigen levels were higher in women with autopsy-proven AFE compared with healthy controls. The optimal threshold value for SCC antigen levels was 7.15 ng/mL; sensitivity was 60% and specificity was 89%.[121] Confirmatory studies are necessary.

Management

Although no single intervention has been shown to reliably reverse the AFE syndrome, prompt recognition and aggressive resuscitation may improve maternal and fetal outcomes. Maternal resuscitation should focus on three priorities: (1) maintenance of oxygenation, (2) hemodynamic support, and (3) correction of coagulopathy (Box 38.3).

At the time the diagnosis of AFE is suspected, 100% oxygen should be delivered to the patient. Given the risk for coagulopathy and hemorrhage, large-bore intravenous access is warranted. An arterial line and central venous pressure catheter may facilitate hemodynamic monitoring, blood sampling, and vasopressor administration. Transesophageal echocardiography may be useful to guide volume resuscitation and selection of appropriate vasopressor therapy.

BOX 38.3 Management of Amniotic Fluid Embolism

Airway
- Administer 100% oxygen.
- Intubate the trachea, support ventilation as needed.

Cardiovascular Support
- Start chest compressions if indicated.
- Ensure left uterine displacement to relieve aortocaval compression if appropriate.
- Administer fluids and vasopressors.
- Establish large-bore intravenous access.
- Consider invasive blood pressure monitoring.

Fetus
- Monitor fetal well-being.
- Expedite delivery for nonreassuring status in a viable fetus or in the event of maternal cardiopulmonary arrest in the second half of pregnancy (i.e., perimortem cesarean delivery).

Hemostatic Support
- Activate the obstetric hemorrhage protocol and massive transfusion protocol.[a]
- Send blood for serial laboratory assessment to monitor for coagulopathy and electrolyte disturbances.
- Provide blood component therapy as indicated.
- Ensure normothermia.

Postresuscitation Care
- Notify the intensive care unit of the potential admission.
- Consider initiation of mild therapeutic hypothermia after cardiac arrest.

[a]See Chapter 37.

In addition to standard resuscitative measures, other management strategies have been reported for AFE. The use of cardiopulmonary bypass, extracorporeal membrane oxygenation, continuous hemofiltration, exchange transfusions, and intra-aortic balloon counterpulsation have all been described.[64,103,109,122,123] It is speculated that filtration technologies may filter amniotic fluid or vasoactive mediators from the systemic circulation. Strategies for management of right-sided heart failure include inhaled nitric oxide, prostacyclin, right ventricular assist devices, and vasopressors such as vasopressin, dobutamine, and milrinone.[124,125]

Intact neonatal survival is related to the time interval from the onset of maternal compromise to delivery.[63] In the event of maternal cardiopulmonary arrest, immediate high-quality cardiopulmonary resuscitation should be initiated (see Chapter 54).[99,126,127] The American Heart Association recommends that delivery of the fetus should occur within 5 minutes to increase the probability of favorable outcomes for both the mother and her neonate.[126] Although the operating room may provide a more favorable environment for surgery

and resuscitation, simulation studies have suggested that resuscitation quality and the arrest-to-delivery interval both suffer with maternal transport[128,129]; therefore, if obstetric conditions do not support an immediate operative vaginal delivery (i.e., forceps or vacuum), a bedside perimortem cesarean delivery is indicated. After cardiac arrest, mild therapeutic hypothermia (temperature between 32° C and 34° C), when maintained for 12 to 24 hours, is associated with improved neurologic outcomes and reduced mortality in the nonpregnant patient population.[130] In the setting of severe coagulopathy, the effects on the coagulation system must be balanced against any neurologic benefit of mild hypothermia.

Because coagulopathy will likely ensue for the majority of AFE survivors, early assessment of coagulation status is indicated, and the massive transfusion protocol should be activated as soon as AFE is suspected.[99] Blood and component therapy should be guided by the clinical presentation (see Chapter 37). Close communication with the blood bank is paramount because large quantities of blood products may be needed. Although the optimal transfusion strategy is not known, one case-control study has shown improved survival with a higher (≥ 1) FFP : RBC transfusion ratio compared with lower ratios (adjusted odds ratio [aOR], 28.32; 95% CI, 4.26 to 188.37).[131] Potential pharmacologic therapies for the coagulopathy associated with AFE include antifibrinolytic agents (e.g., tranexamic acid), recombinant factor VIIa (rVIIa), prothrombin complex concentrate, and fibrinogen concentrate.[100,114,132]

The use of rVIIa to treat intractable hemorrhage in the AFE syndrome remains controversial. Use of rVIIa for obstetric hemorrhage is off-label (see Chapter 37). Recombinant factor VIIa binds to tissue factor and initiates clotting via the extrinsic pathway. Although individual case reports have described improvement in hemostasis, rVIIa has been associated with thrombotic complications. A meta-analysis of 25 trials involving 3849 nonobstetric bleeding patients without hemophilia found a significant increase in arterial thromboembolic events among patients who received rVIIa (RR 1.45; 95% CI, 1.02 to 2.05).[133]

A case-control study based on a systematic review of case reports of women with the AFE syndrome identified a twofold increase in risk for death or permanent disability among 16 women treated with rVIIa compared with 28 control patients who underwent surgery to control bleeding but did not receive rVIIa.[132] Among survivors, treatment with rVIIa was associated with more permanent disability (RR, 4.0; 95% CI, 1.5 to 10.4), largely attributed to thrombosis in major organs.[132] An unmeasured increase in severity of disease in the treatment group compared with the control group could explain these dismal results because the population of patients who did not survive to the time of operation was excluded from the analysis. In this case-control study of case reports,[132] 50% of parturients treated with rVIIa survived, whereas in the 2010 UKOSS dataset,[64] 93% of the parturients treated with rVIIa survived (n = 14).[64] However, the 2016 UKOSS summary did not report differences in survival or neurologic outcomes in AFE patients treated with and without rVIIa.[72] Recombinant factor VIIa should be considered as a last resort should component replacement and other surgical interventions fail.[99]

Maternal and Perinatal Outcomes

The maternal mortality ratio associated with AFE has been reported between 0.5 and 1.7 deaths per 100,000 live births.[134] The pooled AFE-related case-fatality rate from 12 population-based studies published between 1999 and 2016 (n = 17,451,646 deliveries) is 20.4%.[135] This rate is significantly lower than the 61% fatality rate reported in the 1988 to 1994 analysis of the U.S. AFE registry.[63] Suboptimal care was identified in 20 of the 36 AFE mortalities in the French Confidential Enquiry into Maternal Deaths (2007 to 2011), with contributing factors including delays in, or suboptimal, transfusion management, as well as delays or lack of performing indicated hysterectomies.[68]

Cardiac arrest complicated 87% of AFE cases reported to the U.S. registry but only 46% of cases identified by UKOSS.[63,72] This difference may reflect more comprehensive ascertainment in the United Kingdom that captures less severe cases; alternatively, improvements in early recognition and management of AFE over the past 20 years may explain improved outcomes reported more recently from the United Kingdom compared with those previously published from the U.S. registry. Interestingly, in the UKOSS dataset, women with AFE who died were more likely than those who survived to present with cardiac arrest (87% versus 36%, P < .001).[72] Patients who died of AFE were more likely to be from ethnic minority groups than were survivors, even after adjusting for confounders such as age, socioeconomic status, body mass index, parity, and induction of labor (aOR, 2.85; 95% CI, 1.02 to 8.00).[72] Similar racial/ethnic disparities in maternal mortality have been observed in the United States.[136] Improvements in the management of critically ill parturients may have contributed to the decline in the case-fatality rate observed in the two studies, but the disparity in outcomes by race/ethnicity suggests further systems improvements are necessary. Multidisciplinary reviews are currently recommended for all severe obstetric hemorrhages to identify systems issues or breakdowns that contributed to the outcome[137]; implementation of such reviews could be employed for AFE cases, and may reduce current racial/ethnic disparities.[138]

Neurologic outcomes for survivors appear to be improving. The 1995 analysis of the U.S. registry reported a 15% overall rate of intact neurologic survival[63]; by contrast, only 7% of AFE survivors suffered permanent neurologic injury in the 2016 UKOSS dataset.[72]

Neonates have a high overall survival rate, with greater than 90% of infants surviving.[72,73] Intact neurologic survival for infants is related to the cardiac arrest–to–delivery interval; delays of greater than 15 minutes are associated with poor outcomes.[63]

Verified recurrent AFE has not been reported; however, this may be attributable to reproductive choices of AFE survivors.[139] A survey of Amniotic Fluid Embolism Registry

survivors revealed that only 30% subsequently conceived, and 57% of survey participants reported that the diagnosis of AFE affected their decisions about future childbearing.[139]

VENOUS AIR EMBOLISM

Venous air embolism (VAE) is a recognized complication of many surgical procedures.[140] The first study of VAE during cesarean delivery was published in 1987.[141] Subsequent research has revealed that VAE is a common occurrence during cesarean delivery. Most air emboli are small, but volumes greater than 200 to 300 mL, or 3 to 5 mL/kg, may be lethal.[140] Early recognition and appropriate management are necessary for avoiding unfavorable outcomes.

Incidence

The reported incidence of VAE during cesarean delivery varies depending on the method used to ascertain the presence of air (Table 38.5). The most sensitive monitors detect volumes of air as low as 0.02 mL/kg.[140] Studies that have used precordial Doppler monitoring in patients undergoing cesarean delivery with neuraxial anesthesia have found incidence rates ranging from as low as 10%[142] to as high as 65%.[143] One study used precordial Doppler monitoring to detect VAE and correlated the Doppler findings with transthoracic echocardiographic evidence of intracardiac air. Of the 42 patients who underwent cesarean delivery with neuraxial anesthesia, 11 (26%) had evidence of VAE, with perfect agreement between the Doppler and the echocardiographic monitoring (kappa = 1.0).[144] Another study of healthy parturients undergoing elective cesarean delivery with general anesthesia found that 29 of 30 parturients had evidence of intraoperative VAE.[145] The authors defined VAE as a 0.1% increase from the baseline of expired nitrogen concentration (equivalent to 0.25 to 1.0 mL/kg venous air).[145] Although the volume of entrained air may be lower with general anesthesia using positive-pressure ventilation than spontaneous ventilation,[146] the use of prophylactic positive end-expiratory pressure has not been shown to decrease the incidence of VAE in a neurosurgical population.[147]

TABLE 38.5 Methods to Detect Venous Air Embolism

Method of Detection	Sensitivity	Volume of Air Detected (mL/kg)
Transesophageal echocardiography	High	0.02
Precordial Doppler	High	0.05
Pulmonary artery catheter	High	0.25
Expired CO_2	Moderate	0.5
Expired nitrogen	Moderate	0.5

Modified from Mirski MA, Lele AV, Fitzsimmons L, Toung TJK. Diagnosis and treatment of vascular air embolism. *Anesthesiology*. 2007;106:164–177.

The incidence of VAE does not appear to vary with maternal position. Although the Trendelenburg position could produce a pressure gradient between the right side of the heart and open venous sinuses in the surgical field, a meta-analysis of two randomized controlled trials, which compared 5 to 10 degrees reverse Trendelenburg positioning with supine positioning for cesarean delivery (pooled $n = 130$) found no difference in the incidence of air embolism (RR 0.85; 95% CI, 0.28 to 2.57).[148]

The majority of VAE episodes are subclinical. The true incidence of fatal VAE in the obstetric population is unknown. One estimate using data on maternal deaths from the National Center for Health Statistics from 1974 to 1978 found that 25 of 2475 deaths were attributable to air embolism.[149] In recent Confidential Enquiries into Maternal Deaths and Morbidity reports from the United Kingdom, no VAE-related deaths were reported.[8,9]

Pathophysiology

A pressure gradient as small as –5 cm H_2O between the surgical field and the heart allows a significant amount of air to be entrained into the venous circulation. Immediately after placental separation, the raw endometrial surface appears to be a location of significant air entrainment; almost all episodes of VAE during cesarean delivery are noted after delivery of the placenta.[143] In the noncesarean delivery setting, pressurized air in the vagina is believed to traverse the cervical canal, dissect around fetal membranes (if present), and enter the maternal circulation via subplacental sinuses.[150] Venous air embolism has been reported during pregnancy during vaginal examinations and orogenital sex,[151–153] as well as postpartum during manual repositioning of an inverted uterus.[154]

Small volumes of air can precipitate pulmonary vasospasm via a pathophysiologic process that mimics that of other embolic phenomena. Vasoactive mediators or mechanical obstruction of small vessels appear to induce pulmonary vasoconstriction that leads to V/Q mismatch, hypoxemia, right-sided heart failure, arrhythmias, and hypotension. Fluid resuscitation and increased hydrostatic pressure may provoke interstitial pulmonary edema. A paradoxical air embolus into the arterial circulation (by means of a patent foramen ovale) can lead to cardiovascular and neurologic sequelae and morbidity. Large volumes of air (greater than 3 mL/kg) can generate cardiovascular collapse by creating an "air lock" that causes right-ventricular outflow tract obstruction.

Clinical Presentation

Most air emboli are subclinical with no sequelae; however, massive VAE can manifest as a sudden, dramatic, and devastating event with hypotension, hypoxemia, and even cardiac arrest.[155] In awake patients receiving neuraxial anesthesia, transient episodes of hypoxemia, dyspnea, or chest pain during uterine repair suggest VAE.[142,143,156] In the patient receiving general anesthesia, evidence of VAE may be limited to hypoxemia and a slight decrease in end-tidal CO_2.[140] VAE may be more frequent when the uterus is exteriorized than when it is repaired within the abdomen, either caused by

vertical elevation relative to the heart or traction on the uterus that opens venous sinuses.[142,156] A precordial stethoscope may detect a pathognomonic "millwheel murmur." Transesophageal echocardiography may detect air in the right atria or the pulmonary artery. Clinically significant air emboli may be associated with hypotension, heart rate or rhythm changes, evidence of right-sided heart strain on the electrocardiogram, an increase in central venous pressure, and/or an increase in pulmonary artery pressure. Although isolated ST-segment depression during cesarean delivery was once common and thought to be possibly related to VAE,[157] more recent evidence suggests that ST-segment depression in the immediate postdelivery period may be associated with rapid oxytocin administration.[158] One small prospective observational study failed to identify VAE using echocardiography at the time of ST-segment depression during cesarean deliveries.[157]

Management

The clinician should consider VAE in women who complain of intraoperative chest pain or dyspnea or experience sudden hypoxemia, hypotension, or arrhythmia during cesarean delivery. Although continuous precordial Doppler monitoring has been recommended by some experts,[140] the rarity of hemodynamically significant VAE suggests that targeted use in high-risk patients (e.g., women with a known intracardiac shunt) may be more appropriate than routine application. Transthoracic or transesophageal echocardiography may help to confirm a diagnosis of VAE, to exclude alternative causes of hemodynamic instability, and to guide appropriate clinical management. Regardless, clinical suspicion of VAE should prompt appropriate management (Box 38.4).

Currently, there are no data to support central line insertion for air aspiration from the right side of the heart, but central line placement may be indicated to deliver potent vasopressors.[140] Maternal position changes to limit air entrainment are recommended; however, to date, no human data support placing the patient in the left lateral decubitus position to relieve the "air lock."[140] In a canine study of resuscitation positioning after a 2.5-mL/kg VAE, repositioning animals to direct air to the nondependent portion of the right side of the heart did not improve cardiac function or survival.[159] The use of the Valsalva maneuver and positive-end expiratory pressure should be avoided because an increase in right atrial pressure may result in a paradoxical embolism. In patients with delayed emergence from anesthesia, computed tomography or magnetic resonance imaging may be considered to evaluate for intracerebral air. Hyperbaric oxygen may improve neurologic outcomes if instituted within 6 hours of intracerebral air embolism.[160]

BOX 38.4 Resuscitation of the Obstetric Patient with Massive Venous Air Embolism

Air
- Prevent further air entrainment (e.g., flood the surgical field with saline solution, lower the surgical field relative to the heart, if tolerated).

Airway
- Administer 100% oxygen, discontinue nitrous oxide, intubate the trachea, and support ventilation as needed.

Cardiovascular Support
- Support circulation with chest compressions, intravascular volume expansion, and vasopressors as needed.

Fetus
- Expedite delivery.

Postresuscitation Care
- Evaluate for intracerebral air, and consider hyperbaric oxygen therapy if indicated.
- Consider initiation of mild therapeutic hypothermia after cardiac arrest.

KEY POINTS

- Embolic disorders are a major cause of maternal morbidity and mortality.
- Early recognition, diagnosis, and therapy may reduce the incidence of morbidity and mortality associated with embolic disorders.
- During pulmonary embolic phenomena, hemostatic and immunologic mediators may trigger a cascade of physiologic derangements disproportionate to the cross-sectional area of occluded lung tissue.
- Pregnant patients are at a fivefold higher risk than nonpregnant patients for thromboembolic events. The third trimester and first postpartum week are the periods of highest risk.
- Several prophylactic and therapeutic anticoagulation regimens exist for patients with venous thromboembolism or those at increased risk for thromboembolism; anesthesia providers should be aware of the safety implications of anticoagulation therapy on the timing of initiation of neuraxial anesthesia and neuraxial catheter removal.
- Amniotic fluid embolism is a diagnosis of exclusion. It may occur at any time during labor or delivery, as well as antepartum or postpartum.
- Venous air embolism is a common occurrence during cesarean delivery. Most of the emboli are small, transient, and benign. Massive venous air embolism is rare during vaginal or cesarean delivery but can be fatal.

Maternal Mortality

Jill M. Mhyre, MD

CHAPTER OUTLINE

GLOBAL MATERNAL MORTALITY

Globally in 2015, an estimated 303,000 women died while pregnant or within 42 days of the end of pregnancy.[1] This number corresponds to a ratio of 216 maternal deaths per 100,000 live births and to a 1-in-180 lifetime risk for pregnancy-related death for each girl entering her childbearing years (Table 39.1).[1] According to the World Health Organization (WHO), "No issue is more central to global well-being than maternal and perinatal health. Every individual, every family and every community is at some point intimately involved in pregnancy and the success of childbirth."[2]

Definitions for maternal death are listed in Table 39.2, and measures of maternal mortality are listed in Table 39.3. More than 99% of maternal deaths occur in low- and middle-income countries, with 84% in either sub-Saharan Africa or South Asia (Fig. 39.1). Between 1990 and 2015,[1] the global **maternal mortality ratio (MMR)** fell by 44%, an impressive improvement, but less than the 75% reduction targeted by the Millennium Development Goals. In 2015, the United Nations issued 17 Sustainable Development Goals, including a commitment to reduce the global MMR to less than 70 per 100,000 live births by 2030, with no single country having an MMR of more than 140. Several regions will require substantial investment to meet this goal, most notably sub-Saharan Africa, where the lifetime risk for maternal death remains remarkably high, at 1 in 36.[1] There is considerable regional variation. Within sub-Saharan Africa, the highest MMRs are in Sierra Leone (1360), Central African Republic (882), and Chad (856) and represent rates that are 10-fold higher than the lowest ratios in the region.[1] Throughout the world, war, natural disaster, and political conflict can degrade health systems and trigger a rise in deaths caused by complications that would be treatable under stable conditions.[1]

Leading Causes

Hemorrhage, hypertensive disorders of pregnancy, and **sepsis** account for more than one-half of global maternal deaths and for slightly more than one-third of deaths in the developed world.[3] Hemorrhage is the leading direct cause of maternal death worldwide, followed by hypertensive disorders, causing an estimated 27.1% and 14.0% of all deaths, respectively (see Fig. 39.1).[3] Infection and sepsis may be substantially underestimated in regions where laboratory diagnostic tests are unavailable.[4] In one Malawi hospital with full laboratory capabilities, infection played a primary role in almost three-fourths of all maternal deaths.[5]

Rarely, **anemia** can cause lethal congestive heart failure in pregnancy,[6] but more commonly, it increases the risk for maternal death from other complications, particularly hemorrhage and infection.[7] Risk factors associated with anemia include (1) iron and other micronutrient deficiencies, (2) pregnancy intervals of less than 1 year, (3) adolescent pregnancy, (4) hemoglobinopathy, (5) urinary tract infection, (6) human immunodeficiency virus (HIV) infection, (7) parasitic infections including malaria, and (8) recurrent antepartum hemorrhage.[6–8]

Obstructed labor causes less than 10% of maternal deaths worldwide,[3] but it is an important cause of mortality in communities where early adolescent pregnancy is common, childhood malnutrition leads to small maternal pelvices, and operative delivery is unavailable.[9] Death from obstructed labor is largely the result of hemorrhage caused by uterine rupture, or sepsis caused by ascending genital tract infection, and deaths may be coded under those categories.[9,10] Prolonged pressure on the pelvic outlet can lead to tissue necrosis and obstetric fistula, which is thought to affect between 2 and 3.5 million women worldwide.[11,12]

TABLE 39.1 Estimates of Maternal Mortality Ratio (MMR), Number of Maternal Deaths, and Lifetime Risk by United Nations Millennium Development Goal Regions, 2015

Region	MMR	RANGE OF MMR UNCERTAINTY		Number of Maternal Deaths[a]	Lifetime Risk for Maternal Death,[a] 1 in:
		Lower Estimate	Upper Estimate		
World	215	207	249	303,000	180
Developed Regions[b]	12	11	14	1700	4900
Developing Regions	239	229	275	302,000	150

Reproduced from World Health Organization. Trends in Maternal Mortality 1990-2015: Estimates Developed by WHO, UNICEF, UNFPA, World Bank Group and the United Nations Population Division. Geneva, Switzerland: WHO Press; 2015.

HIV/acquired immune deficiency syndrome (AIDS) increases vulnerability to both nonobstetric infection (e.g., tuberculosis, malaria) and obstetric complications (e.g., hemorrhage, pregnancy-related sepsis, septic abortion).[13,14] Global mortality attributed to HIV/AIDS peaked in 2004,[15] and the WHO attributed 1.6% of maternal deaths in 2015 to HIV/AIDS.[1] In countries most severely affected (e.g., Botswana, Malawi, South Africa), MMRs increased between 1990 and 2000, but they have subsequently declined with increasing availability of antiretroviral therapy.[1,14,15]

Maternal deaths attributed to **unsafe abortion** account for 5% to 13% of maternal deaths worldwide.[16] The WHO defines *unsafe abortion* as "a procedure for terminating an unintended pregnancy either by individuals without the necessary skills or in an environment that does not conform to minimum medical standards, or both."[17,18] Worldwide, 45% of abortions were unsafe between 2010 and 2014, compared with 44% in 1995.[18,19] The case-fatality rate (460 maternal deaths per 100,000 unsafe abortions) and the absolute number of maternal deaths per year (28,500) are highest in sub-Saharan Africa.[16,20]

Early marriage (before 18 years of age) has been identified as a major health risk for girls, increasing their exposure to domestic violence, coercion, pregnancy, and sexually transmitted diseases such as HIV/AIDS.[21–23] Girls younger than 15 years of age are four times more likely to die in childbirth than women in their 20s,[24] and pregnancy is among the leading causes of death worldwide for girls 15 to 19 years of age.[25] Early childbearing also increases the likelihood of **high parity birth** (greater than or equal to 5) later in life. With a threefold increase in the MMR, high parity is the most important demographic risk for maternal death because it remains so common, accounting for 29% of births globally between 1990 and 2005.[26] **Advanced maternal age** is

TABLE 39.2 Glossary of Terms Used in Discussions of Maternal Mortality

Source	Term	Definition[a]
World Health Organization	Maternal death	Death while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management but not from accidental or incidental causes. ICD-10 A34, O00-O95, O98-O99[b]
	Direct maternal death	Death resulting from obstetric complications of the pregnant state (pregnancy, labor, and the puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above. A34, O00-O95[b]
	Indirect maternal death	Death resulting from previous existing disease or disease that developed during pregnancy and that was not a result of direct obstetric causes but was aggravated by physiologic effects of pregnancy. O98-O99[b]
	Late maternal death	Death of a woman from direct or indirect obstetric causes more than 42 days but less than 1 year after termination of pregnancy. O96-O97[b]
U.S. Centers for Disease Control and Prevention, Pregnancy Mortality Surveillance System[c]	Pregnancy-associated death	Death while pregnant or within 1 year of termination of pregnancy, irrespective of cause.
	Pregnancy-related death	Death while pregnant or within 1 year of termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes.
	Non–pregnancy-related death	Death while pregnant or within 1 year of termination of pregnancy, from a cause unrelated to pregnancy.

[a]Numbers after some definitions indicate cause of death codes.

TABLE 39.3 Measures of Maternal Mortality

Maternal Mortality Measure	Definitions	Reports Using the Measure
Maternal mortality ratio (MMR)	Direct and indirect maternal deaths, but not late maternal deaths, per 100,000 live births	WHO[1]
Maternal mortality rate	Direct and indirect maternal deaths, but not late maternal deaths, per 100,000 maternities (pregnancies resulting in a live birth or stillbirth ≥ 20 weeks gestational age)	UK CEMD[66]
Pregnancy-related mortality ratio (PRMR)	Pregnancy-related deaths per 100,000 live births	U.S. CDC PMSS[172]
Lifetime risk for maternal death	The lifetime risk for maternal death takes into account both the probability of becoming pregnant and the probability of dying as a result of that pregnancy cumulated across a woman's reproductive years	WHO[1]

UK CEMD, The United Kingdom Confidential Enquiry into Maternal Death; *U.S. CDC PMSS,* U.S. Centers for Disease Control and Prevention Pregnancy Mortality Surveillance System; *WHO,* World Health Organization.

less common globally, but the MMR increases threefold by 35 years, sevenfold by 40 years, and 15-fold after 45 years of age.[27]

Anesthesia providers working in the developing world must contend with profound limitations in staffing, equipment, and other resources.[28–32] In addition, patients who labor at home may face a variety of social and environmental obstacles to reach a facility with the capacity to provide comprehensive emergency obstetric care,[33–35] and many arrive at these facilities in septic or hemorrhagic shock.[36–38] Cesarean delivery is the most common major surgical procedure in Africa.[39] Perioperative maternal mortality is estimated to be between 1.2% and 2%,[40–42] with one in seven deaths associated with cesarean delivery attributed to anesthesia.[43] Although general anesthesia is associated with a threefold increased risk for death (5.9 per 1000 general anesthetics versus 1.2 per 1000 neuraxial anesthetics),[43] reports of high spinal anesthesia and hemodynamic collapse highlight potential hazards with neuraxial anesthesia.[43–45] Failed airway management (including bronchospasm and aspiration of gastric contents) accounts

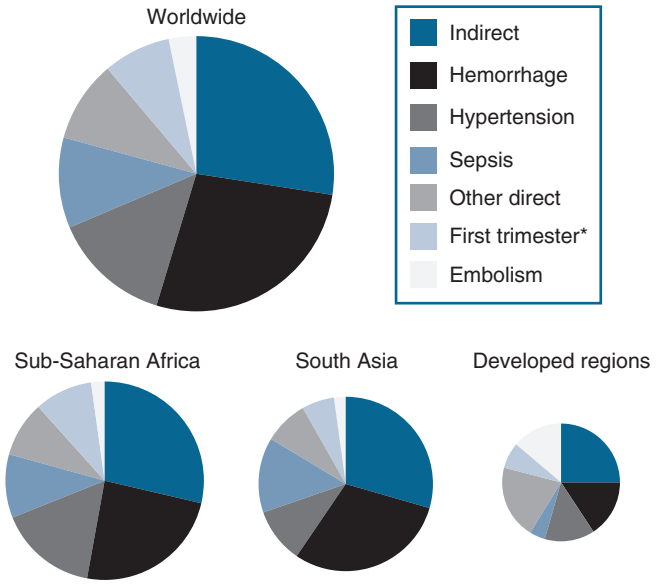

Fig. 39.1 Estimated distribution for the main causes of maternal death worldwide, and in selected regions. The relative size of each circle is illustrative but not directly proportional to the relative numbers of deaths in the three illustrated regions. *First-trimester deaths include those from induced abortion, miscarriage, and ectopic pregnancy. (Data from Say L, Chou D, Gemmill, et al. Global causes of maternal death: a WHO systematic analysis. *Lancet Glob Health.* 2014;2:e323–e333.)

for three-fourths of anesthesia-related deaths reported from low- and middle-income countries.[43] Peripartum deaths have also been attributed to limited availability or affordability of blood products,[37,40,46,47] cardiac arrest at induction of anesthesia, drug overdose, adverse medication reaction, and drug error.[43,48] The number of maternal perioperative deaths likely pales in comparison with maternal deaths that result from the unmet need for lifesaving obstetric procedures, including cesarean delivery.[49]

Strategies to reduce global maternal mortality include (1) improvement in family planning services and a reduction in the performance of unsafe abortion[50,51]; (2) community-based education focused on safe birth practices and indications for transfer to a higher level of care[52–55]; and (3) development of the infrastructure needed to provide timely emergency obstetric care, including the performance of indicated cesarean delivery (and safe administration of anesthesia) by trained care providers,[56,57] who can also provide resuscitation of women in whom shock develops secondary to hemorrhage or infection.[58–62] Cluster randomized trials[53,55,63] and cost-effectiveness analyses[64,65] to evaluate these strategies are beginning to appear. When deployed as part of an integrated, context-specific, and culturally sensitive program,[59] interventions to reduce maternal and fetal mortality can be highly cost effective.[64,65]

MATERNAL MORTALITY IN THE DEVELOPED WORLD

In developed regions of the world, the MMR decreased 48% from 23 in 1990 to 12 (95% confidence interval [CI], 11 to 14) in 2015.[1] The United States was the only high-income country where the MMR increased over this time period.[1]

The most comprehensive maternal surveillance system in the world is the **Confidential Enquiry into Maternal Deaths (CEMD)** in the United Kingdom.[a] Triennial reports of CEMD in England and Wales extend back to 1952 and have covered the entire United Kingdom since the 1985 to 1987 report. Since 2014, annual reports summarize overall mortality statistics and focus on clinical diagnoses on a rolling basis that covers all clinical conditions every 3 years. By government mandate, all maternal deaths are subject to this enquiry, and health professionals have a duty to provide all requested information.[66,67] Once a case is identified, practitioners are asked to provide (1) a full account of the circumstances leading up to the woman's death, (2) all supporting records, (3) any clinical or other lessons that have been learned, and (4) details of any actions that may have been taken as a result.[66,67] Regional assessors review the files to ensure completeness before removing identifying information. Once data are complete, central assessors review the anonymized cases and produce the reports. The reports focus on both medical and nonmedical recommendations for action to improve safety for future pregnant women.

The CEMD reports include both the internationally defined MMR and the UK-defined maternal mortality rate (see Table 39.3). The numerator for the UK-defined maternal mortality rate includes all deaths that in the opinion of the central assessors are related to pregnancy, including some causes that are not internationally coded as maternity related (e.g., suicide attributed to postpartum depression). The denominator includes all pregnancies that resulted in a live birth or stillbirth after 24 weeks' gestation. The international MMR is calculated strictly from data coded on death certificates; the UK maternal mortality rate includes all deaths identified through active surveillance. Over time, these numbers have converged.[67]

National confidential enquiry reports are now published by many other countries, including France,[68] the Netherlands,[69] New Zealand,[70] and South Africa.[14]

In the United States, the **National Center for Health Statistics (NCHS)** has provided maternal death counts since 1900 and MMRs since 1915.[71] Accuracy is limited because (1) the system relies on death certificates rather than active surveillance, (2) the certification of death is the legal responsibility of individual states, and (3) the process of maternal death ascertainment varies by state.

The U.S. MMR reported by the NCHS declined from more than 600 deaths per 100,000 live births in 1915 to

[a]The Confidential Enquiry into Maternal Deaths has been overseen by a series of organizations in recent years, including The Confidential Enquiry into Maternal and Child Health (CEMACH), the Centre for Maternal and Child Enquiries (CMACE), and, currently, Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the United Kingdom (MBRRACE-UK), led by the National Perinatal Epidemiology Unit (NPEU) at the University of Oxford.

fewer than 10 deaths per 100,000 live births by 1980 (Fig. 39.2).[71] Throughout the 1980s and 1990s, the MMR oscillated between 6.6 and 9.2. Then in 1999, the MMR began to increase, reaching 21.0 in 2015 (Fig. 39.3).[72] Improvements in ascertainment explain some of the increase. In 1999, the *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (ICD-10) replaced the ICD-9 as the coding system for U.S. death certificates and liberalized the criteria by which pregnancy could be linked with death. Growing numbers of states perform electronic matches among women's death certificates, live birth certificates, and fetal death files. In addition, increasing numbers of states have adopted the 2003 revision of the U.S. Standard Certificate of Death, which introduced questions about pregnancy status at the time of death (Box 39.1). By 2005, 19 states had adopted the standard pregnancy questions; the MMR calculated from vital records in these states was 17.3, compared with 10.7 from states without any questions about pregnancy on the state death certificate.[73] Subsequent analyses confirmed improved ascertainment with the pregnancy checkbox, but also evidence of misclassification of nonmaternal deaths as maternal, particularly among older women.[74]

In 1987, the U.S. Centers for Disease Control and Prevention (CDC) partnered with state health departments and the American College of Obstetricians and Gynecologists (ACOG) to form the **Pregnancy Mortality Surveillance System (PMSS).**[75] To capture maternal deaths more completely, the PMSS recommended that states develop an active

BOX 39.1 Pregnancy Questions, U.S. Standard Certificate of Death, 2003 Revision

If female:
- Not pregnant within the past year
- Pregnant at the time of death
- Not pregnant, but pregnant within 42 days of death
- Not pregnant, but pregnant 42 days to 1 year before death
- Unknown if pregnant within the past year

Reprinted from National Center for Health Statistics. United States Standard Certificate of Death—Rev. 11/2003. www.cdc.gov/nchs/data/dvs/DEATH11-03final-acc.pdf. Accessed April 2018.

surveillance system and collect death certificates and matching live birth or fetal death certificates for all pregnancy-associated deaths (defined in Table 39.2). These certificates are forwarded to the CDC, where clinically experienced epidemiologists manually review the certificates to identify all pregnancy-related deaths (defined in Table 39.2). Similar surveillance enhancement procedures have been estimated to improve case ascertainment by between 22% and 93%.[76] The pregnancy-related mortality ratio (PRMR) includes deaths that took place up to 1 year after the end of pregnancy and, according to the PMSS, increased from 10.3 in 1991 to 17.0 in 2013.[77,78] Documentation of pregnancy on the death certificate increases ascertainment further. In 2005, among the 19 states with death certificates that include the standard pregnancy questions, the combination of data from the NCHS and the PMSS suggests an MMR of 19.7 and a PRMR of 22.3.[73]

In response to an apparent doubling of the U.S. MMR over two decades, a growing number of states have established maternal mortality review committees to analyze case records in detail, and to publish recommendations to improve safety for future women. Ascertainment and review procedures vary by state,[79] so the CDC has created a national database to facilitate standardized review.[80] To move recommendations into practice, the U.S. Council on Patient Safety in Women's Health Care has partnered with state and regional health care collaboratives to identify and implement evidence-based practices and systems solutions that will improve outcomes for the leading causes of maternal death.[81–83] Ongoing surveillance will determine whether these efforts are effective.

Leading Causes

According to a 2010 systematic review of data from high-income countries, **hypertensive disorders of pregnancy, embolic disorders,** and **hemorrhage** together account for 43% of maternal deaths in the developed world (see Fig. 39.1).[3] **Indirect deaths** account for another 25%.[3]

Indirect deaths have exceeded direct deaths in the United Kingdom since 1997, with cardiac disease being the most common category of death. Similar patterns are seen in the United States, where the combination of cardiovascular conditions and cardiomyopathy comprised 26.4% of all pregnancy-related deaths between 2011 and 2013, and cerebrovascular accidents and noncardiovascular medical conditions represented another 21%.[78] Cardiomyopathy, including both peripartum and other types of cardiomyopathy, is the leading diagnosis underlying maternal cardiac death in the United States. In the United Kingdom, sudden arrhythmia, ischemic cardiac disease, and cardiomyopathy are the leading causes of maternal cardiac death.[67]

Detailed descriptions of hypertensive disorders of pregnancy, obstetric sepsis, maternal hemorrhage, embolic disorders, and cardiovascular diseases in pregnancy are provided in Chapters 35, 36, 37, 38, and 41, respectively. **Injury-related deaths** are considered pregnancy-associated but not pregnancy-related; they are discussed in Chapter 54. Common clinical and sociodemographic factors that increase the risk for maternal death from all of these complications are discussed in the following sections.

Risk Factors

Advanced maternal age increases maternal risk,[84] with a linear trend evident for each 5-year increase in maternal age beyond 34 years.[85] In the United States between 2011 and 2013, the PRMR among women 40 years of age and older was 191.6 for black women (compared with 27.5 for black women 20 to 24 years of age) and 53.9 for white women (compared with 9.9 for white women 20 to 24 years of age).[78] Based on data from the PMSS for 1991 to 1999, the association between age and mortality persisted after data were controlled for parity, prenatal care, race, and education.[85] Among older black women (greater than or equal to 40 years), the excess risks were greatest for hypertensive disorders of pregnancy, infection, cerebrovascular accident, and other medical conditions. Among older white women, the greatest excess risks for death were caused by hemorrhage, cardiomyopathy, embolic disorders, and other medical conditions.[85]

In the United States, **black or African-American race** significantly correlates with the risk for death. Non-Hispanic black women experience a PRMR that is 3.5-fold higher than non-Hispanic white women.[78] In a case series of anesthesia-related maternal deaths in Michigan published in 2007, six of eight deaths occurred among non-Hispanic black women in Detroit, suggesting a profound concentration of maternal risk.[86] The disparity in maternal mortality between black women and white women persists after data are controlled for maternal age, income, and receipt of prenatal care[87] and appears to be related to a higher case-fatality rate.[88]

Other racial and ethnic groups also experience increased risk. In the United States between 2005 and 2014, in comparison with non-Hispanic white women, the MMR was 80% higher for American Indian or Alaskan Native women.[89] In England, black African, black Caribbean, Indian, Pakistani, and Chinese women have higher relative risks for death than white women.[66,90]

Immigrants, asylum seekers, and non-native speakers appear to be particularly vulnerable to both maternal death and substandard care, based on data from the United Kingdom and the Netherlands.[66,69,90,91] In the United States, Hispanic and Asian/Pacific Islander immigrants face increased risk compared with women of these same racial/ethnic groups born in the United States.[92] Significant regional variation

has been identified in France, with increased risk noted for women delivering in Paris (adjusted odds ratio [AOR], 1.6; 95% CI, 1.2 to 2.0) and the overseas districts (AOR, 3.5; 95% CI, 2.4 to 5.0) compared with continental France.[93] Differences in behavior, biology, environmental conditions, social circumstances, and the quality of clinical care may contribute to disparities in outcomes for sociodemographically vulnerable populations.[66,93,94]

Maternal obesity increases the risk for maternal death from a variety of causes, including pulmonary embolism, infection, preeclampsia, and anesthesia-related complications. Remarkably, there are limited epidemiologic data to establish this connection. Obesity is a common feature in case series of maternal deaths. In the 2012 to 2014 CEMD report from the United Kingdom, 51% of women who died were overweight or obese.[67] Among the subset of women experiencing severe obstetric complications (including eclampsia, pulmonary embolism, amniotic fluid embolism, acute fatty liver of pregnancy, and antenatal stroke), obesity (body mass index greater than or equal to 30 kg/m^2) was associated with maternal death [AOR, 5.26; 95% CI, 1.15 to 6.46].[90]

Multifetal pregnancies increase maternal risk for a variety of complications, including preeclampsia, venous thromboembolism, heart failure, myocardial infarction, peripartum hemorrhage, and maternal death.[66,95–98] Compared with twin pregnancies, triplet and higher-order multiple pregnancies further increase maternal risk for preeclampsia, hemorrhage, and emergency peripartum hysterectomy.[96,97] In the United States between 1979 and 2000, the relative risk for death associated with a multifetal pregnancy was 3.6 (95% CI, 3.1 to 4.1) with threefold to fourfold increases in the cause-specific relative risk for death for embolism, hemorrhage, hypertensive disorders of pregnancy, infection, cardiomyopathy, and other medical conditions.[98]

Cesarean delivery has also been associated with an increased risk for maternal death; however, the association does not always reflect a causal relationship. Death can be a consequence of the indication for the operation rather than the mode of delivery itself. In an attempt to estimate the relative risk for death caused by cesarean delivery, a population-based case-control study from France focused on 65 maternal deaths after singleton births among low-risk women in whom complications developed only after delivery.[99] Cases were identified by the French National Confidential Enquiry on Maternal Deaths from 1996 through 2000.[99] These cases were compared with 10,244 singleton births to low-risk women identified through the French National Perinatal Survey conducted in 1998. After data were controlled for maternal age, nationality, parity, and preterm delivery, the AOR for increased risk for death with cesarean delivery was 3.64 (95% CI, 2.15 to 6.19). The increased risk was most dramatic for intrapartum cesarean deliveries (AOR, 4.58; 95% CI, 2.30 to 9.09) but persisted when cesarean delivery preceded labor (AOR, 2.42; 95% CI, 1.14 to 5.13).[99] Among women who underwent cesarean delivery, there was an increased risk for cause-specific maternal mortality from venous thromboembolism, puerperal infection, and complications of anesthesia. There was no difference in risk for death from postpartum hemorrhage or amniotic fluid embolism.

A cohort study of deliveries in Canada between 1991 and 2005 compared 46,766 planned cesarean deliveries for breech presentation with 2,292,420 planned vaginal deliveries in which labor was either spontaneous or induced.[100] Planned cesarean delivery increased the risk for postpartum cardiac arrest (AOR, 5.1; 95% CI, 4.1 to 6.3), major puerperal infection (AOR, 3.0; 95% CI, 2.7 to 3.4), anesthetic complications (AOR, 2.3; 95% CI, 2.0 to 2.6), and puerperal venous thromboembolism (AOR, 2.2; 95% CI, 1.5 to 3.4), but did not increase the risk for in-hospital maternal death.[100]

A medical record review of all in-hospital maternal deaths that occurred in a sample of U.S. hospitals between 2000 and 2006 sought to identify evidence for a causal connection between mode of delivery and the mechanism of maternal death.[101] Among 1,461,270 live births, there were 95 maternal deaths (6.5 per 100,000). Although 61% of the deaths were associated with cesarean delivery, one-third of these were perimortem cesarean deliveries in which the surgical procedure followed maternal cardiac arrest. Four deaths were thought to have been directly caused by cesarean delivery (attributed to hemorrhage or infection), with an additional seven deaths attributed to pulmonary thromboembolism after cesarean delivery. Two deaths were thought to have been causally related to vaginal delivery (one case of uterine inversion and one case of rupture of an unrecognized cerebral berry aneurysm during labor), and two deaths were attributed to pulmonary thromboembolism after vaginal delivery. Another 16 deaths were thought to have been potentially preventable had a cesarean delivery or an earlier cesarean delivery been performed (12 caused by preeclampsia, 3 caused by hemorrhage, and 1 caused by sepsis).[101] The investigators concluded that a policy of universal thromboprophylaxis for all patients undergoing cesarean delivery would eliminate the increased risk for maternal death caused by cesarean delivery as opposed to vaginal delivery.[101]

Regardless of mode of delivery, risk appears to be particularly concentrated in women with preexisting medical conditions; pulmonary hypertension, malignancy, systemic lupus erythematosus, sickle cell disease, and major cardiovascular and renal disease all confer substantially increased risk for maternal death or end-organ injury.[84,102,103] Given the preponderance of indirect deaths documented in recent CEMD reports, central assessors have repeatedly recommended both preconception counseling and intensive multidisciplinary antepartum and intrapartum care for women with serious medical or mental health conditions that may be aggravated by pregnancy.[66,67] These conditions include congenital or acquired cardiac disease, obesity with a body mass index greater than or equal to 30 kg/m^2, epilepsy, diabetes, asthma, autoimmune disorders, renal or liver disease, HIV infection, and a personal or family history of severe mental illness.[66,67] The Joint Commission has advanced a similar proposal in the United States.[104]

Some **health system characteristics** have been associated with a higher risk for maternal death; they include (1) low

maternal-fetal medicine specialist density[105] and (2) a single physician functioning as both the obstetrician and the anesthesia provider.[106]

Severe and Near-Miss Morbidity

Death is considered the extreme outcome of the following continuum of adverse pregnancy events: normal pregnancy → morbidity → severe morbidity → near-miss → death.[107] Approximately one-half of women experience some **morbidity** during pregnancy, most commonly anemia, urinary tract infection, mental health conditions, hypertensive disorders, and pelvic or perineal trauma.[108] Research has focused on severe morbidity, near-miss events, and maternal deaths to elucidate the patient, provider, and health system factors that lead to these adverse outcomes.

Severe maternal morbidity includes unexpected complications of childbirth that result in significant short- or long-term consequences to a woman's health[109]; its estimated incidence depends on the health system evaluated, the method of ascertainment, and the definition of severe morbidity used.[110–113] Waterstone et al.[110] evaluated pregnancies in France between 1997 and 1998 for the presence of severe preeclampsia, severe hemorrhage, or sepsis; the combined incidence for these three conditions was 12.0 per 1000 deliveries (95% CI, 11.2 to 13.2). Zhang et al.[111] applied the same criteria across Western Europe and identified a combined European incidence for these three conditions of 9.5 per 1000 deliveries (95% CI, 9.1 to 9.9). Analyses of administrative codes (ICD-9 or ICD-10) for conditions that indicate severe obstetric morbidity in population-level data suggest rates of 8.1 per 1000 hospitalizations in the United States from 2004 to 2005, 13.8 per 1000 in Canada from 2003 to 2007, and 13.8 per 1000 deliveries in Australia in 2004.[114–117]

Near-miss morbidity occurs when a woman survives a life-threatening complication that occurred during pregnancy, childbirth, or within 42 days of termination of pregnancy.[118] The concept of a near-miss event evolved from early studies of pregnant patients who required intensive care.[119–121] Mantel et al.[122] proposed a definition that requires evidence of severe organ dysfunction, intensive care unit admission, emergency hysterectomy, or an anesthetic accident such as failed intubation. Based on these criteria, a meta-analysis of 11 studies suggests a ratio of 4.2 near-misses per 1000 deliveries (95% CI, 4.0 to 4.4).[123] Geller et al.[124] validated a five-factor scoring system consisting of organ system failure (5 points), intensive care unit admission (4 points), transfusion of more than 3 units of blood products (3 points), extended intubation (2 points), and surgical intervention (1 point); a total score higher than 7 points defines a near-miss event. According to this scoring system, the incidence of a near-miss event was approximately 0.2 per 1000 deliveries in a perinatal tertiary care center in Chicago between 1995 and 2001.[124]

Maternal near-miss morbidity has also been defined using administrative data by combining ICD-9 codes for diagnoses indicating end-organ injury with either a prolonged length of stay (greater than 99th percentile) or transfer to a second health care facility.[102] Based on this administrative data definition, the incidence of near-miss maternal morbidity or maternal death in the United States between 2003 and 2006 was 1.3 per 1000 hospitalizations for delivery.[102]

The WHO Working Group on Maternal Mortality and Morbidity Classification determined that end-organ injury represents the most epidemiologically sound way to identify near-miss morbidity.[125] In 2009 the WHO proposed a panel of clinical, laboratory-based, or management-based criteria to identify maternal end-organ injury (see Box 39.e1 available at ExpertConsult.com).[118,126] Cecatti et al.[127] applied the WHO near-miss criteria to all intensive care unit admissions in a tertiary care facility in Brazil between 2002 and 2007 and found a near-miss morbidity ratio of 14.7 events per 1000 live births, an MMR of 125 deaths per 100,000 live births, and a maternal near-miss–to–mortality ratio of 10.7 : 1.

Preventability has emerged as an important concept in maternal mortality and near-miss morbidity reviews because the opportunities for prevention identified from these reviews can be used to prioritize changes in clinical policy and health system improvements.[104,128,129] The Perinatal and Maternal Mortality Review Committee in New Zealand proposed a comprehensive list of contributory factors, including those attributed to the health care organization, personnel, technology and equipment, the environment and geography, and patient-level barriers to accessing or engaging with care.[70] Although contributory factors may be identified in the majority of maternal deaths, multiple reviews suggest that only 20% to 45% were likely preventable.[70,124,130–132] In a case-control study of maternal death, near-miss events, and severe morbidity, Geller et al.[132] identified a higher proportion of preventability among deaths and near-miss events compared with cases of severe morbidity (41% and 45% versus 17%) and suggested that provider-level improvements in medical care among women who develop severe morbidities represent the most frequent opportunities to prevent both near-miss events and maternal deaths. Across various reviews, the highest rates of preventability are noted among ethnic minorities[66,69] and among deaths attributed to hemorrhage, hypertensive disorders of pregnancy, and sepsis or infection.[66,133]

Anesthesia-Related Maternal Mortality

Anesthesia-related maternal mortality has been defined as "death attributable to anesthesia, either as the result of medications used, method chosen, or the technical maneuvers performed, whether iatrogenic in origin or resulting from an abnormal patient response."[134] A death may be considered anesthesia-related if it can be uniquely attributed to an anesthetic complication.[86] Actual case reports often include layers of comorbidities, anesthetic complications, and problems with nonanesthetic care; these cases may be considered anesthesia-related if optimal anesthetic care would likely have averted the death.[86] If optimal anesthetic care in combination with improvements in obstetric or medical management would likely have saved the woman's life, then the death may be considered anesthesia-contributing.[86] In some cases, the

BOX 39.e1 The WHO Maternal Near-Miss Criteria

Clinical Criteria

- Acute cyanosis
- Gasping[a]
- Respiratory rate > 40 or < 6/min
- Shock[b]
- Oliguria nonresponsive to fluids or diuretics[c]
- Clotting failure[d]
- Loss of consciousness lasting ≥ 12 hours[e]
- Loss of consciousness and absence of pulse/heartbeat
- Stroke[f]
- Uncontrollable fit/total paralysis[g]
- Jaundice in the presence of preeclampsia[h]

Laboratory-Based Criteria

- Oxygen saturation < 90% for ≥ 60 minutes
- Pa_{O_2}/Fi_{O_2} < 200 mm Hg
- Creatinine ≥ 300 μmol/L or ≥ 3.5 mg/dL
- Bilirubin > 100 μmol/L or > 6.0 mg/dL
- pH < 7.1
- Lactate > 5
- Acute thrombocytopenia (< 50,000 platelets)
- Loss of consciousness and the presence of glucose and ketoacids in urine

Management-Based Criteria

- Hysterectomy after infection or hemorrhage
- Use of continuous vasoactive drugs[i]
- Transfusion of ≥ 5 units of red blood cells
- Intubation and ventilation for ≥ 60 minutes not related to anesthesia
- Dialysis for acute renal failure
- Cardiopulmonary resuscitation

[a]Gasping is a terminal respiratory pattern and the breath is convulsively and audibly caught.
[b]Shock is a persistent severe hypotension, defined as a systolic blood pressure < 90 mm Hg for ≥ 60 minutes with a pulse rate at least 120 despite aggressive fluid replacement (> 2 L).
[c]Oliguria is defined as a urinary output < 30 mL/h for 4 h or < 400 mL/24 h.
[d]Clotting failure can be assessed by the bedside clotting test or absence of clotting from the IV site after 7 to 10 minutes.
[e]Loss of consciousness is a profound alteration of mental state that involves complete or near-complete lack of responsiveness to external stimuli. It is defined as a Coma Glasgow Scale < 10 (moderate or severe coma).
[f]Stroke is a neurologic deficit of cerebrovascular cause that persists beyond 24 hours or is interrupted by death within 24 hours.
[g]Condition in which the brain is in a state of continuous seizure.
[h]*Preeclampsia* is defined as the presence of hypertension associated with proteinuria. *Hypertension* is defined as a blood pressure of at least 140 mm Hg (systolic) or at least 90 mm Hg (diastolic) on at least two occasions and at least 4 to 6 h apart after the 20th week of gestation in women known to be normotensive before pregnancy. *Proteinuria* is defined as excretion of 300 mg or more of protein every 24 hours. If 24-h urine samples are not available, proteinuria is defined as a protein concentration of 300 mg/L or more (≥ 1+ on dipstick) in at least two random urine samples taken at least 4 to 6 hours apart.
[i]For instance, continuous use of any dose of dopamine, epinephrine, or norepinephrine.

TABLE 39.4 Anesthesia-Related Maternal Mortality Ratios in the United States and the United Kingdom[a]

Triennium	United States (95% CI)	United Kingdom (95% CI)
1979–1981	4.3 (3.1–5.7)	8.7 (5.5–13.2)[b]
1982–1984	3.3 (2.3–4.5)	7.2 (4.3–11.4)[b]
1985–1987	2.3 (1.5–3.4)	2.6 (1.2–5.8)
1988–1990	1.7 (1.1–2.7)	1.7 (0.7–4.4)
1991–1993	1.4 (0.8–2.2)	3.5 (1.8–6.8)
1994–1996	1.1 (0.6–1.9)	0.5 (0.1–2.6)
1997–1999	1.2 (0.7–2.0)	1.4 (0.5–4.2)
2000–2002	1.0 (0.5–1.7)	3.0 (1.4–6.6)
2003–2005	Not available	2.8 (1.3–6.2)
2006–2008	Not available	3.1 (1.5–6.4)
2009–2011	Not available	1.2 (0.3–3.7)
2012–2014	Not available	0.9 (0.1–3.1)

CI, confidence interval.
[a]Reported rates refer to the risk for anesthesia-related death during pregnancy per million live births in the United States[138] or per million maternities in the United Kingdom.[66,67]
[b]Rates for England and Wales only.

TABLE 39.5 Case-Fatality Rates per Million Anesthetics for Cesarean Delivery in the United States (95% CI)

Year of Death	General	Neuraxial	Risk Ratios
1979–1984	20.0 (17.7–22.7)	8.6 (7.8–9.4)	2.3 (1.9–2.9)
1985–1990	32.3 (25.9–49.3)	1.9 (1.8–2.0)	16.7 (12.9–21.8)
1991–1996	16.8 (8.9–28.7)	2.5 (1.2–4.5)	6.7 (3.0–14.9)
1997–2002	6.5 (2.1–15.3)	3.8 (2.3–6.1)	1.7 (0.6–4.6)

Data from Hawkins JL, Chang J, Palmer SK, et al. Anesthesia-related maternal mortality in the United States: 1979-2002. *Obstet Gynecol.* 2011;117:69–74.

anesthetic complication is tragic but incidental (e.g., failed intubation during advanced cardiac life support for massive pulmonary embolism).

Anesthesia-related maternal death is extremely rare in the developed world. Table 39.4 shows recent MMRs attributed to anesthesia in the United States and the United Kingdom. Comparable ratios reported elsewhere in recent years include 1.4 per million live births in France for 2001 to 2006 and 1.0 per million in the Netherlands for 1993 to 2005.[69,130] Active surveillance in the United Kingdom may be particularly effective at comprehensive identification of anesthesia-related maternal deaths.

A number of clinical and sociodemographic factors commonly appear among cases of anesthesia-related maternal death and may play a causal role in the mechanism of death. These include (1) maternal obesity; (2) patient refusal of neuraxial anesthesia; (3) remote anesthetic location; (4) delay in anesthesia provider consultation; (5) insufficient multidisciplinary planning, communication, and coordination; and (6) inadequate supervision of care.[66,86,134–137] In the United States, the relative risk for anesthesia-related maternal death appears to be increased for African-American women.[86,134,138]

Anesthesia-related maternal deaths are distributed throughout the perioperative period and follow both neuraxial and general anesthesia, primarily administered for cesarean delivery, but occasionally for vaginal delivery or another obstetric or nonobstetric surgical procedure.[86,135,137,138] Case-fatality rates according to mode of anesthesia for cesarean delivery are presented in Table 39.5. To generate these estimates, the authors identified cases from death certificate data collected by the PMSS and estimated the total number of anesthetics delivered based on the national incidence of cesarean delivery and the proportions of cesarean deliveries completed with neuraxial and general anesthesia according to national surveys of anesthesia providers.[138,139]

Anesthesia-related maternal deaths are almost always preventable,[b] as evidenced by both individual case analysis and review of historical trends. The relative risks of general and neuraxial anesthesia for cesarean delivery in the United States have shifted over time (see Table 39.5), reflecting three major safety initiatives in anesthesia practice.[141] The first initiative addressed the hazard of **local anesthetic systemic toxicity (LAST),** identified as a major problem in a series of editorials published in the early 1980s.[142,143] In response, in 1984, the U.S. Food and Drug Administration recommended that bupivacaine 0.75% not be used for epidural anesthesia in obstetric patients. Also, anesthesiologists developed a series of safety procedures to avoid the unintentional intravascular administration of a toxic dose of local anesthetic through an epidural catheter. Case-fatality rates for neuraxial anesthesia subsequently declined 78% between 1979 to 1984 and 1985 to 1990 (see Table 39.5). Despite this improvement in prevention, LAST remains a rare and potentially lethal complication in obstetric anesthesia, with recent events attributed to drug error by nonanesthesia providers, cumulative dosing above the toxic threshold, epidural catheter migration, and single-shot transversus abdominis plane (TAP) blocks.[135,144–146] Lipid emulsion is now recommended as part of a comprehensive resuscitation strategy.[147,148]

The second initiative involved a shift toward **greater use of neuraxial anesthesia for cesarean delivery.**[139] Between 1985 and 1990, the relative risk associated with general anesthesia compared with neuraxial anesthesia for cesarean delivery was 16.7 (see Table 39.5), and much of the increase in risk was attributed to failed intubation or aspiration of gastric contents during induction of general anesthesia, or both. In response, anesthesia providers now reserve general anesthesia for specific indications, including (1) emergency cesarean delivery with insufficient time to establish neuraxial anesthesia; (2) medical conditions that make neuraxial anesthesia unsafe, such as maternal coagulopathy, hemorrhagic shock, and septic shock; and (3) failed neuraxial anesthesia with intraoperative pain.[149]

[b]66,86,128,135,137,140

The third initiative introduced a series of **protocols and devices to improve the safety of general anesthesia.**[141,150] Pulse oximetry and capnography have been widely credited with the decline in the incidence of unrecognized esophageal intubation.[151] Failed intubation algorithms, extraglottic airway devices (particularly the laryngeal mask airway), and a heightened focus on simulation and practice have impelled a transformation in airway management toward a clear focus on effective oxygenation and ventilation as well as ongoing preparation for airway emergencies.[128,150,152] Consequently, the case-fatality rate for general anesthesia decreased by 80% between 1985 to 1990 and 1997 to 2002 (see Table 39.5).[138] Nevertheless, recent series continue to report deaths from difficult intubation, unrecognized esophageal intubation, pulmonary aspiration of gastric contents (both with anesthetic induction and emergence), postextubation airway obstruction, and postoperative respiratory arrest attributed to opioids or other respiratory depressants.[66,86,135,153] Strategies to limit the risk for airway complications are discussed in Chapters 28 and 29.

The relative risk associated with general anesthesia in comparison with neuraxial anesthesia has fallen since 1990 and was estimated to be 1.7 (95% CI, 0.6 to 4.6) between 1997 and 2002.[138] In contemporary anesthesia practice, both general anesthesia and neuraxial anesthesia carry remote, but tangible risks for maternal death.

Why do women die of neuraxial anesthesia? **High neuraxial block** was the leading cause of anesthesia-related maternal death among women receiving neuraxial anesthesia for cesarean delivery in the United States between 1997 and 2002.[138] It was also the leading cause of legal claims for maternal death or permanent brain injury filed between 1990 and 2003 ($n = 15/25$; 60%), with the majority of these attributed to unrecognized intrathecal catheters intended for the epidural space.[153] Single-shot spinal anesthesia administered after failed epidural anesthesia for cesarean delivery represents a second clinical scenario associated with high neuraxial block.[154] More details on high neuraxial block and its management may be found in Chapters 23 and 26.

Potentially lethal **infectious complications of neuraxial block** include meningitis, encephalitis, and neuraxial abscess.[155–157] The CEMD 2006 to 2008 report included a case of acute hemorrhagic disseminated leukoencephalitis attributed to thoracolumbar spinal canal empyema.[66] Current guidelines stress the importance of strict aseptic technique during neuraxial block administration, as well as appropriate monitoring and management for any infectious complications that may develop.[158,159] Further details are available in Chapter 31.

Other series suggest that neuraxial cardiac arrest and hypotensive arrest may be important mechanisms by which neuraxial anesthesia can lead to maternal death.[45,160] Prevention likely depends on careful attention to intravascular volume status, as well as the prompt, aggressive treatment of maternal hypotension to prevent reflex-mediated bradycardia and cardiovascular collapse.[161] Finally, perioperative respiratory arrest can result from neuraxial opioids or intravenous opioids or other respiratory depressants administered during or after neuraxial anesthesia.[86,135]

Further efforts to improve maternal safety must include a comprehensive approach to **high-quality perioperative patient care.** Timely preanesthesia evaluation and ongoing communication with obstetric providers are essential to limit the number of patients who require emergency administration of anesthesia without sufficient evaluation and preparation. Problems with **postoperative care** have long been recognized[162] but appear to account for a growing proportion of perioperative maternal deaths,[135–137,163] particularly those attributed to respiratory events, hemorrhage, and maternal sepsis.[69,70,94,154,156] The physiology of pregnancy and the compensatory physiologic responses that occur in young pregnant women may obscure early signs of septic or hemorrhagic shock. **Early warning scoring systems** may facilitate the early identification of women who have, or are beginning to develop, a critical illness.[66,104,135,137,164] Postanesthesia and postpartum care are commonly provided by labor and delivery nurses (as opposed to perianesthesia care nurses[165]) with limited training and experience with major anesthetic complications, noninvasive ventilation, and advanced cardiopulmonary life support.

Fortunately, severe morbidity and mortality are rare in obstetrics; as an unfortunate consequence of this rarity, individual clinical experience with serious adverse events will always be limited. Simulation may be an effective strategy for all obstetric and anesthesia providers to prepare for a wide variety of obstetric emergencies, including postoperative airway obstruction, failed intubation, eclampsia, anaphylaxis, maternal cardiac arrest, and maternal hemorrhage. Chapter 11 details additional strategies to enhance patient safety.

KEY POINTS

- Ninety-nine percent of maternal deaths worldwide occur in developing countries. More than one-half of global maternal deaths are attributed to direct obstetric causes, including maternal hemorrhage, hypertensive disorders of pregnancy, and infection.
- In the developed world, 12 women die per 100,000 live births. In the United States, the maternal mortality ratio is increasing; in 2015, 21 women died per 100,000 live births.
- Advanced maternal age, maternal obesity, multiple gestation, cesarean delivery, and nonwhite race increase the risk for maternal death.
- Hypertensive disorders of pregnancy, embolic disorders, and hemorrhage together account for just under one-half

of maternal deaths in the developed world but appear to be eclipsed by indirect deaths in some countries.
- Death is considered the extreme outcome of the following continuum of adverse pregnancy events: normal pregnancy → morbidity → severe morbidity → near-miss → death.
- In the developed world, the anesthesia-related maternal mortality ratio is estimated to range between 1 and 3 per million live births.
- Anesthesia safety for obstetric patients depends on the provision of high-quality perioperative patient care.

Autoimmune Disorders

Phil Popham, BSc, MBBS, FRCA, MD, PG Cert US

CHAPTER OUTLINE

In the late 19th century, Ehrlich proposed the dictum of *horror autotoxicus,* the belief that immunity is directed against foreign material and never against one's own body. The demonstration of autoantibodies in the 1950s disproved the theory and demonstrated the failure of self-tolerance.[1]

Autoimmunity has been described in more than 40 disorders, and may result in chronic illness and severe disability. The classification of autoimmune diseases has been controversial since it is recognized that both genetic and epigenetic (potentially heritable changes in gene expression that are not associated with changes in DNA sequencing) factors play a role. The traditional clinical classification recognizes immune responses that are directed against a particular antigen and are limited to a particular organ or cell type **(organ-specific disease),** and those that are directed against a range of antigens that produce multisystem involvement **(systemic disease).** Some examples are shown in Box 40.1. Classification now incorporates a "spectrum of autoimmunity" from low-level (possibly beneficial to self) to high-level (clearly detrimental to self) autoimmunity.[2]

The pathogenesis of autoimmunity is complex. A genetic predisposition underlies abnormal reactivity of B cells and immunoglobulins, T-cell receptors, and genes within the major histocompatibility complex (MHC).[3] Specific allotypes within the MHC are associated with certain diseases; for example, HLA-DR2 is strongly positively associated with **systemic lupus erythematosus (SLE)** but negatively associated with **diabetes mellitus type 1.** Genome-wide association studies have identified genetic associations between single-nucleotide polymorphisms (SNPs) and some autoimmune conditions.[4] Meta-analyses of HLA subclasses show similar associations with autoimmunity.[5] More recently, epigenetic factors, including dysregulation of DNA expression (but not of its sequencing), noncoding RNA, histone (a nucleosomal protein) modification, and immunoendocrine status, have been shown to influence immune status.[6,7]

Other factors (e.g., environmental conditions) may predispose to autoimmunity. Parasitic infection may reduce the incidence of autoimmunity, whereas bacterial infection with *Klebsiella* may predispose to ankylosing spondylitis. Drug-induced SLE is well described.

Sex hormones, notably the androgen-estrogen balance and its effect on cytokine production, have been implicated in the development of autoimmunity.[8] Autoimmune

BOX 40.1 Classification of Some Autoimmune Diseases

Organ-Specific Disease

Neurologic: Myasthenia gravis, autoimmune peripheral neuropathy, Hashimoto's encephalopathy, temporal arteritis
Hematologic: Autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, cold agglutinin disease
Skin: Vitiligo, pemphigus vulgaris, alopecia areata, autoimmune urticaria, psoriasis
Gastrointestinal: Crohn's disease, celiac disease, autoimmune hepatitis, primary biliary cirrhosis, ulcerative colitis
Endocrine: Hashimoto's thyroiditis, Addison's disease, diabetes mellitus type 1, Graves' disease
Skeleton: Ankylosing spondylitis, psoriatic arthropathy
Cardiovascular: Autoimmune cardiomyopathy
Renal: Goodpasture's syndrome

Systemic Disease

Systemic lupus erythematosus
Rheumatoid arthritis
Multiple sclerosis
Sjögren's syndrome
Dermatomyositis
Scleroderma
Polymyositis
Mixed connective tissue disease
Wegener's granulomatosis

BOX 40.2 Diagnostic Criteria for Systemic Lupus Erythematosus

- Malar rash (butterfly rash over malar region)
- Discoid rash (erythematous, raised patches with scaling)
- Photosensitivity
- Oral ulceration
- Arthritis
- Serositis (pleuritis or pericarditis)
- Renal disorder (persistent proteinuria or cellular casts)
- Neurologic disorder (seizures or psychosis)
- Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
- Immunologic disorder (anti-DNA, anti-Sm nuclear antigen, anticardiolipin antibodies, lupus anticoagulant, or false-positive syphilis test)
- Antinuclear antibody

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982;25:1271–1277; Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1997;40:1725.

disorders are more common in women than in men, with the highest incidence of several conditions occurring during the childbearing years,[9] and occasionally the initial diagnosis is made during pregnancy. During normal pregnancy, altered immune function allows maternal tolerance of the fetal allograft. It has been known for decades that both mother and fetus produce immunologic factors that inhibit maternal cell-mediated immunity,[10] prevent rejection of the fetus, and limit the expression of autoimmunity. The high estrogen environment of pregnancy may enhance immune function and protect the mother and fetus from peripartum infection, but at the expense of an increased likelihood of autoimmune conditions.[7,11]

Systemic lupus erythematosus, lupus anticoagulant, scleroderma, and **polymyositis/dermatomyositis** are discussed in this chapter. Other autoimmune disorders are discussed elsewhere in this text, including **diabetes mellitus type 1** (see Chapter 43) **autoimmune thrombocytopenic purpura** and **autoimmune hemolytic anemia** (see Chapter 44), **rheumatoid arthritis** and **ankylosing spondylitis** (see Chapter 47), and **myasthenia gravis** (see Chapter 48.)

SYSTEMIC LUPUS ERYTHEMATOSUS

Definition and Epidemiology

Systemic lupus erythematosus (SLE) is a multisystem inflammatory disease of unknown etiology that is characterized by the production of autoantibodies against nuclear, cytoplasmic, and cell membrane antigens. Although its overall prevalence is about 50 per 100,000 population,[12] it is recognized most commonly in women during their childbearing years, with a female-to-male ratio of 9:1. Certain groups have a higher prevalence, including African-Americans (2- to 3-fold risk), Asians, and Native Americans.[9] An estimated 1 in 1200 deliveries occur in women with SLE.[13]

Pathophysiology

The etiology of SLE remains unclear. The principal mechanism is thought to be an immune complex disease involving IgG antibodies to double-stranded DNA and other nuclear proteins. Intracellular autoantigens are released by necrotic and apoptotic cells, leading to aberrant sensitization against these antigens. Impaired clearance of apoptotic cells and prolonged exposure to nuclear autoantigens may be involved.[14] Affected individuals have both hyperactivity of the antibody-producing B cells and defects of the helper and suppressor T cells.[15] Genetic defects of immune regulation and possibly environmental triggers including viruses and bacteria lead to a proliferation of B cells capable of producing autoantibodies that may target more than 30 classes of antigens. A variety of antigen-antibody immune complexes are formed, followed by secondary inflammatory responses. Deposits may occur within the skin, choroid plexus, and other endothelial surfaces, with or without an inflammatory response. In certain locations (e.g., the renal glomerulus), deposition of immune complexes and continued inflammation may lead to irreversible injury. However, SLE is not simply an immune complex disorder because some autoantibodies actively bind to erythrocytes, granulocytes, lymphocytes, and macrophages, leading to their removal from the circulation.[16]

Diagnosis

Clinical manifestations of SLE are diverse, owing to the widespread antigenic targets. Box 40.2 outlines objective criteria

for the diagnosis of SLE.[17] Although epidemiologic studies require the presence of four or more of these criteria, the clinical diagnosis may be suspected if fewer features are present without another explanation. Typically, the diagnosis of SLE is made before conception, but in 20% of cases the initial diagnosis is made during pregnancy.[18]

Effect of Pregnancy

SLE disease activity may increase during pregnancy,[19,20] and some pregnancy-related complications may have long-term effects on women with SLE.[18,21,22] The PROMISSE study, an observational prospective outcome study of 385 women with SLE with or without antiphospholipid antibodies (aPL), used formal measurements of disease activity to delineate risk.[23] Renal disease, SLE disease activity, and the presence of aPL are considered significant risk factors for maternal deterioration during pregnancy. Assessments using the SLE Disease Activity Index found that 50% to 65% of women with active disease had deterioration during pregnancy in both retrospective[24] and prospective[23] studies. Such flares occur most commonly in the second and third trimesters and the puerperium, are not more severe than those in nonpregnant patients, and mostly respond to conservative management. The risk for significant disease activity during pregnancy is increased sevenfold if active disease is present in the 6 months before conception,[25] and a preconception history of nephritis predicts adverse maternal outcome.[26]

Women with SLE have a 2- to 4-fold increase in the overall rate of pregnancy complications, with increased rates of hypertension, renal disease, preeclampsia, preterm delivery, cesarean delivery, and maternal and neonatal death.[18] Nevertheless, maternal and fetal outcomes have improved with advances in disease management.[9]

Effect on the Mother

Most women with SLE do not have renal impairment at conception, possibly because renal insufficiency impairs fertility. If lupus nephritis pre-exists, deterioration in renal function may occur during pregnancy. Although mild and reversible in about 8% of pregnant patients with SLE, 3% of women may suffer irreversible progression of renal dysfunction.[27] Long-term glomerular filtration rate may be preserved.[28]

Renal involvement is also associated with maternal hypertension. The presence of hypertension, edema, and proteinuria in both lupus nephritis and preeclampsia makes distinguishing between the two difficult. It is not clear whether preeclampsia is more common in patients with SLE, but a large meta-analysis suggested an association between lupus nephritis and preeclampsia.[29] The distinction is critical because treatments are different (immunosuppressive therapy for lupus nephritis *versus* delivery for preeclampsia). Increased serum uric acid concentration, proteinuria without active urinary sediment, and liver enzyme abnormalities suggest preeclampsia rather than SLE. The two conditions may also co-exist.

SLE may cause thrombocytopenia. When thrombocytopenia occurs in a pregnant woman, preeclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, and disseminated intravascular coagulation must also be considered. Anemia, a common manifestation of SLE, must be differentiated from nutritional anemia and the physiologic anemia of late pregnancy.

Ligamentous relaxation often occurs during late pregnancy and may worsen the pain of lupus arthritis. Patients with SLE occasionally require joint replacement, most commonly of the femoral head. These prostheses may become painful, dislocated, or infected during pregnancy.[30] Neurologic complications of SLE are rare during pregnancy but include seizures, chorea gravidarum, and stroke.

Effect on the Fetus

Maternal SLE impairs fetal survival and increases the risk for preterm delivery. The primary predictor for adverse pregnancy outcomes is the presence of lupus anticoagulant (LAC).[23] A systematic review of papers published between 1980 and 2009 showed that preterm delivery occurred in 39.4% of 2751 pregnancies in 1842 patients.[29] In the Hopkins Lupus Pregnancy Cohort, preterm birth occurred in 38 of 57 (67%) pregnancies in women with moderate to severe active SLE, compared with 68 of 210 (32%) pregnancies in women with inactive or mild active SLE.[31] Improved perinatal management and control of disease activity have reduced the rate of fetal loss from 43% (between 1960 and 1965) to 17% (between 2000 and 2003).[32] Data from California showed a preterm delivery rate in SLE that was six times higher than that found in the general population.[33]

Neonatal lupus erythematosus (NLE) is a syndrome that results from maternal autoantibodies against Ro (SS-A) or La (SS-B) crossing the placenta and binding to fetal tissue. These autoantibodies are found in up to 87% of patients with SLE,[34] but NLE occurs in only a small proportion of patients. The condition is generally benign and self-limiting, and reversible manifestations such as cutaneous lupus, elevation in aminotransferase levels, and thrombocytopenia resolve as maternal antibodies disappear from the neonatal circulation within 8 months of birth. Anti-Ro/anti-La antibodies may bind to fetal cardiac conduction cells *in utero,* leading to cell death and irreversible fetal heart block. Neonatal congenital heart block occurs in 2% of neonates when anti-Ro antibody is detected in the mother, and mortality occurs in about 18% of affected babies.[12,35] Fetal echocardiography reveals atrioventricular dissociation, cardiac dilation, and pericardial effusion. Treatment includes prompt delivery, newborn cardiac pacing, antepartum administration of dexamethasone, and consideration of apheresis to remove maternal antibodies.[36]

Medical Management

Optimally, women with SLE should delay pregnancy until their disease has been quiescent for at least 6 months, and they should be taking "acceptably safe" medications at the time of conception.[20,23,25,37,38] Medications with acceptable safety are used to minimize disease activity during gestation.

Disease-modifying antirheumatic drugs (DMARDs) and immunosuppressive agents form the mainstay of treatment.

Antimalarial drugs, most notably **hydroxychloroquinine (HCQ),** are frequently used to reduce SLE activity.[39] Discontinuation of HCQ just before conception or in early pregnancy leads to a significant increase in disease activity.[40] A systematic review of English literature (1982 to 2007) found that antimalarial drugs, particularly HCQ, prevent lupus flares; increase long-term survival; contribute to protection against irreversible organ damage, thrombosis, and bone loss; and have low toxicity.[41] HCQ should be continued in all women who were taking it before conception, and it may be used to treat flares during gestation. In contrast, **mycophenolate mofetil** should be discontinued before conception owing to the risk for teratogenicity.

Immunosuppressive agents such as **azathioprine, cyclosporine,** and **tacrolimus** are considered safe for use in pregnancy and may be considered if corticosteroid avoidance is desirable.[18] Azathioprine should be continued if used before conception.[20,25] The fetal liver does not express the enzyme necessary to convert azathioprine to its active form,[42] but maternal use of azathioprine has been associated with reversible neonatal lymphopenia, depressed serum immunoglobulin levels, and decreased thymic size in the newborn.[42] Transplant registries do not report increased risk for congenital abnormalities after its use.[43]

Corticosteroids may be used to treat flares of SLE disease activity. Antenatal exposure to low-dose **prednisone** (less than 20 mg daily) appears to be safe, and most children born to mothers who have used antenatal corticosteroids develop normally. However, fluorinated glucocorticoids such as **dexamethasone** or **betamethasone** readily cross the placenta and may cause fetal growth restriction and abnormal neuronal development,[44] although orofacial cleft abnormalities are not associated with their use.[45] Corticosteroid therapy may precipitate gestational diabetes, and patients should be monitored for evidence of glucose intolerance. Striae, gastrointestinal ulceration, and bone demineralization may complicate long-term corticosteroid therapy. Regular use of antacids may be required. The pediatrician should be alerted to the possibility of neonatal adrenal suppression.

Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and stronger analgesics may be used to manage lupus arthritis. Although there is no evidence of teratogenicity with these agents,[42] concern exists that NSAIDs may cause premature closure of the fetal ductus arteriosus, and high-dose aspirin and NSAIDs ideally should be discontinued by 30 weeks' gestation.[18]

Biologic agents such as rituximab and belimumab are being used more frequently, but assessment of their efficacy has been limited by the heterogenous nature of SLE and the connective tissue disorders. There is little consensus on their use at present.[46]

Obstetric Management

Patients with SLE are at increased risk for intrauterine fetal death and preterm delivery. Estimation of the gestational age is obtained with ultrasonography at the first prenatal visit and again at 20 weeks' gestation. Continued surveillance consists of nonstress testing, biophysical profile measurement, and/or umbilical artery Doppler velocimetry beginning at 26 to 28 weeks' gestation and performed weekly until delivery.[38]

The coexistence of **antiphospholipid antibodies** (either lupus anticoagulant or triple-positive antiphospholipid antibody; see later discussion) predicts a much higher maternal and fetal risk. Maternal serologic markers are checked regularly, together with platelet count, creatinine clearance, 24-hour urine protein level, uric acid, and complement levels.[18] In normal pregnancy, serial complement levels gradually increase. However, declining levels of C3 and C4 suggest active disease and lupus nephritis.[20] Thromboprophylaxis is important in patients with **antiphospholipid syndrome** (see later discussion). Aspirin resistance may predict adverse maternal and neonatal outcomes.[47] Regular assessment of blood pressure, weight gain, and proteinuria is performed to detect the development of preeclampsia. Prediction of cardiovascular risk in women with SLE may be possible using the Pulse-Mass Index.[48]

The timing and route of delivery are individualized. Although vaginal delivery is preferred, a cesarean delivery rate of 40% has been reported in parturients with SLE.[13]

Anesthetic Management

The obstetrician, rheumatologist, and anesthesia provider should formulate a joint plan for delivery. Maternal organ system involvement, current disease severity, and particularly the presence of flares must be assessed.[49]

Pericarditis is common in patients with SLE and is typically asymptomatic. A history of dyspnea on exertion or unexplained tachycardia may suggest pericarditis or **myocarditis. Cardiac tamponade** has been reported.[50] Prolongation of the PR interval or nonspecific T-wave changes may be seen on the electrocardiogram. Coronary artery vasculitis, accelerated atherosclerosis leading to **myocardial ischemia,** and even **myocardial infarction** in young women have been reported.[51,52]

An echocardiographic study in 69 patients with SLE showed a high incidence of **valvular abnormalities,** including valvular thickening in 51%, vegetation in 43%, regurgitation in 25%, and stenosis in 4%.[53] Current American Heart Association guidelines recommend antibiotic prophylaxis only for patients at highest risk for infective endocarditis in whom there is both significant risk and consequence of infection.[54,55] Prophylactic antibiotics are not recommended for women with common valvular lesions undergoing genitourinary procedures, including vaginal delivery, but are specifically indicated for those with previous infective endocarditis, unrepaired cyanotic congenital heart disease, implanted prosthetic material or devices, or a history of cardiac transplantation with cardiac valvulopathy.

The prevalence and progression of **pulmonary hypertension** in 28 patients with SLE has been studied.[56] The prevalence increased from 14% at initial evaluation to 43% 5 years later. Epidural anesthesia for cesarean delivery in parturients with pulmonary hypertension has been reported (see Chapter 41). The abrupt onset of sympathetic blockade and decreased

venous return may cause precipitous systemic hypotension and hypoxemia. One report described the administration of general anesthesia in a parturient with SLE and pulmonary hypertension, with coexisting SLE-related restrictive lung disease, pulmonary edema, and orthopnea.[57] In one report of three parturients with pulmonary hypertension secondary to SLE and antiphospholipid syndrome, two died of right-sided heart failure within 48 hours of delivery.[58]

Subclinical **pleuritis** is common, but significant **pleural effusions** are rare. Patients may suffer from **infectious pneumonia** or **lupus pneumonitis.** The latter condition is characterized by fleeting hemorrhagic infiltrates that may become consolidated. **Pulmonary embolism** and **diaphragmatic dysfunction** have been reported.[51]

Central and peripheral sensorimotor and autonomic neuropathies are observed in as many as 25% of patients with SLE,[59] and **vocal cord palsy** has been reported.[49,60] These deficits should be documented before the administration of either neuraxial or general anesthesia. **Migraine headache** and **cerebral vasculitis** resulting from SLE must be considered in the differential diagnosis of a postpartum headache. **Psychological disorders** and frank **psychosis** can occur during disease flares.[61] **Seizures** can occur, especially if chronic anticonvulsant medications are discontinued inadvertently.

Hematologic abnormalities, including **anemia, thrombocytopenia,** and **coagulopathy,** should be documented. An abnormality of the activated partial thromboplastin time (aPTT), which is not corrected with a 1:1 control plasma mix, suggests the presence of either lupus anticoagulant (a coexistent but separate disease entity) or, more rarely, true autoantibodies against specific coagulation factors (e.g., VIII, IX, XII). Lupus anticoagulant is a laboratory artifact that does not cause clinical coagulopathy. True coagulation factor autoantibodies (or inhibitors) may result in a significant bleeding diathesis, which contraindicates the administration of neuraxial anesthesia.

Long-term use of NSAIDs leads to qualitative platelet abnormalities, but their role in causing spinal epidural hematoma remains conjectural. In prospective studies of patients undergoing orthopedic procedures (924 patients receiving spinal or epidural anesthesia, and with preoperative antiplatelet medications taken by 39% of patients)[62] and epidural steroid injection for chronic pain management (1035 patients, with NSAID use reported by 32% of patients),[63] no cases of spinal epidural hematoma were observed. In the Collaborative Low-dose Aspirin Study in Pregnancy (CLASP), a large, multicenter randomized trial, 9364 pregnant women received either low-dose aspirin (60 mg daily) or placebo for prevention and treatment of preeclampsia.[64] Of 5000 enrollees, at least 1069 patients received epidural analgesia, and no cases of epidural hematoma were observed.[65] Measurement of the bleeding time before neuraxial injection in patients taking aspirin or NSAIDs is not indicated. Thromboelastography has been suggested as an alternative but is not widely available.[66] One case report described administration of general anesthesia for cesarean delivery in a patient with SLE and antiphopholipid syndrome who had suffered a thrombotic cerebrovascular event; thromboelastography was used as an adjunct to coagulation studies.[67] Atypical blood antibodies may complicate cross-matching of blood for patients with SLE, and additional time may be required.

Prosthetic orthopedic joints should be positioned carefully during vaginal or cesarean delivery. Lupus arthritis rarely involves the cervical spine. Women who have undergone long-term corticosteroid therapy should receive a peripartum stress dose of a corticosteroid.

ANTIPHOSPHOLIPID SYNDROME

Definition and Epidemiology

Antiphospholipid syndrome (APS, also known as Hughes' syndrome) was first recognized in the early 1980s[68,69] and classified by international consensus in 2005.[70] It is an autoimmune prothrombotic disorder characterized by the presence of aPL, namely lupus anticoagulant, anticardiolipin antibodies (aCL), and anti-beta$_2$-glycoprotein I (aβ_2GPI). Affected patients are at risk for arterial and venous thrombosis and pregnancy-related complications.[71]

Although initially described as a subset of patients with SLE, it is now accepted that APS is a distinct and separate disease entity from SLE.[72] About 40% of patients with SLE may have aPL (lupus anticoagulant in 34% and aCL in 44%),[73] but few of these will progress to develop thrombotic events. Long-term follow-up suggests that more than one-half of patients with SLE and aPL will progress to APS, but few patients with APS progress to SLE.[72]

The population prevalence of APS is unclear. Most information has been derived from the "Euro Phospholipid" cohort of 1000 patients.[74] Prevalence of aPL in the general population is 1% to 5%, but APS occurs in only a small proportion of people with aPL; the estimated population prevalence is 20 to 50 per 100,000 people.[75] In 1990, commenting on the volume of publications on APS, Harris remarked that the syndrome "probably occurs less frequently than the number of papers published on the subject."[76] However, with greater clinical recognition, Hughes predicted that the prevalence of APS will exceed that of SLE.[69]

Pathophysiology

APS is associated with two important misnomers. First, the antiphospholipid antibodies do not bind directly to phospholipids but to phospholipid-binding plasma proteins such as β_2GPI, prothrombin, and annexin V. Second, the lupus anticoagulant has no true anticoagulant activity *in vivo* but is a laboratory artifact that affects phospholipid-dependent coagulation assays: the aPTT, the kaolin clotting time (KCT), the tissue thromboplastin inhibition (TTI) test, and the dilute Russell viper venom time (dRVVT). These times remain prolonged even when the tests are repeated with a 1:1 mixture of the patient's plasma and control plasma. Typically the prothrombin time (PT) is normal. Lupus anticoagulant appears to block *in vitro* assembly of prothrombinase (a phospholipid complex), thus preventing the conversion of prothrombin to thrombin. True bleeding associated with lupus anticoagulant is extremely rare and, in most cases, is caused by an underlying factor deficiency or inhibitor.[77]

Contrary to expectation, lupus anticoagulant and aCL are associated with both arterial and venous **thrombotic events.** The current model by which this thrombotic tendency occurs involves aPL antibodies binding to β_2GPI, which then bind to glycoprotein Ibα on platelets, monocytes, and endothelial cells. These complexes cause platelet adhesion, expression of prothrombotic molecules, and local complement activation.[77] Complement activation may lead to inflammation, placental insufficiency, and fetal loss, while aPL interference with fibrinolysis may predispose to thrombotic events.[75]

Diagnosis

The diagnosis of APS depends on a clinical history of unexplained recurrent venous or arterial thrombosis, pregnancy loss, and laboratory evidence of aCL or lupus anticoagulant.[70] The latter is demonstrated by (1) evidence of abnormal phospholipid-dependent coagulation (elevated aPTT); (2) evidence that this abnormality is caused by an inhibitor rather than a factor deficiency (elevated aPTT with 1:1 mix); and (3) proof that the inhibitor is directed against phospholipid rather than specific coagulation factors. Antibodies should be demonstrable on two occasions separated by 12 weeks.[78] The presence of lupus anticoagulant, aCL, and aβ_2GPI antibodies (triple positivity) with a clinical diagnosis of APS predicts severe disease.[79] Results from different laboratories show considerable variability, and guidelines on diagnostic criteria have been published.[80] Tests for syphilis detect the antiphospholipid antibodies present in syphilis, and consequently the Venereal Disease Research Laboratory (VDRL) and Wasserman test results may be falsely positive. Some 20% of patients with APS may present with an initial diagnosis of idiopathic thrombocytopenic purpura.[75]

Effect on the Mother

Pregnant women with APS are at risk for **venous and arterial thrombosis, pulmonary embolism, myocardial infarction, cerebral infarction,** and **fetal loss**. Cohort studies suggest that contemporary management strategies may improve maternal outcome. The PROMISSE study showed that higher risk was indicated by African or Hispanic descent, presence of lupus anticoagulant, moderate clinical disease activity when pregnancy was diagnosed, thrombocytopenia, and flare activity.[23]

Silver et al.[81] reported that of 130 women with APS followed over a 3-year period, 48% experienced at least one of the following disorders: **transient ischemic attack, peripheral thrombosis** (of which one-fourth occurred in pregnancy and the puerperium), **stroke, amaurosis fugax, autoimmune thrombocytopenia**, and **SLE.** Clark et al.[82] reported that women diagnosed with APS on the basis of recurrent pregnancy loss and evidence of aPL, but without prior thrombotic events, rarely suffered thrombosis during pregnancy. A history of thromboembolic events significantly worsens prognosis and increases the likelihood of future events, an effect ameliorated by the use of oral anticoagulants.[83] Thrombocytopenia, present in one-fourth of patients with APS, is generally mild and responds to prednisone therapy. More recently, rituximab[71] and rivaroxaban[84] have been used, and occasionally splenectomy may be required.[85] The use of HCQ for women with pregnancies at particular risk has, in the absence of study findings, been the subject of expert consensus, with the conclusion that its use may be justified in certain cases or when treatment with aspirin and heparin has been ineffective.[86] **Catastrophic antiphospholipid syndrome** (CAPS or Asherson's syndrome), an accelerated form of the condition that results in multisystem organ thrombosis and failure, may be triggered by pregnancy in 1% of cases.[87]

Effect on the Fetus

Pregnant women with APS are at high risk for intrauterine fetal death. Early studies showed that only 7.5% of pregnancies resulted in the delivery of a live newborn,[88] whereas recent reports have shown live-birth rates up to 100%.[89] Pregnant women with so-called triple positivity (lupus anticoagulant, aCL, and aβ_2GPI antibody titers greater than four times the upper limit of normal) have a twofold increase in risk for fetal loss compared with women with positive titers only (35% live-birth rate versus 77%).[90] The PREGNANTS study, a retrospective cohort study, recorded that only 30% of women with triple positivity had a live born neonate.[91] Placental infarction is the apparent mechanism of mortality, and most fetal deaths occur during mid- and late pregnancy. There is no high-level evidence to guide management of pregnant women with high antibody titers.[92]

Most infants born to women with APS do not have an increased rate of neonatal or childhood complications,[93] although cases of antiphospholipid-related **fetal and neonatal thrombosis** (mainly cerebral thrombosis) have been reported.[94]

Medical and Obstetric Management

The mainstay of obstetric management is thromboprophylaxis.[75] Fetal survival and maternal thrombotic risk may be improved when affected pregnant women are treated with low-dose aspirin and heparin. A 2005 meta-analysis found that combined treatment with unfractionated heparin and aspirin can reduce pregnancy loss by 54%.[95] Recommendations on investigation and management of APS have been made.[96] Women with more than three unexplained pregnancy losses before 10 weeks' gestation should be tested for antiphospholipid antibodies; women with APS and recurrent pregnancy loss should receive prophylactic doses of **heparin** and **low-dose aspirin** throughout pregnancy, and administration for 6 to 8 weeks postpartum should be considered. A history of APS with thrombosis may require full anticoagulation throughout pregnancy and the postpartum period. A meta-analysis suggested that unfractionated heparin in combination with aspirin increases the live-birth rate in women with APS, but the benefit of **low-molecular-weight heparin (LMWH)** is unclear; neither type of heparin crosses the placental barrier.[97]

Catastrophic antiphospholipid syndrome occurs in 1% of patients with APS.[87] It is characterized by rapidly progressive thromboses with organ damage, thrombotic microangiopathy, and a systemic inflammatory response syndrome.

Diagnosis requires the presence of antiphospholipid antibodies with involvement of at least three organs and rapid onset and progression of disease. Urgent management strategies include elimination of precipitating causes, antibiotic cover for a precipitating bacterial infection, full anticoagulation, intravenous corticosteroids and immunoglobulin, and plasma exchange. **HCQ** and **rituximab** are increasingly used.[98] Mortality is as high as 50%.[70]

Anesthetic Management

There are no large scale studies describing anesthetic management of patients with APS, and management is similar to that of the patient with SLE. Coexisting autoimmune disorders, secondary organ involvement, and thrombotic phenomena should be evaluated. The term *lupus anticoagulant* is a misnomer (as discussed earlier) and does not warrant withholding neuraxial anesthesia. Infrequently, antiphospholipid antibodies can cause coagulation factor deficiencies, and in such patients neuraxial anesthesia is relatively contraindicated. In the absence of an underlying coagulation deficit or anticoagulant therapy, the prolonged aPTT does not suggest a bleeding tendency, and neuraxial anesthesia may be administered safely.

The anesthetic management of pregnancies complicated by APS has been reviewed.[99,100] All subjects received aspirin (75 to 150 mg daily) throughout pregnancy, and aspirin therapy alone was not considered a contraindication to neuraxial anesthesia. In parturients who received thromboprophylaxis with standard unfractionated heparin, spinal or epidural anesthesia was administered 4 hours after the last dose of heparin. The use of LMWH for thromboprophylaxis precludes administration of neuraxial anesthesia until at least 12 hours have elapsed since the time of the last dose.[101] Further, therapeutic anticoagulation with high-dose LMWH precludes the administration of neuraxial anesthesia until at least 24 hours have elapsed since the time of the last dose (see Chapters 38 and 44). The use of **thromboelastography** to document clearance of heparin before administration of neuraxial anesthesia in parturients with lupus anticoagulant has been described.[102]

If fetal compromise secondary to multi-infarct placental insufficiency exists, hypotension from sympathetic blockade should be prevented. Neuraxial anesthesia with an epidural, intrathecal, or combined spinal-epidural technique is not contraindicated provided that blood pressure is closely controlled. Parturients with APS who undergo general anesthesia are at risk for venous thrombosis. Compression stockings, warm intravenous fluids, and early ambulation should be used, whereas hypothermia and dehydration should be avoided.[99,100,103] There is no evidence that a "walking epidural" confers benefit.

SYSTEMIC SCLEROSIS (SCLERODERMA)

Definition and Epidemiology

Systemic sclerosis or scleroderma is a chronic progressive autoimmune disease of unknown etiology characterized by deposition of fibrous connective tissue in the skin and other tissues, microvascular changes, and chronic inflammation. It is a heterogeneous disorder and may be in the form of **limited** or **diffuse cutaneous scleroderma.** A subset of patients exhibit systemic sclerosis without cutaneous involvement.[104] The annual incidence of scleroderma in the United States is 19 per million. The prevalence is 240 per million, which is four to nine times greater than the reported global prevalence. Scleroderma is almost five times more common in women than in men and occurs primarily between 30 and 50 years of age.[105]

Pathophysiology

Epigenetic regulation of gene expression through cellular transcription, without changes in gene sequence, plays a key role in phenotypic expression, and is a possible mechanism by which the same genotype can be expressed as different phentoypes.[106] Possible mechanisms include chemical modification of DNA (particularly methylation), histone coding, modification of RNA, and environmental influences. Although the stimulus for fibroblasts to produce excessive collagen and other matrix constituents is unknown, their accumulation leads to microvascular obliteration and fibrosis in the skin and other target organs. Endothelial cells undergo vasomotor and permeability changes, producing cyclic vasoconstriction-vasodilation and edema. Patients with scleroderma produce autoantibodies against nuclear and centromere structures, although their significance is unclear. Scleroderma exhibits a strong female predilection, a steep rise in incidence after the childbearing years, and features that are similar to graft-versus-host disease after bone marrow transplantation, prompting some to postulate that microchimerism may be involved in its pathogenesis. Fetal cells gain access to the maternal circulation during gestation and may be detected in maternal blood for decades after delivery. After some unknown stimulus but possibly including environmental factors,[107] they may differentiate and initiate a reaction similar to graft-versus-host disease.

Diagnosis

Raynaud's phenomenon, characterized by cyclic pallor and cyanosis of the digits in response to cold or emotion, may be a prodrome to scleroderma, with 1% of patients progressing to scleroderma. The triad of Raynaud's phenomenon, nonpitting edema, and hidebound skin establishes the diagnosis of scleroderma.

Limited cutaneous scleroderma, also termed **CREST syndrome**, involves calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia. Skin involvement is limited to the hands, face, and feet in this form of the disease. The more extensive clinical manifestations of diffuse cutaneous scleroderma are summarized in Box 40.3.

Effect of Pregnancy

Progression of scleroderma tends to be slow. More than 70% of patients with diffuse cutaneous scleroderma and more than 90% of those with limited cutaneous scleroderma are

BOX 40.3 Manifestations of Diffuse Cutaneous Systemic Sclerosis

Skin
- Raynaud's phenomenon
- Nonpitting edema
- Hidebound skin (involves all but back and buttocks)

Gastrointestinal
- Hypomotility
- Dysphagia
- Reflux esophagitis
- Postprandial fullness
- Constipation
- Abdominal pain
- Intermittent diarrhea
- Malnutrition
- Ileus

Pulmonary
- Interstitial fibrosis
- Pleuritis
- Pulmonary hypertension

Renal
- Proteinuria
- Renal insufficiency and failure
- Malignant hypertension

Cardiac
- Chronic pericardial effusion
- Myocardial ischemia and infarction
- Conduction disturbances
- Heart failure

Musculoskeletal
- Arthritis (symmetric, small joints)
- Myopathy
- Muscle wasting

Other
- Peripheral or cranial neuropathy
- Facial pain
- Trigeminal neuralgia
- Keratoconjunctivitis sicca
- Xerostomia
- Absence of anticentromere antibodies

From LeRoy EC. Systemic sclerosis (scleroderma). In Wyngaarden JB, Smith LH, Bennett JC, eds. *Cecil Textbook of Medicine*. 19th ed. Philadelphia, PA: WB Saunders; 1992:1530–1535.

alive 15 years after diagnosis.[108] Renal failure and malignant hypertension are the most common causes of death. Successive reviews by Steen[109–111] indicate that improvements in management allow patients with scleroderma to have successful maternal and fetal outcomes. Maternal symptoms were unchanged in 62% of pregnancies and improved in 20%. In the other 18% of pregnancies, esophageal reflux, cardiac arrhythmias, arthritis, skin thickening, and/or renal crisis occurred or worsened. Deterioration of renal function is of greatest concern.[112]

Effect on Pregnancy and the Fetus

The frequency of preterm births and small-for-dates infants is higher in pregnant women with scleroderma.[112] Preterm birth occurs in 25% of pregnancies (compared with 5% in control pregnancies), and most preterm deliveries occur in women with unstable diffuse scleroderma of less than 4 years' duration. Miscarriage occurs more commonly in women with long-standing diffuse scleroderma.[109]

Medical Management

Management is symptomatic rather than curative, and is directed toward slowing end-organ damage. When lifestyle alterations (e.g., avoidance of cold, cessation of smoking) are no longer effective, management may include **calcium entry–blocking agents** for skin manifestations; **proton-pump inhibitors**, and occasionally **esophageal dilation** for gastrointestinal tract symptoms; and **phosphodiesterase inhibitors** and **prostaglandins** for pulmonary arterial hypertension. No disease modification benefits have been shown by administration of **penicillamine, methotrexate,** or other immunosuppressive agents (other than the use of glucocorticoids for inflammatory myositis).[113,114]

Drugs with unproven or potential teratogenicity are relatively contraindicated during pregnancy. However, **angiotensin-converting enzyme (ACE) inhibitors** are the agents of choice for treating scleroderma-associated renal crisis and malignant hypertension, despite the potential for fetal teratogenicity, renal atresia, pulmonary hypoplasia, anhydramnios, and fetopathy.[110] ACE inhibitors provide the only effective control of hypertension during scleroderma-associated renal crisis and should be started immediately if maternal hypertension occurs. Their use should be avoided if hypertension or overt renal crisis are not present. **Nitric oxide donors** and possibly **heparin** may provide some protection against placental dysfunction in pregnant women with scleroderma.[115]

Obstetric Management

Pregnant women with scleroderma should be specifically evaluated for evidence of renal, pulmonary, and cardiac dysfunction. Preterm delivery or termination of pregnancy may be required in the presence of advanced or rapidly progressive disease. Frequent assessment of renal function and intensive observation for the onset of systemic or pulmonary hypertension, cardiac dysfunction, and fetal compromise, combined with improvements in monitoring and treatment, allow most mothers to deliver healthy infants. Although the prevalence of left ventricular diastolic dysfunction is known to be higher in patients with scleroderma than in the general population,[116] an association with pregnancy has not been noted. However, additional monitoring based on clinical findings may be indicated. Obstructive uropathy may result from an enlarging uterus trapped within a noncompliant abdomen.[117] Uterine and cervical wall thickening may lead to ineffective uterine contractions or cervical dystocia at delivery.[111] Even the tightest abdominal skin usually heals if cesarean delivery is necessary.[111]

Anesthetic Management

The pregnant woman with scleroderma presents several challenges to the anesthesia provider and should be assessed before labor and delivery. Early multidisciplinary involvement is required. History and physical examination should be directed toward detection of underlying systemic dysfunction. Laboratory tests include complete blood cell count, coagulation screen, electrolyte concentrations and creatinine clearance, arterial blood gas analysis, urinalysis, and urine protein determination. An electrocardiogram and pulmonary function testing should be performed in all patients. Echocardiography is increasingly used to assess ventricular dysfunction, pericardial and pleural effusions, and pulmonary hypertension.[118] Particular attention should be paid to arterial pulses, noninvasive blood pressure measurement, peripheral venous access, extent of Raynaud's phenomenon involvement, and special positioning requirements.

Severe limitation of mouth opening caused by hidebound perioral skin may make direct laryngoscopy impossible and mandates careful airway assessment.[119] The patient should be prepared for the possibility of an awake intubation. Specialized airway equipment (e.g., fiberoptic laryngoscope, videolaryngoscope, emergency cricothyrotomy set) should be immediately available. The changes in airway assessment scores that occur during labor should also be borne in mind.[120]

Patients with scleroderma may develop pulmonary hypertension as a consequence of vascular changes, fibrosis, or left ventricular dysfunction. Administration of a pulmonary vasodilator may increase the likelihood of a favorable outcome.[121]

If cesarean delivery is required, the decision to use neuraxial or general anesthesia depends on the urgency of delivery, anticipated airway difficulty, and operator skills. One report of two pregnant women with scleroderma and pulmonary hypertension described administration of neuraxial anesthesia in one patient and general anesthesia in the other patient, highlighting the complexity of management choices.[121] Gastric hypomotility increases the risk for esophageal reflux and aspiration. Epidural anesthesia has been used successfully.[122,123] Early administration of epidural analgesia in laboring women in whom tracheal intubation is likely to be difficult is encouraged. Even when severe diffuse cutaneous involvement is present, the skin of the lumbar back is spared. Spinal anesthesia for cesarean delivery complicated by precipitous hypotension in a parturient with scleroderma has been reported[124]; recovery was uneventful with full return of motor function within 3.5 hours.

Prolonged duration of regional anesthesia has been observed in some patients with scleroderma, and may be caused by reduced uptake of the local anesthetic agent as a consequence of microvasculature changes. These cases have included (1) an axillary block performed with 1% lidocaine with epinephrine (reported to have persisted for 24 hours)[125]; (2) a digital nerve block performed with 1% lidocaine without epinephrine (10-hour duration)[126]; (3) a sciatic nerve block that persisted for 16 hours[127]; and (4) prolonged epidural anesthesia with 2% 2-chloroprocaine.[128] This is not a contraindication to neuraxial techniques but should prompt the use of small incremental boluses of the local anesthetic agent, and the patient should be warned of the possibility of prolonged neural blockade.[129] Incremental bolus or patient-controlled injection techniques may be preferable to continuous infusion techniques that may result in the administration of an excessive dose with prolonged neural blockade. Whether this consideration makes epidural (with the ability to titrate the dose) rather than spinal anesthesia preferable for cesarean delivery is unclear.

Venous access may be difficult. Diffuse cutaneous involvement may indicate the need for central venous catheterization, and for invasive arterial monitoring if noninvasive blood pressure measurement is inaccurate. Radial artery catheterization is contraindicated in patients with Raynaud's phenomenon because of the risk for hand ischemia. Brachial artery catheterization may be necessary. Pulmonary artery catheterization may be indicated in the presence of cardiac dysfunction or pulmonary hypertension.[130] The use of noninvasive assessment of cardiac function with transthoracic echocardiography is likely to increase.[131] Warming of the patient, and especially of the extremities affected by Raynaud's phenomenon, is required. Scleroderma reduces tear production, and the eyes should be protected against corneal abrasions.

POLYMYOSITIS AND DERMATOMYOSITIS

Definition and Epidemiology

Polymyositis and **dermatomyositis** represent two members of a larger disease group, the idiopathic inflammatory myopathic diseases. Polymyositis is characterized by nonsuppurative inflammation of muscle, primarily skeletal muscles of the proximal limbs, neck, and pharynx. This inflammation leads to symmetric weakness, atrophy, and fibrosis of affected muscle groups. Dermatomyositis represents the same disorder, with the addition of a characteristic heliotrope eruption (blue-purple discoloration of the upper eyelid) and Gottron's papules (raised, scaly, violet eruptions over the knuckles). These disorders are quite rare, with a prevalence of 10 per million and an annual incidence of 5.5 per million. Women are affected twice as often as men. The age at onset is bimodal, with peaks before puberty and during the fifth decade.[132]

Pathophysiology

Both polymyositis and dermatomyositis are associated with other autoimmune disorders, notably scleroderma. The etiology of inflammatory muscle disease is unknown and probably multifactorial. An initial insult mediated by viral or other infectious agent, or exposure to environmental substances, may lead to initial muscle damage in genetically susceptible individuals. This initial process may then trigger an autoimmune response involving chronic muscle inflammation. A viral etiology is suggested by seasonal and geographic clustering of new cases. However, viral genomic material has

BOX 40.4 Diagnostic Criteria for Polymyositis and Dermatomyositis

Polymyositis
- Symmetric weakness of proximal muscles
- Histologic evidence of muscle inflammation and necrosis
- Elevation of serum skeletal muscle enzymes
- Electromyographic evidence of myopathy

Dermatomyositis
- Three or four of the above, plus heliotrope eruption or Gottron's papules

From Bohan A, Peter JB. Polymyositis and dermatomyositis (second of two parts). *N Engl J Med.* 1975;292:403–407.

not been identified in affected muscle tissue. Many drugs, including lipid-lowering drugs in the statin group and antiretroviral drugs, are associated with the development of myopathy. The presence of cellular infiltrates within affected muscle tissue and complement-mediated capillary damage are features of inflammatory muscle diseases. More than 12 autoantibodies have been identified in affected individuals. Underlying malignancy has been associated with both conditions, although causality is unclear; the association is stronger for dermatomyositis than polymyositis.[132,133]

Diagnosis

The diagnostic criteria proposed by Bohan and Peter remain the standard for classification of polymyositis and dermatomyositis (Box 40.4).[134] After exclusion of other conditions that can mimic polymyositis or dermatomyositis, clinical features together with electromyographic and laboratory evidence of myositis (both through blood tests and muscle biopsy) establish the diagnosis. Serum creatine kinase concentration correlates with disease activity. Systemic involvement may be variable. Pharyngeal muscle involvement leads to **dysphagia** and **reflux,** and most patients exhibit **impairment of gastric and esophageal motility.**[135] Pulmonary involvement is present in 50% of patients with polymyositis/dermatomyositis, and **chronic aspiration pneumonitis** and **pneumonia** are the most common pulmonary manifestations. **Pulmonary fibrosis** is present in 30% of patients and may rarely lead to **pulmonary hypertension.**[136,137] **Myositis of the respiratory muscles** may cause respiratory insufficiency. **Cardiac involvement** includes nonspecific repolarization abnormalities, conduction disturbances, arrhythmias, coronary artery vasculitis, and, rarely, heart failure.[138] **Arthritis** generally involves the small joints of the hands and fingers. Renal or hematologic involvement is rare. The onset of a pregnancy-associated form of dermatomyositis has been described postpartum.[139]

Effect of Pregnancy

Reports of polymyositis or dermatomyositis during pregnancy are rare. Ishii et al.[140] reviewed 12 reports of 29 pregnancies during a 30-year period. In 11 (40%) of the patients, the initial diagnosis was made during gestation or the immediate postpartum period. Among the 18 patients with previously diagnosed disease, the disease remained inactive in 11 (61%) of the patients, and 2 (11%) had an exacerbation of disease activity. Pregnancy may be a trigger for induction of dermatomyositis in some women.[141]

Effect on the Fetus

Fetal outcome is influenced by disease activity; it has been reported that 60% of women with minimal activity delivered healthy newborns at term,[140] but fetal survival is affected by concurrent polymyositis/dermatomyositis. Consequences may include fetal growth restriction, preterm delivery, and fetal death.[142] A similar correlation was noted between outcome and disease activity in four pregnant women with polymyositis/dermatomyositis: two with active disease and fetal death and two with disease remission and uneventful outcome.[142] A large cohort study from Brazil documented 98 female patients (60 with dermatomyositis and 38 with polymyositis), of whom 78 women had an obstetric history; 57 women had been pregnant before their myositic diagnosis; 15 women became pregnant after the diagnosis was made; and 6 women were diagnosed with myositis while pregnant or in the postpartum period.[143] Adverse pregnancy outcomes (either as worsening of maternal condition or of fetal compromise) were associated with intercurrent clinical conditions such as diabetes mellitus, hypertension, and hypothyroidism, rather than as a direct consequence of dermatomyositis or polymyositis.

Medical and Obstetric Management

Pregnancy should be planned during periods of disease inactivity. Serum creatine kinase, glutamic oxaloacetic transaminase, and aldolase determinations can guide this decision. Obstetric management involves frequent monitoring of disease activity and fetal well-being.

Glucocorticoid treatment remains the mainstay of medical management of active disease. Efficacy of steroids has not been demonstrated in controlled studies, but improvement in muscle strength and decreased creatine kinase concentrations are usually seen after 1 to 2 months of either continuous or pulsed steroid therapy. **Methotrexate, azathioprine**, and **intravenous immunoglobulin** may be beneficial; there is limited evidence for their use and safety in pregnant patients.[144–146] A recent systematic review suggested, but could not confirm, benefit from methotrexate, azathioprine, **cyclosporine, rituximab,** and intravenous immunoglobulin,[147] but very few data relate to pregnant patients. The first-line drug for treatment of skin manifestations is **HCQ.**[148]

Anesthetic Management

Anesthetic management of the pregnant woman with polymyositis/dermatomyositis begins with the evaluation of disease activity and underlying cardiopulmonary involvement. If muscle weakness is present, spirometry should be performed to determine whether respiratory muscles are affected. Maximum breathing capacity and peak expiratory flow rate are the most helpful measurements. Pharyngeal

weakness may cause chronic aspiration and pulmonary diffusion defects. Arterial blood gas analysis and a chest radiograph should be obtained in patients with a history of aspiration. An electrocardiogram should be obtained to exclude conduction abnormalities and arrhythmias.

Although neuraxial anesthesia has been used safely,[149] its use in patients with muscle weakness requires caution because excessive cephalad spread may further impair intercostal muscle function and lead to ventilatory failure. Abdominal muscle paralysis may slow progress of the second stage of labor. Careful epidural administration of a dilute solution of local anesthetic may provide effective pain relief without adverse effect on the progress of labor. Intrathecal opioid administration is an attractive alternative method of labor analgesia in these patients.

Patients with polymyositis/dermatomyositis may exhibit an **atypical response to muscle relaxants.** A short-lived thumb contracture after **succinylcholine** administration in a child with dermatomyositis has been reported.[150] Direct laryngoscopy was not impaired, the contracture resolved within 3 minutes, and normal neuromuscular recovery occurred. Prolonged paralysis of 50 minutes after **succinylcholine** administration in a patient with dermatomyositis has been noted.[151] The patient was found to be homozygous for an atypical pseudocholinesterase. Of four other patients with dermatomyositis in whom the dibucaine number was measured, one was heterozygous for atypical pseudocholinesterase. The occurrence of benign contractures and the possibility of atypical pseudocholinesterase do not preclude the use of succinylcholine if it is required for cesarean delivery. Rocuronium may be an alternative agent for rapid-sequence induction.

An atypical response to **nondepolarizing muscle relaxants** may also occur. A case of prolonged paralysis (9.5 hours) after administration of vecuronium in a patient with polymyositis has been reported.[152] However, underlying malignancy, to which patients with dermatomyositis and polymyositis are prone, may have an associated **myasthenic syndrome** that can prolong neuromuscular blockade. Other reports of nondepolarizing neuromuscular blockade in patients with polymyositis/dermatomyositis have described a normal response and recovery.[153–155] Parturients who have undergone long-term corticosteroid therapy should receive a peripartum stress dose of a corticosteroid.

Neuromuscular recovery should be verified before tracheal extubation. Some investigators have advocated the avoidance of agents known to trigger malignant hyperthermia in patients with polymyositis/dermatomyositis and elevated creatine kinase levels,[155,156] but the association is speculative and is not supported by published clinical experience.

KEY POINTS

- Pregnancy does not worsen the long-term course of autoimmune disorders.
- Autoimmune disorders can lead to renal, cardiac, and pulmonary dysfunction.
- Systemic lupus erythematosus can result in maternal thrombocytopenia.
- Systemic lupus erythematosus is associated with a higher incidence of spontaneous abortion, intrauterine fetal demise, and preterm delivery.
- Antiphospholipid syndrome is characterized by the presence of the autoantibodies lupus anticoagulant and anticardiolipin antibody.
- The term *lupus anticoagulant* is a misnomer because it has no true anticoagulant activity *in vivo*.
- Patients with lupus anticoagulant do not have a bleeding tendency in the absence of an underlying coagulation disorder and can safely receive neuraxial anesthesia.
- Patients with scleroderma are at increased risk for difficult airway management.
- Scleroderma can prolong the duration of neuraxial anesthesia.
- The severity of polymyositis/dermatomyositis affects fetal survival.
- Patients with polymyositis/dermatomyositis may have an atypical response to succinylcholine.
- Neuraxial anesthesia must be administered cautiously to parturients with polymyositis/dermatomyositis and intercostal muscle weakness.

Cardiovascular Disease

Mladen I. Vidovich, MD, FACC, FSCAI

CHAPTER OUTLINE

Evidence suggests that an individual's sex has a significant impact on cardiovascular disease. The etiology of coronary thrombosis causing acute myocardial infarction is different in women than in men. Plaque erosion, rather than plaque rupture, occurs at a higher rate in women than in men. Coronary artery diameter is smaller in women,[1] and women frequently develop more diffuse atherosclerosis than men. Female aortas appear to be stiffer because of underlying fibrosis or remodeling. Women have more microvascular coronary artery dysfunction than men and frequently demonstrate impaired coronary artery vasodilator response.

Autoimmune rheumatic diseases are associated with premature atherosclerosis; vasculitides such as Takayasu's arteritis, temporal arteritis, rheumatoid vasculitis, lupus vasculitis, and polymyalgia rheumatica are all more common in women than in men. During exercise stress testing, women more often have atypical and nonanginal pain than men, who more often have typical angina.[2] Women with acute myocardial infarction more frequently do not have chest pain, especially those who have the infarction at a younger age. In-hospital mortality for acute myocardial infarction is higher for women than for men.[3] Although women who have non–ST-segment elevation myocardial infarction have a poorer risk profile than men, the infarction is frequently treated less aggressively.[4] Yet women are more likely than men to summon emergency medical services during a myocardial infarction.

Whether women have poorer outcome after percutaneous coronary intervention has been a matter of debate.[5] At the time of presentation for both percutaneous and surgical coronary revascularization procedures, women are older than men and have more cardiovascular risk factors and comorbid conditions.[5] Older studies demonstrated poorer overall outcome in women than in men; however, more recent studies have demonstrated a narrowing or disappearance of the sex-related outcome gap. Similarly, several studies have demonstrated that female sex was an independent predictor of coronary artery bypass grafting (CABG) operative mortality. However, after extensive baseline risk adjustment, outcomes after CABG or aortic valve replacement have been reported to be similar for men and women.

Number of pregnancies has been associated with the future risk for coronary artery disease[6] and progression of atherosclerosis.[7] Hypertensive disorders of pregnancy, preeclampsia, and gestational diabetes mellitus are risk factors for future development of cardiovascular disease.[8,9] Earlier identification of these women with an increased lifetime risk for developing cardiovascular disease may present a unique opportunity for prevention of subsequent cardiovascular events.

Historically, rheumatic mitral stenosis represented the most common cardiac condition encountered in pregnant women. This disease continues to be a major problem in the developing world and in certain immigrant populations in the United States. In industrialized countries, congenital heart disease has become the most common cardiac condition complicating pregnancy. This demographic change is a result of significant advances in the treatment of complex congenital heart conditions and survival of these patients into childbearing age. In the United States, maternal mortality caused by hemorrhage and hypertensive disorders of pregnancy has declined, whereas mortality caused by cardiovascular conditions has steadily increased.[10]

The optimal management of women with cardiovascular disease begins *before* conception. Normal physiologic changes of pregnancy may exacerbate preexisting cardiovascular disease. For most women with heart disease, pregnancy is associated with favorable outcome; however, even with modern advances in treatment and monitoring, there remains a high incidence of morbidity and mortality for some conditions. Thus, for some women, it may be advisable to avoid pregnancy.

There is significant individual variability in the severity of specific cardiovascular disease entities. Additionally, several cardiovascular conditions may be simultaneously present in one individual. Management may be further complicated by the presence of noncardiovascular pathologic processes. The anesthetic management of the parturient with cardiovascular disease should be individualized, and a multidisciplinary team should plan peripartum care. Some case reports and small series have described the anesthetic management of these patients, but, in general, few data justify choosing one anesthetic technique over another. Therefore, the anesthesiologist must have a thorough understanding of the normal physiologic changes of pregnancy as well as the individual parturient's pathophysiology, and then plan anesthetic management that best achieves the desired hemodynamic goals. Optimal *analgesia* is often an important part of safe childbirth in these patients.

The anesthetic care of women with cardiovascular disease does not end with labor and delivery; rather, it continues postpartum when the physiologic changes of pregnancy may be at their greatest. Inadequate postpartum analgesia may be associated with hypertension and tachycardia. Postoperative shivering increases oxygen consumption and may cause myocardial ischemia in patients with limited cardiac reserve.

CARDIOVASCULAR PHYSIOLOGIC CHANGES OF PREGNANCY

The **electrocardiogram (ECG)** typically changes during pregnancy. During the third trimester, the enlarging gravid uterus causes upward and lateral rotation of the heart, which may result in left-axis deviation of 15 to 20 degrees. Overall, however, the QRS axis is quite variable during pregnancy. At rest, nonspecific ST-segment and T-wave changes are very common during normal pregnancy.[11] Exercise in healthy pregnant women does not cause distinctive ECG changes compared with nonpregnant subjects.

No repolarization abnormalities are observed with uncomplicated vaginal delivery. ST-segment *elevation* is never seen in normal pregnancy and should always be considered pathologic. ST-segment *depression* is seen in 25% to 81% of parturients undergoing cesarean delivery, regardless of the type of anesthesia. Oxytocin administration during the third

stage of labor has been associated with ST-segment depression.[12,13] However, these oxytocin-associated ECG changes are not associated with myocardial damage. Whether these ECG changes are caused by underlying ischemia or some other mechanism remains unclear.

Left ventricular mass increases during normal pregnancy.[14] The increase in left ventricular mass is greater in multiple gestation than in singleton gestation.[15] Preeclampsia also results in a greater increase in left ventricular mass.[16]

Plasma lipid concentrations, including total serum cholesterol, triglycerides, and low-density lipoprotein cholesterol concentrations, increase during pregnancy.[17] Obese pregnant women have an even greater increase in plasma lipids. This increase in plasma lipids results in part from insulin resistance and an increase in estrogen levels during pregnancy. The effects of these physiologic changes in plasma lipid concentrations on long-term cardiovascular outcomes are unclear.

Brain natriuretic peptide (BNP) is a natriuretic hormone synthesized primarily in the heart ventricles. BNP levels increase as a response to increased filling pressures in patients with heart failure. Physiologically, BNP has hypotensive, diuretic, and natriuretic effects. During uncomplicated normal pregnancy, BNP levels are double the nonpregnant level with return to baseline approximately 3 days after delivery. The BNP level appears to be unchanged between the trimesters.[18] BNP levels are increased in preeclamptic women[19] and in pregnant women with heart disease.[20] A correlation exists between BNP and the increases in left ventricular mass and end-diastolic and end-systolic volumes observed in preeclampsia.[16] The increase in BNP with fluid administration in preeclamptic women further confirms that this hormone is secreted in response to increased intracavitary pressures. Intravenous fluid administration does not increase BNP levels in healthy women.[21] BNP is elevated in women with complex congenital heart disease, but it varies considerably among anomalies. Therefore, its role for individual patient management remains unclear.[22]

Cardiac enzyme levels may be altered by pregnancy or pregnancy-associated disease. Myocardial cell death is associated with elevation of sensitive and specific cardiac biomarkers—creatine kinase MB fraction (CK-MB) and cardiac troponins.[23] Cardiac troponin levels are not elevated above the upper limits of normal during uncomplicated pregnancy. Troponin levels are elevated in women with gestational hypertension or preeclampsia.[24,25] By contrast, CK-MB levels may be elevated up to two to four times the upper limit of normal owing to the presence of these enzymes in the uterus and placenta (see Fig. 46.1). Thus, elevated CK-MB levels are not specific for the diagnosis of myocardial infarction during pregnancy.[25,26] In patients with preeclampsia who have concurrent myocardial infarction, the observed troponin levels are higher than expected for the underlying preeclampsia.[27] Heterophil antibody interference with the troponin assay may cause a false-positive increase in troponin levels during pregnancy. However, both CK-MB and troponin are sensitive markers for the diagnosis of myocardial infarction during pregnancy.

Cardiac output increases as early as 5 weeks' gestation and continues to increase throughout the second trimester until it is approximately 50% greater than nonpregnant values (see Fig. 2.2). Cardiac output does not change from this level during the third trimester; it may actually be reported as decreased in the third trimester if measurements are made in the supine position, which causes aortocaval compression. Both an increase in heart rate and stroke volume contribute to the increase in cardiac output. Distribution of cardiac output to the uterine circulation increases from 1% in the nonpregnant state to 12% during the second half of pregnancy (see Chapter 2).

CARDIAC EXAMINATION DURING PREGNANCY

Pregnant women frequently complain of mild dyspnea at rest and exertion; on occasion, exercise tolerance is decreased. Therefore, it is important to recognize normal changes in the physical examination associated with pregnancy (Table 41.1).

Resting heart rate is higher in pregnancy, and peripheral pulses are "well filled" with rapid upstroke and collapse, primarily owing to lower systemic vascular resistance (SVR). Central venous pressure remains unchanged during pregnancy, and any elevation of jugular venous pressure is an abnormal finding. Basilar rales may be heard on lung auscultation; however, these are no longer heard after deep inspiration, a brief breath-hold, or a cough. These evanescent rales likely result from basilar atelectasis.

The heart examination during pregnancy is altered as a result of uterine enlargement. Consequently, the point of maximum impulse (left ventricular apex) is displaced superiorly and laterally during advanced pregnancy. It remains crisp, well defined, and hyperdynamic. In thin women, the right ventricular impulse may become visible owing to an increase in circulating blood volume and the proximity of this chamber to the anterior chest wall.

Recognition of normal auscultatory changes helps distinguish pathologic from physiologic changes. New murmurs are heard in more than 90% of pregnant women. The loudest murmurs are heard between 15 and 25 weeks' gestation; murmur intensity decreases toward term and increases again during labor and the early postpartum period. This peripartum increase in murmurs is followed by a gradual decrease; most of these pregnancy-associated murmurs are no longer appreciated by 6 weeks postpartum.[28] Importantly, there is no correlation between the disappearance of physiologic murmurs of pregnancy and the return of cardiac output and blood volume to prepregnancy levels.[29]

The first heart sound (S1) becomes louder and is widely split owing to early closure of the mitral valve during pregnancy. The second heart sound (S2) is unchanged. It is quite common to appreciate the third heart sound (S3), although considerable expertise and a quiet environment are necessary because of the presence of underlying tachycardia and an increased basal respiratory rate. The fourth heart sound (S4) is rarely appreciated. Owing to increased cardiac output and

TABLE 41.1 Cardiovascular Physical Examination in Pregnancy

Feature	Normal Pregnancy	Implication of Abnormal Findings
Jugular venous pressure	Normal	Any elevation warrants further evaluation of volume status
Carotid pulse	Normal upstroke Normal volume	Decreased or delayed upstroke (aortic stenosis), bifid pulse (hypertrophic cardiomyopathy)
Peripheral pulses	Well filled	Diminished or delayed (aortic stenosis, left ventricular outflow obstruction)
Point of maximum impulse	Crisp, slightly laterally displaced	Any enlargement or more than slight lateral displacement warrants further evaluation.
S1	Louder and widely split	
S2	Unchanged	Soft/absent/paradoxically split (aortic stenosis) Loud P2, fixed split (pulmonary hypertension)
S3	Normally present	
S4	Rarely heard	
Aortic stenosis murmur	Increased	Helpful to confirm physical examination findings with echocardiography
Aortic regurgitation murmur	Decreased	
Mitral stenosis murmur	Increased	
Mitral regurgitation murmur	Decreased	
Hypertrophic cardiomyopathy murmur	Decreased	Not all hypertrophic cardiomyopathies have obstructive murmurs; helpful to confirm with echocardiography
Peripheral edema	Mild edema normally present	Asymmetric edema warrants further evaluation
Stigmata of Marfan syndrome		Risk for aortic dissection
Stigmata of Turner syndrome		Risk for aortic dissection

increased flow through cardiac valves, a systolic ejection murmur, usually soft (grade 2/6 to 3/6), is appreciated over the upper sternal border and the right side of the heart.

The murmurs of aortic and mitral regurgitation generally decrease and may become inaudible during pregnancy owing to the decrease in SVR. However, administration of phenylephrine or development of hypertension during pregnancy, both of which increase the SVR, increases the intensity of these murmurs.[30]

The murmur associated with aortic stenosis increases in intensity during pregnancy from increased flow through the stenotic valve. A diminished carotid upstroke, soft or inaudible S2, and a grade 4/6 murmur are almost always indicative of severe aortic stenosis. An audible, physiologic split S2 almost invariably rules out severe aortic stenosis. Diastolic murmurs during pregnancy are almost always associated with an underlying pathologic process.

The murmur of hypertrophic cardiomyopathy may have decreased intensity because the pregnancy-associated increase in intravascular volume may result in decreased outflow tract obstruction. The murmur of an atrial septal defect may become more audible during pregnancy.

Mammary souffle ("soo-fuhl") is a noncardiac sound; it describes the continuous hum heard over the breasts. It becomes audible during late pregnancy and lactation, and it disappears at the end of lactation.

Most pregnant women display some degree of peripheral edema, in part owing to uterine compression of the inferior vena cava, which impedes venous return. This physiologic edema is symmetric and decreases with leg elevation and the left lateral decubitus position. The pathologic edema of preeclampsia should be differentiated from the physiologic edema of pregnancy. Asymmetric lower extremity edema is almost invariably pathologic. A tender and warm lower extremity may suggest deep vein thrombosis or cellulitis.

Funduscopic examination in pregnancy may help differentiate chronic hypertension from hypertensive disease of pregnancy (preeclampsia/eclampsia) and may identify changes caused by long-standing diabetes.

It is important to look for stigmata of Marfan syndrome. Tall stature, large arm span, or other stigmata may alert the practitioner to the presence of a previously undiagnosed condition. Patients with Marfan syndrome frequently demonstrate scoliosis and may have dural ectasia. Turner syndrome is characterized by short stature and webbed neck. Both conditions predispose pregnant women to aortic dissection (see later discussion).

CARDIAC RISK PREDICTION

The New York Heart Association (NYHA)[31] and Heart Failure Stage[32] classifications describe symptoms and predict risk in the nonpregnant population (Box 41.1). Several classifications have been proposed to specifically predict cardiac risk during pregnancy, including the ZAHARA I (Zwangerschap bij vrouwen met een Aangeboren HARtAfwijking),[33] CARPREG (CARdiac disease in PREGnancy),[34] and modified World Health Association (WHO)[35,36] risk scores (Box 41.2).

BOX 41.1 New York Heart Association Functional Classification of Heart Failure

Classification of Heart Failure

Class I
- No limitation of physical activity

Class II
- Mild limitation of physical activity; regular physical activity causes symptoms

Class III
- Marked limitation of physical activity; no symptoms at rest; minimal activity causes symptoms

Class IV
- Symptoms at rest

Stages in the Development of Heart Failure

Stage A
- At risk for heart failure but without structural heart disease or symptoms (e.g., hypertension, coronary artery disease, obesity)

Stage B
- Structural heart disease but without signs or symptoms (e.g., previous myocardial infarction, asymptomatic valvular heart disease)

Stage C
- Structural heart disease with prior or current symptoms of heart failure (e.g., known structural heart disease and symptoms)

Stage D
- Refractory heart failure requiring specialized interventions (e.g., marked symptoms at rest with maximal medical therapy)

Modified from Kosman CE, ed. New York Heart Association. *Diseases of the Heart and Blood Vessels; Nomenclature and Criteria for Diagnosis*. 6th ed. Boston, MA: Brown and Co., 1964; Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2013;128:e240–e327.

BOX 41.2 Modified World Health Organization Cardiac Risk Assessment

Class I (no increase or a mild increase in morbidity)
- Mild pulmonic stenosis
- PDA
- Mitral valve prolapse
- Repaired ASD, VSD, PDA, anomalous pulmonary venous return

Class II (small increase in maternal mortality, moderate increase in maternal morbidity)
- Unrepaired ASD or VSD
- Repaired tetralogy of Fallot
- Most arrhythmias
- Mild left ventricular dysfunction
- Hypertrophic cardiomyopathy
- Marfan syndrome without aortic dilation
- Bicuspid aortic valve with aortic diameter < 45 mm

Class III (significant increase in maternal mortality and severe increase in maternal morbidity)
- Mechanical valve(s)
- Systemic right ventricle
- Fontan circulation
- Unrepaired cyanotic heart disease
- Complex congenital heart disease
- Marfan syndrome with aortic dilation 40 to 45 mm
- Bicuspid aortic valve with aortic dilation 45 to 50 mm

Class IV (pregnancy is not recommended or is contraindicated)
- Pulmonary arterial hypertension of any cause
- Severe left ventricular dysfunction
- Previous peripartum cardiomyopathy with residual left ventricular dysfunction
- Severe mitral stenosis
- Severe aortic stenosis
- Marfan syndrome with aortic dilation > 45 mm
- Bicuspid aortic valve with aortic dilation > 50 mm
- Severe unrepaired aortic coarctation

PDA, Patent ductus arteriosus; *ASD,* atrial septal defect; *VSD,* ventricular septal defect.
Modified from Thorne S, MacGregor A, Nelson-Piercy C. Risks of contraception and pregnancy in heart disease. Heart. 2006;92:1520–1525; Regitz-Zagrosek V, Roos-Hesselink JW, Bauersachs J, et al. 2018 ESC guidelines on the management of cardiovascular diseases during pregnancy. *Eur Heart J.* 2018;39:3165–3241.

These classifications may help predict the individual pregnant woman's cardiac risk and, combined with the clinical constellation and results of cardiac imaging, may help guide clinical management.[34–37] When studied prospectively, the modified WHO classification outperformed the ZAHARA I and CAPREG risk scores.[38] Implementation of a standardized and guideline-based approach to care, based on risk assessment, provides consistency in treating pregnant women with cardiac disease.

Maternal cardiac disease is associated with an increased incidence of **neonatal complications.** The most widely accepted associations are cyanosis, NYHA functional class greater than II, presence of a mechanical valve prosthesis, heparin or warfarin use during pregnancy, multiple gestation, smoking during pregnancy, left-sided heart obstruction, and use of cardiac medications before pregnancy.[34,37] At the current time, the risk-estimation models to predict neonatal events will require further refinement to afford clinical utility.[38,39]

CARDIOVASCULAR IMAGING DURING PREGNANCY

Echocardiography

Echocardiography allows for safe and noninvasive assessment of heart structure and function. Both transthoracic and transesophageal echocardiography can be performed at any stage of pregnancy. Echocardiography helps predict overall cardiac risk and guides anesthetic management in pregnant women with cardiac disease. Echocardiography also allows assessment of intravascular volume and may obviate the need for right-sided heart catheterization to determine ventricular

filling pressures. Contemporary evidence suggests that for most common cardiac conditions, handheld transthoracic echocardiography provides more accurate diagnosis than physical examination.[40]

One of the most commonly used echocardiographic assessments of left ventricular function—left ventricular ejection fraction—remains unchanged during pregnancy. Echocardiographic measurements of cardiac output increase during pregnancy owing to increases in stroke volume and heart rate. Importantly, stroke work is increased during pregnancy, which is consistent with augmented myocardial fiber function. Both the right and left ventricular chamber size are increased in end-diastole and end-systole, and the heart becomes more globular. This increase in chamber size results in increased left ventricular end-systolic and end-diastolic volumes and is accompanied by an increase in left ventricular wall thickness (eccentric left ventricular hypertrophy). These parameters return to baseline within 3 to 6 months postpartum.[41] Left ventricular end-diastolic and end-systolic volumes are further increased with multiple gestation; the stroke volume is increased an additional 15%. Combined with a small additional increase in heart rate, this change results in a 20% greater increase in maternal cardiac output with multiple gestation compared with singleton gestation.[15]

Left atrial size is increased during pregnancy[14]; the increase is even greater with multiple gestation than with singleton gestation.[15] Preeclampsia results in an adaptive concentric hypertrophy and an increase in left ventricular mass caused by increased afterload.

In normal pregnancy, left ventricular diastolic function is increased in the first two trimesters and declines in the third trimester.[42] Twenty percent of women with preeclampsia have evidence of global diastolic dysfunction.[43] Diastolic function is most commonly assessed echocardiographically by evaluating mitral valve inflow, pulmonary venous flow, and myocardial tissue motion (tissue Doppler imaging).

Cardiac Magnetic Resonance Imaging

The risks associated with magnetic resonance imaging (MRI) in pregnant women are similar to those in nonpregnant patients, and there is no evidence that MRI causes harm to the fetus.[44] Similar to the use of all imaging modalities during pregnancy, cardiac magnetic resonance (CMR) imaging should be performed during pregnancy only after consideration of both the maternal and fetal benefits and risks. However, given the quality of images and diagnostic yield, CMR is preferable to any modality that uses ionizing radiation. Gadolinium crosses the placenta and has been found to be teratogenic in animal models. Currently available human data suggest that gadolinium should be used in pregnant women only if it significantly improves diagnostic performance and is expected to improve maternal or neonatal outcome.[44]

Cardiac Catheterization

Coronary angiography remains the "gold standard" for diagnosis of coronary artery disease, and it can be performed at any time during pregnancy. Radial arterial access is preferable to femoral access because it is associated with earlier ambulation, increased patient comfort, and a significant reduction in access-related bleeding complications. Additionally, during the procedure, the left lateral decubitus position can be more easily maintained with radial access. Cardiologists should strictly adhere to the ALARA principle (as low as reasonably achievable) to limit both maternal and fetal ionizing radiation exposure.

The use of pulmonary artery catheterization has significantly declined in the United States in recent years. Similar information can be obtained noninvasively by transthoracic or transesophageal echocardiography. However, thermodilution and Fick cardiac output measurements can be obtained only with the use of a pulmonary artery catheter. Similarly, right-sided heart catheterization is required for vasoreactivity testing in patients with pulmonary hypertension.

Iodinated Contrast Use during Pregnancy

The use of iodinated contrast media in pregnant women appears safe.[44] To date, there has been no report of fetal teratogenic or mutagenic effects after maternal administration of iodinated contrast media. Free iodide in the contrast medium administered to the mother may depress fetal, and subsequently neonatal, thyroid function. Therefore, it has been suggested that neonatal thyroid function be checked during the first week postpartum. Minimal amounts of iodinated contrast media are excreted in breast milk; even smaller amounts are absorbed by the neonate's gastrointestinal tract. The slight potential risk associated with absorption of contrast medium is thought to be insufficient to recommend interruption of breast-feeding after maternal administration of iodinated contrast media.

Computed Tomographic Angiography

Multidetector computed tomography (CT) allows noninvasive imaging of the coronary arteries along with cardiac structure and function. Use of contemporary CT with aggressive dose-reduction techniques can significantly limit the radiation dose. The overall radiation dose of coronary CT angiography may be equivalent to, or even lower than, radiation doses delivered with conventional invasive coronary angiography. Although soft cardiac structures not seen by conventional coronary angiography are well visualized by CT angiography, the intravenous contrast medium load is greater with CT angiography, and coronary intervention cannot be performed at the time of imaging. Thus, in pregnancy, invasive coronary angiography appears preferable under most circumstances.

Ionizing Radiation Risks to the Fetus

The ionizing radiation dose to the fetus can be limited by the use of echocardiography, intracardiac echocardiography, reduced fluoroscopy frame rates, and contemporary image noise-reduction technology. Because the fetus is not directly within the radiation beam for cardiac procedures, the fetal exposure occurs through indirect scatter radiation. Therefore,

external shielding of the fetus is ineffective. The fetal radiation dose cannot be measured and is therefore estimated; however, it is reassuring that the estimated fetal doses are low. Nonetheless, the safest approach is to avoid ionizing radiation during pregnancy if possible, and to assess both the maternal and fetal risks and benefits before deciding on the most appropriate imaging modality.

CARDIAC DRUGS AND PREGNANCY

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are the mainstay treatment of coronary artery disease, left ventricular dysfunction, and hypertension in nonpregnant patients. These drugs are particularly useful in nonpregnant patients with diabetes mellitus.

In the first trimester, the use of ACE inhibitors has been associated with an increased risk for fetal cardiovascular and central nervous system malformations. Use of ACE inhibitors during the second and third trimesters of pregnancy has also been associated with adverse fetal and neonatal outcomes as a result of the ACE inhibitors' effect on fetal renal vascular tone. These drugs cause fetal kidney malfunction and decreased fetal urine output, which results in oligohydramnios. Positional limb deformities, skull ossification retardation, and lung hypoplasia are seen with ACE inhibitor–associated oligohydramnios. Thus, despite the exceptionally useful profile of ACE inhibitors in nonpregnant patients with cardiovascular disease, their use in pregnancy is contraindicated (see Chapter 14).[45]

Angiotensin Receptor–Blocking Agents

Fewer data are available on the use of angiotensin receptor–blocking agents in pregnancy. Nonetheless, given the adverse outcomes associated with use of ACE inhibitors in pregnancy and the mechanism of action of angiotensin receptor–blocking agents, the use of these drugs is not recommended in pregnancy.[45]

Beta-Adrenergic Receptor Antagonists

Beta-adrenergic receptor antagonists are often used for treatment of coronary artery disease, myocardial infarction, hypertension, many arrhythmias, and a wide spectrum of cardiomyopathies. There is no evidence that beta-adrenergic receptor antagonists are teratogenic. Prolonged and high-dose use of these drugs has been associated with fetal growth restriction; however, the overall risk is likely small.[45] Neonatal bradycardia, hypotension, and hypoglycemia are rarely encountered.

Calcium Entry–Blocking Agents

First-trimester maternal use of **verapamil** and **diltiazem** is likely not teratogenic. Both drugs appear to be safe and effective treatments for cardiac arrhythmias in the second and third trimesters.[45] The use of **amlodipine,** a dihydropyridine calcium entry–blocking agent, appears safe during pregnancy.[45]

Other Drugs

Hydralazine is used in the treatment of cardiomyopathy and is also an excellent antihypertensive agent. It has a long track record of safe use during pregnancy.[45]

The use of **nitrates** for treatment of angina during pregnancy appears safe. Nitrates likely can be safely used long term in pregnant women with cardiomyopathy.[45]

Digoxin may be useful for the treatment of various cardiomyopathies and some arrhythmias. Digoxin freely crosses the placenta, but its use has not been associated with congenital abnormalities or untoward fetal effects.[45] Digoxin's pharmacokinetics are altered during pregnancy, and monitoring of blood levels is recommended.

Eptifibatide, tirofiban, and **abciximab** are potent intravenous platelet aggregation inhibitors (**IIB/IIIA receptor inhibitors**) used to inhibit platelet aggregation during percutaneous coronary intervention. Both the American Society of Regional Anesthesia and Pain Medicine (ASRA) and the European Society of Anaesthesiology (ESA) guidelines strongly advise avoidance of neuraxial anesthesia until platelet function has recovered after administration of these agents.[46,47]

Statins interrupt cholesterol synthesis and result in a lowering of plasma cholesterol levels. The widespread use of statins (which are associated with exceptionally robust cardiovascular outcome data) has transformed the treatment of coronary artery disease. Nonetheless, given the critical importance of cholesterol synthesis in the normal development of the embryo and placenta, and thus their potential for teratogenicity, statins are contraindicated in pregnancy.[45]

Thiazide diuretics do not appear to be teratogenic. Long-term use may result in a reduction in uteroplacental perfusion, which may be associated with fetal growth restriction and oligohydramnios.[45] Neonatal hypoglycemia and thrombocytopenia have been reported.

Loop diuretics are likely not teratogenic.[45] Similar to thiazide diuretics, fetal growth restriction may be associated with long-term use during pregnancy. **Spironolactone** is an aldosterone antagonist frequently used in the treatment of patients with congestive heart failure and cardiomyopathy, but because of its antiandrogenic potential its use during pregnancy is not recommended.[45]

AORTIC DISEASES AND AORTIC DISSECTION

The cardiovascular changes of pregnancy may to lead to increased arterial wall tension and intimal shear forces. However, the full impact of pregnancy on changes in aortic wall structure is not fully understood. Estrogen-induced changes in collagen deposition, as well as circulating elastases and relaxin, may weaken the aortic media and thus predispose the aorta to dissection during pregnancy. Approximately one-half of aortic dissections and ruptures in women younger than 40 years of age are associated with pregnancy.[48] Dissection of the ascending aorta (Stanford type A or DeBakey type I or II) is a surgical emergency, whereas dissection of the

descending aorta (Stanford type B or DeBakey type III) is predominantly treated medically.

Conditions that predispose women to aortic dissection during pregnancy include Marfan syndrome, Ehlers-Danlos syndrome, bicuspid aortic valve,[49] Turner syndrome, and non–Marfan syndrome–associated familial thoracic aneurysms.[50,51] Aortic dissection has been associated with preeclampsia and chronic hypertension in pregnancy.[52] Most aortic dissections that occur during pregnancy are type A (ascending aorta); the average aortic diameter at the time of dissection is 4.8 cm.[53] The majority of dissections occur in the third trimester of pregnancy, but aortic dissections may also occur at the time of delivery or in the early postpartum period. It has been hypothesized that contraction of the uterus causes outflow resistance, thus predisposing to aortic dissection after delivery.

Marfan Syndrome

Marfan syndrome is an autosomal-dominant connective tissue disorder. The penetrance is high, but the expression is variable. Marfan syndrome is caused by a mutation in the *FBN1* gene encoding fibrillin-1, a glycoprotein. Sporadic mutations are seen in approximately 25% of patients without a family history of this syndrome. Aortic dilation and aortic dissection contribute significantly to cardiovascular complications in these patients. In addition to aortic disease, affected patients often have valvular disease (e.g., aortic regurgitation, mitral regurgitation, mitral valve prolapse). Aortic dissection has been observed during pregnancy and in the peripartum period.[54,55] Most patients have type A aortic dissection; type B aortic dissection and abdominal aortic aneurysm are less commonly seen.

Based on observational studies, current guidelines recommend that women with Marfan syndrome who are planning pregnancy undergo replacement of the ascending aorta and the aortic root if the diameter is greater than 4.0 cm (class IIa, level of evidence C).[50] The aortic root dilation rate increases during pregnancy and does not return to baseline after delivery. Subsequent pregnancies further increase the aortic dilation rate.[56]

Aortic Disease Associated with a Bicuspid Aortic Valve

Bicuspid aortic valve has been associated with dissection during pregnancy.[51] Affected women are slightly younger, and the dissection occurs earlier in pregnancy than in patients with Marfan syndrome.[53] Because the disease is familial, first-degree relatives of patients with a bicuspid aortic valve should be screened for this disease.[57]

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is an inherited connective tissue disorder. Ehlers-Danlos syndrome type IV has been associated with severe complications and maternal mortality. Rupture of the bowel, aorta, vena cava, and uterus may occur.[50] Pregnancy outcomes in patients with Ehlers-Danlos syndrome types I, II, and III are generally favorable, although these women may have a higher incidence of pelvic instability, preterm delivery, perineal lacerations, and postpartum hemorrhage than the general population.[58]

Turner Syndrome

Turner syndrome is caused by complete or partial absence of an X chromosome. In addition to short stature, webbed neck, and characteristic facial features, Turner syndrome is associated with aortic coarctation and hypertension. Approximately 30% of patients with Turner syndrome have a bicuspid aortic valve. During pregnancy, the syndrome is associated with aortic dissection.[50] Preconception echocardiographic evaluation of patients with Turner syndrome is recommended.[50,59] Given the frequent aortic abnormalities in these patients, preconception MRI is also recommended. Because of short stature in some patients with Turner syndrome, absolute aortic root measurements may not accurately predict the risk for aortic dissection.[60] Cesarean delivery is frequently required in these patients because of cephalopelvic disproportion.[59]

Aneurysm-Osteoarthritis Syndrome

Aneurysm-osteoarthritis syndrome is a recently described autosomal-dominant condition caused by mutations in the *SMAD3* gene.[61] Mutations in the *SMAD3* gene lead to increased aortic expression of several components in the TGF-β pathway and subsequent aneurysm formation. In addition, visceral and iliac aneurysms, arterial tortuosity, and early-onset joint abnormalities may be present. In a cohort of 17 patients and 34 pregnancies, no maternal mortality or aortic dissection was observed. Cesarean delivery was performed for mainly obstetric indications without increased bleeding complications. The type of anesthesia was not reported.[62]

Obstetric and Anesthetic Management

Given the inherent risk for aortic dissection, parturients with aortic disease should deliver in a center that has immediate access to a cardiothoracic surgeon with expertise in aortic endovascular repair techniques. Current guidelines are based on expert opinion, case reports, and current standard of care (level C evidence) (Box 41.3; Table 41.2). The 2010 American College of Cardiology (ACC) Foundation/American Heart Association (AHA) guidelines recommend the following for pregnant women with chronic aortic dilation: (1) strict blood pressure control; (2) monthly or bimonthly echocardiographic measurement of aortic dimension; (3) cesarean delivery in women with significant aortic enlargement, dissection, or severe aortic valve regurgitation; and (4) prophylactic surgery in the setting of progressive aortic dilation and/or advancing aortic valve regurgitation.[50]

All patients with Marfan syndrome should receive beta-adrenergic receptor antagonist therapy throughout pregnancy to decrease the rate of aortic dilation.[50] The risk for major aortic complications during pregnancy appears low if the aortic root diameter is less than 4.0 cm.[50] In the event of a type A aortic dissection in the first or second trimester,

BOX 41.3 Management of Chronic Aortic Diseases in Pregnancy[a]

Class I[b]

- Women should be counseled about the risk for aortic dissection as well as the heritable nature of the disease before pregnancy.
- Strict blood pressure control, specifically to prevent stage 2 hypertension, is recommended.[c]
- Monthly or bimonthly echocardiographic measurements of the ascending aortic dimensions are recommended to detect aortic expansion.
- For imaging of pregnant women, magnetic resonance imaging (without gadolinium) is recommended over computed tomography to avoid both maternal and fetal radiation exposure. Transesophageal echocardiography is an option for imaging of the thoracic aorta.
- Women should be delivered in a center where cardiothoracic surgery is available.

Class IIa[b]

- Cesarean delivery is reasonable for patients with significant aortic enlargement, dissection, or severe aortic valve regurgitation.

Class IIb[b]

- If progressive aortic dilation and/or advancing aortic valve regurgitation is documented, prophylactic surgery may be considered.

[a]All recommendations are *Level of Evidence C* (very limited populations have been evaluated, and recommendations are based on consensus opinion of experts, case studies, or standard of care).
[b]Class I: Procedure/treatment should be performed/administered; Class IIa: It is reasonable to perform procedure/administer treatment; Class IIb: Procedure/treatment may be considered.
[c]Stage 2 hypertension: blood pressure ≥ 160/100 mm Hg.
Modified from Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. *Circulation*. 2010;121:e266–e369.

surgical repair should be performed with the knowledge of fetal risk during hypothermic circulatory arrest. If the dissection occurs in the third trimester and the fetus is deemed viable, an urgent cesarean delivery followed by aortic surgery may be performed.

Both neuraxial[63,64] and general anesthesia[65] may be safely performed in these patients, with emphasis on meticulous blood pressure stability and control. Invasive blood pressure monitoring is recommended to facilitate tight hemodynamic control. Dural ectasia and scoliosis may complicate neuraxial anesthetic techniques in parturients with Marfan syndrome.[66] The increase in lumbar cerebrospinal fluid volume associated with dural ectasia may cause unpredictable and inadequate spread of intrathecal local anesthetic solutions; thus, it may be prudent to obtain lumbar spine MRI before planned pregnancy.

CONGENITAL HEART DISEASE

Atrial Septal Defect

Patients with an atrial septal defect may remain asymptomatic until the fourth decade of life. Not infrequently, women with an atrial septal defect may become symptomatic during pregnancy. The most common defect is the secundum-type atrial septal defect (80%), whereas the primum, sinus venosus, and coronary sinus types of atrial septal defect are less common. Right ventricular overload leads to pulmonary hypertension and Eisenmenger syndrome in less than 5% of patients with an atrial septal defect. In women with both an atrial septal defect and Eisenmenger syndrome, pregnancy carries a significant risk for both maternal and fetal mortality, and is not recommended.[67,68] In the absence of pulmonary hypertension, pregnancy is overwhelmingly well tolerated in women with an atrial septal defect.

Cardiac complications are similar in women with unrepaired and repaired atrial septal defects. Preeclampsia, fetal demise, and small-for-gestational-age infants are more common in pregnant women with an unrepaired atrial septal defect than in the general obstetric population.[69] Pregnant women with an atrial septal defect are more likely to develop supraventricular and ventricular arrhythmias than women who are not pregnant.[70]

The risk for paradoxical embolism is increased in patients with an unrepaired atrial septal defect. It is critically important to ensure that intravenous catheters are de-aired.[67] Transesophageal echocardiography demonstrates the presence of microbubbles in the right-sided cardiac chambers within 15 seconds of the epidural injection of air or fluid.[71] Therefore, it seems prudent to avoid using the loss-of-resistance-to-air technique to identify the epidural space (see Table 41.2). Both neuraxial and general anesthesia are appropriate for patients with a repaired or unrepaired atrial septal defect.

Ventricular Septal Defect

There are four types of ventricular septal defects; the most common type is a perimembranous ventricular septal defect. Pregnancy is well tolerated in women with a repaired ventricular septal defect or a small ventricular septal defect in the absence of pulmonary hypertension. An unrepaired ventricular septal defect with Eisenmenger syndrome is associated with a high risk for maternal cardiac complications (see later discussion). Pregnancy is not recommended in patients with a ventricular septal defect and Eisenmenger syndrome.[67,68] Preeclampsia is encountered more frequently in women with an unrepaired ventricular septal defect.[72] Echocardiography allows assessment of right-sided pressures and shunt fraction.

Patent Ductus Arteriosus

Pregnancy is well tolerated in patients with patent ductus arteriosus, and complications are rare. A left-to-right shunt may cause pulmonary hypertension. Pregnancy is not recommended in women with patent ductus arteriosus with Eisenmenger syndrome.[67,68]

TABLE 41.2 Anesthetic Considerations for Specific Cardiovascular Pathologic Processes

Disease	Modifier	Anesthetic Considerations	Monitoring
Ascending aortic dilation/aneurysm	Bicuspid aortic valve Marfan syndrome Turner syndrome	Meticulous attention to blood pressure control Maintain beta-adrenergic receptor antagonist therapy Possible dural ectasia (Marfan syndrome) may increase risk for failed spinal anesthesia	Low threshold for invasive blood pressure monitoring
Unrepaired ASD	PAP < 40 mm Hg	Pregnancy/labor usually well tolerated Meticulous attention to de-airing all venous access tubing Consider potential for air embolism with loss-of-resistance-to-air epidural technique	
	PAP ≥ 40 mm Hg	High-risk group Maintain preload Positive-pressure ventilation decreases preload and increases intrathoracic pressure, which is deleterious to RV function	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Repaired ASD	PAP < 40 mm Hg	Pregnancy well tolerated	
	PAP ≥ 40 mm Hg	High-risk group Maintain preload Positive-pressure ventilation decreases preload and increases intrathoracic pressure, which is deleterious to RV function	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring May require pulmonary vasodilators
Unrepaired or repaired VSD	PAP < 40 mm Hg	Pregnancy well tolerated	
	PAP ≥ 40 mm Hg	High-risk group	Invasive blood pressure monitoring Central venous access/filling pressure monitoring May require pulmonary vasodilators
Patent ductus arteriosus		Pregnancy well tolerated	Echocardiographic evaluation to rule out pulmonary hypertension (rare)
Fontan repair		Meticulous attention to preload; low and high preload poorly tolerated Positive-pressure ventilation poorly tolerated because increased intrathoracic pressure impedes venous return	Continuous telemetry monitoring indicated because of high incidence of arrhythmias
Transposition of the great arteries	Complete/repaired	Caution with preload because of propensity for RV dysfunction Meticulous attention to preload in early postpartum period	Low threshold for central venous access/filling pressure monitoring in patients with RV dysfunction Continuous telemetry monitoring indicated because of high incidence of arrhythmias
	Congenitally corrected	Pregnancy well tolerated	Echocardiographic assessment of ventricular function is helpful
Ebstein's anomaly		Pregnancy well tolerated with normal RV function May have associated ASD detected by echocardiography (see above for ASD considerations)	Low threshold for continuous telemetry monitoring because of high incidence of arrhythmias
Tetralogy of Fallot (repaired)		Pregnancy well tolerated	Echocardiographic assessment of RV structure and function and evidence of pulmonary hypertension

TABLE 41.2 Anesthetic Considerations for Specific Cardiovascular Pathologic Processes—cont'd

Disease	Modifier	Anesthetic Considerations	Monitoring
Pulmonary hypertension	Mild-moderate	Attention to preload	Low threshold for central venous access/filling pressure monitoring
	Severe	Very high-risk group Maintain SVR Maintain preload/venous return Prevent/treat pain, hypoxemia, hypercarbia, and acidosis Avoid myocardial depression	Multidisciplinary approach Echocardiography May require pulmonary vasodilators Invasive blood pressure monitoring Central venous access/filling pressure monitoring Caution with pulmonary artery catheterization without fluoroscopic guidance
Aortic stenosis	Transvalvular gradient < 25 mm Hg, valve area > 1.5 cm^2, normal LV function	Neuraxial anesthesia generally well tolerated Attentive preservation of preload and afterload Monitor closely for volume overload during the first 24 hours after delivery	Low threshold for invasive blood pressure monitoring
	Transvalvular gradient ≥ 25 mm Hg, valve area < 1.0 cm^2, LV dysfunction	High-risk group Consider risks/benefits of neuraxial versus general anesthesia Avoid myocardial depressants and vasodilators Meticulously maintain preload and afterload Avoid abrupt decrease in SVR with sympathectomy Maintain sinus rhythm Address new-onset atrial fibrillation (rate control, consider cardioversion) Monitor very closely for volume overload during first 24 hours after delivery	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Mitral stenosis	Valve area > 1.5 cm^2, no pulmonary hypertension	Neuraxial anesthesia generally well tolerated Maintain sinus rhythm and prevent tachycardia Increase in preload not well tolerated Address new-onset atrial fibrillation (rate control, consider cardioversion) Monitor closely for volume overload during first 24 hours after delivery	Low threshold for central venous access/filling pressure monitoring
	Valve area ≤ 1.5 cm^2, pulmonary hypertension	High-risk group Consider percutaneous mitral valvuloplasty before labor/delivery Maintain sinus rhythm and prevent tachycardia Increase in preload not well tolerated Address new-onset atrial fibrillation (rate control, consider cardioversion) Prevent/treat pain, hypoxemia, hypercarbia, and acidosis	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring
Pulmonary stenosis	Mild-moderate	Pregnancy well tolerated	
	Severe	High-risk group Consider balloon valvuloplasty Prevent tachycardia Mitigate increase in pulmonary artery resistance (e.g., hypoxemia, positive-pressure ventilation)	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring

Continued

TABLE 41.2 Anesthetic Considerations for Specific Cardiovascular Pathologic Processes—cont'd

Disease	Modifier	Anesthetic Considerations	Monitoring
Hypertrophic cardiomyopathy	Without LVOT obstruction	Pregnancy well tolerated	
	With LVOT obstruction	Maintain beta-adrenergic receptor antagonist therapy Low preload and low afterload worsen outflow gradient Treat hypotension with phenylephrine Maintain sinus rhythm and prevent tachycardia Address new-onset atrial fibrillation (rate control, consider cardioversion)	Low threshold for invasive blood pressure monitoring and central venous access/filling pressure monitoring Echocardiography helpful to follow outflow tract gradient
Cardiac tamponade		Meticulous attention to preload Maintain spontaneous ventilation Positive-pressure ventilation is deleterious to preload Volatile anesthetic agents depress ventricular function	Invasive blood pressure monitoring Central venous access/filling pressure monitoring

All patients with cardiovascular disease should labor in the lateral position to decrease aortocaval compression. Central venous pressure monitoring should be performed above the diaphragm.
ASD, Atrial septal defect; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *PAP,* pulmonary artery pressure; *RV,* right ventricle; *SVR,* systemic vascular resistance; *VSD,* ventricular septal defect.

Coarctation of the Aorta

Women with repaired coarctation of the aorta tolerate pregnancy well. Systemic arterial hypertension is often observed during labor. The coarctation may be associated with a bicuspid aortic valve in more than half the patients.[73] Prepregnancy evaluation of the coarctation, including the residual degree of obstruction and associated anomalies (e.g., bicuspid aortic valve), is recommended.[67]

Vaginal delivery with neuraxial anesthesia is the preferred mode of delivery; cesarean delivery is reserved for obstetric indications.[74,75] Epidural anesthesia has been successfully administered in a patient with an uncorrected coarctation.[76] One report described the use of remifentanil to control blood pressure during administration of general anesthesia for cesarean delivery.[77]

Fontan Repair

The Fontan repair is a surgical procedure that establishes blood flow from the venous system to the pulmonary artery by bypassing the right ventricle (Fig. 41.1). It can be performed for valvular defects such as tricuspid or pulmonic atresia, or other anomalies with a single ventricle. Because there is no functional right ventricle, blood flow from the periphery to the lungs occurs at *very low* pressure gradients. Owing to the presence of surgical scar tissue in the atrium, patients with a Fontan repair are prone to supraventricular and, less commonly, ventricular arrhythmias.[78,79] The Fontan repair is associated with the highest prevalence of arrhythmias during pregnancy of any congenital heart condition.[37] Deterioration in the NYHA functional status during pregnancy can occur.[79]

Administration of neuraxial analgesia/anesthesia for labor and vaginal delivery[80] and emergency cesarean delivery[81] has been described.[82] Administration of neuraxial anesthesia, with meticulous attention to maintenance of normal intravascular preload, appears to be the preferred anesthetic technique for cesarean delivery. Use of neuraxial anesthesia avoids the adverse effects of myocardial depression and positive-pressure ventilation on the Fontan circulation, which lacks a functioning right ventricle (see Table 41.2).[80,81]

Transposition of the Great Arteries

Transposition of the great arteries comprises two distinct groups: complete transposition of the great arteries (d-transposition) and congenitally corrected transposition of the great arteries (l-transposition). In both conditions, the aorta originates from the right ventricle and the pulmonary artery originates from the left ventricle. Complete transposition of the great arteries manifests as neonatal cyanosis.

Pregnant women born with d-transposition of the great arteries have undergone surgical correction—traditionally an *atrial* switch procedure (Senning or Mustard) or the more contemporary *arterial* switch procedure (Jatene or Rastelli). In the atrial switch procedure, the right ventricle functions as the systemic ventricle. Atrial arrhythmias, right ventricular (systemic ventricle) dysfunction, tricuspid regurgitation (systemic atrioventricular valve), atrial baffle obstruction or leaks, and pulmonary hypertension are some of the long-term complications of the traditional atrial switch surgical repair of d-transposition of the great arteries.[68] The advantage of the Jatene and Rastelli procedures is that the left ventricle functions as the systemic ventricle. However, myocardial ischemia

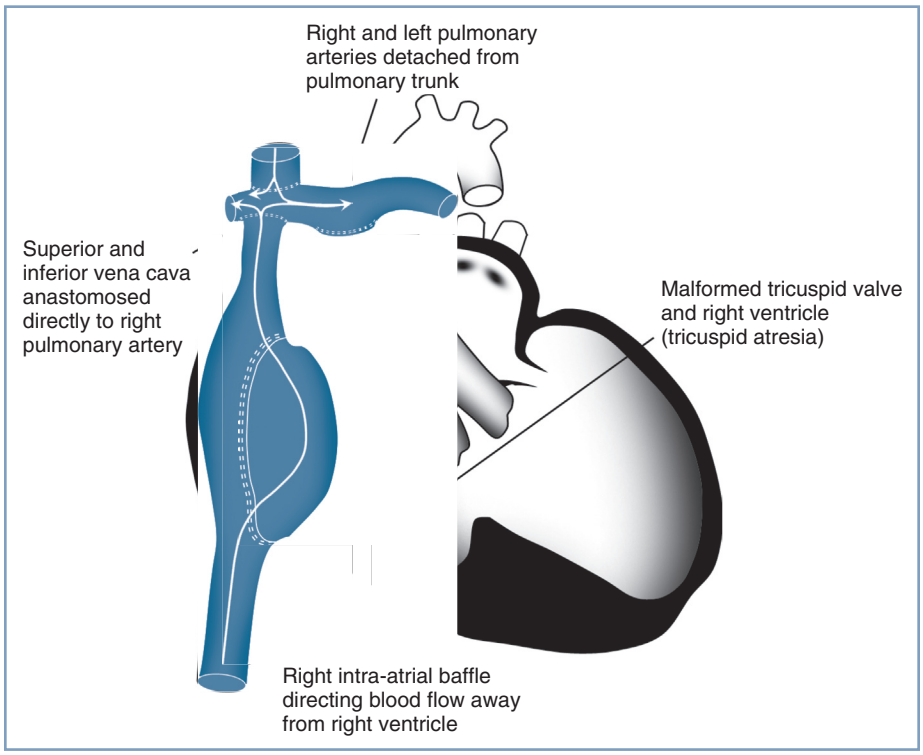

Fig. 41.1 Schematic depiction of a Fontan repair. There is no functional right ventricle. The white lines with arrows represent the pathway of venous blood returning to the heart. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

may occur after arterial switch operations, because the coronary arteries are reimplanted during these procedures.[83]

All women with repaired d-transposition of the great arteries require detailed echocardiography and, ideally, CMR imaging before planned pregnancy.[67,68] Owing to the propensity for arrhythmias in these patients,[37,84] continuous telemetry monitoring during labor and delivery seems appropriate. Women who have undergone the Mustard operation tolerate pregnancy well[85,86]; however, there is a risk for right ventricular dysfunction[84,87] that may be irreversible.[88] The physiologic changes of pregnancy and/or the natural progression of disease result in an increased right ventricular volume in pregnant women who have undergone a Mustard procedure.[85,88] There are limited data about pregnancy in patients who have undergone an arterial switch operation. Overall, pregnancy outcomes after arterial switch operations appear favorable.[89,90]

Patients with congenitally corrected transposition (l-transposition) of the great arteries tolerate pregnancy well.[91–93] Thorough echocardiographic evaluation before and throughout pregnancy is advisable.[67,68,83]

Both neuraxial and general anesthesia appear to be reasonable options for parturients with surgically corrected and congenitally corrected transposition of the great arteries (see Table 41.2). Successful cesarean delivery with general anesthesia has been reported in a parturient with d-transposition of the great arteries corrected with a Jatene procedure.[94]

Ebstein's Anomaly

In Ebstein's anomaly, the tricuspid valve is displaced toward the apex of the right ventricle, which results in severe tricuspid regurgitation and right atrial enlargement (Figs. 41.2 and 41.3). It is commonly associated with an atrial septal defect and preexcitation syndromes. Accessory pathways result in arrhythmias in approximately 30% of patients; the most commonly observed arrhythmias include atrial tachycardia, atrial flutter, and atrial fibrillation. Pregnancy appears to be well tolerated in patients with Ebstein's anomaly, especially in women with preserved ventricular function (see Table 41.2).[68,95,96] Patients with a concomitant atrial septal defect and cyanosis have an increased risk for fetal loss and low infant birth weight.[67]

Tetralogy of Fallot

Unrepaired tetralogy of Fallot consists of a ventricular septal defect, an aorta that overrides the ventricular septal defect, and right ventricular outflow tract obstruction (infundibular, valvular, or both), with resulting right ventricular hypertrophy.[67,69] Most women born with tetralogy of Fallot in the United States now present in pregnancy with surgically repaired tetralogy of Fallot. Unrepaired tetralogy of Fallot is rarely seen in developed countries; pregnancy is associated with significant risk in patients with unrepaired defects and is not recommended.[67,68]

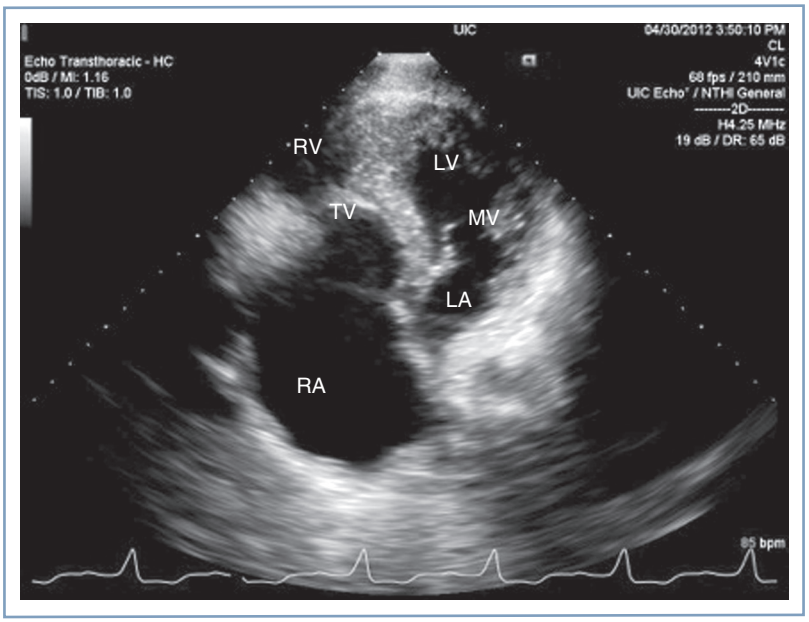

Fig. 41.2 Echocardiographic image of Ebstein's anomaly. Fig. 41.3 Schematic depiction of Ebstein's anomaly and atrial septal defect. An atrial septal defect is present in more than one-third of patients with Ebstein's anomaly. The white lines with arrows represent the pathway of venous blood returning to the heart. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

During surgical repair, the ventricular septal defect is closed and the right ventricular outflow obstruction is repaired. After surgery, important considerations include residual pulmonic valve insufficiency and resulting right ventricular dilation and dysfunction. The preanesthesia evaluation of these patients should include detailed echocardiographic evaluation of cardiac structure and function. Preferably, preconception CMR imaging should be performed because it provides superior imaging of the right-sided chambers. Patients with repaired tetralogy of Fallot are at risk for atrial and ventricular arrhythmias. Sudden cardiac death has been observed late after repair.[97]

Women with repaired tetralogy of Fallot and well-compensated hemodynamic function tolerate pregnancy well (see Table 41.2).[98] However, the presence of pulmonary hypertension, right ventricular dysfunction, right ventricular dilation, and/or pulmonic regurgitation predisposes these patients to adverse peripartum complications such as arrhythmias and right-sided heart failure.[68,98,99]

The safe management of neuraxial analgesia/anesthesia for labor and vaginal or cesarean delivery has been described in parturients with repaired tetralogy of Fallot and a wide range of residual pathologic processes.[100] In patients with unrepaired tetralogy of Fallot or tetralogy of Fallot with residual pathology, the anesthesiologist should avoid a decrease in SVR, which worsens the severity of the right-to-left shunt. It is also important to maintain adequate intravascular volume and venous return. In the presence of right ventricular compromise, high filling pressures are needed to enhance right ventricular performance and ensure adequate pulmonary blood flow. Administration of neuraxial analgesia during early labor (low-dose local anesthetic–opioid epidural

analgesia or opioid-only intrathecal analgesia) may attenuate the surge of catecholamines and subsequent hemodynamic instability. It may be advisable to choose a titratable neuraxial technique for cesarean delivery (epidural or low-dose sequential spinal-epidural anesthesia; see Chapter 26) to avoid the abrupt decrease in SVR associated with single-shot spinal anesthesia.

PULMONARY HYPERTENSION

Box 41.4 outlines the current classification of pulmonary hypertension. Group 1 (pulmonary arterial hypertension or PAH) includes idiopathic pulmonary arterial hypertension. Other clinical conditions associated with Group 1 pulmonary hypertension include connective tissue disease, human immunodeficiency virus (HIV) infection, portal hypertension, drugs/toxins (e.g., selective serotonin reuptake inhibitors, anorectics, methamphetamine, cocaine). The 2013 updated classification lists pulmonary hypertension caused by congenital heart disease in Group 2.[101] Pulmonary hypertension associated with chronic hemolytic anemia (e.g., sickle cell disease) is now listed as Group 5.[101-103]

All of these conditions are associated with exceptionally high maternal mortality. Older studies reported maternal mortality rates as high as 56%[104]; however, more contemporary studies have demonstrated some improvement in maternal mortality, with rates ranging from 16% to 33%.[105] The contemporary Registry of Pregnancy and Cardiac Disease (ROPAC) reported the highest mortality associated with idiopathic PAH (43%) followed by left-heart disease PAH (2.7%) and congenital heart disease PAH (2.7%).[106] Similarly, among 49 women with pulmonary hypertension who gave birth in one of four U.S. institutions between 2001 and 2015, the overall mortality rate was 16%; seven of eight deaths occurred in women with idiopathic PAH (mortality rate 23%). These differences in mortality rates underline the importance of PAH etiology on maternal outcomes. Of note, all deaths in both studies occurred in the postpartum period, most within the first postpartum week.[106] Thus, pregnancy should be discouraged in women with pulmonary hypertension.

Normal mean (± SD) pulmonary artery pressure (PAP) at rest is 14 ± 3 mm Hg (upper limit of normal = 20 mm Hg). Pulmonary arterial hypertension is defined as a mean PAP greater than 25 mm Hg with a *normal* pulmonary artery occlusion pressure (PAOP) (less than or equal to 15 mm Hg) and pulmonary vascular resistance (PVR) greater than 3 Wood[a] units.[102,107] In contrast, in "postcapillary" pulmonary hypertension caused by left-sided heart failure (Group 2), PAOP is *elevated* (greater than 15 mm Hg). Increased PVR results in right ventricular overload, which is followed by right ventricular hypertrophy. Right ventricular hypertrophy progresses to dilation of the right-sided chambers, eventually leading to right ventricular failure and death.[107]

A loud pulmonic heart sound (P2) can be heard on physical examination. The second heart sound is widely split owing to delayed closure of the pulmonic valve resulting from high right-sided pressures (pulmonary valve closes *after* the aortic valve). A right-sided holosystolic murmur of tricuspid regurgitation is frequently appreciated. Palpation of the precordium demonstrates the classic right ventricular heave. The most commonly encountered ECG findings in patients with pulmonary hypertension are right-axis deviation and right ventricular hypertrophy.

Echocardiography helps establish the diagnosis and prognosis of pulmonary hypertension because it demonstrates the degree of right ventricular hypertrophy and allows estimation of PAP by assessing the velocity of the tricuspid regurgitant jet (Fig. 41.4). Echocardiography also allows assessment of right ventricular function.

Echocardiographic assessment of right-sided pressures may be inaccurate; therefore, invasive right-sided—and frequently left-sided—heart catheterization is required for the definitive diagnosis of pulmonary arterial hypertension. Right-sided heart catheterization allows pressure measurements, thermodilution and Fick cardiac output determination, and vasoreactivity testing. Vasoreactivity testing is usually performed with inhaled **nitric oxide** or intravenous infusion of **sodium nitroprusside, epoprostenol,** or **adenosine** in the cardiac catheterization laboratory. Patients who achieve a decrease in mean PAP of 10 mm Hg or more and achieve a mean PAP of 40 mm Hg or less, without a decrease in cardiac output, are "positive acute responders."[102,107] Patients with a positive response have a better prognosis and may respond to oral therapy with a calcium entry–blocking agent.[102]

BOX 41.4 Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
1′. Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
2. Pulmonary hypertension due to left-sided heart disease
   - 2.1. Left ventricular systolic dysfunction
   - 2.2. Left ventricular diastolic dysfunction
   - 2.3. Valvular disease
   - 2.4. Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. Pulmonary hypertension due to lung disease and/or hypoxia
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms

Updated clinical classification of pulmonary hypertension. Modified from Simonneau G, Gatzoulis MA, Adatia I, et al. Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol.* 2013;62:D34–D41.

Eisenmenger Syndrome

In patients with an anatomic shunt between the systemic and pulmonary circulations at the atrial, ventricular, or

[a]Wood unit, unit of measure of vascular resistance (mm Hg • min/L); multiply by 80 to convert to dyne • s • cm^{-5}.

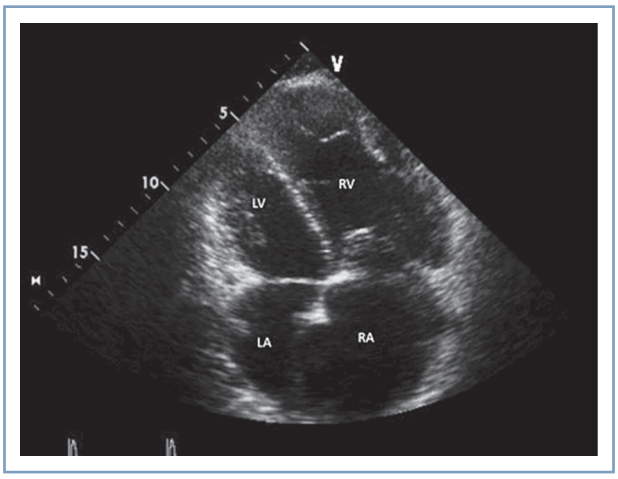

Fig. 41.4 Echocardiographic image of pulmonary hypertension with severe right-chamber enlargement. The RV basal measurement is 55 mm (upper limit of normal 42 mm); the RA minor axis dimension is 70 mm (upper limit of normal 44 mm). *RA,* right atrium; *LA,* left atrium; *RV,* right ventricle; *LV,* left ventricle. (Courtesy of Dr. Mayank Kansal, University of Illinois at Chicago, Chicago, IL.)

aortopulmonary artery level, a left-to-right shunt initially causes increased pulmonary blood flow. Over time, PVR increases and pulmonary hypertension develops. The development of pulmonary hypertension results, at least in part, from endothelial dysfunction and vascular remodeling of the pulmonary vascular bed. This increase in PVR causes reversal of the shunt (from left-to-right to right-to-left), which results in hypoxemia and cyanosis. This anatomic and physiologic scenario is referred to as *Eisenmenger syndrome.*

Maternal mortality in women with Eisenmenger syndrome is exceptionally high (i.e., 30% to 50%), although outcomes appear to have improved in the past two decades.[104,105] The cardiovascular physiologic changes of pregnancy present a significant hemodynamic challenge for women with pulmonary hypertension and may lead to development of right ventricular failure. The peripartum period, with its rapid fluid shifts and increased oxygen demand, is particularly challenging. Death usually occurs peripartum or postpartum. In a systematic review of case reports of pulmonary hypertension associated with congenital heart disease published between 1997 and 2007 ($n = 29$),[105] all eight maternal deaths occurred postpartum (range, 0 to 24 days after delivery).

Women with Eisenmenger syndrome often cannot respond to the increased oxygen demands of pregnancy. The normal pregnancy-related decrease in PVR does not occur because PVR is fixed. In addition, the normal pregnancy-associated decrease in SVR tends to exacerbate the severity of the right-to-left shunt. These changes, together with the normal pregnancy-associated decrease in functional residual capacity, predispose women with Eisenmenger syndrome to hypoxemia. Maternal hypoxemia leads to a high incidence of fetal growth restriction and fetal demise. With contemporary drug therapy, cardiac imaging, and collaborative care, successful pregnancy has been described in patients with Eisenmenger syndrome.[105]

Pulmonary arterial hypertension due to congenital heart disease can be caused by a number of unrepaired congenital heart defects with a left-to-right shunt. Eisenmenger syndrome is associated with ventricular septal defect, atrial septal defect, patent ductus arteriosus, and atrioventricular septal defect (also referred to as endocardial cushion defect). More rarely encountered congenital heart defects (e.g., partial or total anomalous pulmonary venous return, transposition of the great arteries) may also lead to pulmonary arterial hypertension and Eisenmenger syndrome.[67]

Medical and Obstetric Management

Pregnant women with pulmonary hypertension should receive multidisciplinary care in a referral center. Diuretics are frequently needed to manage volume overload in patients with pulmonary arterial hypertension. Diuretics may be particularly helpful in the immediate postpartum period, when uterine contraction and autotransfusion cause an increase in ventricular preload. Dobutamine infusion may help improve right ventricular function. It is unclear whether all of these patients should receive thromboprophylaxis. Both hemorrhage and thromboembolism are causes of maternal mortality.[105]

Therapy for pulmonary arterial hypertension includes general supportive measures, assessment of vasoreactivity, and administration of vasoactive drugs.[107] Inhaled **nitric oxide** selectively dilates the pulmonary vasculature. Case reports have described the successful use of nitric oxide for vaginal and cesarean deliveries in parturients with pulmonary arterial hypertension.[108-110] **Epoprostenol**, **treprostinil**, and **iloprost** are **prostacyclins** used in the treatment of pulmonary hypertension. Successful pregnancy has been described in patients with pulmonary arterial hypertension treated with epoprostenol.[111–114] Similarly, **sildenafil,** a **phosphodiesterase type-5 inhibitor,** has been successfully used in pregnant women with pulmonary arterial hypertension.[115,116] **Endothelin receptor antagonists** (e.g., **bosentan, ambrisentan**) are likely teratogenic, and therefore their use is contraindicated during pregnancy.

The optimal mode of delivery in patients with pulmonary hypertension is unknown. In a systematic review that included reports from 1978 to 1996,[104] operative delivery was an independent risk factor for maternal mortality. In contrast, the mode of delivery was not identified as a risk factor for maternal death in a systematic review that included more recent cases.[105] In a contemporary study, the overall cesarean delivery rate was 54%. Cesarean delivery is associated with larger changes in intravascular volume, more bleeding complications and blood loss, and a greater risk for thromboembolism; therefore, it seems reasonable to reserve cesarean delivery for obstetric indications.

Anesthetic Management

The primary goals of anesthetic management are (1) maintenance of adequate SVR; (2) maintenance of intravascular volume and venous return; (3) avoidance of aortocaval compression; (4) prevention of pain, hypoxemia, hypercarbia,

and acidosis, which may increase PVR; and (5) avoidance of myocardial depression during general anesthesia (see Table 41.2).

Current evidence on choice of anesthetic technique for patients with pulmonary arterial hypertension is based on case reports and series from high-volume referral centers. The use of both general,[114,117] epidural,[118,119] and combined spinal-epidural (CSE) anesthesia has been reported.[120] Neuraxial (epidural and CSE) anesthesia with use of pulmonary vasodilators in highly specialized centers appears to be associated with favorable overall outcomes.[121,122] In published case reports, cautious administration of epidural anesthesia did not affect the shunt flow in parturients with Eisenmenger syndrome. Slowly titrated epidural or combined spinal-epidural anesthesia eliminates the undesirable effects of myocardial depression and positive-pressure ventilation (with its associated decrease in preload) associated with general anesthesia.

Intravascular volume assessment in patients with pulmonary arterial hypertension is of utmost importance. It is likely best achieved with central venous pressure monitoring; pulmonary artery catheterization without the use of fluoroscopy is technically challenging owing to the frequent presence of tricuspid regurgitation and right-sided chamber enlargement in these patients. Pulmonary artery catheterization has not been shown to improve outcome. Both transthoracic and transesophageal echocardiography are very helpful, and invasive blood pressure monitoring is indispensable. Because patients with pulmonary arterial hypertension frequently require systemic anticoagulation, the choice of anesthesia in these patients is best determined by a multidisciplinary team.

Because of its ease of administration, **nitric oxide** can be readily administered in the urgent setting. Nitric oxide has been administered during epidural anesthesia for emergency cesarean delivery using a noninvasive ventilation device.[123] Successful cesarean delivery with inhaled **iloprost** and slowly titrated epidural anesthesia has been reported.[124,125]

Given the high rate of postpartum mortality, patients should be monitored in an intensive care setting for a number of days postpartum.

INFECTIVE ENDOCARDITIS

Endocarditis during pregnancy is rare. It is most frequently associated with intravenous drug use or preexisting structural heart and valve abnormalities (e.g., rheumatic valvular disease, congenital heart disease). Maternal and fetal mortality rates are both high (approximately 15% and 22% respectively).[126]

Antibiotic Prophylaxis

Currently, the ACC, the AHA, and the American College of Obstetricians and Gynecologists (ACOG)[127] do not recommend infective endocarditis antibiotic prophylaxis during vaginal or cesarean delivery in the absence of structural heart disease.[67,128,129] In patients with congenital heart disease and the *highest* risk for adverse outcomes, it is *reasonable* to administer antibiotic prophylaxis against infective endocarditis before *vaginal* delivery at the time of membrane rupture.[67] High-risk patients include those with one or more of the following: (1) a prosthetic cardiac valve or a valve repaired with prosthetic material, (2) unrepaired or palliated cyanotic congenital heart disease, and (3) surgically constructed palliative shunts and conduits (Box 41.5). In patients with one of these high-risk conditions who have an established infection (e.g., chorioamnionitis), the underlying infection should be treated. Additional antibiotics specific to endocarditis prophylaxis are not recommended.[127] Mitral valve prolapse is *not* an indication for antibiotic prophylaxis. It is important to note that the level of evidence for these recommendations is B (data from a single randomized trial or nonrandomized trials). In young women of childbearing age, there is no difference in the rate of prosthetic valve endocarditis with mechanical or bioprosthetic valves.

Diagnosis and Treatment

The diagnosis of endocarditis rests on a very high index of suspicion, physical examination, laboratory findings, and cardiac imaging. The modified Duke criteria are the most widely accepted criteria for the diagnosis of endocarditis (Box 41.6). Patients with endocarditis may have negative blood cultures. Therefore, absence of bacterial growth in blood cultures does not automatically rule out endocarditis.

In addition to systemic antibiotic therapy, valve replacement may be required in pregnant women with endocarditis. Alternatively, successful treatment with aggressive antibiotic therapy has been described.

Neuraxial Anesthesia in Patients with Systemic Infection

The safety of neuraxial anesthesia in patients with systemic infection has been debated for many years (see Chapter 36).[130]

BOX 41.5 High-Risk Cardiac Conditions for Which Antibiotic Endocarditis Prophylaxis for Vaginal Delivery at Time of Membrane Rupture Is Reasonable

- Prosthetic heart valve
- Prosthetic material used for heart valve repair
- History of infective endocarditis
- Unrepaired cyanotic congenital heart disease
- Repaired congenital disease
  - Palliative shunts and/or conduits
  - Prosthetic material or percutaneously inserted devices/material during the first 6 months after the procedure
  - Residual defects in proximity to prosthetic material or percutaneously inserted device
- Cardiac transplantation recipient with valvulopathy

Modified from American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation.* 2007;116:1736–1754.

BOX 41.6 Modified Duke Criteria for the Diagnosis of Bacterial Endocarditis

Major Criteria

- Positive blood culture with typical infective endocarditis microorganism
- Evidence of endocardial involvement with positive echocardiogram

Minor Criteria

- Predisposing factor: known cardiac lesion, recreational drug injection
- Fever > 38°C
- Evidence of embolism: arterial emboli, pulmonary infarcts, Janeway lesions, conjunctival hemorrhage
- Immunologic problems: glomerulonephritis, Osler's nodes
- Positive blood culture (with an atypical microorganism that does not meet a major criterion) or serologic evidence of infection with organism consistent with infective endocarditis but not satisfying a major criterion

The diagnosis of infective endocarditis is confirmed if two major criteria, one major and three minor criteria, or five minor criteria are present.

Modified from Durack DT, Lukes AS, Bright DK. New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings. Duke Endocarditis Service. *Am J Med.* 1994;96:200–209.

Neurologic infectious complications after spinal or epidural anesthesia are rare in large observational series[131]; however, there is general agreement that patients with *untreated* systemic infection should *not* receive neuraxial anesthesia.

Published data and clinical experience suggest that spinal anesthesia may be safely administered in patients who have received antibiotic treatment and are responding to treatment at the time of dural puncture. Similarly, it is likely that epidural anesthesia may be safely administered to patients with treated systemic infection.[130] In patients with endocarditis, bacteremia may seed the epidural space and cause epidural abscess in the absence of neuraxial anesthesia. Similarly, meningitis is a recognized neurologic complication of endocarditis. Therefore, it may be difficult to determine whether the neuraxial procedure contributed to the development of the infection if meningitis or epidural abscess should develop in a patient with endocarditis receiving neuraxial anesthesia.

IMPLANTABLE CARDIAC DEVICES

Permanent and Temporary Pacemakers

Permanent pacemakers implanted before pregnancy are occasionally encountered. Pregnancy and labor and delivery are generally well tolerated in these patients.[132]

Advanced second-degree (two or more nonconducted P waves) or third-degree atrioventricular block is rare in pregnant women and is most commonly seen in patients with congenital heart disease. Recommendations are inconsistent as to whether temporary pacing is required for labor and delivery.[133–137] Some of the principal indications for pacemaker placement (e.g., symptomatic bradycardia, periods of asystole greater than 3 seconds, escape rhythms below the atrioventricular node with rates less than 40 bpm) also appear to be appropriate indications for parturients; the decision to electively place either a temporary or permanent device should be made by a multidisciplinary team. Patients who develop hemodynamic instability caused by bradycardia should receive a temporary venous pacemaker. Transcutaneous pacing is an attractive alternative, but it is uncomfortable for prolonged use. Because the majority of patients requiring temporary pacing have underlying congenital heart disease, it is critically important to understand the cardiac anatomy before placing the venous pacemaker to minimize complications such as perforation or valve injury.

Implantable Cardioverter-Defibrillators

Pacemaker and implantable cardioverter-defibrillator (ICD) implantation during pregnancy may be performed with echocardiographic guidance, thus reducing fetal radiation exposure. A wearable automatic defibrillator is an attractive option for pregnant women, because it may allow ICD implantation to be postponed until after delivery. Subcutaneous ICD placement during pregnancy has been described.[138] The advantage of this approach is that it eliminates the need for fetal radiation exposure.

Women with previously placed ICDs usually tolerate pregnancy and delivery well. Pregnancy does not increase the risk for ICD-related complications, and it does not increase the number of ICD discharges. Rather, the severity of underlying structural heart disease determines the overall complication rate.[139] Case reports suggest that pregnant women tolerate ICD shocks as well as nonpregnant women.[139,140]

Peripartum Management

Pacemakers and ICDs should be interrogated before or during pregnancy, and before and after labor and vaginal or cesarean delivery (Fig. 41.5). The type of device, manufacturer, and model should be documented. The indication for the device, the patient's underlying rhythm, and whether the patient is pacemaker dependent should be identified. Given the complexity of contemporary pacing and ICD devices, it is imperative to perform this evaluation in collaboration with an electrophysiologist or a cardiologist familiar with device management. It is helpful to obtain a 12-lead ECG before and after delivery, and before and after any change in device programming.

The response of the device to magnet placement and removal should be known. It is important to recognize that different devices may respond quite differently to magnet placement. Most pacemakers will pace in an asynchronous mode after application of an external magnet. For most ICDs, the magnet will disable tachycardia detection (i.e., the device will not deliver a shock for ventricular tachycardia or ventricular fibrillation), but the magnet will *not* alter the pacing mode and rate settings. Magnets do *not* change bradycardia pacing settings for ICDs.

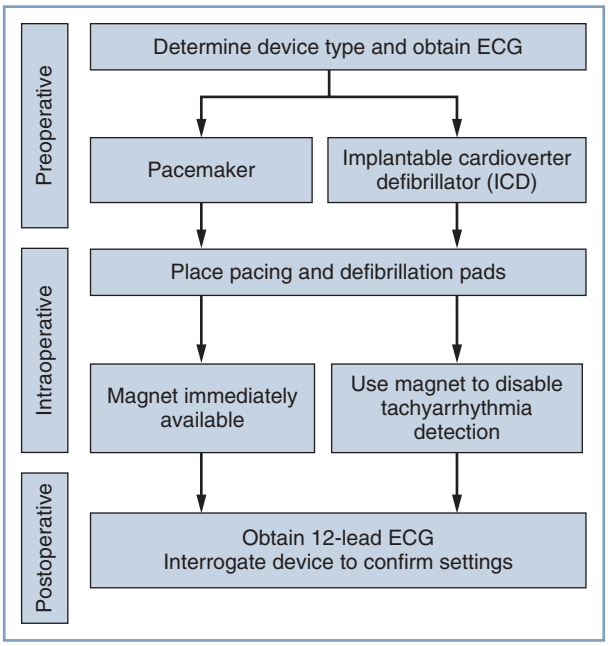

Fig. 41.5 A suggested perioperative approach to the management of implantable cardiac devices during cesarean delivery. *ECG,* electrocardiogram.

Because of the variability of pacemaker design from different manufacturers, and the highly sophisticated programming settings, peripartum device management should be individualized. Management is best planned before labor and delivery using a collaborative approach. For operative obstetric procedures, electromagnetic interference is unlikely given the distance of the site of surgery from the implanted device. Because pacemaker electrical activity can occur without resulting ventricular contraction, monitoring patients with an implantable cardiac device includes continuous ECG *together with* either plethysmography (pulse oximetry) or invasive blood pressure monitoring to ascertain the presence of a pulse.

For all procedures in patients with a pacemaker, a magnet should be immediately available. Immediate availability of external pacing and defibrillation capability is mandatory for all patients regardless of the type of device and urgency of the surgery. For most obstetric surgeries, it is recommended that devices *not* be reprogrammed and that ICDs *not* be deactivated by reprogramming. If deactivation of an ICD is necessary, the patient must remain in a monitored setting with external defibrillation pads placed on the patient until it is confirmed that the ICD has been reactivated. If the ICD is not deactivated by reprogramming, a magnet should be placed over the device intraoperatively to disable tachyarrhythmia detection. Removal of the magnet will restore previous ICD settings.

In patients with a pacemaker or an ICD, central intravenous catheter placement in the upper body needs to be performed with extreme caution so as not to damage or entangle device leads; this is particularly important in leads that were recently inserted (less than 3 months earlier).

ADULT ARRHYTHMIAS

The incidence of arrhythmias is increased during pregnancy in patients with and without structural heart disease. The mechanisms have been attributed to atrial[14] and ventricular stretch[41] caused by increased intravascular volume as well as the increase in resting heart rate. Additionally, autonomic and hormonal changes of pregnancy have been proposed as putative mechanisms.

Palpitations are frequent during pregnancy, and Holter monitoring often reveals premature atrial and ventricular contractions. The frequency of ectopy decreases after delivery. Interestingly, there is no correlation between symptomatic palpitations and frequency of underlying arrhythmias.[141] Therefore, no treatment is needed in asymptomatic patients with **premature atrial contractions** or **premature ventricular contractions.** Substances such as caffeine, alcohol, and cocaine should be discontinued, and treatment with a beta-adrenergic receptor antagonist may be considered in symptomatic patients.

Women who have been diagnosed with an arrhythmia before pregnancy frequently develop an exacerbation of arrhythmia during pregnancy. Recurrence of a preexisting arrhythmia is associated with adverse fetal events.[142]

Supraventricular Arrhythmias

Overall, **supraventricular tachycardia (SVT)** during pregnancy is rare, with an estimated 24 episodes/100,000 pregnancies.[143] It is unclear whether pregnancy increases the risk for new-onset supraventricular tachycardia,[144,145] although the first onset of **paroxysmal supraventricular tachycardia** during pregnancy is unusual. Symptoms of supraventricular tachycardia may be exacerbated during pregnancy.[144]

Premature atrial contractions are frequently encountered during pregnancy. Their frequency generally decreases in the postpartum period.[141] Premature atrial contractions are generally benign and rarely cause significant palpitations. Symptomatic patients can be treated with a low dose of a beta-adrenergic receptor antagonist.

Atrial fibrillation is encountered rarely during pregnancy. Rate and/or rhythm control along with prevention of thromboembolism are the mainstays of treatment of atrial fibrillation. The ventricular rate can be successfully controlled with **digoxin,** a beta-adrenergic receptor antagonist, or a non-dihydropyridine calcium entry–blocking agent.[146] Alternatively, **quinidine**, **sotalol**, **flecainide**, or **amiodarone** may be used to control rapid ventricular response. These drugs also allow for pharmacologic cardioversion of atrial fibrillation. Although restoration of sinus rhythm reduces the risk for thromboembolism and may provide considerable short-term hemodynamic advantages in certain patients, the impact of a rhythm-control treatment strategy on long-term outcome is unclear.

Because atrial fibrillation during pregnancy most frequently results from underlying structural heart disease (rheumatic mitral stenosis or congenital heart disease), systemic anticoagulation during pregnancy is recommended.

There is extensive published experience with the use of unfractionated heparin and warfarin during pregnancy; limited data are available with low-molecular-weight heparin (LMWH).

Use of $CHADS_2$ and CHA_2DS_2-VASc scores facilitates risk stratification for predicting stroke and thromboembolism associated with atrial fibrillation.[146] This risk stratification provides guidance for choice of anticoagulation. In the CHA_2DS_2-VASc score, points are assigned for **C**ongestive heart failure, **H**ypertension, **A**ge 75 years or older (doubled), **D**iabetes mellitus, prior **S**troke or transient ischemic accident or thromboembolism (doubled), **V**ascular disease, **A**ge 65 to 74 years, and female **S**ex. The CHA_2DS_2-VASc score appears to have improved predictive ability in patients with low baseline $CHADS_2$ scores. Nonpregnant patients at low risk for stroke generally receive **aspirin**, whereas those at high risk receive oral anticoagulation with **warfarin** or a newer (direct) oral anticoagulant (e.g., **dabigatran, apixaban, rivaroxaban**). There are case reports of unplanned pregnancy while women were receiving rivaroxaban anticoagulation for venous thromboembolism.[147,148] These reports stress the need to educate women of childbearing age that direct-acting anticoagulants are contraindicated during pregnancy.

Atrial flutter is an organized macro-reentrant arrhythmia rarely seen during pregnancy. The atrial rate is usually 300 bpm; ventricular rate control may be difficult to achieve medically. Electric cardioversion is recommended for unstable patients, although pharmacologic cardioversion with **ibutilide** during pregnancy has been reported.[149]

In a recent report from the ROPAC registry, atrial fibrillation and atrial flutter were found in 1.3% of pregnant patients with structural heart disease. The highest incidence was seen at the end of the second trimester. Both of these arrhythmias were associated with higher maternal mortality and low birth weight.[150]

Atrial tachycardia most frequently results from increased automaticity of atrial cells. Incessant atrial tachycardia has been successfully ablated during pregnancy.

Ventricular preexcitation syndromes (e.g., **Wolff-Parkinson-White syndrome**) are rarely encountered in pregnancy; these patients are usually identified at a younger age and have undergone highly effective electrophysiologic treatment. A few case reports suggest that preexcitation syndromes may be associated with an increased rate of supraventricular arrhythmias during pregnancy.

Ventricular Arrhythmias

Ventricular arrhythmias are commonly associated with underlying structural heart disease. The diagnostic evaluation warrants a baseline ECG and echocardiography. During pregnancy, peripartum cardiomyopathy as cause of ventricular arrhythmias should be ruled out.

Idiopathic ventricular tachycardia is most commonly monomorphic, originating from the right ventricular outflow tract. New-onset idiopathic ventricular tachycardia during pregnancy has been reported in a very small series of patients. These reported arrhythmias were catecholamine sensitive and responsive to beta-adrenergic receptor antagonist therapy.[151] Idiopathic ventricular tachycardia may also be sensitive to treatment with **verapamil**[152] or **isoproterenol.**[153] Polymorphic ventricular tachycardia[154] and electrical storm with **Brugada syndrome**[155] have also been reported during pregnancy.

Sudden cardiac death caused by idiopathic ventricular tachycardia has been described in pregnant women with hypertrophic cardiomyopathy.[156-158] Sustained idiopathic ventricular tachycardia, successfully treated with lidocaine infusion, has been described in patients with repaired tetralogy of Fallot.

Congenital Long QT Syndrome

The congenital long QT syndrome is caused by mutations in cardiac ion channels resulting in prolongation of ventricular repolarization. The clinical spectrum ranges from a lack of symptoms to arrhythmia-associated syncope and sudden cardiac death. Risk for cardiac events (syncope, arrhythmias, or death) is decreased in pregnant women with long QT syndrome, owing at least in part to the increase in heart rate that occurs during pregnancy.[159] Compared with the 40-week prepregnancy period, the 40-week postpartum period has been associated with an increased risk for ventricular tachycardia in women with long QT syndrome.[159] Different long QT syndrome genotypes may have different risks associated with pregnancy. The LQT2 genotype is associated with a higher rate of cardiac events in the 9-month postpartum period than the LQT1 and LQT3 genotypes.[159,160] Prophylactic treatment with a beta-adrenergic receptor antagonist is recommended during pregnancy and postpartum in patients with long QT syndrome.[159,161]

Antiarrhythmic Drugs

The risk for adverse fetal effects of antiarrhythmic drugs should be assessed on an individual basis (see Chapter 14). Beta-adrenergic receptor antagonists, **amiodarone**, and **sotalol** are effective in preventing idiopathic ventricular tachycardia during pregnancy. Fetal exposure to amiodarone has been associated with hypothyroidism and, possibly, fetal growth restriction.[45] Sotalol appears to be safe in pregnancy.[45] Because sotalol is a beta-adrenergic receptor antagonist, its use may be associated with neonatal bradycardia and hypoglycemia.

Electric Cardioversion

Life-threatening or hemodynamically unstable arrhythmias should be terminated by electric cardioversion.[146,161] **Defibrillation** refers to administration of electrical energy to terminate ventricular fibrillation. By contrast, **synchronized cardioversion** is delivery of an electric shock synchronized to the QRS complex. Synchronized cardioversion is administered for supraventricular rhythms (i.e., atrial fibrillation, atrial flutter, atrial tachycardia) as well as for monomorphic ventricular tachycardia with a pulse.[161] Pulseless ventricular tachycardia and polymorphic ventricular tachycardia should be treated with **unsynchronized cardioversion**.

Electric cardioversion can be performed safely throughout pregnancy without apparent adverse effects on fetal hemodynamic function.[162] Nonetheless, it is prudent to monitor the fetal heart rate (FHR) during cardioversion.[163] Current guidelines recommend the use of a biphasic defibrillator. Ventricular fibrillation can be successfully terminated with biphasic devices that use lower energy than is required with monophasic devices. Biphasic automatic external defibrillators (AEDs) are more effective in terminating ventricular fibrillation with lower energy than older monophasic devices.

If hemodynamically significant or severely symptomatic arrhythmias develop during pregnancy, electrophysiologic interventional management may be performed. Successful **radiofrequency catheter-based ablation** has been reported in pregnant women with no or minimal ionizing radiation exposure.

Patients usually require anesthesia care for cardioversion. The risk for pulmonary aspiration of gastric contents associated with sedation (with an unprotected airway) should be weighed against the risks associated with general anesthesia and tracheal intubation. The judicious use of sedation rather than general anesthesia is usually preferred. A benzodiazepine or propofol can provide satisfactory sedation and amnesia. Regardless of whether sedation or general anesthesia is selected, a nonparticulate oral antacid should be administered; administration of a histamine-2 (H_2)-receptor antagonist to increase gastric pH should also be considered. The use of metoclopramide in these patients is controversial owing to its possible association with tachyarrhythmias.

Maintenance of Sinus Rhythm

Development of atrial fibrillation may cause significant hemodynamic compromise, particularly in pregnant women with stenotic valvular lesions (aortic stenosis or mitral stenosis) or hypertrophic cardiomyopathy with its associated diastolic dysfunction. Hemodynamic compromise results from the diminished diastolic filling time and loss of the atrial contraction contribution to ventricular filling. Maintenance of sinus rhythm and strict rate control have *not* been shown to be beneficial in older (nonpregnant) patients with paroxysmal or permanent atrial fibrillation. However, published studies are largely not applicable to pregnant women, and it seems reasonable to maintain sinus rhythm and control heart rate in this population. Rate control is particularly important in patients with stenotic valvular lesions and hypertrophic cardiomyopathy because the hemodynamic condition of these patients may quickly deteriorate in the presence of tachycardia.

MYOCARDIAL INFARCTION

The term *myocardial infarction* signifies myocardial cell death caused by ischemia.[23] Myocardial infarction is diagnosed by clinical signs and symptoms, ECG patterns, elevation of biomarkers (CK-MB fraction, troponin), and various imaging modalities (echocardiography, radionuclide imaging, CMR imaging, CT). The current Universal Classification of Myocardial Infarction recognizes five types of myocardial infarction (Box 41.7).[23]

Myocardial infarction during pregnancy is rare; the estimated incidence is 6.2 to 6.5 per 100,000 deliveries.[164,165] It occurs most commonly in the third trimester or the immediate postpartum period. Myocardial infarction during pregnancy is associated with maternal use of tobacco, dyslipidemia, family history of myocardial infarction, hypertension, African race, Hispanic ethnicity, and diabetes. Using data from the U.S. National Inpatient Sample for 2000 to 2002, James et al.[164] estimated the maternal mortality rate from myocardial infarction during pregnancy at approximately 5%.

Acute coronary syndrome is an encompassing term used to describe unstable angina, non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). Unstable angina is differentiated from NSTEMI by lack of elevation of cardiac biomarkers. Compared with unstable angina or NSTEMI, STEMI is an emergency and requires early reperfusion; a "door-to-balloon" interval of less than 90 minutes is optimal.

Only 40% of pregnant patients with myocardial infarction have evidence of coronary artery atherosclerosis (type I myocardial infarction); spontaneous coronary artery dissection (type II myocardial infarction) is observed in as many as 27% of patients. Angiographically normal coronary arteries are seen in 13% of patients[166]; in these cases, myocardial infarction likely results from coronary artery spasm or embolism.

BOX 41.7 Universal Classification of Myocardial Infarction

Type 1—Spontaneous Myocardial Infarction
Caused by atherosclerosis and plaque rupture/erosion resulting in intracoronary thrombus formation

Type 2—Myocardial Infarction Caused by Ischemic Imbalance
Caused by conditions other than atherosclerosis (e.g., supply-demand mismatch, coronary vasospasm, coronary embolism, coronary dissection, stress of noncardiac surgery)

Type 3—Cardiac Death Caused by Myocardial Infarction
Cardiac death highly suggestive of myocardial infarction without the availability of biomarker confirmation

Type 4a—Myocardial Infarction Related to Percutaneous Coronary Intervention
Caused by distal plaque embolization and side-branch occlusion; directly related to coronary intervention (e.g., stenting or balloon angioplasty)

Type 4b—Myocardial Infarction Caused by Stent Thrombosis
Detected by autopsy or angiography

Type 5—Myocardial Infarction Caused by Coronary Artery Bypass Grafting (CABG)
Cardiac biomarker elevation associated with surgical revascularization procedure

Modified from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. *Circulation.* 2012;60:1581–1598.

Spasm can be spontaneous, or it can be caused by cocaine or ergot alkaloids. Septic and metastatic neoplastic coronary embolism after abortion have been described. Atherosclerosis is more commonly the cause of myocardial infarction in the antepartum period than in the peripartum or postpartum period, whereas **spontaneous coronary artery dissection** is observed more frequently in the peripartum and postpartum periods.[166] It has been hypothesized that the high rate of spontaneous coronary artery dissection is related to hormonal changes of pregnancy. The left anterior descending coronary artery is frequently the culprit vessel, and ST-elevations with reduced ejection fraction are often present. Recurrent spontaneous coronary dissection is common during follow-up.[167,168]

Cesarean delivery is commonly associated with ischemic-appearing ST-segment depression.[169–172] These changes have been attributed, at least in part, to oxytocin administration (see earlier discussion).[12,13] ST-segment elevation is *not* a normal occurrence during labor and delivery or with any type of intrapartum anesthesia. Hence, ST-segment elevation should always be considered abnormal, and ST-segment depression should be carefully evaluated.

CK-MB fraction may be elevated during normal pregnancy and labor (see Fig. 46.1); thus, measurement of this enzyme is less useful for the diagnosis of myocardial infarction in pregnant women than in nonpregnant women.[26] An elevated troponin level is much more specific, although troponin may be elevated in patients with gestational hypertension and preeclampsia/eclampsia.[24,25] Both markers are quite sensitive for the diagnosis of myocardial infarction.

Percutaneous Coronary Intervention

STEMI during pregnancy should be treated with primary percutaneous coronary intervention.[173] Although successfully used in anecdotal reports, use of thrombolytic therapy for STEMI in pregnant women should be reserved for rare instances. Radial arterial access for the percutaneous coronary intervention procedure is preferable because it has fewer bleeding complications and a lower mortality rate than femoral arterial access. Systemic anticoagulation with unfractionated heparin appears most reasonable owing to its short half-life, the availability of activated clotting time (ACT) monitoring, and the ability to rapidly reverse its anticoagulant effect. Importantly, larger doses of heparin are needed to achieve the desired level of anticoagulation in pregnant than in nonpregnant patients. Anticoagulation for percutaneous coronary intervention can be achieved with LMWH, although inability to rapidly assess its anticoagulant effect and its altered pharmacokinetics during pregnancy are disadvantages.

Percutaneous coronary interventions for treatment of myocardial infarction include conventional "plain old balloon angioplasty" and stent placement. An advantage of conventional balloon angioplasty is that it does not require dual antiplatelet therapy; however, placement of a stent is associated with a lower risk for abrupt vessel closure in the short term and a lower long-term risk for restenosis.

Dual antiplatelet therapy is mandatory after placement of a coronary artery stent to prevent stent thrombosis (Table 41.3). This therapy consists of both **aspirin** (81 to 325 mg daily) and **clopidogrel.** Clopidogrel can be substituted with a newer agent (e.g., **prasugrel**, **ticagrelor**) in specific nonpregnant patients. However, the safety and efficacy of these newer antiplatelet agents in pregnancy are unknown.

Stent Type Choice

In patients with a nonacute coronary syndrome (e.g., chronic stable angina), bare-metal stents require a minimum of 1 month of dual antiplatelet therapy, whereas drug-eluting stents require a minimum of 6 months. When either bare-metal stents or drug-eluting stents are placed in a patient with any *acute* coronary syndrome (e.g., unstable angina, NSTEMI, STEMI), 12 months of dual antiplatelet therapy is recommended. The advantage of drug-eluting stents is a decreased risk for in-stent restenosis than occurs with bare-metal stents. Drug-eluting stents elute an antiproliferative agent (e.g., **everolimus, sirolimus, paclitaxel**) into the arterial wall and reduce the neointimal proliferation that causes in-stent restenosis. However, the stent strut endothelialization process is slower with drug-eluting stents than with bare-metal stents; thus, a longer duration of dual antiplatelet therapy is required to prevent stent

TABLE 41.3 Dual Antiplatelet Therapy Recommendations

		PERCUTANEOUS CORONARY INTERVENTION (PCI)			
		Balloon Angioplasty	**Bare-Metal Stent**	**Drug-Eluting Stent[a]**	**Polymer-Free Biolimus A9 Stent**
Stable Coronary Artery Disease	Aspirin	Indefinitely	Indefinitely	Indefinitely	Indefinitely
	Clopidogrel	None	1 month	6 months	1 month
Acute Coronary Syndrome[b]	Aspirin	Indefinitely	Indefinitely	Indefinitely	Indefinitely
	Clopidogrel	12 months	12 months	12 months	12 months
High Bleeding Risk/Pregnancy	Aspirin	Indefinitely	Indefinitely	–[a]	Indefinitely
	Clopidogrel	None	1 month	–[a]	1 month

[a]Given the fact that placement of drug-eluting stents requires prolonged dual antiplatelet therapy, drug-eluting stents are not recommended in pregnant women at high risk for bleeding. However, drug-eluting stent technology is advancing, and in the future, new generation drug-eluting stents may allow for shorter durations of dual antiplatelet therapy.

[b]Acute coronary syndrome includes unstable angina, non–ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction.

thrombosis. Overall rates of death and myocardial infarction are similar with drug-eluting and bare-metal stents. The risk for stent thrombosis may be lower with contemporary drug-eluting stents than with bare-metal stents. Polymer-free biolimus A9 drug-eluting stents allow for 1 month of dual antiplatelet therapy and will likely supplant the use bare-metal stents in patients with high bleeding risk.[174] Polymer-free drug-eluting stents are approved for use outside the United States and are undergoing clinical trials in the United States.

Dual Antiplatelet Therapy

Bare-metal and polymer-free drug-eluting stents[174] allow for discontinuation of dual antiplatelet therapy 1 month after percutaneous coronary intervention, if necessary, even in the setting of acute coronary syndrome (see Table 41.3). This may be advantageous in pregnant women who are at risk for intrapartum and postpartum hemorrhage. Therefore, although prospective clinical trials are not available, most interventional cardiologists will implant a bare-metal stent or a contemporary polymer-free drug-eluting stent in a pregnant woman with acute coronary syndrome.[175] Although it appears reasonable to continue dual antiplatelet therapy as long as feasible in a pregnant woman with acute coronary syndrome, there are few data on the optimal duration of dual antiplatelet therapy in this unique clinical setting. Continuing research is being performed to determine the optimal duration of dual antiplatelet therapy after percutaneous coronary intervention in the nonpregnant population.

It is not advisable to perform neuraxial anesthesia in patients receiving dual antiplatelet therapy.[46] After clopidogrel is discontinued, aspirin should be continued indefinitely in patients with any type of stent. Both spinal and epidural anesthesia can be performed safely in patients receiving aspirin. Clopidogrel should be discontinued 7 days before performance of neuraxial anesthesia.[46]

Aspirin crosses the placenta. A 2002 meta-analysis found no *overall* increase in the risk for congenital malformations when aspirin was administered in the first trimester; however, a twofold increase in the risk for gastroschisis was observed.[176] Another meta-analysis that evaluated the use of aspirin for prevention of preeclampsia found no evidence of increased risk for fetal growth restriction, pregnancy loss, or neonatal hemorrhage.[177] Most evidence suggests that aspirin use is safe during pregnancy.[178]

Coronary Artery Anomalies

Coronary artery anomalies occur in approximately 1% of the general population. Coronary artery anomalies are frequently associated with congenital heart disease such as d-transposition of the great arteries and tetralogy of Fallot.

There are numerous types of coronary anomalies, and most are benign. The two most common clinically significant anomalies are (1) a left main coronary artery that originates from the right coronary cusp and (2) a right coronary artery that originates from the left coronary cusp. External mechanical compression of those anomalous coronary vessels may cause myocardial ischemia and eventually lead to arrhythmias. The resulting ischemia and arrhythmias have been associated with sudden cardiac death. The effect of the physiologic changes of pregnancy in women with coronary artery anomalies has not been well studied.

VALVULAR HEART DISEASE

Pregnancy and its associated changes in cardiovascular physiology present a unique clinical challenge to women with underlying valvular heart disease. The general management principles for pregnant women with valvular heart disease are directed toward specific hemodynamic goals and the need for anticoagulation in patients with a mechanical valve.

Aortic Stenosis

The most common cause of aortic stenosis in pregnant women is a congenital bicuspid aortic valve. Less common causes/types of aortic stenosis include rheumatic, supravalvular, and subvalvular aortic stenosis.[179] Rheumatic aortic stenosis is invariably associated with some degree of mitral valve involvement. The hemodynamic implications of the various causes of aortic stenosis are similar. Calcific aortic stenosis of an anatomically normal tricuspid aortic valve occurs much later in life and is unlikely to be encountered in women of childbearing age.

Bicuspid aortic valve, the most common congenital heart defect, occurs in 0.5% to 2% of the population; women are affected four times less commonly than men. It is heritable; therefore, first-degree relatives of patients with a bicuspid aortic valve should be screened.[57] Bicuspid aortic valve is associated with accelerated and premature valve stenosis as well as aortic valve regurgitation. Symptoms of aortic stenosis (dyspnea on exertion, chest pain, syncope) generally present in the third and fourth decades of life. Importantly, patients with a bicuspid aortic valve have underlying aortic root pathology in the media that is associated with aortic root dilation, thus predisposing to ascending root dissection.[53]

The normal aortic valve area is 3.0 to 4.0 cm^2. There is no pressure gradient across a normal aortic valve with normal resting cardiac output. Patients generally develop symptoms when the valve area is less than 1.0 cm^2 and the pressure gradient across the valve is greater than 40 mm Hg. An aortic valve area less than 1.0 to 1.5 cm^2 and a mean valve gradient of 25 to 50 mm Hg generally define the group of patients with a high risk for cardiovascular complications caused by aortic stenosis.[34,33,36]

Traditional criteria for aortic stenosis included patient symptoms, pressure gradients and flow velocity across the aortic valve, and calculated aortic valve area. The updated valvular aortic stenosis classification takes into account valve anatomy, valve hemodynamic characteristics, structural heart consequences of stenotic valve hemodynamics, and patient symptoms (Table 41.4).[57] It should be noted that this new staging classification has not been evaluated in pregnant patients and will require further study in this particular population. Therefore, the traditional and new nomenclature are used interchangeably in this chapter.

TABLE 41.4 Stages of Valvular Aortic Stenosis

Stage	Definition	Valve Anatomy	Valve Hemodynamics	Hemodynamic Consequences	Symptoms
A	At risk for AS	• Bicuspid aortic valve	• Aortic V_{max} < 2 m/s	• None	• None
B	Progressive AS	• Mild-moderate leaflet calcification • Rheumatic valve changes	• Mild AS, V_{max} 2.0 to 2.9 m/s or mean gradient < 20 mm Hg • Moderate AS, V_{max} 3.0 to 3.9 m/s or mean gradient 20 to 39 mm Hg	• Normal LVEF	• None
C	Asymptomatic severe AS	• Severe leaflet calcification/ severely reduced leaflet opening	• Aortic V_{max} ≥ 4 m/s • Mean gradient ≥ 40 mm Hg • Aortic valve area ≤ 1.0 cm^2	• Mild LV hypertrophy • Normal LVEF • May have reduced LVEF < 50%	• May require exercise testing to confirm symptom status
D	Symptomatic severe high-gradient AS	• Severe leaflet calcification/ severely reduced leaflet opening	• Aortic V_{max} ≥ 4 m/s or mean gradient ≥ 40 mm Hg • Aortic valve area ≤ 1.0 cm^2	• LV hypertrophy • LV diastolic dysfunction • Pulmonary hypertension may be present • May have LVEF < 50%	• Dyspnea • Decreased exercise tolerance • Angina • Syncope/presyncope • Heart failure

AS, Aortic stenosis; *LV,* left ventricle; *LVEF,* left ventricular ejection fraction; V_{max}, maximum aortic velocity.
Modified from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;129:e521–e643.

Classically, the aortic valve area is estimated invasively in the cardiac catheterization laboratory using the Gorlin equation. Forward cardiac output is determined by thermodilution and/or Fick methods, and left ventricular and aortic pressures are simultaneously recorded. Doppler velocity measurements during echocardiography allow noninvasive estimation of aortic valve area using the continuity equation.

Using both methods, the estimated transvalvular *gradient* increases during pregnancy because of the physiologic increase in cardiac output. The calculated valve *area* remains unchanged, however, because both the Gorlin equation and the continuity equation take cardiac output into account. The echocardiographic dimensionless *valve index* is useful in pregnant women as well as other patients; it takes into account both left ventricular outflow velocity and the aortic velocity. Because both velocities are increased during pregnancy, the dimensionless index and estimated valve area remain unchanged during pregnancy.

The severity of aortic stenosis affects maternal risk during pregnancy. *Mild* and *moderate* aortic stenosis (corresponding to stages A and B) are associated with favorable pregnancy outcomes.[179–181] Women with *severe* aortic stenosis (stages C and D) experience frequent cardiac complications during pregnancy (e.g., worsening NYHA functional class, pulmonary edema, congestive heart failure, arrhythmias, hospitalization). The reported rates of these complications during pregnancy vary widely (e.g., heart failure and pulmonary edema 4% to 78%, arrhythmias 2% to 33%, hospitalization rate as high as 78%). Additionally, women with severe disease are more likely to require a cardiac intervention (balloon valvuloplasty, valve replacement) during pregnancy or immediately postpartum. Percutaneous balloon valvuloplasty of the aortic valve is a palliative procedure that allows completion of pregnancy before definitive repair. Mortality is rare with contemporary care.[179,182] Nonetheless, similarly to previously published data, severe aortic stenosis remains associated with significant risk for heart failure, hospitalizations, and low-birth-weight infants.

Successful **transcatheter aortic valve replacement (TAVR)** during pregnancy has been described in a single case report in a symptomatic patient with bicuspid aortic valve.[183] This early successful experience offers an encouraging alternative for treatment of aortic stenosis during pregnancy beyond palliative balloon valvuloplasty.

Obstetric and Anesthetic Management

Labor and assisted vaginal delivery are preferred. Cesarean delivery is reserved for obstetric indications.

Whether general or neuraxial anesthesia is more appropriate for parturients with aortic stenosis has been a matter of debate.[184] Historically, neuraxial anesthesia has been thought to be relatively contraindicated in patients with aortic stenosis; the simultaneous decrease in preload and afterload associated with neuraxial anesthesia may be particularly hazardous in these patients. However, case reports have documented successful administration of neuraxial anesthesia (spinal,[185] continuous spinal,[186] CSE,[184,187] epidural[188]) and

general anesthesia[189,190] with favorable maternal and neonatal outcomes.

The choice between neuraxial and general anesthesia should not be made based on the aortic valve gradient or aortic valve area alone. The preanesthetic assessment should include physical examination, symptom evaluation, and comprehensive assessment of the right and left ventricular structure and function, as well as the structure and function of other cardiac valves. The presence or absence of pulmonary hypertension should also be determined.

Echocardiography offers indispensable information regarding left and right ventricular ejection fraction, left ventricular wall thickness, PAP, presence of aortic insufficiency, mitral valvular structure and function, and aortic root size. Serial assessment of the aortic valve area before and during pregnancy is very helpful in managing these patients. Patients with normal right and left ventricular function are more likely to tolerate fluid shifts and the depressant effects of general anesthetic agents. If left ventricular dysfunction develops in the presence of aortic stenosis, a condition referred to as **low-output, low-gradient aortic stenosis** may be present.

The presence of pulmonary hypertension, right ventricular dysfunction, or mitral regurgitation is associated with greater dependence on preload and may unfavorably affect the hemodynamic response to neuraxial anesthesia. Patients with a dilated aortic root will likely benefit from gradual blood pressure changes, because aortic root dilation has been associated with aortic dissection. Left ventricular hypertrophy, frequently present with aortic stenosis, is associated with significant diastolic dysfunction and may impede left ventricular filling. The presence of left ventricular hypertrophy will render these patients more sensitive to the adverse effects of decreased preload, tachycardia, and the development of congestive heart failure, especially in the setting of acute-onset atrial fibrillation. Aortic regurgitation is quite common in patients with a bicuspid aortic valve. The ventricles are exposed to both pressure and volume overload, further complicating hemodynamic management and response to anesthesia.

The goals of anesthetic management are (1) maintenance of a normal heart rate, sinus rhythm, and adequate systemic vascular resistance; (2) maintenance of intravascular volume and venous return; (3) avoidance of aortocaval compression; and (4) avoidance of myocardial depression during general anesthesia (see Table 41.2). In the absence of prospective randomized trials in this patient population, current clinical evidence suggests that either neuraxial analgesia/anesthesia or general anesthesia is safe for patients with mild or moderate aortic stenosis with normal right and left ventricular ejection fraction and the absence of other significant valvular lesions or pulmonary hypertension. Neuraxial anesthetic techniques that allow gradual titration of anesthesia seem advantageous in these patients.

In patients with severe aortic stenosis, general anesthesia remains the gold standard. Although published reports have described successful administration of neuraxial anesthesia for labor and vaginal and cesarean delivery in women with severe aortic stenosis, the influence of publication bias in these reports cannot be excluded. In contemporary obstetric anesthesiology practice, an opioid-based neuraxial labor analgesia technique, along with alternative forms of analgesia (e.g., pudendal nerve block, intravenous opioids) is well tolerated in parturients with severe aortic stenosis. A slowly dosed, low-concentration local anesthetic epidural technique, or a sequential CSE technique, with careful titration of a vasopressor to prevent the decrease in SVR, may be safely performed with vigilant blood pressure monitoring. The anesthesiologist may choose to avoid use of an epinephrine-containing local anesthetic solution because the unintentional intravenous injection of epinephrine can precipitate tachycardia; further, systemic absorption of epinephrine can diminish SVR and reduce venous return. General anesthesia may be the best choice for cesarean delivery in patients with severe aortic stenosis and other significant valvular lesions, pulmonary hypertension, and/or left ventricular dysfunction. Induction of anesthesia with a combination of etomidate and a moderate dose of a lipid-soluble opioid may be preferable to agents that cause myocardial depression and vasodilation (propofol, thiopental) and tachycardia (ketamine). Anesthesia can be maintained with an opioid and a low-dose volatile anesthetic technique.

Peripartum invasive arterial blood pressure monitoring is recommended for parturients with moderate and severe aortic stenosis. Pulmonary artery catheterization is unlikely to provide much clinical benefit in this patient population. Development of atrial fibrillation with rapid ventricular response is deleterious in these patients because it decreases diastolic filling time and eliminates the atrial component of left ventricular filling. If new-onset atrial fibrillation results in hypotension or pulmonary edema, sinus rhythm should be promptly restored.

Aortic Regurgitation

The most common etiology of chronic aortic regurgitation in pregnant women is a degenerated bicuspid aortic valve; rheumatic aortic regurgitation occurs less frequently. Dilation of the ascending aorta and the resulting aortic leaflet separation may also result in aortic regurgitation. Most commonly, aortic root dilation results from cystic medial necrosis associated with Marfan syndrome, or it occurs in association with a bicuspid aortic valve. Chronic aortic regurgitation is generally well tolerated during pregnancy, especially in patients with preserved left ventricular ejection fraction.[191] The physiologic changes of pregnancy (increased heart rate resulting in a shorter duration of diastole, as well as reduced SVR) contribute to an overall reduction in regurgitant aortic flow.

Although patients with chronic aortic regurgitation can compensate for the hemodynamic stress over time, patients with acute aortic regurgitation are frequently very ill and may require surgery. Endocarditis is the most common etiology of acute aortic regurgitation during pregnancy. Ascending aortic dissection may also result in severe acute aortic regurgitation. Affected patients may require valve replacement during pregnancy.

Anesthetic Management

The goals of anesthetic management are (1) maintenance of a normal to slightly elevated heart rate, (2) prevention of an increase in SVR, (3) avoidance of aortocaval compression, and (4) avoidance of myocardial depression during general anesthesia (see Table 41.2).

Antepartum echocardiography may guide decisions regarding the choice of anesthesia and monitoring. Patients with chronic, compensated aortic insufficiency and normal ejection fraction tolerate the hemodynamic changes of pregnancy well; however, patients with left ventricular dysfunction will likely require careful assessment of volume status and PAP during labor and delivery. Traditionally, a pulmonary artery catheter has been used for this purpose; in the future, transthoracic echocardiography will likely be used.

The degree of aortic insufficiency, concomitant involvement of the mitral valve, and the size of the aortic root help define hemodynamic goals. Patients with a bicuspid aortic valve may have simultaneous aortic stenosis and aortic regurgitation. Both neuraxial analgesia/anesthesia and general anesthesia can be safely performed in patients with aortic regurgitation and preserved left ventricular ejection fraction. Severe aortic insufficiency with left ventricular dysfunction is not a contraindication for neuraxial anesthesia. Initiation of neuraxial analgesia during early labor may mitigate pain-associated increases in SVR that can be deleterious in patients with aortic regurgitation. Intra-aortic balloon pump placement is contraindicated in patients with aortic regurgitation because its use increases regurgitant flow.

Mitral Stenosis

Mitral stenosis frequently becomes symptomatic during pregnancy owing to the increase in maternal blood volume and heart rate. Increased blood volume with decreased diastolic filling time can result in pulmonary edema. Additionally, mitral stenosis predisposes patients to development of atrial tachyarrhythmias (atrial fibrillation, atrial flutter) as well as thromboembolic complications, with or without atrial arrhythmias. The underlying hypercoagulable state of pregnancy also increases the risk for thromboembolic complications in patients with mitral stenosis. Therefore, systemic anticoagulation is recommended for the duration of pregnancy and postpartum.

The etiology of mitral stenosis is almost invariably rheumatic.[192] Severe mitral stenosis (stages C and D) is defined as a valve area less than 1.5 cm^2 (Table 41.5). In addition to valve area, diastolic pressure half-time, presence of pulmonary hypertension, and symptoms define severe mitral stenosis stages.[57] Transmitral valve gradients measured by echocardiography increase during pregnancy.[193] Therefore, while transmitral gradients greater than 5 to 10 mm Hg are usually present in severe mitral stenosis, the dependence of this measure on underlying heart rate and forward flow may limit its usefulness during pregnancy. Similarly, diastolic pressure half-time is affected by the physiologic changes of pregnancy, and its use and interpretation can present a diagnostic challenge.

Poor functional status NYHA (e.g., III to IV) portends a greater risk for adverse outcomes.[194,195] When possible, preconception treatment of symptomatic moderate or severe mitral stenosis is preferred.[36,57] The procedure of choice is percutaneous balloon mitral valvuloplasty. Suitability for percutaneous balloon valvuloplasty is determined by an echocardiography-based scoring system, which takes into account valve calcification and mobility as well as valvular and subvalvular thickening.[196]

TABLE 41.5 Stages of Mitral Stenosis

Stage	Definition	Valve Anatomy	Valve Hemodynamics	Hemodynamic Consequences	Symptoms
A	At risk for MS	Mild valve doming during diastole	• Normal • Mitral valve area > 1.5 cm^2	None	None
B	Progressive MS	Rheumatic valve changes	• Increased transmitral flow velocity • Mitral valve area > 1.5 cm^2 • Diastolic pressure half-time < 150 ms	• Mild-moderate left atrial enlargement • Normal pulmonary artery pressure	None
C	Asymptomatic severe MS	Rheumatic valve changes	• Mitral valve area ≤ 1.5 cm^2 • Diastolic pressure half-time ≥ 150 ms	• Severe left atrial enlargement • Elevated pulmonary artery pressure ≥ 30 mm Hg	None
D	Symptomatic severe MS	Rheumatic valve changes	• Mitral valve area ≤ 1.5 cm^2 • Diastolic pressure half-time ≥ 150 ms	• Severe left atrial enlargement • Elevated pulmonary artery pressure ≥ 30 mm Hg	• Dyspnea • Decreased exercise tolerance

MS, Mitral stenosis.

Modified from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;129:e521–e643.

For patients who require percutaneous valvuloplasty during pregnancy, the procedure is ideally performed after 12 to 14 weeks' gestation to minimize fetal radiation exposure during the period of organogenesis. If the patient can be stabilized with medical management, delaying the procedure to 26 to 30 weeks' gestation will reduce the risk for preterm delivery. Using data from 1990 to 1995, de Souza et al.[197] found that open surgical mitral valve commissurotomy was associated with higher rates of fetal mortality than percutaneous valvuloplasty (38% versus 5%).[197]

Standard medical therapy during pregnancy includes a reduction in activity level (e.g., bed rest), beta-adrenergic receptor antagonist and diuretic therapy, and anticoagulation.

Obstetric and Anesthetic Management

Cesarean delivery is typically reserved for obstetric indications. Vaginal delivery is usually assisted, because the Valsalva maneuver during the second stage of labor may result in a sudden increase in central venous pressure. Regardless of the method of delivery, patients are at risk for both intrapartum and postpartum hemodynamic compromise and pulmonary edema; therefore, these patients usually require postpartum intensive care.[198] The important anesthetic goals are (1) maintenance of a low-normal heart rate and preservation of sinus rhythm; (2) aggressive treatment of atrial fibrillation, if present; (3) avoidance of aortocaval compression; (4) maintenance of venous return; (5) maintenance of adequate SVR; and (6) prevention of pain, hypoxemia, hypercarbia, and acidosis, which may increase PVR (see Table 41.2).

Intrapartum and postpartum invasive hemodynamic monitoring is often helpful, and close peripartum monitoring of filling pressures is important. Echocardiographic assessment of right-sided pressures appears to somewhat overestimate true pressures; therefore, in selected patients with severe mitral stenosis, a pulmonary artery catheter may help guide fluid management. The decision to place a pulmonary artery catheter should be guided by assessment of NYHA functional status, right ventricular function, PAP, and severity of symptoms related to mitral stenosis before pregnancy.

Neuraxial analgesia/anesthesia for labor and vaginal or cesarean delivery can be safely performed in patients with mitral stenosis.[192] Adequate analgesia during the first stage of labor is essential. Intrathecal administration of a lipid-soluble opioid during the first stage of labor provides excellent analgesia without causing sympathetic blockade. Neuraxial administration of an opioid with a small dose of local anesthetic may provide satisfactory analgesia for the second stage of labor. Hypotension should be treated with a direct-acting vasoconstrictor (phenylephrine).

Neuraxial anesthesia for cesarean delivery is best administered with a titratable technique (epidural anesthesia, sequential CSE anesthesia), judicious intravenous fluid administration, and titration of phenylephrine to maintain hemodynamic stability. During induction and maintenance of general anesthesia, tachycardia should be prevented by administration of a beta-adrenergic receptor antagonist and/or an opioid. After delivery, care should be taken with the administration of the uterotonic agent 15-methyl prostaglandin-$F_{2\alpha}$, because it may increase PVR.

Mitral Regurgitation

Mitral regurgitation is generally well tolerated during pregnancy. Nonetheless, some evidence suggests that the volume overload associated with pregnancy may induce unfavorable structural alterations in women with mitral regurgitation.[199] Both neuraxial and general anesthesia are well tolerated. Chronic mitral regurgitation may be associated with left ventricular dysfunction; thus, echocardiographic assessment of left ventricular function helps guide anesthetic and fluid management. The goals of anesthetic management in patients with mitral regurgitation include (1) prevention of an increase in SVR, (2) maintenance of a normal to slightly increased heart rate, (3) maintenance of sinus rhythm, (4) aggressive treatment of acute atrial fibrillation, (5) avoidance of aortocaval compression, (6) maintenance of venous return, (7) prevention of an increase in central venous volume, (8) avoidance of myocardial depression during general anesthesia, and (9) prevention of pain, hypoxemia, hypercarbia, and acidosis, which may increase PVR (see Table 41.2).

Mitral Valve Prolapse Syndrome

Historically, before the contemporary understanding of the complex three-dimensional echocardiographic anatomy of the mitral valve, mitral valve prolapse tended to be overdiagnosed. Currently, the term *mitral valve prolapse* should be restricted to conditions in which the free margin of the anterior, posterior, or both leaflets of the mitral valve is displaced superior to the annular plane of the mitral valve.[200] With these diagnostic criteria, the prevalence of mitral valve prolapse in the general population is 2% to 3%, with no female preponderance.[201] Mitral valve prolapse is a heterogeneous disorder with various causes and associations, including familial and degenerative or myxomatous disorders, Marfan syndrome, Ehlers-Danlos syndrome, a redundant papillary chordal apparatus, and many other diseases.[202] Varying degrees of mitral regurgitation can be associated with this condition. Therefore, along with the history and physical examination, echocardiography plays a central role in the diagnosis, treatment, and ongoing assessment of these patients.

The overall clinical course in patients with mitral valve prolapse is excellent.[203] Pregnancy and vaginal or cesarean delivery with either neuraxial or general anesthesia are well tolerated. Patients with moderate or severe mitral regurgitation and/or depressed left ventricular function are at increased risk for morbidity and mortality.[204] The recommendations for anesthetic management of parturients with mitral regurgitation and/or left ventricular dysfunction also apply to patients with these conditions associated with mitral valve prolapse. Antibiotic endocarditis prophylaxis is not recommended.[128]

Tricuspid Stenosis and Regurgitation

Rheumatic **tricuspid stenosis** is rarely encountered in pregnancy; most frequently, it accompanies rheumatic mitral

stenosis. Clinically, it is associated with dyspnea, pulmonary hypertension, and congestive heart failure. Successful treatment with balloon valvuloplasty has been described.

Tricuspid regurgitation is rarely found in isolation during pregnancy. Functional tricuspid regurgitation is often observed in normal pregnancy with little clinical consequence. Severe tricuspid regurgitation is often associated with congenital heart disease such as Ebstein's anomaly. Overall, pregnancy is well tolerated in the presence of tricuspid regurgitation; patients may be susceptible to hypotension with a decrease in preload.[57]

Pulmonic Stenosis and Regurgitation

Pregnancy is well tolerated in patients with **pulmonic stenosis,** and isolated pulmonic stenosis has not been found to affect maternal and fetal outcomes[205] (see Table 41.2). In a small series of cases, affected patients had normal right ventricular function and only mild symptoms on initial presentation.[205] Nonetheless, valvuloplasty is recommended in asymptomatic nonpregnant patients with pulmonic stenosis and a transpulmonic valve gradient greater than 40 mm Hg and in symptomatic nonpregnant patients with a gradient greater than 30 mm Hg.[57]

Pulmonic regurgitation occurs infrequently as an isolated valvular lesion; it is most commonly associated with congenital heart disease, such as repaired tetralogy of Fallot[99] or repaired pulmonic stenosis. Physiologic pulmonic regurgitation is commonly seen during pregnancy.[206] Overall, pregnancy and labor are well tolerated in the presence of mild or moderate pulmonic regurgitation; however, severe pulmonic regurgitation is highly associated with maternal cardiac events during pregnancy.[207,208] Right-sided heart failure caused by pulmonic regurgitation occurs more commonly in patients with multiple gestation, pulmonary artery stenosis distal to the left and right pulmonary arteries, preexisting right ventricular systolic dysfunction, and/or right ventricular hypertrophy.[208]

Prosthetic Heart Valves

Bioprosthetic Valves

In a 2015 systematic review of 11 studies capturing 499 pregnancies (1995 to 2014), the estimated maternal mortality rate in women with prosthetic heart valves was 1.2/100 pregnancies (95% CI, 0.5 to 2.2).[209] The study was too small to determine if the mortality rate differed between mechanical and bioprosthetic valves. The advantage of bioprosthetic valves is that long-term systemic anticoagulation is not required and the risk for thromboembolic events in pregnancy is lower than for mechanical values.[209] However, bioprosthetic values incur a higher and earlier risk for valve deterioration requiring replacement.[210] It is unclear whether pregnancy accelerates bioprosthetic valve structural degeneration; studies report inconsistent results. The 15-year incidence of bioprosthetic valve replacement is 50% for patients 20 years of age.[210] Thus, although a bioprosthetic valve simplifies the required anticoagulant regimen during pregnancy, it may expose the mother to a high risk for reoperation and associated operative mortality. Current guidelines from the AHA/ACC suggest that a mechanical valve is a reasonable choice for patients less than 50 years of age unless anticoagulation is contraindicated or not desired (e.g., in women who desire childbirth).[210] Thus, the choice of valve prosthesis type must balance the benefits and risks for individual patients.

Anticoagulation for Patients with a Mechanical Valve

All patients with a mechanical valve require systemic anticoagulation. Mechanical valves have a higher risk for thromboembolism than bioprosthetic valves. Valves in the mitral position have a higher risk for thromboembolism than valves in the aortic position. A higher risk for mechanical valve thromboembolic complications has been observed during pregnancy.[211] No large prospective randomized trials have examined the use of various anticoagulation strategies for pregnant women with a mechanical valve. Additionally, newer prosthetic valve designs may have a lower risk for thromboembolism than older models. The current anticoagulation recommendations are based on expert consensus guidelines from three major professional organizations: the ACC/AHA,[57] the American College of Chest Physicians (ACCP),[178,212] and the European Society of Cardiology (ESC).[36] Differences among these guidelines are summarized in Table 41.6.

Warfarin. In patients with a mechanical valve, anticoagulation with warfarin is associated with lower rates of thromboembolic complications and maternal death compared with unfractionated heparin or LMWH.[213] However, warfarin crosses the placenta. The use of warfarin between 6 and 12 weeks' gestation has been associated with embryopathy, and the use of warfarin at any time during pregnancy has been associated with fetal wasting, central nervous system abnormalities, and fetal hemorrhagic complications.[178] Thus, there has been significant controversy about its use during pregnancy, particularly during the period of organogenesis, and previous guidelines have recommended substitution with unfractionated heparin or LMWH during this period. However, because of warfarin's superior effectiveness in preventing thromboembolism compared with unfractionated heparin or LMWH, and a dose-dependent risk for embryopathy, the current guidelines state that after careful counseling about risks and benefits, women may continue warfarin during the first trimester if they can achieve a therapeutic international normalized ratio (INR) goal with daily doses less than 5 mg.[36,57]

Warfarin anticoagulation effect is monitored by periodic assessment of the INR. Low-dose aspirin may be safely administered in addition to warfarin in the second and third trimester. Warfarin should be discontinued before delivery; in patients with a mechanical heart valve, heparin must be substituted.

Warfarin anticoagulation should be stopped for 5 days and the INR measured immediately before administration of a neuraxial block (see Chapter 38).[46] Concurrent administration of other anticoagulants or antiplatelet agents increases the risk for bleeding complications. After delivery, patients with a mechanical valve typically require bridging to warfarin;

TABLE 41.6 Major Professional Society Guidelines for Anticoagulation in Pregnant Patients with Mechanical Valve(s)

	American College of Cardiology/ American Heart Association[a]	European Society of Cardiology[b]	American College of Chest Physicians[c]
Warfarin	Continuation of warfarin during first trimester (dose < 5 mg daily) after discussion of risks and benefits with patient	May consider continuing low-dose warfarin (< 5 mg daily) throughout pregnancy with informed patient consent	UFH or LMWH until 13 weeks' gestation, then warfarin In high-risk patients (older-generation valves in mitral position, previous thromboembolism), continue warfarin throughout pregnancy
INR goal	Aortic valve: 2.5 (range 2.0–3.0) Mitral valve: 3.0 (range, 2.5–3.5)	2.5–4.0[d] 2.5–4.0[d]	Aortic valve: 2.5 (range, 2.0–3.0) Mitral valve: 3.0 (range, 2.5–3.5)
Unfractionated heparin	Continuous infusion during first trimester if warfarin dose needed to achieve therapeutic INR > 5 mg daily	In high-risk patients, continuous infusion	Subcutaneous administration twice daily
aPTT goal	aPTT twice control value	aPTT 4–6 h after subcutaneous injection: twice control value	Mid-interval aPTT (6 h after injection): twice control or anti–factor Xa level of 0.35–0.70 U/mL
Low-molecular-weight heparin	Subcutaneous administration at least twice daily during first trimester if warfarin dose needed to achieve therapeutic INR > 5 mg daily	Subcutaneous administration twice daily	May give adjusted dose of LMWH throughout pregnancy, twice daily
Anti–factor Xa level goal	Maintain peak level 0.8–1.2 U/mL 4–6 h after administration	Maintain peak level 0.8–1.2 U/mL 4–6 h after administration	Maintain manufacturer's recommended peak level (approximately 1.0 U/mL) 4 h after administration
Aspirin	Low-dose aspirin (75–100 mg daily) recommended in second and third trimesters in addition to warfarin or heparin (both bioprosthesis or mechanical prosthesis)	Not recommended	Low-dose aspirin (75–100 mg daily) added to thromboprophylactic regimen for patients with valves at high risk for thromboembolism
Peripartum[e]	Discontinue warfarin before planned delivery, and start continuous intravenous UFH	Discontinue warfarin at 36 weeks' gestation, and start dose-adjusted UFH or LMWH. Replace LMWH at least 36 h before planned delivery, and substitute with UFH. Discontinue UFH 4–6 h before planned delivery	Discontinue warfarin close to delivery; replace with UFH or LMWH

aPTT, Activated partial thromboplastin time; *INR,* international normalized ratio; *LMWH,* low-molecular-weight heparin; *UFH,* unfractionated heparin.

[d]Specific goal dependent on patient risk factors and prothesis thrombogenicity.

[e]For resumption of anticoagulation in the postoperative period, the 2018 American Society of Regional Anesthesia and Pain Medicine Practice Advisory[46] recommends the following: (1) Warfarin: The indwelling neuraxial catheter should be removed when the INR is less than 1.5, 12 to 24 hours after last warfarin administration. (2) UFH: The indwelling neuraxial catheter should be removed 4 to 6 hours after the last dose of UFH, after checking the patient's coagulation status (aPTT). The next dose of UFH should not be given until at least 1 hour has elapsed after removal of the catheter. (3) LMWH: The first therapeutic dose should not be administered until 24 hours after the initiation of the neuraxial procedure. The U.S. Food and Drug Administration recommends waiting at least 4 hours after removal of a neuraxial catheter before administering a postprocedure dose of LMWH. (U.S. Food and Drug Administration. Drug Safety Communication—Updated Recommendations to Decrease Risk of Spinal Column Bleeding and Paralysis in Patients on Low Molecular Weight Heparins. November 6, 2013. https://www.fda.gov/drugs/drugsafety/ucm373595.htm. Accessed January 2018.)

the type of anesthesia and timing of neuraxial catheter removal may significantly affect the timing of anticoagulation after delivery.[46,47]

Unfractionated heparin. Unfractionated heparin does not cross the placenta and therefore may be safer for the fetus than warfarin. However, use of unfractionated heparin in the first trimester and close to term has been associated with an increased risk for valve thrombosis.[57,213] Unfractionated heparin can be administered subcutaneously or preferably as a continuous intravenous infusion. Its therapeutic efficacy is monitored with the activated partial thromboplastin time (aPTT). Heparin requirements are higher during pregnancy caused by underlying physiologic changes (e.g., increased levels of heparin-binding proteins, factor VIII, fibrinogen). The incidence of heparin-induced thrombocytopenia is three times higher in women than in men.

Intravenous unfractionated heparin should be discontinued 4 to 6 hours before administration of a neuraxial anesthetic technique or anticipated delivery (see Table 38.3).[46] The aPTT should be determined to verify normalization of coagulation function, and a platelet count should be checked to rule out heparin-induced thrombocytopenia. An indwelling neuraxial catheter can be removed 4 to 6 hours after the last dose of unfractionated heparin. Unfractionated heparin can be restarted 1 hour after removal of a neuraxial catheter.

Low-molecular-weight heparin. LMWH does not cross the placenta and is administered subcutaneously for most indications. The pharmacokinetics of LMWH are altered in pregnancy. Use of LMWH for thromboprophylaxis during pregnancy has been associated with mechanical valve thrombosis.[214–217] The efficacy of LMWH can be monitored with anti–factor Xa levels. *Peak* anti–factor Xa levels should be checked 4 to 6 hours after LMWH administration in pregnant women with a mechanical valve. Importantly, in pregnant women with a mechanical valve, the required doses of LMWH are considered *therapeutic* and are therefore higher than those required for deep vein thrombosis prophylaxis. In the absence of anti–factor Xa monitoring, therapeutic use of LMWH in pregnant women with a mechanical valve is not advisable.[36]

A neuraxial block should not be performed until at least 24 hours have elapsed after the last therapeutic dose of LMWH (see Table 38.3). Anti–factor Xa levels do not predict the risk for bleeding. Other anticoagulants or antiplatelet agents coadministered with LMWH increase the risk for bleeding complications. After delivery, therapeutic LMWH should *not* be administered until at least 24 hours have elapsed after performance of the neuraxial block procedure (see Chapter 38).[46] After removal of a neuraxial catheter, at least 4 hours should elapse before administration of the next dose of LMWH.

Newer anticoagulants. The use of oral **direct thrombin inhibitors (dabigatran)** or oral **anti–factor Xa inhibitors (apixaban, rivaroxaban)** is *contraindicated* in patients with mechanical heart valves.

There are no published reports of the administration of **bivalirudin** during pregnancy; the use of **argatroban** during pregnancy has been described.[218] The current ASRA guidelines recommend against neuraxial anesthesia administration in patients receiving bivalrudin or argatroban.[46]

Neuraxial anesthesia in patients with a mechanical valve. No published observational or prospective randomized trials have investigated the use of neuraxial anesthetic techniques in patients with a mechanical heart valve who require systemic anticoagulation. Therefore, current clinical practice is guided by consensus guidelines.[46,47,219,220] Systemic anticoagulation may affect the choice and timing of anesthesia, and the neuraxial anesthetic technique and timing of catheter removal may influence the choice and timing of resumption of systemic anticoagulation after vaginal or cesarean delivery. Therapeutic anticoagulation is usually not resumed for at least 12 hours *after* delivery. The choice and timing of the anesthetic technique should be developed in discussion with the patient, the cardiologist, and the obstetrician, with consideration of consensus guidelines (see Table 38.3).

CARDIOMYOPATHIES

Heart Failure Nomenclature

Accurate description of patients with heart failure is important for diagnostic, therapeutic, and prognostic purposes. It is helpful to broadly describe symptoms of heart *failure* as **new-onset (acute)** or **chronic. Acute-on-chronic** heart failure describes patients with worsening symptoms after an earlier diagnosis of heart failure.

Heart failure can be separated into **left sided** (predominantly pulmonary congestion and pulmonary edema) and **right sided** (predominantly peripheral edema). **Biventricular** heart failure describes symptoms that result from both right and left ventricular involvement.

Assessment of ventricular function allows for differentiation between **systolic** and **diastolic** heart *dysfunction*. Arbitrarily, left ventricular dysfunction is defined by a left ventricular ejection fraction less than 45% to 50%.

Left ventricular systolic or diastolic dysfunction are *not* synonymous with left- or right-sided heart failure. Therefore, **heart failure with reduced ejection fraction (HFrEF)** and **heart failure with preserved ejection fraction (HFpEF)** are currently the preferred terms used to describe these clinical conditions.[32]

The NYHA classification describes patients' *functional status* (see Box 41.1), and the functional status can change over time. In contrast, the *staging classification* of heart failure recognizes that heart failure is a progressive condition and may manifest as variable symptoms over time.[32,221] Both classifications remain highly useful in clinical practice.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a unique cardiomyopathy of unknown cause that occurs during pregnancy or the postpartum period.[222,223] The *timing* of development of heart failure is important to help exclude other causes of heart failure. To make the diagnosis of peripartum cardiomyopathy, the development of heart failure should occur in the last month

of pregnancy or within 5 months of delivery (Box 41.8).[223] Other identifiable causes of heart failure should be excluded, and the absence of other recognizable cardiac disease before the last month of pregnancy should be verified. Echocardiographic diagnostic criteria include (1) left ventricular ejection fraction less than 45% (and/or M-mode fractional shortening less than 30%) and (2) end-diastolic left ventricular dimension greater than 27 mm/m^2 body surface area.[224] Some women develop cardiomyopathy before the last month of pregnancy. This condition is referred to as *pregnancy-associated cardiomyopathy*. Its clinical signs, symptoms, and outcomes are similar to those for peripartum cardiomyopathy.[225]

BOX 41.8 Diagnostic Criteria for Peripartum Cardiomyopathy

Traditional Criteria

- Onset of heart failure during the last month of pregnancy or within 5 months of delivery
- No other identifiable cause of heart failure
- No known heart disease before pregnancy

Echocardiographic Criteria

- Left ventricular ejection fraction < 45%
- Fractional shortening < 30%
- Left ventricular end-diastolic dimension ≥ 27 mm/m^2

Modified from Pearson GD, Veille JC, Rahimtoola S, et al. Peripartum cardiomyopathy: National Heart, Lung, and Blood Institute and Office of Rare Diseases (National Institutes of Health) workshop recommendations and review. *JAMA*. 2000;283:1183–1188; Hibbard JU, Lindheimer M, Lang RM. A modified definition for peripartum cardiomyopathy and prognosis based on echocardiography. *Obstet Gynecol*. 1999;94:311–316.

The incidence of peripartum cardiomyopathy varies around the world and has been reported to be as high as 1 in 300 live births in Haiti[226] and 1 in 3000 to 4000 live births in the United States.[227,228] The cause(s) for such regional variation are unclear. Risk factors for peripartum cardiomyopathy include African race, multiparity, multiple gestation, preeclampsia, gestational hypertension, use of tocolytic agents, cocaine abuse, and age older than 30 years.[229] A possible genetic component has been identified, with overlap between genetic mutations linked to dilated cardiomyopathy and peripartum cardiomyopathy.[229]

The etiology of this relatively rare condition remains unclear; several possible causes have been proposed, including underlying myocarditis, apoptosis, inflammation, pathologic maternal immune response to fetal antigens, effects of prolactin, viral triggers, and hereditary/familial factors.[230]

Patients with peripartum cardiomyopathy have typical signs and symptoms of systolic heart failure. On clinical examination, the apical impulse is displaced laterally and an S3 gallop is appreciated. Because of left ventricular enlargement (Fig. 41.6) and changes in ventricular cavity geometry, functional mitral regurgitation is frequently seen. Peripartum cardiomyopathy is a diagnosis of exclusion, and the symptoms may be disguised as physiologic changes of pregnancy; thus, the use of echocardiography helps confirm the diagnosis. Right-sided heart pressures can almost always be assessed by echocardiography; hence, right-sided heart catheterization is rarely necessary. Left-sided heart catheterization may be necessary to assess the coronary arteries. However, given that the risk for ischemic cardiomyopathy in pregnancy is very low, and because coronary angiography results in fetal radiation exposure, left-sided heart catheterization is infrequently used to make the diagnosis. Ischemic cardiomyopathy is

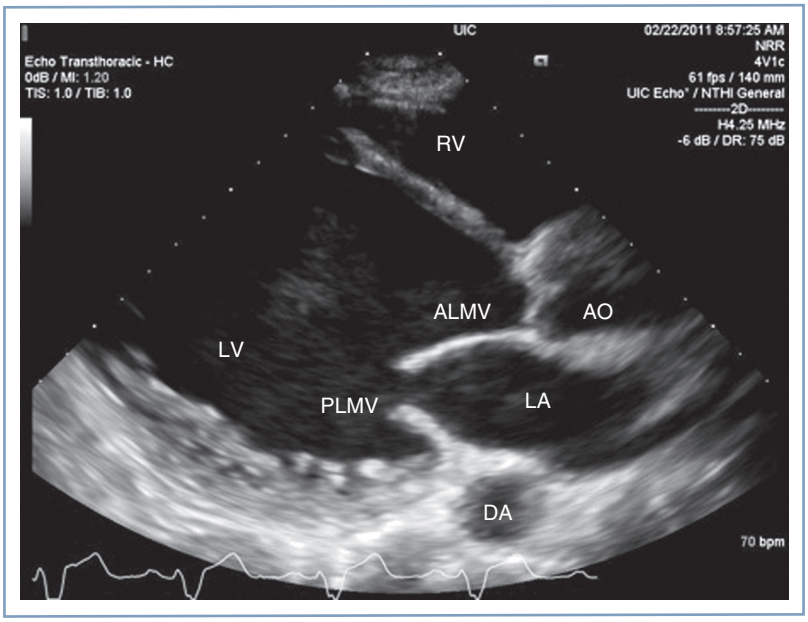

Fig. 41.6 Echocardiographic image of dilated cardiomyopathy. *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle; *ALMV,* anterior leaflet of the mitral valve; *PLMV,* posterior leaflet of the mitral valve; *AO,* aorta; *DA,* descending aorta. typically accompanied by regional wall motion abnormalities, whereas peripartum or nonischemic cardiomyopathy typically results in a global decrease in contractility.

Medical management of peripartum cardiomyopathy rests on basic treatment paradigms for congestive heart failure and dilated cardiomyopathy (see later discussion). The all-cause 5-year survival rate of peripartum cardiomyopathy in the United States is greater than 95%.[227,228] African American women are almost three times more likely to die of peripartum cardiomyopathy than white women.[228]

The risk associated with subsequent pregnancy is substantially higher in women who do not recover normal left ventricular function.[231] In a series of 44 women with peripartum cardiomyopathy, the maternal mortality rate in subsequent pregnancies was 19% in women with persistent left ventricular dysfunction compared with 0% in women without residual dysfunction.[231] Therefore, subsequent pregnancy should be discouraged if left ventricular function has not recovered. Even in patients with normalized left ventricular function, careful counseling is advised owing to a significant risk for recurrence of left ventricular dysfunction in a subsequent pregnancy.[36]

Obstetric and Anesthetic Management

Obstetric management involves expedient delivery after stabilization of the mother; in most cases, cesarean delivery is reserved for obstetric indications. Continuous spinal anesthesia[232] and CSE anesthesia[233,234] have been safely administered in patients with severe peripartum cardiomyopathy. Given the intravascular fluid shifts associated with labor, delivery, and the immediate postpartum period, invasive blood pressure and central venous pressure monitoring are recommended. Neuraxial anesthesia appears ideally suited for these patients because it results in a beneficial decrease in both preload and afterload. Particular attention should be paid to the immediate postpartum period when autotransfusion combined with the regression of neuraxial anesthesia may cause worsening of heart failure.

Other Nonischemic Cardiomyopathies

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is relatively common, with a prevalence estimated at 1 in 500. It is an autosomal dominant disorder associated with various forms of left ventricular hypertrophy; the risk that an affected patient will transmit the disease to offspring is 50%. Additionally, hypertrophic cardiomyopathy mutations are highly penetrant. Preconception genetic counseling is recommended.[156]

The complications that result from hypertrophic cardiomyopathy can be separated into two categories: mechanical and electrophysiologic. The mechanical consequences relate to left ventricular outflow tract obstruction, mitral regurgitation, diastolic dysfunction, and development of heart failure. The electrophysiologic complications include atrial and ventricular arrhythmias and, most important, the risk for sudden cardiac death. The myocardial ischemia observed in patients with hypertrophic cardiomyopathy, often at ages younger than expected, is caused by supply-demand mismatch rather than coronary atherosclerosis. Hypertrophic cardiomyopathy is associated with disorganized myocardial architecture, myocardial disarray, and fibrosis (Fig. 41.7).

One of the hallmarks of hypertrophic cardiomyopathy is the dynamic left ventricular outflow tract obstruction. The obstruction gradient typically increases after a premature ventricular contraction. One-third of patients have left ventricular outflow tract obstruction at rest, one-third have a physiologically provocable gradient, and one-third have no gradient (nonobstructive form of hypertrophic cardiomyopathy). A gradient of 30 mm Hg or more is clinically significant.[235]

Pregnant women with hypertrophic cardiomyopathy may have dyspnea, fatigue, angina, palpitations, and/or syncope. Symptoms of congestive heart failure are rarely seen in patients in sinus rhythm; these symptoms are more frequently encountered when atrial fibrillation is present.

On physical examination, the classic obstructive systolic murmur is heard at the apex (grade 3/6 to 4/6), and it radiates to the left sternal border. Although most patients will have a displaced and forceful left ventricular impulse, the presence of a murmur depends on the degree and type of obstruction. The intensity of a hypertrophic cardiomyopathy murmur increases with the Valsalva maneuver or standing (decreased preload or afterload causes more obstruction), and it decreases with squatting (increased afterload causes less obstruction). Invasive arterial pressure monitoring allows recognition of a *bifid* arterial pulse waveform.

The ECG is abnormal in the vast majority of patients and demonstrates an increase in voltage, T-wave inversions, and pathologic Q waves. ECG abnormalities correlate poorly with the severity of hypertrophic cardiomyopathy.[157] Transthoracic echocardiography is indispensable for making the diagnosis, determining prognosis, and guiding management decisions.[156] Diagnostic criteria include a septal thickness greater than 15 mm, although it should be emphasized that individuals may carry the genotype without evidence of increased wall thickness (so-called "subclinical hypertrophic cardiomyopathy").[156] Systolic anterior motion of the mitral valve has a specificity of 98% for hypertrophic cardiomyopathy. Left ventricular outflow tract obstruction is apparent during Doppler interrogation; the continuous wave tracing has a classic "dagger-shaped" contour (Fig. 41.8). In addition, echocardiography allows identification of various morphologic variants and assessment of the extent of hypertrophy. A wall thickness of 30 mm or greater is associated with a high risk for sudden cardiac death.[236] Patients with a gradient of 50 mm Hg or greater are at highest risk for complications.[156]

Fortuitously, the increase in blood volume allows most patients with hypertrophic cardiomyopathy to tolerate pregnancy well.[158] Both asymptomatic and symptomatic women with hypertrophic cardiomyopathy should continue taking a beta-adrenergic receptor antagonist throughout pregnancy and the peripartum period.[156]

Patients with hypertrophic cardiomyopathy are at increased risk for developing atrial fibrillation. Treatment

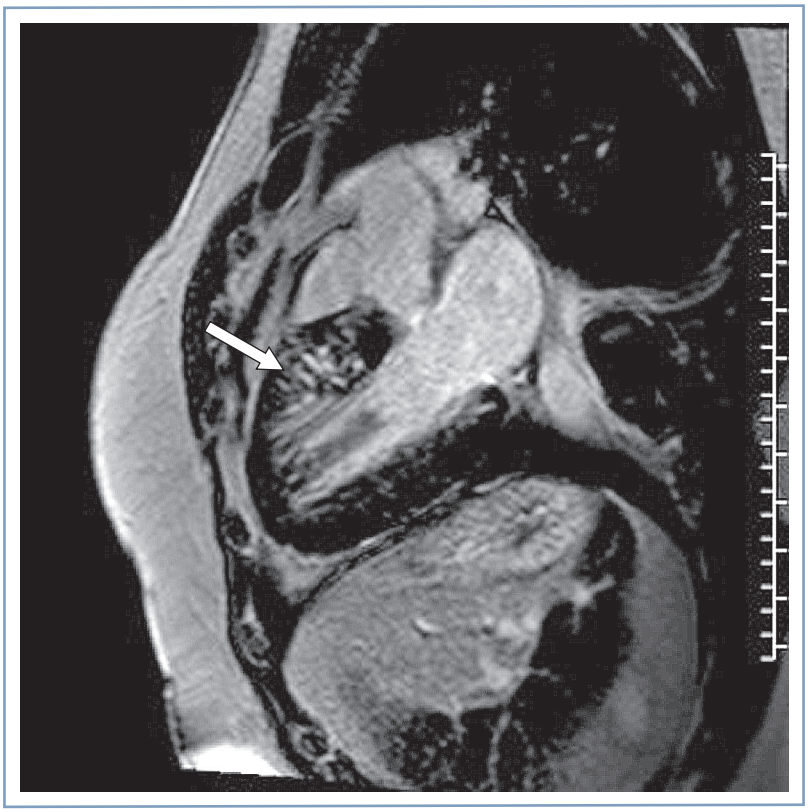

Fig. 41.7 Cardiac magnetic resonance image of hypertrophic cardiomyopathy with myocardial scar. Arrow shows scar with delayed enhancement with gadolinium in the hypertrophied myocardium. (Courtesy of Dr. Afshin Farzaneh-Far, University of Illinois at Chicago, Chicago, IL.)

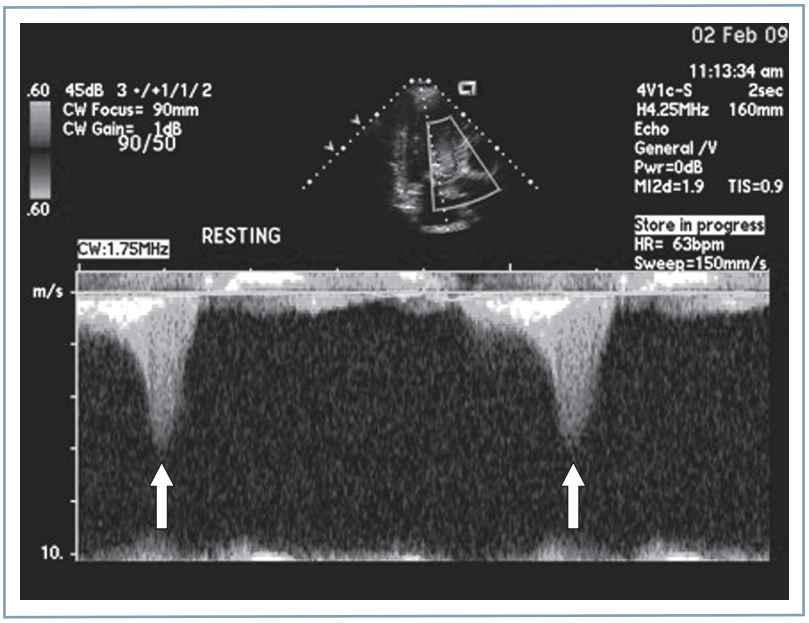

Fig. 41.8 Dynamic left ventricular outflow obstruction in hypertrophic cardiomyopathy. Continuous wave Doppler tracing in left ventricular outflow tract displays typical late-peaking ("dagger-shaped") contour of dynamic outflow obstruction *(arrows).* (Courtesy of Dr. Mayank Kansal, University of Illinois at Chicago, Chicago, IL.)

of atrial fibrillation rests on rate and rhythm control as well as systemic anticoagulation to prevent thromboembolic stroke. Rate control can alleviate symptoms; beta-adrenergic receptor antagonists and nondihydropyridine calcium entry–blocking agents (e.g., **verapamil**, **diltiazem**) provide the best results. **Digoxin** is less effective in controlling rate and may be harmful in patients with hypertrophic cardiomyopathy in the absence of atrial fibrillation.[156] **Amiodarone** can be successfully used for rate control in patients with hypertrophic cardiomyopathy. Rhythm control can be attempted pharmacologically with amiodarone and **sotalol.** In patients with a rapid ventricular response and significant hemodynamic compromise, electric cardioversion should be performed.

In the contemporary Registry of Pregnancy and Cardiac Disease (ROPAC), the rate of cesarean delivery was 60%, and pregnancy outcomes were similar between obstructive and nonobstructive hypertrophic cardiomyopathy.[237]

Obstetric and anesthetic management. Traditionally, general anesthesia has been considered the anesthetic technique of choice for parturients with hypertrophic cardiomyopathy.[238–242] It avoids a precipitous decrease in preload, and the negative inotropic effect of inhalation anesthetic agents may help reduce the degree of dynamic obstruction (see Table 41.2). No prospective controlled trials have compared general anesthesia with neuraxial anesthesia in parturients with hypertrophic cardiomyopathy; numerous case reports have described successful use of neuraxial anesthesia in these patients.[243–250] Given that hypertrophic cardiomyopathy is a heterogeneous condition, and given the high likelihood of selection and publication bias in these case reports, it is difficult to make generalized recommendations for these patients. In deciding whether to administer general or neuraxial anesthesia, it is important to recognize the degree of left ventricular outflow tract obstruction. For cesarean delivery, it appears reasonable to recommend general anesthesia for patients with a gradient of 50 mm Hg or greater, or for those with symptoms of heart failure during pregnancy. In asymptomatic parturients with a lower gradient, slowly titrated neuraxial analgesia/anesthesia appears safe.

Because a decrease in preload is expected to increase the degree of left ventricular outflow tract obstruction, central venous pressure monitoring seems reasonable. Similarly, invasive arterial blood pressure monitoring may be helpful. Transthoracic echocardiography facilitates assessment of intravascular volume. Beta-adrenergic receptor antagonists decrease myocardial contractility and decrease the severity of left ventricular outflow tract obstruction. **Phenylephrine** is the drug of choice for the treatment of hypotension. Inotropic agents (e.g., **dopamine**, **dobutamine**) may be harmful in these patients.[156] Rapid administration of intravenous oxytocin has been associated with hypotension; slow administration is therefore recommended.

Stress-Induced Cardiomyopathy

Stress-induced cardiomyopathy, also known as *Takotsubo cardiomyopathy, broken heart syndrome,* or *apical ballooning syndrome,* is a transient cardiomyopathy with typical left ventricular systolic dysfunction of the apical and mid-cavity segments.[251] The basal ventricular segments are frequently hyperkinetic and may cause left ventricular outflow tract obstruction. Affected patients typically do not have underlying coronary artery disease. Stress-induced cardiomyopathy occurs predominantly in postmenopausal women in the seventh and eight decades of life and is frequently associated with emotional and physical stressors. It has also been described during pregnancy in the setting of emotional and physical triggers, postpartum depression, and administration of pharmacologic triggers such as ergot alkaloids. It has been reported in the absence of apparent triggers[252] during otherwise uncomplicated spinal anesthesia for cesarean delivery.[253,254]

Clinically, patients have chest pain, dyspnea, and symptoms of left ventricular systolic dysfunction and heart failure. ECG abnormalities are frequently observed in the left precordial leads and may mimic STEMI because of plaque rupture. Coronary angiography is required to rule out STEMI; ventriculography or echocardiography allows recognition and characterization of wall motion abnormalities. The most critical differential diagnoses are STEMI and peripartum cardiomyopathy. When treating patients who develop shock, it is critically important to determine the degree of left ventricular outflow tract obstruction. Shock without left ventricular outflow tract obstruction can be treated in standard fashion with an inotropic agent. Patients with left ventricular outflow tract obstruction require optimization of intravascular volume and administration of a beta-adrenergic receptor antagonist; use of an intra-aortic balloon pump may be necessary to relieve the obstruction.

Dilated and Other Cardiomyopathies

In women with **idiopathic** or **anthracycline-induced cardiomyopathy,** pregnancy is associated with a high risk for adverse maternal, fetal, and neonatal outcomes. Pregnancy appears to unfavorably affect the short-term course of these cardiomyopathies. The NYHA functional status and ejection fraction may predict outcomes in this population.[255] Other causes of cardiomyopathy during pregnancy include **cocaine abuse** and **hemochromatosis;** the latter results in an infiltrative cardiomyopathy.

Rapid atrial or ventricular rates caused by arrhythmia can cause **tachycardia-induced cardiomyopathy.** This cardiomyopathy is a potentially reversible condition that has been described in pregnancy[256] and successfully treated with radiofrequency ablation.[257,258] Differentiation from other forms of cardiomyopathy may be difficult, but it is important from a prognostic standpoint.

Medical Management of Heart Failure

Principles of heart failure management for pregnant patients are similar to those for nonpregnant patients with two notable exceptions: **angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor–blocking agents** and **aldosterone antagonists (spironolactone, eplerenone)** should *not* be used in pregnant women. A beta-adrenergic

receptor antagonist should be administered, and **hydralazine** can be substituted for ACE inhibitors/angiotensin receptor–blocking agents. Digoxin use is safe in pregnancy. Loop diuretics and sodium restriction are indicated to prevent or treat volume overload. In patients with decompensated heart failure, treatment with intravenous **nitroglycerin** and **dopamine** or **dobutamine** is indicated.

Observational studies have reported two distinct peaks of exacerbation of heart failure during pregnancy. The first one occurs between the second and third trimester and is more frequently seen in patients with pulmonary hypertension and mitral stenosis. The other peak occurs around the time of delivery with predominance of other cardiomyopathy etiologies.[259]

Ventricular Assist Devices

Anecdotal reports have described ventricular assist device use during pregnancy. A successful completion of pregnancy with cesarean delivery in a patient with a ventricular assist device has been reported.[260] In another patient with myocardial infarction and subsequent severe left ventricular dysfunction, a ventricular assist device was placed, although pregnancy was not recognized at the time of placement; fetal death subsequently ensued.[261] The preconception presence of a ventricular assist device remains a contraindication to pregnancy.

PERICARDIAL DISEASE

Pericardial Effusion

Asymptomatic pericardial effusions are frequently found in otherwise healthy pregnant women (Fig. 41.9). A pericardial effusion may be seen in 15% to 20% of pregnancies in the first and second trimester; this rate increases to approximately 40% in the third trimester. The effusion is seen more often in nulliparous women than in parous women.[262] These effusions are transudative and disappear within 2 months after delivery. Treatment is rarely required. Physical signs of tamponade or pulsus paradoxus are rarely seen. Similarly, electrical alternans is not seen on the ECG.

Acute Pericarditis

Pericarditis remains a clinical diagnosis confirmed by ECG and echocardiography. Patients typically have precordial pain that improves with sitting and leaning forward. A pericardial friction rub may be appreciated on physical examination; this finding is frequently evanescent, and repeat examinations may be required. ECG findings consist of diffuse concave ST-segment elevations. Diffuse PR interval depression is frequently seen except in lead aVR, which demonstrates near-pathognomonic PR-interval elevation. Echocardiography may demonstrate various degrees of pericardial effusion. Importantly, the presence of a pericardial effusion is not

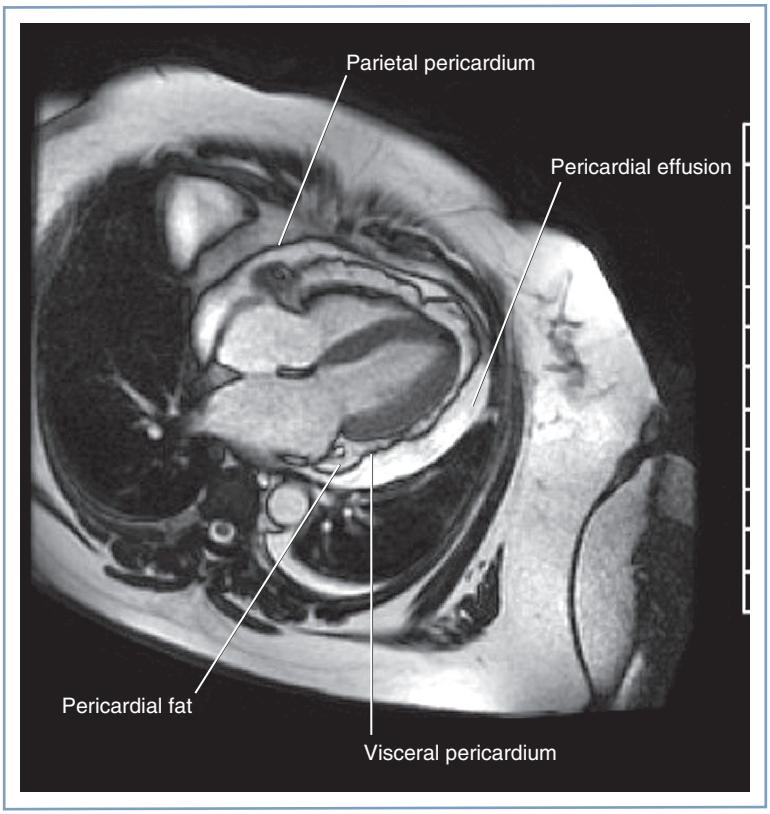

Fig. 41.9 Cardiac magnetic resonance image of pericardial effusion. (Courtesy of Dr. Afshin Farzaneh-Far, University of Illinois at Chicago, Chicago, IL.)

synonymous with pericarditis; pericarditis remains a clinical diagnosis.

The etiology of acute pericarditis during pregnancy is most likely similar to that in the general population. A viral etiology is most common. Less common causes include tuberculosis, connective tissue disease (e.g., systemic lupus erythematosus), and neoplasm.

Treatment of pericarditis in the general population includes nonsteroidal anti-inflammatory drugs, glucocorticoids, colchicine, and, rarely, immunosuppressant drugs. During pregnancy, the maternal and fetal risks and benefits of these agents should be weighed carefully.

Cardiac Tamponade

Therapeutic and diagnostic pericardiocentesis or a surgical pericardial window can be safely performed during pregnancy. However, echocardiographic rather than fluoroscopic guidance is preferred because it avoids fetal radiation exposure.

Constrictive Pericarditis

Constrictive pericarditis is a condition in which a noncompliant pericardium prevents filling of the right- and left-sided heart chambers; specific hemodynamic features include equalization and elevation of both left and right ventricular diastolic pressures, preserved systolic function, and a "dip and plateau" pattern of the ventricular pressure tracing. Potential causes of constrictive pericarditis during pregnancy include previous irradiation, recurrent pericarditis caused by rheumatoid arthritis, tuberculosis, and neoplasm. Patients may be asymptomatic before pregnancy; the physiologic changes of pregnancy may exacerbate the condition.

Anesthetic Management

Constrictive physiology and cardiac tamponade share some common pathophysiologic features that are important for the conduct of anesthesia (see Table 41.2). Impaired filling of the right side of the heart results from either a noncompliant pericardium (constrictive physiology) or pericardial fluid (tamponade physiology). Cardiac output is reduced by any intervention that reduces preload (e.g., aortocaval compression, sympathectomy with neuraxial anesthesia, positive-pressure ventilation with general anesthesia). Therefore, maintenance of preload is critically important; this goal can be achieved with central venous pressure monitoring, slowly titrated neuraxial anesthesia, and avoidance of positive-pressure ventilation. Invasive blood pressure monitoring is recommended.

CARDIOPULMONARY RESUSCITATION DURING PREGNANCY

Cardiac arrest during pregnancy is rare; it occurs in 1 in 12,000 admissions for delivery. Older data suggested that overall survival rates were poorer than expected compared with other clinical arrest scenarios in nonpregnant patients, but newer data suggest that survival rates may be higher in pregnant women than in nonpregnant patients.[263,263a] The reversible causes of cardiac arrest during pregnancy are similar to those in nonpregnant patients. Additional causes specific to pregnancy include amniotic fluid embolism, eclampsia, placental abruption, and uterine atony (see Chapter 54).

Standard Basic Life Support (BLS) and Advanced Cardiac Life Support (ACLS) principles apply to these patients. However, anatomic and physiologic changes of pregnancy require several specific modifications to the resuscitation protocol (Box 41.9; see also Box 54.5).[264] Current scientific evidence does not support previous recommendations to place the hands performing chest compressions higher on the sternum. This recommendation was based on the belief that compressions would be less effective because of cephalad displacement of abdominal contents and the diaphragm during the third trimester of pregnancy. Intravenous access should be obtained above the diaphragm. In pregnant patients, aortocaval compression reduces the cardiac output that results from chest compressions. Although it was typically advised to tilt the patient leftward 15 to 30 degrees to facilitate left uterine displacement and optimize venous return and cardiac output, such a maneuver may impede the effectiveness of chest compressions. Therefore, current recommendations advocate manual left uterine displacement rather than the usual whole-body tilt (see Fig. 54.2). If this technique is not successful, a firm wedge may be placed under a resuscitation board to tilt the patient approximately 30 degrees. In the field, the responder may use his or her knees to tilt the patient.

If spontaneous circulation does not return within 4 minutes of cardiac arrest, hysterotomy or cesarean delivery should be performed (also referred to as postmortem cesarean delivery [PMCD]), with the goal of achieving delivery within 5 minutes of cardiac arrest. The primary purpose of cesarean

BOX 41.9 Modifications of Cardiopulmonary Resuscitation in Pregnancy

- Manual left uterine displacement from left or right side
- Airway
  - Consider airway edema associated with pregnancy
- Breathing
  - Be aware of the impact of decreased functional residual capacity in pregnancy
- Circulation
  - Perform chest compressions on the sternum as in nonpregnant patients
- Defibrillation
  - May use automated external defibrillator (AED)
  - Apply same energies as in nonpregnant patients
  - Do not delay defibrillation to remove fetal monitoring probes and leads
- Drugs
  - Drugs (and doses) are the same as those used in nonpregnant patients

Modified from Jeejeebhoy FM, Zelop CM, Lipman S, et al. Cardiac arrest in pregnancy: a scientific statement from the American Heart Association. *Circulation.* 2015;132:1747–1773.

delivery is to improve the chance of *maternal* survival, but timely delivery also improves the chances of infant survival. PMCD should be performed at the site of cardiac arrest.[265]

Defibrillation should be performed based on current ACLS protocols. Transthoracic impedance is not changed during pregnancy, and the standard recommended electric energies should be used. Both cardioversion and defibrillation are considered safe at all stages of pregnancy. Although previous guidelines advised disconnecting fetal monitoring probes, it is unlikely that defibrillation is hazardous in the presence of external and internal fetal monitoring probes. The treatment delay and resulting risk to the mother outweighs any potential risks to the fetus; current guidelines have removed this recommendation.[264]

An intra-aortic balloon pump, a percutaneous left ventricular assist device, cardiopulmonary bypass, and extracorporeal membrane oxygenation have been successfully used in pregnant women with cardiac arrest; favorable outcomes have been reported. Therapeutic hypothermia has also been used after cardiac arrest during pregnancy, with successful delivery and favorable neonatal outcome.

PREGNANCY AFTER HEART TRANSPLANTATION

The first successful pregnancy in a heart transplant recipient was described in 1988. Subsequently, several reports have documented the feasibility and relative safety of pregnancy and delivery in female heart transplant recipients.[266,267] Successful patient management requires an interdisciplinary team approach.

The transplanted heart is denervated, and the increase in cardiac output with pregnancy primarily results from an increase in stroke volume rather than heart rate. Because the risk for acute rejection is not increased in pregnant patients with a heart transplant, the immunosuppressant medications should be maintained at the lowest possible dose. The risk for infection is greater in patients receiving immunosuppression therapy. The AHA considers the presence of valvulopathy in heart transplant recipients a high-risk lesion for the development of bacterial endocarditis. Thus, given the unfavorable outcomes in heart transplant recipients who develop endocarditis, it appears reasonable to recommend antibiotic endocarditis prophylaxis at the time of membrane rupture for these parturients undergoing labor and vaginal delivery (see Box 41.5).[128]

Cardiac transplant vasculopathy is a disease specific to transplanted hearts; it consists of concentric and longitudinal intimal hyperplasia in the coronary arteries. In contrast, native coronary atherosclerosis manifests as focal, noncircumferential lesions. After malignancy, cardiac transplant vasculopathy constitutes the second most common cause of death 1 year after heart transplantation. Therefore, monitoring for ischemia appears prudent in these patients, especially because they may not present with classic anginal symptoms owing to denervation of the transplanted heart.

Baseline echocardiography allows assessment of ejection fraction and the presence of transplant valvulopathy. Most parturients with a heart transplant with a normal ejection fraction and normal right-sided pressures tolerate labor and delivery well; both neuraxial and general anesthesia are acceptable. Peripartum immunosuppression therapy should be managed by a multidisciplinary team.

CARDIOPULMONARY BYPASS DURING PREGNANCY

In the current era, maternal mortality associated with elective cardiopulmonary bypass during pregnancy is comparable to that for nonpregnant women.[268] Fetal mortality remains high (14% in a single-center retrospective study of cases from 1976 to 2009[268]), although some series report excellent fetal outcomes.[269] The optimal timing of cardiopulmonary bypass appears to be the second trimester of pregnancy. Procedures performed immediately after delivery and on an emergency basis appear to confer added risk for maternal mortality. The degree of hypothermia is associated with poor fetal outcome. There is no evidence that anesthesia *per se* contributes to adverse maternal or fetal outcomes in this setting.[268] The need for intraoperative FHR monitoring is universally accepted. Measures to lower fetal mortality include normothermic cardiopulmonary bypass with flow rates greater than 2.4 L/min/m^2 while maintaining mean arterial blood pressure above 70 to 75 mm Hg. Left uterine displacement and maintenance of a hematocrit greater than 28% are recommended.

KEY POINTS

- Heart disease is the primary medical cause of nonobstetric maternal mortality.
- Congenital heart disease is the cause of 60% to 80% of cases of cardiac disorders in pregnant women in developed countries such as the United States.
- The management of most forms of congenital heart disease, including Eisenmenger syndrome, rarely requires pulmonary artery catheterization.
- Intrathecal administration of a lipophilic opioid is an excellent choice of intrapartum analgesia for women who may not tolerate decreased systemic vascular resistance and decreased venous return.
- Cardiac lesions do not represent an absolute contraindication to the use of neuraxial anesthesia, assuming that the induction of anesthesia proceeds slowly and the potentially adverse hemodynamic changes are prevented or corrected promptly. Single-shot spinal anesthesia can produce circulatory collapse in parturients with severe aortic stenosis, primary pulmonary hypertension, and Eisenmenger syndrome.

- The treatment of most arrhythmias during pregnancy is similar to that for nonpregnant women.
- When cardiopulmonary resuscitation is required during pregnancy, the standard advanced cardiac life support protocols should be used. Manual left uterine displacement should be employed to prevent aortocaval compression and a reduction in preload. Choice of drugs (and doses) as well as indications for defibrillation are the same as those for nonpregnant adult women. After 20 weeks' gestation, early hysterotomy and uterine evacuation may be necessary to facilitate resuscitation of the mother. Rescuers should be prepared to proceed with cesarean delivery if spontaneous circulation does not return within 4 minutes of cardiac arrest.
- Infective endocarditis prophylaxis is not recommended for vaginal or cesarean delivery except in patients with cardiac conditions at highest risk for endocarditis.

Chronic Pain during and after Pregnancy

Jessica Ansari, MD, Pamela Flood, MD

CHAPTER OUTLINE

Chronic pain is common among young women. According to the *2016 Health, United States Report*,[1] 25% of women of childbearing age (18 to 44 years of age) report migraine headaches, 26% report low back pain, and 15% report neck pain. An increasing prevalence of chronic pain conditions in recent years has been attributed to a rise in risk factors, including obesity, sedentary lifestyle, and social and socioeconomic circumstances. The increasing prevalence of chronic pain is associated with an exponential increase in opioid use, which has contributed, in part, to the rapid rise in the incidence of neonatal opioid withdrawal syndrome in recent years (Fig. 42.1).[2] This increase is not restricted to the United States. As far back as 2001, Blyth et al.[3] reported a 10% to 15% prevalence of chronic pain in women of childbearing age in Australia, with doubling predicted by 2050.

Any painful condition that occurs in young women can coexist with pregnancy, and pregnancy itself has variable impact on chronic pain conditions. Common chronic pain conditions in women include headache, fibromyalgia, pelvic pain, rheumatoid arthritis, and back pain.[4] Although migraine and autoimmune disease–mediated symptoms often improve or even resolve in pregnancy, back pain and pelvic girdle pain frequently worsen as a direct result of the pregnancy.[5,6]

In a prospective study of 133 nulliparous women with uncomplicated singleton pregnancies recruited in the third trimester at a large perinatal center in Canada, 38% reported a chronic pain condition or pain before pregnancy, and 55% reported pain during the current pregnancy.[7] Forty-three percent of the cohort reported pain that persisted at 2 weeks postpartum and 25% at 3 months postpartum. Table 42.1 summarizes the characteristics of pain reported before pregnancy; migraine was the most common source of chronic pain, and lower back pain was the most common source of pain overall.[7] Pain during pregnancy was primarily described as mild or discomforting (Table 42.2); the average numerical rating scale (NRS; 11-point scale from 0 to 10) was 4. Lower back, hips, legs, and feet were the most common sites of pain. Table 42.3 summarizes pain characteristics at 3 months postpartum[7]; lower back pain was the most common site of pain. Not surprisingly, prepregnancy and early postpartum pain was predictive of pain after delivery. Although pain before pregnancy is predictive of pain after delivery, pain during pregnancy and delivery can presage pain that persists during the postpartum period and beyond.

This chapter will identify factors that have been noted to be predictive of pain during pregnancy and persistence of pain during and after delivery. It will address the most common pain syndromes that complicate pregnancy and the pharmaceutical and nonpharmaceutical management approaches indicated for treatment of pregnant patients with chronic pain. Finally, the management of pain in women with chronic pain conditions during and after pregnancy will be discussed.

PREDICTORS OF CHRONIC PAIN AFTER CHILDBIRTH

A small number of patients will have new and persistent pain after cesarean and vaginal delivery. The estimated number of women with persistent pain has varied widely among studies, in part related to the study design and the population studied. Some studies with very high estimates used a retrospective cohort design that suffers from recall bias, and others with the

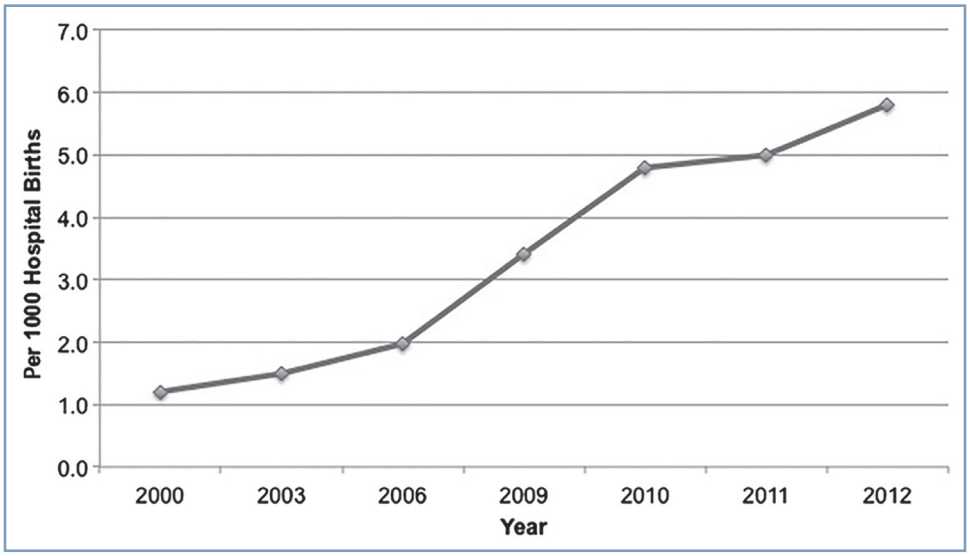

Fig. 42.1 The incidence of neonatal opioid withdrawal syndrome in the United States, 2000 to 2012. (From Pryor JR, Maalouf FI, Krans EE, et al. The opioid epidemic and neonatal abstinence syndrome in the USA: a review of the continuum of care. *Arch Dis Child Fetal Neonatal Ed.* 2017;102:F183–F187.)

TABLE 42.1 Prevalence of Chronic Pain Conditions and Pain before Pregnancy

	Frequency
Chronic pain condition and/or pain before pregnancy	38%
Chronic pain condition	28%
Migraine	10%
Irritable bowel syndrome	6%
Back pain	1%
Other	11%
Pain before pregnancy[a]	17%
Lower back	11%
Hips	5%
Genital/pelvic	5%
Legs	5%
Feet	6%
Head	3%
Other (wrists, knees, neck, shoulders)	7%

Prevalence of chronic pain conditions and pain before pregnancy in a cohort of women with subsequent uncomplicated singleton pregnancies.
[a]Pain before pregnancy was defined as pain more than once per week or more than five times per month.
Modified from Munro A, George RB, Chorney J, et al. Prevalence and predictors of chronic pain in pregnancy and postpartum. *J Obstet Gynaecol Can.* 2017;39:734–741.

TABLE 42.2 Characteristics and Prevalence of Pain during Pregnancy

Pain Variable	Frequency
Incidence of pain[a]	55%
Site of pain[b]	
Lower back	41%
Hips	28%
Legs	19%
Feet	22%
Head	8%
Other (ribs, upper back)	23%
Present pain intensity	
No pain	9%
Mild	13%
Discomforting	29%
Distressing	3%
Horrible	0.75%
Excruciating	0.75%
Pain severity	**Median [IQR]**
Average pain score during pregnancy[c]	4 [3–6]
Worst pain score during pregnancy[c]	6 [5–8]
Average unpleasantness score of pain during pregnancy[c]	6 [4–7]

Characteristics and frequency of pain during pregnancy in a cohort of women with uncomplicated singleton pregnancies.
[a]Pain during pregnancy was defined as pain more than once per week or more than five times over the past 4 weeks.
[b]Patients were allowed to select more than one site.
[c]11 point scale (0 to 10) with 0 = no pain and 10 = worst pain.
Modified from Munro A, George RB, Chorney J, et al. Prevalence and predictors of chronic pain in pregnancy and postpartum. *J Obstet Gynaecol Can.* 2017;39:734–741.

TABLE 42.3 Characteristics and Frequency of Postpartum Pain Conditions

Pain Variable	Frequency
Incidence of pain[a]	25%
Site of pain[b]	
Lower back	13%
Hips	5%
Legs	5%
Feet	3%
Head	3%
Other (abdomen/incision site, knee, mid-back, wrist)	11%
Present pain intensity	
No pain	5%
Mild	9%
Discomforting	9%
Distressing	2%
Horrible	0%
Excruciating	0%
Pain severity[c]	**Median [IQR]**
Average pain score during the last month	4 [3–6]
Worst pain score during the past 2 weeks	6 [4–7]
Average unpleasantness score of pain during the past 2 weeks	5 [3–7]

Characteristics and frequency of pain conditions 3 months postpartum in a cohort of women with uncomplicated singleton pregnancies.
[a]Pain at 3 months postpartum was defined as pain more than once per week for the past 2 weeks.
[b]Patients were allowed to select more than one site.
[c]11 point scale (0 to 10) with 0 = no pain and 10 = worst pain.
Modified from Munro A, George RB, Chorney J, et al. Prevalence and predictors of chronic pain in pregnancy and postpartum. *J Obstet Gynaecol Can.* 2017;39:734–741.

lowest estimates discontinued prospective follow-up of enrolled patients at the first report of no pain and thus may have missed those with episodic symptoms. Although most women have an uneventful recovery from peripartum pain and use opioids only briefly in the peripartum period, a 2016 systematic review and meta-analysis that included 15 studies suggested that 11% of women who deliver by cesarean report chronic pain at 12 months postpartum or later.[8] Among women who had chronic pain, 10% described severe pain, 24% described moderate pain, and 50% described mild pain at 6 months.[8]

Intrinsic Patient Factors

Many studies have proposed predictors of persistent pain, opioid use, and poor recovery after childbirth. A large prospective study followed women after planned vaginal delivery until resolution of pain, opioid use, and functional recovery (composite outcome).[9] Factors predicting the longest resolution of the composite outcome were investigated. Even after correction for the effect of cesarean delivery, induction of labor was strongly predictive of more severe pain, prolonged opioid use, and delayed functional recovery. Cesarean delivery was predictive of longer use of opioid analgesics compared with vaginal delivery. Prenatal anxiety and poor physical function were also predictive of prolonged opioid use. The pain score reported on postpartum day 1 was predictive of overall postpartum pain burden and prolonged time to functional recovery. Poor breast-feeding on postpartum day 1 was also predictive of prolonged opioid use.

Preexisting Chronic Pain and Postpartum Pain

The strongest predictor of postpartum pain is previous chronic pain.[10] Additionally, in women without a history of chronic pain, severe pain in the early postpartum period is a predictor of persistent pain after childbirth.[11] Possible reasons for this association include a more extreme response to the normal tissue trauma of delivery, inadequate response to normally prescribed analgesics, or a kindling response in which the experience of extreme pain makes one more sensitive to subsequent stimuli. It is unknown whether aggressive pain treatment in the early postpartum period is protective for the initiation of chronic pain.

Patient Expectations

Patient expectations greatly impact the experience of pain. In a large, multicenter study of the association of maternal expectations with labor pain, the most satisfied mothers were those who expected more pain and had good pain relief from their analgesic treatment.[12] Another study found that women's preoperative expectation of pain was predictive of the severity of acute post–cesarean delivery pain at rest but not during activity.[13] Simply asking women how much pain they expect and allowing them to choose a high- or low-dose pain regimen allows for better pain control and increased patient satisfaction.[14] These results suggest that key factors predictive of post–cesarean delivery pain severity are the parturient's expectation of pain and autonomy in its management.

Anxiety and Depression

The interaction between pregnancy, pain, and emotional distress is complex and multidirectional. Preexisting chronic pain disorders are associated with absenteeism, depression, and disordered sleep during pregnancy.[15,16] The severity of postdelivery pain and the likelihood of developing chronic pain after childbirth has been shown in numerous studies to be associated with psychological comorbidities, particularly depression and anxiety.[10,11,17–19]

Anxiety is a complex state with both intrinsic and environmental contributions. The prevalence of generalized anxiety and pregnancy-related anxiety in early pregnancy is high.[20–23] Maternal anxiety is associated with genetic variability in the catechol-*O*-methyltransferase gene *(COMT)* that encodes for regulation of response to catecholamines.[24] The finding that a preoperative increase in blood pressure is strongly correlated with postpartum pain may be reflective of these genetic differences.[13] In several studies, anxiety was predictive of increased labor pain and requirement for analgesia.[13,22,25] Higher prenatal state anxiety scores were associated with higher mean pain scores and greater opioid

consumption within the first several days after cesarean delivery.[22] Similarly, in a large French cohort, persistent pain 6 months after cesarean delivery was also associated with preoperative anxiety.[25]

Depression is also closely linked with chronic pain. Both prepregnancy anxiety and depression were predictive of physiosomatic symptoms (fatigue, back pain, muscle pain, dyspepsia, obstipation) during pregnancy and postpartum.[26] In a large, prospectively followed cohort, women with severe acute postpartum pain had a threefold increased risk for postpartum depression compared with women who had mild postpartum pain.[11]

Genetic and Epigenetic Variability

In addition to *COMT,* the experience of postpartum pain and opioid use may also be associated with genetic variability in other genes, including the gene encoding the μ-opioid receptor *(OPRM1)*. Data, however, are inconsistent. In one study, higher experimental pressure pain thresholds, but higher heat pain ratings, were observed in women who express the *OPRM1* G118 allele.[27] In a study in Asian women who received intrathecal morphine post–cesarean delivery analgesia, women with the G118 allele had higher pain scores and required a higher rescue dose of intravenous morphine.[28] In another study in women of mixed ethnicity, no differences were observed in pain scores and rescue opioid requirements in women who received intrathecal morphine post–cesarean delivery analgesia.[29] Possible explanations for these conflicting results include lack of control for other variables likely to influence pain after cesarean delivery, epigenetic influences on gene expression, the presence of linkage disequilibrium, differences in response to various pain stimuli, and differences in metabolic enzymes, transporters, and signal transduction pathway molecules, among other explanations.[30]

There is also complex interplay between genetic variability in cytochrome P450 (CYP) enzymes required for opioid metabolism and pregnancy. For example, CYP2D6 is induced during pregnancy. After the administration of codeine, oxycodone, tramadol, and hydrocodone, increased expression of the metabolic enzyme, combined with intrinsic genetic variability in receptor affinity for opioid ligands, affects both production of the active opioid metabolites morphine, oxymorphone, O-desmethyltramadol, and hydromorphone, respectively, and their signal transduction.[31]

Little is known about epigenetic effects on gene expression and their possible link to pain in pregnancy. Epigenetic processes, including DNA methylation, histone modifications, and the activity of microRNAs, have been shown to alter the sensitivity to pain in nonpregnant individuals.[32] The most commonly described epigenetic change, methylation, normally reduces gene transcription. Methylation of the gene for transient receptor potential ankyrin-1 *(TRPA1)* is inversely associated with the threshold for heat-induced pain and alters pressure-induced pain.[33] Hypermethylation of the promotor for *TRPA1* is associated with a low threshold for clinical pain.[33] Decreased DNA methylation in genes related to the stress response and free radical clearance has been found in patients with fibromyalgia.[34] The interaction between prepregnancy pain experiences and the hormonal and physiologic changes of pregnancy, and as well as effects on epigenetic modulation, is an important area for future research.

Environmental Factors

Sleep deprivation accentuates responses to noxious stimuli. Research subjects who sleep less than 6.5 hours per day have greater sensitivity to experimental pain than rested individuals.[35] Sleep deprivation accentuates pain, and pain in turn interrupts sleep, creating a vicious cycle that commonly exacerbates pain after delivery. Painful labor lasting many hours to days may precede delivery. Afterward, care of the newborn requires frequent interruptions in sleep. It is important to facilitate sleep as a therapeutic intervention as much as possible by decreasing environmental stimuli and reducing light during the evening to prevent exacerbation of chronic pain.

Stress is also an important factor that can worsen postsurgical pain and can facilitate conversion of acute to chronic pain. Antepartum stressors induced by fear of surgery, parenting, or other changes that are associated with childbirth may factor into postdelivery pain. In nonpregnant patients who underwent back surgery, preoperative report of worry and intrusive memories were associated with chronic preoperative pain, failed back syndrome, and chronic postoperative pain.[36] In the same study, biochemical evidence of preoperative stress, as measured by abnormal reactivity of the hypothalamic-pituitary-adrenal axis, was also associated with prolonged chronic pain after surgery.[36] Evidence specific to obstetric surgery is limited, but there is no reason to expect that the common stressors that accompany a significant life change such as childbirth, and specific individual stressors, would not have a similar impact on post–cesarean delivery pain and conversion to chronic pain.

In summary, the presence of intrinsic and extrinsic factors predicts severe acute pain. Additionally, conversion from acute to chronic pain is associated with the presence of these factors. Patients may have an intrinsic tendency toward severe pain in response to injury. This tendency toward severe acute pain and its persistence may be genetically inherited or may be acquired through life experiences expressed through epigenetic changes. Measurement of these predictive factors with validated scales may be useful in identifying a subset of women for whom aggressive treatment of acute postsurgical pain with multimodal analgesia may prevent conversion of acute to chronic pain[9,37,38]

Depression, anxiety, sleep deprivation, and disability, in addition to being risk factors for the development of chronic pain, are predictable consequences of severe acute pain, thus creating a positive reinforcing cycle. Interruption of this cycle by predicting and treating severe pain after delivery may be critical to preventing the development of acute severe and chronic pain. Identification and treatment of coexisting psychological distress and sleep disorders are key to effective

postoperative pain management and may prevent conversion of acute to chronic pain.

COMMON CHRONIC PAIN CONDITIONS IN PREGNANT WOMEN

Migraine

Migraine and other headaches are common in women of reproductive age, with a peak prevalence of up to 25% per year in women between 30 and 40 years of age.[39] A majority of women with migraine experience improved symptoms or even symptomatic remission during pregnancy, but migraine symptoms will worsen during pregnancy in 4% to 8% of women.[40] Some women experience a first migraine in pregnancy, usually during the first trimester. In a cohort study of 3480 women who reported migraine during pregnancy, 73% reported using antimigraine drugs, including nonopioid analgesics (54%) and triptans (25%).[41] Headaches are very frequent during the first 8 weeks after delivery and more than one-half of women will return to baseline frequency and severity of migraines within the first month after delivery.[40] As such, understanding the safety and role of both abortive and preventive migraine treatments during pregnancy and breast-feeding are important.[42]

Migraine preventive therapy can often be discontinued in pregnancy given the high likelihood of improvement in frequency of attacks and severity of symptoms during pregnancy. Behavioral sleep modification and dietary changes should be the first-line therapy for women with significant migraine burden in pregnancy, as placebo-controlled trials have demonstrated significant efficacy in female chronic migraineurs.[43,44] Pharmaceutical prophylaxis is recommended in pregnancy if women continue to experience frequent and/or prolonged severe attacks, especially if there is limited response to symptomatic treatment or significant nausea, vomiting, or evidence of fetal compromise (see later discussion).[42]

Back Pain

Preexisting chronic back pain is reported in 2% of women who become pregnant, but more than two-thirds of women complain of back pain over the course of pregnancy.[5] Back pain persists postpartum in approximately 25% of women, and there is significant relapse in subsequent pregnancies.[45–47] Proposed etiologies include weight gain, increased lumbar lordosis, and inefficient core muscle control (see Fig. 2.10).[45-47] Thus, pregnancy is a significant life event that is associated with the onset of chronic back pain in many young women.

A 2015 meta-analysis provided moderate-quality evidence that an 8- to 12-week exercise program during pregnancy, whether land- or water-based, reduced the number of women who reported back pain and functional impairment (relative risk [RR] 0.66; 95% confidence interval [CI], 0.45 to 0.97) and sick leave (RR 0.76; 95% CI, 0.62 to 0.94).[5] Pain and functional disability were also reduced by a multimodal intervention that included exercise, manual therapy, and education.[5] One small study evaluated the efficacy of transcutaneous electrical nerve stimulation (TENS) and found that it was associated with reduced pain and functional disability without adverse effects.[48] The same study also showed a small effect for acetaminophen (paracetamol).[48] In spite of their common use, little evidence exists to support the use of rigid pelvic support belts for the treatment of back pain.[49] There is broad consensus that the use of imaging, rest, opioids, spinal injections, and surgery are inappropriately high in the general population.[50] Despite emphasis on these modalities in recent years, there has been an increase in reports of back pain and disability.[50] Use of these modalities is even less desirable during pregnancy because of the possible fetal exposure to potentially dangerous medications and ionizing radiation. More favorable outcomes are achieved through promotion of activity and function, including work participation.[50]

Basic early management of low back pain does not differ from management in nonpregnant individuals, and includes biopsychosocial management and nonpharmacologic treatment (e.g., education supporting self-management, resumption of normal activities, and exercise).[50] Psychological support programs and judicious pharmacologic intervention are indicated for those with persistent symptoms. Pharmacologic management of moderate to severe pain follows the World Health Organization (WHO) pain ladder[51]; acetaminophen and other nonopioid drugs (see later discussion) are the foundation of treatment, with supplementation by opioid analgesics as the second and third steps on the ladder.

Cauda equina syndrome and preexisting cancer are indications for immediate imaging and acute intervention. The benefits and risks of diagnostic imaging using modalities that expose the fetus to ionizing radiation should always be considered during pregnancy (see Chapter 17); however, magnetic resonance imaging (MRI) is considered safe and is useful for the diagnosis of acute back and pelvic pain in pregnancy.[52] Advances are being made in ultrasonography for use in the diagnostic and therapeutic management of low back pain.[53]

Pelvic Pain

Approximately 20% of women report pelvic pain during pregnancy. A long-term follow-up study found that 10% of women with pelvic girdle pain in pregnancy continued to suffer up to 10 years later.[54,55] Thus, similar to other persistent pain conditions, pregnancy may be the condition that initiates long-term chronic pelvic pain. Pelvic pain can originate from various elements of the pelvic girdle, including the sacroiliac joints and pubic symphysis (Fig. 42.2). These joints are stabilized by thick ligaments that usually do not allow much motion. Increasing estrogen and progesterone in pregnancy cause softening of the ligaments, allowing important skeletal reconfiguration to support the enlarging pregnancy and future delivery. Systematic review and meta-analysis of studies assessing physical exercise and manipulation found no benefit to these therapies for reduction in pelvic pain.[45,56,57]

Questions about the management of pelvic pain in pregnancy are common. Like low back pain, integration of a biopsychosocial model and identification of addressable risk factors, such as fears about delivery, are important.

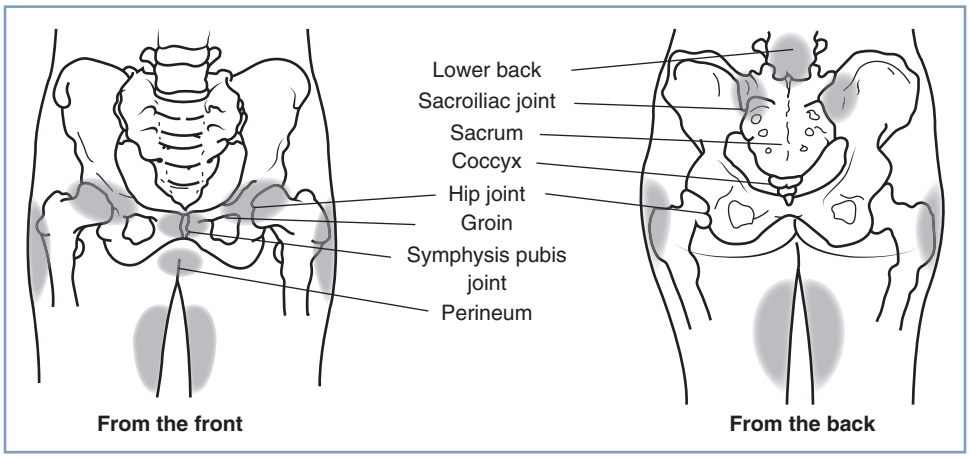

Fig. 42.2 Common areas for pelvic pain in pregnancy related to changing body mechanics, shifting center of gravity, and hormonally induced changes in ligamentous attachments.

Unlike back pain, there is no role for exercise therapy as the causes are largely ligamentous rather than muscular. Pain is relieved by rest. The FABER (flexion, abduction, and external rotation of the lower extremity) sign is commonly positive, and overextension during delivery, particularly in the setting of neuraxial analgesia (which can mask pain caused by maternal malpositioning) should be avoided. Pharmacologic treatment is similar to that for back pain, and follows the WHO ladder.[51,58,59]

Fibromyalgia

Fibromyalgia is a common pain syndrome in young women, and is associated with central nervous system sensitization to pain. Current criteria for diagnosis include myofascial pain in multiple body regions, fatigue, and cognitive symptoms.[60] In a population-based study of more than 12 million pregnancies, mothers with fibromyalgia were more commonly older, obese, and users of alcohol, tobacco, and illicit drugs.[61] Pregnancies among mothers with fibromyalgia are more likely to be complicated by fetal growth restriction, but not preterm birth, compared with the general population.[62] Symptoms of fibromyalgia, especially pain in various parts of the body and generalized fatigue, may be difficult to differentiate from normal symptoms of pregnancy. In one study, 27% of otherwise healthy women had symptoms that technically meet criteria for fibromyalgia in term pregnancy.[63] Therefore, fibromyalgia should not be diagnosed during pregnancy. Pain caused by fibromyalgia may increase during pregnancy; in a prospective case-controlled study, pain was associated with increasing depression scores.[64] Lifestyle modification, including sleep hygiene and exercise, are mainstays for the treatment of fibromyalgia during and outside of pregnancy. Migraine headache is a frequent comorbidity with fibromyalgia, and if present, migraine management is helpful.[65,66] The benefits and risks of pharmacologic management should be weighed for each individual as commonly used drugs, such as antidepressants, may have adverse fetal effects (see later discussion).[67-69]

MANAGEMENT OF CHRONIC PAIN DURING PREGNANCY

Multimodal Approach

Multimodal analgesia, also known as "balanced analgesia," has been used effectively in treatment of cancer and chronic pain for many decades. The rationale behind its use is the optimization of additive and/or synergistic analgesic effects among different modes of analgesia or drug classes, while reducing doses and minimizing the side effects of each drug.[70] Various combinations of opioids, nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, local anesthetics, and other drugs have been used with varying degrees of success in patients with chronic pain.[71]

A primary goal of multimodal analgesia for the pregnant patient is to provide adequate analgesia with minimum side effects to the mother balanced by minimal risk to the fetus/neonate. The use of nonpharmacologic interventions, including pain psychology and physiotherapy techniques, are particularly useful for the pregnant woman with chronic pain to reduce the amount of medication and support a positive pregnancy experience. Interventional techniques, including nerve blocks and radiofrequency techniques, are limited by the requirement to minimize radiation exposure from fluoroscopy. However, many of these procedures can now be accomplished with ultrasound guidance, and local anesthetic and low-dose steroid use are not contraindicated during pregnancy.[72,73]

Important postpartum concerns include minimizing transfer of drugs to breast milk and reducing maternal side effects that may interfere with breast-feeding or caring for the neonate. In general, medications for which infant plasma concentration is less than 10% of maternal plasma concentration are considered safe for the breast-feeding infant (Box 42.1).[74] It is important that mothers not be expected to choose between severe pain and the benefits of breast-feeding. Although transferred into breast milk, the infant plasma concentration of anesthetic and analgesic drugs used for

BOX 42.1 Drugs with Breast-fed Infant Plasma Concentrations Greater Than 10% of Maternal Plasma Concentrations

Citalopram	Lithium
Clomipramine	Mirtazapine
Diazepam	Nortriptyline
Doxepin	Olanzapine
Fluoxetine	Sertraline
Fluvoxamine	Venlafaxine
Lamotrigine

peripartum anesthesia and analgesia is almost always clinically insignificant and poses little or no risk to the nursing infant (see Chapter 14).[75] There is no need to "pump and dump" after general anesthesia. Specifically, acetaminophen, low-dose aspirin, and NSAIDs are considered compatible with breast-feeding.[76–79]

Nonpharmacologic Interventions

Psychological Preparation and Support

Psychological preparation has long been used to prepare for and manage labor pain. Several techniques, including mindfulness-based practices, have been associated with reduced opioid use in labor.[80] Mindfulness-based therapies are established techniques for treating chronic pain and have efficacy in the treatment of acute pain.[80] Indeed, a randomized controlled clinical trial suggested a medium-term impact on reducing the incidence of postpartum depressive symptoms in women assigned to mindfulness training compared with standard childbirth preparation.[80]

Physiotherapy

Muscle-stabilizing exercises are useful in the management of chronic back pain but not chronic pelvic pain (see earlier discussion).[45,56,57] There are limited studies regarding physiotherapy for pain syndromes other than back and pelvic pain. Postpartum physiotherapy may be useful to reverse and/or adapt to the musculoskeletal changes induced by pregnancy.

Pharmacologic Treatments

Pharmacologic intervention is used variably during pregnancy according to different perspectives on the risks and benefits of medication use.[81] Fig. 42.3 shows the prevalence of pharmacologic treatments during pregnancy in four European countries. A general philosophy to guide the use of pharmacologic therapy in pregnancy, including the treatment of chronic pain, is to use the smallest amount of the safest drug for the shortest period. However, some chronic pain syndromes require continuing analgesic management throughout pregnancy. Important pharmacokinetic and pharmacodynamic changes occur during pregnancy (see Chapter 14).[82] In general, drugs not indicated specifically for pregnancy are usually not studied during the drug development process because of perceived risk and a small market. Most information comes from drug registries, case-control studies, and national databases. These sources and reports are valuable as they provide important safety information, but they should be viewed through a lens that considers the limitations inherent to these types of studies and information sources. The impact of individual medications may vary depending on gestational age (early exposure may induce structural teratogenicity or embryonic loss; later exposure may induce preterm delivery or behavioral teratogenicity). Administration after childbirth requires consideration of the breast-fed infant. An important resource for information about the impact of individual drugs on breast-feeding can be found on LACTMED (/toxnet.nlm.nih.gov/newtoxnet/lactmed.htm) (see Chapter 14).

Nonsteroidal Antiinflammatory Drugs

All NSAIDs have opioid-sparing activity. **Ibuprofen** is one the most widely recognized and used NSAIDs; it is available without prescription. It nonselectively inhibits cyclooxygenase-1 and -2 enzymes (COX-1 and COX-2, respectively), which in turn reduces production of prostaglandins, leukotrienes, and other essential fatty acids and proinflammatory cytokines. NSAIDs are primarily classified as peripherally acting analgesics as they prevent peripheral release of substances that potentiate pain perception. They also have central antinociceptive activity.[83] In addition to antiinflammatory, analgesic, and antipyretic properties, NSAIDs inhibit platelet adhesion and cause renal artery vasoconstriction and gastrointestinal irritation; therefore, use in patients at risk for hemorrhage and renal failure warrants caution. The American College of Obstetricians and Gynecologists (ACOG) has warned against their use in women recovering from preeclampsia with persistent postpartum hypertension[84]; however, more recent data have called this recommendation into question.[85]

Use during pregnancy. Despite a general recommendation to avoid the use of NSAIDs during pregnancy unless maternal benefit is deemed to significantly outweigh risk to the fetus, over-the-counter NSAID use is common during pregnancy. In one multicenter survey of more than 5000 parturients, 24% reported use of ibuprofen, 5% reported use of aspirin, and 4% reported use of naproxen.[86]

NSAIDs should also be used sparingly and avoided when possible in the first trimester.[87] Several large observational studies have suggested a small increase in the risk for congenital defects, generally small cardiac septal defects, but also possibly gastroschisis.[87–89] Compared with neonates exposed to acetaminophen alone, neonates exposed to NSAIDs in the first trimester were found to have an increased risk for gastroschisis, hypospadias, cleft lip and palate, anencephaly, spina bifida, hypoplastic left heart syndrome, pulmonary valve stenosis, and tetralogy of Fallot (adjusted odds ratio [aOR] range, 1.2 to 1.6).[88] Of course, association does not demonstrate causation, and it is possible that the

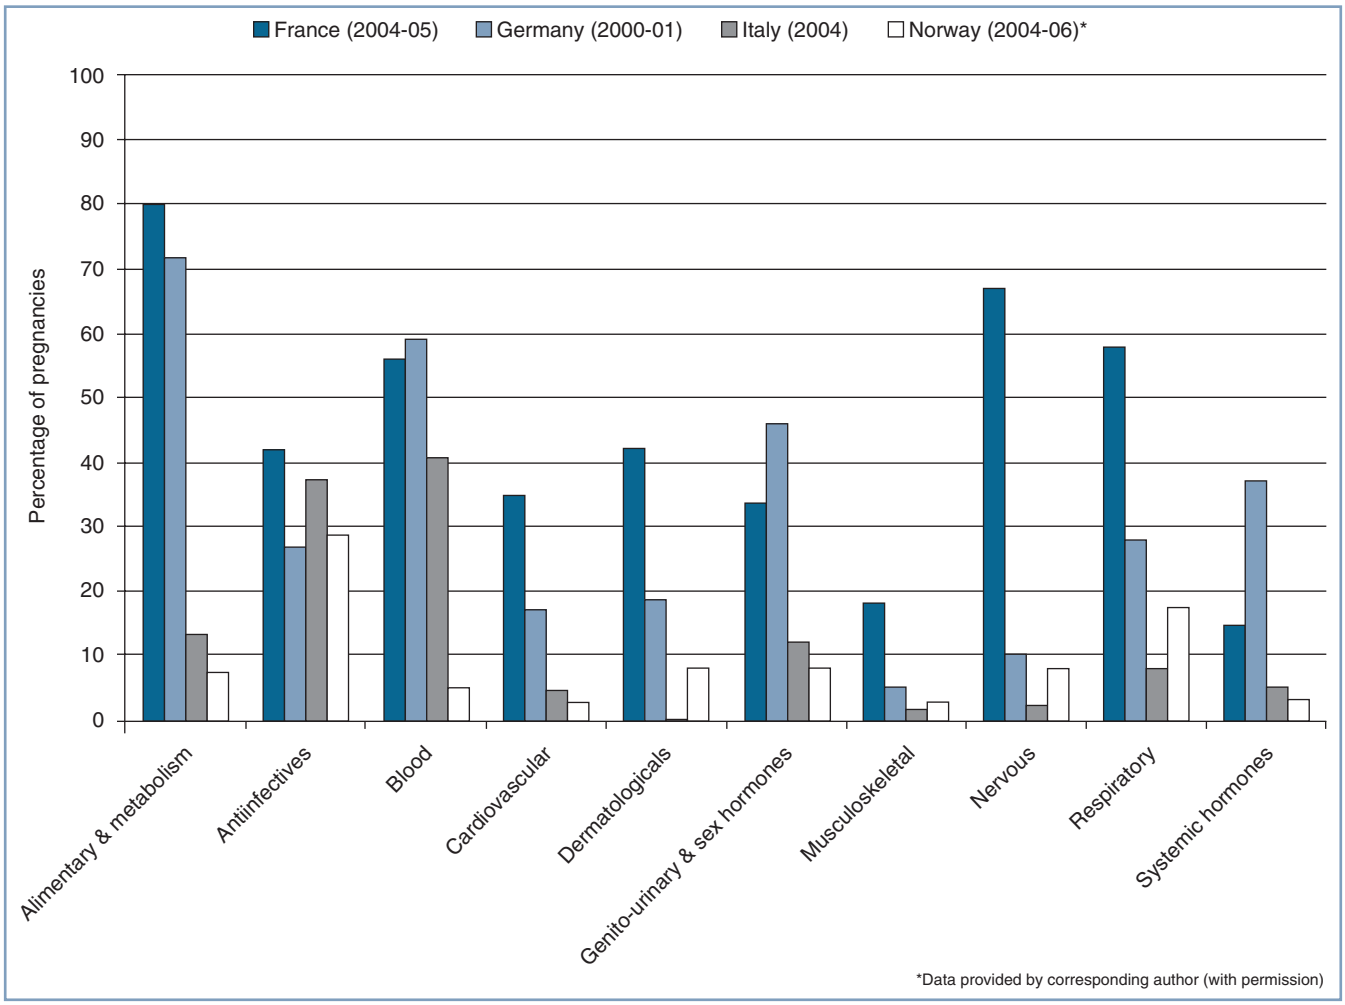

Fig. 42.3 Percentage of pregnancies in which at least one prescription was filled by therapeutic category in European countries. Chronic pain treatments are included in the musculoskeletal or nervous categories. (From Daw JR, Hanley GE, Greyson DL, Morgan SG. Prescription drug use during pregnancy in developed countries: a systematic review. *Pharmacoepidemiol Drug Saf.* 2011;20:895–902.)

increased risk for congenital anomalies may be related to the indication for use rather than a pharmacologic effect of NSAIDs.

Older literature suggested that there may be an increase in the risk for spontaneous abortion associated with NSAID use in early pregnancy, but other studies suggested a protective effect.[90] More up-to-date analyses have identified the association with abortion as a statistical aberration; there is likely no effect of NSAID use on early pregnancy loss.[91,92]

Unless the maternal benefits significantly outweigh the risks, NSAIDs are generally contraindicated in the third trimester because of increased risk for premature closure of the ductus arteriosus as well as fetal renal dysfunction and oligohydramnios.[87,93]

Use immediately postpartum and during lactation. NSAIDS are an important component in the multimodal management of postpartum pain in patients with chronic pain and opioid tolerance. NSAIDs are widely utilized and extremely effective for postdelivery pain. There is limited transfer of **ibuprofen** to breast milk, making it particularly useful for lactating mothers. Published data on other NSAIDs (e.g., etodolac, fenoprofen, meloxicam, oxaprozin, piroxicam, sulindac, and tolmetin) are limited, and U.S. Food and Drug Administration labeling discourages their use. Meloxicam concentrations in milk of lactating *animals* exceed maternal plasma concentrations, but the human implications of this finding are not known.[74] Similar to other NSAIDs, its use is likely safe during lactation.[87] Diflunisal has a long half-life and is not recommended because cataracts and fatality have been observed in neonatal animals.[74] Mefenamic acid has a long half-life in preterm infants. Less than 1% of the maternal dose of **ketorolac** is excreted into human milk, and adverse events in nursing mothers have not been reported.[87]

Low-dose **aspirin** is increasingly used beginning at 12 weeks' gestation until delivery for preeclampsia prophylaxis

in women at high risk for the disease. To date, no significant adverse fetal effects have been noted in the offspring of women allocated to aspirin compared with placebo therapy in these large clinical studies.[94]

Selective Cyclooxygenase-2 Inhibitors

Like nonselective NSAIDs, COX-2 inhibitors are additive or synergistic with opioids and other analgesics. Selective inhibitors of the COX-2 isoenzyme inhibit the form of cyclooxygenase that is produced by inflamed tissue in preference to the form made constitutively that is important for gut integrity and other functions. Thus, compared with nonselective NSAIDs, COX-2 inhibitors have minimal effects on platelet adhesion and are less likely to contribute to suboptimal response to hemorrhage. However, concerns about potential increased risk for cardiovascular and thrombotic events, combined with the baseline elevated risk for these events during pregnancy and the postpartum period, have prevented COX-2 inhibitors from playing a major role in postpartum analgesia.[95] In addition, use of celecoxib in late pregnancy has been associated with an increased risk for preterm delivery (aOR, 2.46; 95% CI, 1.28 to 4.72).[96]

In a study in six lactating women, the breast milk content of celecoxib was sampled 48 hours after a 200-mg oral dose. The median milk-to-plasma (M/P) ratio was 0.23; thus the drug is considered safe during breast-feeding.[87]

Acetaminophen

The mechanism of action of acetaminophen is still only partially understood. It has both antipyretic and mild analgesic properties.[97] Central analgesia is thought to be mediated via activation of descending serotonergic pathways. In addition, acetaminophen may inhibit prostaglandin synthesis as well as interact with cannabinoid receptors. Peripherally, acetaminophen is thought to have nonselective inhibitory action at COX receptors.[97]

Use during pregnancy. Acetaminophen is the first-line analgesic drug during pregnancy and a mainstay for multimodal therapy. It has few side effects at recommended doses and is additive or synergistic with other analgesic drugs.[97] Large population studies have shown no association between acetaminophen use and congenital anomalies.[89,98,99] Of note, although past evidence has found no adverse effects except in cases of maternal overdose, a small body of recent research has linked maternal acetaminophen use during pregnancy to neurobehavioral disorders such as attention deficit disorders and autism as well as asthma in children.[100] These concerning associations remain to be confirmed.[100] Despite increased clearance of acetaminophen in pregnancy, there is no evidence that changes in dose or frequency are required for therapeutic efficacy in pregnant women.

Use immediately postpartum and during lactation. Numerous studies in breast-feeding mothers have shown that infants solely ingesting breast milk from a mother who is taking acetaminophen receive no more than 3.6% of the maternal dose; thus, acetaminophen is safe for the breast-feeding infant.[101,102]

Gabapentin

Gabapentin is a mainstay in the management of chronic pain. It is thought to provide analgesia by binding presynaptic voltage-gated calcium channels in the dorsal root ganglia of the spinal cord, thereby inhibiting the release of excitatory neurotransmitters.[103] Although initially developed and still widely used as an antiepileptic drug, gabapentin is increasingly used for the management of chronic pain conditions.[104] Perioperative gabapentin has been shown to decrease acute pain after a variety of surgical procedures,[105] although data from healthy women undergoing elective cesarean delivery are conflicting (see Chapter 27).

Use during pregnancy. Gabapentin crosses the placenta. Studies on its use during pregnancy show a wide range of fetal-to-maternal (F/M) drug ratios, likely reflecting the timing of sampling after delivery. In a randomized controlled trial of gabapentin administered immediately before cesarean delivery, there was no difference in Apgar scores, interventions, or umbilical artery pH in neonates whose mothers were randomized to receive gabapentin compared with placebo.[106]

In a study of six women with epilepsy who were treated with chronic daily gabapentin (900 to 2100 mg) during pregnancy, there were no observed adverse neonatal effects.[107] The gabapentin F/M ratios in this study, reflecting steady-state concentrations, were much higher than the single-dose studies, ranging from 1.3 to 2.1. These ratios suggest active transplacental transport of gabapentin, possibly by the L-type amino acid transporter expressed in the placenta, resulting in fetal accumulation of gabapentin.[107] The drug is rapidly metabolized by the newborn.[107] Mean neonatal plasma concentrations were 27% of the umbilical artery plasma levels at 24 hours postpartum.

The Gabapentin Pregnancy Registry examined outcomes of 39 pregnancies in which mothers received gabapentin for epilepsy or chronic pain conditions.[108] Thirty-six of these mothers received gabapentin continuously throughout pregnancy. The author concluded that there was no evidence of increased risk for adverse maternal or fetal/neonatal effects compared with the general population.[108] In a prospective cohort study, Fujii et al.[109] compared 223 pregnancies with gabapentin exposure to 223 control pregnancies and found no increased risk for major malformations in the gabapentin group. Their results did suggest a possible association between gabapentin use and preterm birth as well as low birth weight (less than 2500 g); however, the analysis did not control for maternal indications for gabapentin, which included epilepsy and psychiatric disease, or concomitant drug therapy. The indications for gabapentin therapy were pain ($n = 90$), epilepsy ($n = 71$), and other (mostly psychiatric) reasons.[109]

Use immediately postpartum and during lactation. The M/P ratio of gabapentin was assessed in five lactating mothers whose chronic gabapentin dose ranged from 600 to 2100 mg/day.[107] The mean ratio was 1.0 (sampling ranged from 2 weeks to 3 months of neonatal age). The infant dose (mg/kg body

weight) of gabapentin was estimated to be 1.3% to 3.8% of the maternal dose. Finally, the infant plasma concentration in the breast-fed infants was as high as 12% of the maternal plasma concentration, but no adverse effects were observed in the five mother-infant dyads.[107] Current data suggest that gabapentin use by lactating mothers is probably safe.[87]

Pregabalin

Like gabapentin, pregabalin is structurally related to the inhibitory neurotransmitter γ-aminobutyric acid (GABA); its analgesic properties are attributed to binding to presynaptic calcium channels in the spinal cord and brain. The inhibition of these presynaptic voltage-dependent calcium channels reduces the influx of presynaptic calcium and the subsequent release of pronociceptive excitatory neurotransmitters.[103] Gabapentin and pregabalin have similar indications and adverse reaction profiles.[103] Pregabalin is not as well studied for the treatment of chronic pain in pregnancy.

Use during pregnancy. Though concerns were raised in a small 2016 study for a possible link between pregabalin use in the first trimester and increased risk for major fetal malformations, follow-up studies have proven more reassuring. A 2016 study included 116 pregnancies with first trimester exposure; 6% ($n = 7$) of offspring had malformations compared with 2% ($n = 2$) in the reference group.[110] Four of the six fetal malformations in the pregabalin group were cerebral ventriculomegaly.[110] By contrast, results from a subsequent, much larger, cohort study from the Medicaid Analytic eXtract database (477 infants exposed to pregabalin in the first trimester) were reassuring.[111] After propensity score adjustment for indication, the relative risk for major fetal malformations in the pregabalin group was 1.16 (95% CI, 0.81 to 1.67). When limited to patients on pregabalin monotherapy, the relative risk for malformations was 1.0 (95% CI, 0.7 to 1.5). Additionally, none of the 477 pregabalin-exposed infants in this study carried a diagnosis of cerebral ventriculomegaly or other brain anomalies reported in the initial smaller study.[110,111]

Use postpartum and during lactation. Pregabalin crosses into breast milk, as predicted by its low molecular weight and lack of plasma protein binding. In 10 lactating women receiving daily pregabalin 300 mg, the calculated amount of pregabalin present in 24-hour breast milk collections was 0.2% of the administered daily maternal dose.[112] The calculated average daily infant dose was 0.31 mg/kg/day, or 7% of the maternal dose. No adverse effects were reported.[112] Nipple latching does not appear to be affected by the use of pregabalin.[113,114]

Antidepressants

Antidepressants are commonly used to treat chronic pain conditions ranging from migraine disorders to fibromyalgia and neuropathic pain conditions.[78] Two classes of antidepressants have demonstrated efficacy in the management of chronic pain: tricyclic antidepressants (TCAs) and serotonin-norepinephrine reuptake inhibitors (SNRIs). The precise mechanism of action for the beneficial effects of these drugs on pain remains incompletely understood; however, both classes increase the synaptic concentrations of serotonin and norepinephrine.[115] They are thought to increase inhibition of excitatory pain transmission in both the brain and spinal cord. Centrally, animal models demonstrate that increased norepinephrine levels act on the locus coeruleus to enhance the activity of the descending noradrenergic inhibitory system. In the spinal cord, norepinephrine directly inhibits neuropathic pain through alpha$_2$-adrenergic receptors. Increased serotonin and dopamine levels may reinforce these effects.[115]

Tricyclic antidepressants. TCAs used for chronic pain management include amitriptyline, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortriptyline, and protriptyline. Among these drugs, amitriptyline and nortriptyline have the largest body of reassuring safety data in pregnancy and lactation. TCAs cross the placenta; the approximate F/M ratio is 0.6.[116]

Although most epidemiologic studies show no association between maternal TCA use and the risk for major congenital malformation, the largest and most recent studies have yielded conflicting results.[69,117,118] Using data from a research database from five U.S. health maintenance organizations, investigators identified 221 infants exposed to TCAs and compared them to almost 50,000 infants without exposure.[117] No increased risk for major congenital malformations was identified (RR, 0.86; 95% CI, 0.57 to 1.3). Similarly, in a large 2013 study of 1608 women exposed to TCAs, 1875 women exposed to selective serotonin reuptake inhibitors (SSRIs), and 6617 women with no exposure to any antidepressants during pregnancy, no increased risk for congenital anomalies with TCA exposure was observed (RR, 0.9; 95% CI, 0.6 to 1.2).[69] By contrast, a large Swedish registry study published in 2010 identified a possible link between *in utero* exposure to TCAs and an increased risk for congenital malformations.[118] Almost 2500 women who took TCAs during pregnancy (early pregnancy, $n = 1662$; later pregnancy, $n = 782$) were compared with over 1 million control patients in the same population. A small increase in the risk for severe malformations (aOR, 1.36; 95% CI, 1.07 to 1.72) as well as overall cardiac malformations (aOR, 1.63; 95% CI, 1.12 to 2.36) was identified after adjusting for maternal age, parity, smoking, and body mass index (but not psychiatric diagnoses or concurrent medication use).[118] Among the TCAs, clomipramine was the most strongly implicated in increased risk, although in most studies, amitriptyline is the most commonly prescribed TCA.[118] Overall rates of congenital malformations in this study were less than 5%, even in the TCA group. Many smaller studies have failed to show any link between maternal TCA use and increased risk for congenital anomalies.[68,87]

There are some reports of neonatal symptoms possibly related to TCA withdrawal, including transient tachypnea, tachycardia, irritability, spasms, hypertonus, and clonus.[68] A meta-analysis spanning studies from 1966 to 2010 found that TCAs, mostly clomipramine, were associated with transient poor neonatal adaptation, including an increased rate of respiratory distress, temperature instability, hypoglycemia,

and convulsions.[119] Thus, close observation of the neonate in the immediate postdelivery period is likely warranted.

To date, maternal exposure to TCAs has not been linked to neuropsychiatric disorders in children. A 2017 meta-analysis included studies assessing the association between *in utero* antidepressant exposure and the risk for attention deficit disorder.[120] After controlling for the presence of a maternal psychiatric disorder, the initial positive association disappeared (hazard ratio, 0.96; 95% CI, 0.76 to 1.2).[120] Maternal TCA use has not been linked to differences in children's global IQ scores.[68]

Tricyclic antidepressants have a long history of use in breast-feeding mothers, although most data on safety are from small case series. Nursing infants ingest approximately 1% of the maternal dose; the ingested drug undergoes significant first-pass metabolism; thus the nursing infant is exposed to a small proportion of the mother's total dose.[121] However, the American Academy of Pediatrics (AAP) suggests that this class of medications should be "used with caution" in breast-feeding mothers, given that long-term neurodevelopmental outcomes with chronic exposure are unknown.[74] Reassuringly, numerous small studies have failed to show significant effects on neonates.[87]

Serotonin-norepinephrine reuptake inhibitors. Duloxetine and venlafaxine are the two most commonly used SNRIs for chronic pain conditions. Overall, these drugs are generally considered to be safe in pregnancy, with a much larger body of reassuring literature for venlafaxine than duloxetine. SSRIs, in contrast with mixed serotonin and norepinephrine reuptake inhibitors, are used primarily for the treatment of depression.

In 2010, Broy and Bérard[67] reviewed the literature on rates of spontaneous abortion in women taking various antidepressants; venlafaxine was associated with an increased risk for spontaneous abortion (aOR, 2.1, 95% CI, 1.3 to 3.3). The only other antidepressant medication associated with increased risk for abortion was the SSRI paroxetine.[67] A 2016 systematic review concluded that there was no associated risk for congenital malformations with venlafaxine or duloxetine based on data from 3186 infants exposed to venlafaxine and 668 infants exposed to duloxetine in the first trimester.[122] These drugs have been linked with an increased risk for persistent pulmonary hypertension of the newborn[123,124] and preeclampsia,[125] but further confirmatory study is required.[87] Like the TCAs, neonates of mothers taking SNRIs at the end of pregnancy should be monitored for transient agitation and withdrawal symptoms; the risk is greater in drugs with shorter half-lives, such as venlafaxine.[126]

Venlafaxine is excreted in the breast milk, with reported M/P ratios ranging from 1 to 4, depending on the study design.[87] The calculated mean infant exposure has ranged from 2% to 8% of the maternal dose of both venlafaxine and its active metabolite desvenlafaxine.[87] No adverse effects were reported among 7 breast-fed neonates in a 2002 study[127] or among 13 neonates in a 2009 study.[128] Very little data on use during breast-feeding are available for duloxetine. Based on two very small studies, infant exposure to duloxetine in breast milk is less than 1% of the maternal weight-adjusted dose; therefore, this drug may be safe for lactating mothers.[129] In general, the AAP recommends using SNRIs with caution in lactating mothers because the long-term effects of chronic exposure on neurodevelopment are unknown.[74,87]

Opioids

Although opioids are commonly prescribed in the United States to pregnant women, practitioners should bear in mind that there is no indication for long-term treatment with opioids for many common pain syndromes, including headache, fibromyalgia, and chronic back pain.[130] The prevalence of opioid prescription is increasing in publicly insured populations in the United States.[131] Opioids are prescribed for the treatment of acute and chronic pain as well as the management of opioid use disorder, or they may be taken illicitly. Within the United States, there is significant regional variation in prescription practice. Depending on the state of residence, between 10% and 42% of pregnant women with public insurance filled a prescription for an opioid between 2000 and 2007 (Fig. 42.4).[131,132] Studies show that most patients who use opioids for chronic pain will continue their use during pregnancy.

Use during pregnancy and lactation. The mixed population of patients receiving opioids under medical care and those taking illicit opioids makes interpretation of epidemiologic data complex. Pregnant women who use illicit opioids or are prescribed opioid maintenance treatment for opioid use disorders often have concomitant chronic disease and life circumstances that may confound analyses of the effects of opioid use during pregnancy. These confounders include a higher incidence of tobacco use, frequent alcohol and/or polysubstance use disorder, and life stressors and experiences that may independently alter their pregnancy outcome. The indication for opioid prescription may also influence pregnancy outcome. Women prescribed opioids for opioid use disorder have longer gestations (median, 39 weeks), but a greater risk for low-for-gestational weight infants than mothers treated with opioids for chronic pain (median gestation, 36 weeks).[133] The infants born to women who have been prescribed opioids for treatment of opioid use disorder have a greater risk for neonatal opioid withdrawal syndrome. The incidence of this syndrome has increased rapidly since 2000 (see Fig. 42.1).

A 2017 systematic review examined the effects of chronic maternal opioid use on the incidence of congenital malformations.[134] The authors concluded that uncertainty remains regarding the teratogenicity of opioids because of variabilities in study design, poor-quality studies, and weaknesses in outcome and exposure measurement. The data were mixed, but some studies included in the systematic review identified statistically significant positive associations between maternal opioid use and oral clefts, atrial and ventricular septal defects, neural tube defects, and club feet in neonates exposed to opioids *in utero* compared with control populations.[134] Two retrospective case-controlled studies showed an association between first-trimester opioid use and neural

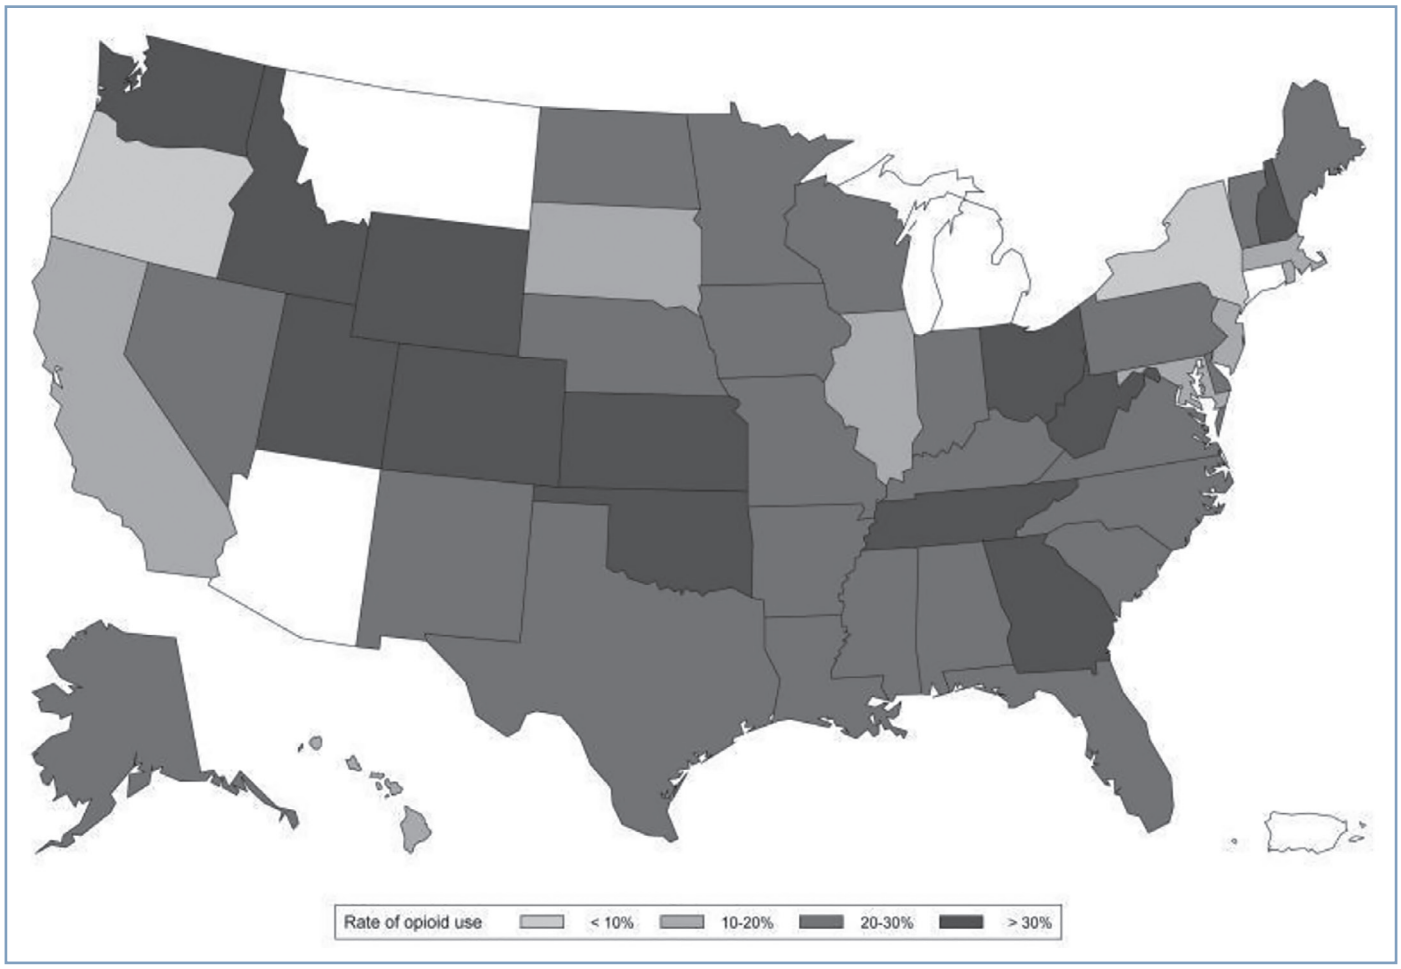

Fig. 42.4 The prevalence of opioid prescription during pregnancy, stratified by state, among U.S. Medicaid beneficiaries, 2000 to 2007. (From Desai RJ, Hernandez-Diaz S, Bateman BT, Huybrechts KF. Increase in prescription opioid use during pregnancy among Medicaid-enrolled women. *Obstet Gynecol.* 2014;123:997–1002.)

tube defects, particularly with codeine and hydrocodone.[135,136] One study also found an association with gastroschisis and cardiovascular defects.[136] Källén and Reis[137] suggested that synthetic opioids such as tramadol should be avoided in early pregnancy as they identified an association with its use and cardiac defects and talipes equinovarus.[137] Overall, information is inadequate to support a choice of one opioid over another with respect to risk for miscarriage.[89]

Fetal growth restriction may occur later in gestation. The neonate is at risk for neonatal opioid withdrawal syndrome if opioids are used by the mother in the third trimester.[138,139] In a meta-analysis of studies of neurobehavioral outcomes in infants and preschool children who were chronically exposed to opioids *in utero,* no significant impairment was identified compared with nonexposed peers.[140] However, the subset of infants born to mothers with opioid use disorder may have risks that are not directly attributable to *in utero* opioid exposure. Behavioral issues have been identified in children raised by mothers with untreated opioid use disorder.[140,141]

For the purposes of analgesia, short-acting opioids such as oxycodone and hydrocodone are preferred to long-acting opioids in opioid-naïve women, as the risk for overdose is lower with short-acting opioids.[142] This recommendation is particularly relevant during the first 2 weeks of treatment when the hazard rate for overdose is elevated fivefold for long-acting compared with short-acting opioids in the general population.[142]

Methadone. Two drugs commonly used for treating chronic pain and opioid use disorder, methadone and buprenorphine, have special considerations during pregnancy. Total daily methadone doses for chronic pain management are generally less than doses used for opioid replacement therapy. Methadone is a full opioid agonist with high affinity for the μ-opioid receptor, affinity for the *N*-methyl-D-aspartate (NMDA) receptor, and a long half-life. These properties make it an attractive drug for management of addiction as once-daily observed dosing is possible. However, pharmacokinetic changes in late pregnancy may make twice-daily maintenance dosing a more rational choice.[82]

One major concern of methadone use during pregnancy is the risk for the development of neonatal opioid withdrawal syndrome when there is continuing fetal exposure at the time

of delivery. Approximately 50% of infants born to mothers treated with methadone for opioid use disorder require treatment for neonatal opioid withdrawal syndrome.[143] However, opioid doses used in the treatment of chronic pain are often lower than those used for opioid replacement therapy. Lower rates of neonatal opioid withdrawal syndrome were observed with maternal doses less than 20 mg/day compared with higher doses; these low doses are more commonly used to treat chronic pain.[144]

Many women treated for pain or opioid use disorder during pregnancy are exposed to multiple pharmaceutical agents as part of multimodal regimens intended to reduce the required amount of opioid or as part of treatment for comorbid psychiatric disease. In a large cohort study using 2000 to 2010 data from publicly insured patients in the United States, an increased risk for neonatal opioid withdrawal syndrome was identified in infants exposed *in utero* to gabapentin, antidepressants, and benzodiazepines in combination with opioid, when compared with opioid-only exposure.[139] Although the finding of an association between polypharmacy and neonatal withdrawal syndrome suffers from the usual limitations of retrospective cohort studies, the authors did not identify an association between nonbenzodiazepine hypnotics or antipsychotics and neonatal withdrawal syndrome, suggesting a direct drug effect rather than other causes.

In a retrospective cohort study from Ireland, 618 mother-infant dyads treated with methadone during pregnancy were compared with the overall population of 61,000 singleton pregnancies.[145] Methadone exposure was associated with preterm birth (aOR, 2.5; 95% CI, 1.4 to 4.3), small-for-gestational-age infants (aOR, 3.3; 95% CI, 2.5 to 4.3), admission to the neonatal intensive care unit (aOR, 9.1; 95% CI, 7.2 to 11.6), and a major birth anomaly (aOR, 1.9; 95% CI, 1.1 to 3.4). Of note, most of these women were receiving other drugs as well as methadone and/or were using illicit substances.[145] Greater than 90% used tobacco during pregnancy. The authors did identify a dose-response relationship between methadone dose and neonatal opioid withdrawal syndrome.[146]

Similarly, in a Danish study of pregnant women treated with buprenorphine and methadone for opioid use disorder, the risk for adverse pregnancy outcomes, including preterm birth, low birth weight, and small-for-gestational-age, was greater in exposed infants.[147] Neonatal opioid withdrawal syndrome was more common in methadone- than buprenorphine-exposed infants.[147]

In one of the few studies of methadone use for chronic pain, Sharpe and Kuschel[133] retrospectively compared 19 pregnant women who received methadone for chronic pain to 24 women who received it to treat opioid use disorder. The women receiving methadone for chronic pain were also taking regular acetaminophen and amitriptyline, along with other medications for management of their pain. As anticipated, daily doses of methadone were lower in the chronic pain than in the opioid use disorder group.[133] Only 11% of infants in the chronic pain methadone group required treatment for neonatal opioid withdrawal syndrome compared with 58% in the opioid use disorder group.[133] However, the risk for preterm birth was greater in the pain group. Delivery was induced in many of these women because of pain exacerbation, emphasizing the importance of pain management during pregnancy.[133]

The AAP considers methadone to be compatible with breast-feeding.[87] Methadone is detected in very low levels in maternal breast milk, but M/P ratios vary significantly from 0.05 to 1.2 among different studies. Although the concentration of methadone in breast milk is probably insufficient to prevent neonatal opioid withdrawal syndrome, breast-feeding has been associated with reduced severity and duration of neonatal withdrawal.[148]

Buprenorphine. Buprenorphine is used for treatment of both opioid use disorder and chronic pain; typically doses are lower when used to treat pain.[149] It is a partial agonist at the μ-opioid receptor and an antagonist at the κ-opioid receptor (see Chapter 13). This profile allows for a ceiling effect for respiratory depression and an improved side-effect profile compared with full μ-opioid agonists. Partial μ-opioid agonism reduces the overdose risk, and daily observed dosing for the treatment of opioid use disorder is less commonly required than for methadone.[150] However, the strong binding affinity to the μ-opioid receptor, combined with its action as a partial agonist, has raised the concern that it may not be possible to overcome the ceiling effect, and adequate treatment of post–cesarean delivery pain may be difficult to achieve. It is not known whether this problem is specific to buprenorphine treatment or a consequence of opioid use disorder and the use of high doses of opioids in general. One study found that post–cesarean delivery opioid requirements were high but equivalent in women treated with either methadone or buprenorphine.[151]

Buprenorphine is currently available in multiple formulations, including tablets, buccal films, transdermal patches, subcutaneous implants, and depo injections.[152] Formulations that allow high doses (greater than 2 mg) may be combined with naloxone to prevent illicit injection. Some depo and implant forms of buprenorphine are very long lasting; strategies other than conversion to full-agonist opioid agonist therapy may need to be considered for peripartum pain management.

The Maternal Opioid Treatment: Human Experimental Research (MOTHER) trial compared the incidence of neonatal opioid withdrawal syndrome after maternal treatment with buprenorphine ($n = 58$) or methadone ($n = 73$) for maternal opioid use disorder.[143] Treatment for withdrawal was required in 57% of neonates in the methadone group and 47% in the buprenorphine group, a nonsignificant difference (OR, 0.7; 95% CI, 0.2 to 1.8). However, the neonates in the buprenorphine group who did require treatment required significantly less morphine; duration of therapy and hospital stays were shorter than for neonates exposed to methadone. These results have led many clinicians to recommend buprenorphine over methadone for treatment of maternal opioid use disorder. It should be noted, however, that the maternal attrition rate was significantly greater in the buprenorphine group than in the methadone group.[143]

The peripartum management of pregnant patients receiving buprenorphine may be challenging, especially if treatment doses are high. Possible reasons include the high μ-opioid receptor affinity and partial agonist mechanism of buprenorphine, opioid tolerance, and/or opioid-induced hyperalgesia. Because buprenorphine can be administered in many forms and doses, the daily dose may not be immediately obvious (e.g., the extended-release subcutaneous formulation).[152]

Adequate pain control during labor, cesarean delivery, and the postpartum period requires planning and coordination among clinicians caring for the mother and infant, including the addiction medicine specialist.[150,152] The decision to continue buprenorphine therapy throughout the peripartum period, transition to a full μ-opioid agonist (with subsequent reinduction of buprenorphine in the postpartum period), or implement detoxification should consider the risk for opioid overdose and recidivism. Conversion from buprenorphine to a full μ-opioid agonist should be supervised by a clinician with expertise, as partial agonism binding can last significantly longer than analgesic effects, and dose requirements for the full μ-opioid agonist may decrease over the first few days of transition. Lower-dose buprenorphine regimens commonly used for management of chronic pain (less than 1 mg) usually do not result in full occupancy of available opioid receptors; thus, the partial agonism effect can be overcome by using higher doses of full μ-opioid receptor agonists.

The primary analgesic modality for managing labor and vaginal delivery analgesia for women receiving buprenorphine is regional analgesia/anesthesia. According to the ACOG, women on methadone or buprenorphine maintenance therapy should, at a minimum, continue their maintenance therapy without a change in dose through the peripartum period.[153] For the treatment of short-term moderate pain, the buprenorphine dose can be increased to up to 32 mg/day. Buprenorphine can be administered up to 4 times per day when used for acute pain management. Opioid adjuvant medications with different mechanisms of action are useful to increase analgesic efficacy.[154–157]

Buprenorphine is found in the breast milk 2 hours after maternal dosing, but the overall concentration is low (approximately 1% of the maternal dose). As such, it is unlikely that buprenorphine in human milk has any negative effects on the neonate. Because studies have shown that breast-fed infants may have reduced severity of neonatal opioid withdrawal syndrome, women receiving buprenorphine therapy are encouraged to breast-feed in the absence of contraindications.[148]

Drugs for Migraine Headache

Migraine headache is common in women of childbearing age. Although its frequency and severity improve during pregnancy for many women, prophylaxis and treatment may be necessary during pregnancy in others. Acetaminophen is generally thought to be safe during pregnancy and lactation and is the first-line therapy for migraine headache. Magnesium, both oral and intravenous formulations, is also thought to be safe and often efficacious in both acute treatment and headache prophylaxis. Opioids have limited efficacy in migraine headache and create a risk for opioid use disorder and medication overuse headache.

Triptans. Triptans are highly efficacious for the treatment of acute migraine headache. They act as serotonin 5HT 1B-, 1D-, and 1F-receptor agonists. These receptors are present in the umbilical artery and fetal brain. Of the seven triptans available worldwide, the longest clinical experience and greatest body of literature demonstrating safety in pregnancy and breast-feeding exist for **sumatriptan.**[42]

In a large study using the Swedish birth registry, 3286 women used **ergot alkaloids** or triptans in the first trimester, and 1394 women used these medications after the first trimester.[99] No increased risk for congenital malformations was identified (OR, 0.86; 95% CI, 0.51 to 1.44). Most patients included in the analysis were taking sumatriptan; thus, the authors concluded that sumatriptan is likely safe for use in pregnancy, but data were lacking to assess the safety of other triptans and ergot alkaloid exposure.[99] In a comprehensive 2015 review on management of migraine headache in pregnancy, the authors concluded that data on the use of triptans during pregnancy are reassuring, and that sporadic use of sumatriptan is probably safe during pregnancy.[42] Given the limited data on other triptan medications, sumatriptan is the first choice among triptans.[42]

The AAP considers sumatriptan to be compatible with breast-feeding. In five women who received 6 mg of subcutaneous sumatriptan, breast milk was collected hourly for 8 hours; the mean M/P ratio was 4.9.[158] The calculated infant dose of sumatriptan was 3.5% of the maternal dose. Oral bioavailability of sumatriptan is low (approximately 15%); thus the amount of sumatriptan that reaches the infant circulation is likely exceedingly low.

Eletriptan may be even safer than sumatriptan for breast-feeding mothers because its high plasma protein binding results in even lower concentrations in breast milk (M/P ratio 0.25).[79] Oral bioavailability is approximately 50%, and the estimated relative infant dose is 0.02% of the maternal dose. Because data regarding the safety of use other triptans during breast-feeding are lacking, sumatriptan and eletriptan should be selected for lactating mothers.[79]

Ergot alkaloids. Ergotamine and other ergot alkaloids that are used for migraine treatment are generally contraindicated during pregnancy because of known vasoconstrictive and uterotonic effects; the closely related drug, methylergonovine, is commonly used as a second-line agent for the treatment of uterine atony.

No systematic evidence of increased risk for congenital malformations exists for ergot alkaloids, but there are case reports of sirenomelia (fusion of the lower limbs, lower spinal column defects, and malformations of the urogenital and gastrointestinal tracts), renal agenesis, and urethral atresia associated with methylergonovine use in the first weeks of pregnancy.[159,160] The association has biological plausibility, as it is hypothesized that sirenomelia results from vascular

insufficiency. One study of 77 neonates born to mothers who had received ergotamine during pregnancy found a significant increase in the risk for low-birth-weight infants (16.4% versus 4.7%) and preterm births (16.4% versus 9.2%) compared with nonexposed infants.[161] The authors proposed that placental vasoconstriction caused by ergot alkaloids may have contributed to these unfavorable outcomes.[161] Using data from 53 cases of maternal dihydroergotamine use for migraine treatment during pregnancy from the Quebec Pregnancy Registry, no increase in the risk for major congenital malformations, low birth weight, or spontaneous abortion was identified, but there was an increased risk for prematurity (OR, 4.2; 95% CI, 1.3 to 13.0).[162] As such, mothers who use ergot alkaloids for migraine headache treatment in the first and second trimesters, usually because the pregnancy is not recognized, should be assessed carefully, and ergot alkaloid therapy should be avoided, if possible, once pregnancy is diagnosed.

Breast-feeding data for ergot alkaloids are limited. In a 1965 review article, Knowles[163] cited a 1934 German study in which 90% of nursing infants of mothers using ergot alkaloids displayed vomiting, diarrhea, convulsions, and other symptoms of ergotism. As such, the AAP recommends that the drug be used with extreme caution in nursing mothers.[87] However, methylergonovine is commonly used to treat uterine atony in the first 24 hours after delivery, and many mothers breast-feed during this interval. A small prospective controlled study found no differences in neonatal complication rate or growth or neurodevelopment outcomes in the infants whose mothers received short-term postpartum methylergonovine treatment compared with a control group without exposure.[164]

Beta-adrenergic blocking agents. Beta-adrenergic blocking agents are frequently used in pregnancy for a variety of indications, including migraine headache prophylaxis. Their use is generally considered safe. The largest and most recent population-based studies show no overall increase in the risk for major congenital malformations.[165] **Metoprolol** and **propranolol** at the lowest possible effective doses have been suggested as first-line medications for migraine prophylaxis in pregnancy. The increased volume of distribution and clearance during pregnancy require that metoprolol dose and dosing frequency be increased significantly to maintain efficacy.[82] Transfer across the placenta to the fetus with subsequent risk for neonatal bradycardia and hypoglycemia have been observed when beta-adrenergic blocking agents are used in the peripartum period; however, these drugs have a long safety record when used to treat hypertension in women with preeclampsia.[87]

Beta-adrenergic blocking agents are considered compatible with breast-feeding by the AAP.[87] Although metoprolol concentrates in breast milk (approximate M/P ratio, 3), no adverse effects have been observed in nursing infants. The reported propranolol M/P ratio ranges widely from 0.2 to 1.5.[87]

Calcium entry–blocking agents. **Verapamil** is generally considered to be safe in pregnancy. Retrospective and prospective studies have not identified increased risk for major malformations with first-trimester use.[87] Data suggest a possible increase in preterm birth in patients taking verapamil; however, poor placental perfusion caused by hypertension, rather than a direct effect of hypertensive therapy, explains this finding.[166]

The AAP considers verapamil to be compatible with breast-feeding. The estimated relative infant dose is less than 0.01% of the maternal dose; no adverse effects have been reported.[87] Verapamil has been recommended as the second-line prophylactic medication for migraine headache in women who are breast-feeding if beta-adrenergic blocking agents are contraindicated or ineffective.[79] Data are lacking for safety in pregnancy and breast-feeding for the newer calcium entry–blocking agents, flunarizine and cinnarizine.

Tricyclic antidepressants. Amitriptyline has been used effectively for migraine prevention and has been suggested to be another second-line agent for migraine prevention in pregnancy.[167] Although data are conflicting, the risk for teratogenicity from early gestational exposure is likely low (see earlier discussion).

Anticonvulsants

Valproic acid and **topiramate** are the two anticonvulsant medications with demonstrated efficacy in migraine prophylaxis that are considered teratogens and should not be used in pregnant women for migraine headache prophylaxis.[42] Studies have shown an 11% risk for major congenital malformations, primarily an increased risk for cleft palate and neural tube defects, in infants with *in utero* topiramate exposure.[168] In addition, valproic acid use in late pregnancy has been associated with autism, lower cognitive function, and lower intelligence in offspring.[168]

Valproic acid can be resumed for migraine prophylaxis in the postpartum period; the AAP believes the drug is compatible with breast-feeding.[87] Valproic acid is almost completely bound to plasma proteins. In a study of six nursing mothers who were receiving valproate for epilepsy, milk concentrations were less than or equal to 15% of the maternal serum concentration.[169] Infant serum levels of valproate were 0.9% to 2.3% of maternal values. However, one report described neonatal thrombocytopenia, anemia, and purpura that resolved after maternal discontinuation of valproate.[170] Thus, nursing infants exposed to valproic acid who exhibit thrombocytopenia or jaundice should have serum valproate levels measured.[79]

Topiramate is excreted into the breast milk.[87] The estimated M/P ratio is 0.86, and the relative infant dose is 3% to 23% of the maternal dose.[87] Breast-feeding mothers who are taking topiramate should be advised to watch for adverse effects in their infants, including decreased alertness, fatigue, anorexia, and weight loss. Although topiramate is considered safe for breast-feeding mothers, its use for migraine prophylaxis should be considered only if other medications are contraindicated or have been shown to be ineffective.

Interventional Treatments

Interventional treatments for pain syndromes in pregnancy are commonly deferred until the postpartum period, in part because many of these treatments, including nerve blocks, stimulators, and radiofrequency treatment, are done with the assistance of fluoroscopy. However, an increasing number of practitioners are forgoing fluoroscopy and using ultrasonography to facilitate a wide array of interventional pain procedures. The drugs used in most of these procedures, local anesthetics and low-dose corticosteroids, are commonly used in the antenatal period for other indications. Corticosteroids used as part of interventional pain procedures have been safely used in women with gestational diabetes.[73,171] Therefore, wider availability and use of interventional pain procedures for pregnant women may be anticipated and prudent. Peripheral nerve blocks (e.g., greater occipital nerve blocks for the treatment of migraine headache) have been reported to be safe and efficacious in pregnancy.[172] Similarly, local injection of a corticosteroid can be considered for severe radicular back pain and plantar fasciitis.[72]

At the current time, advanced pain management treatment is increasingly being used for a broader array of indications in young people. For example, spinal cord stimulators may increasingly be implanted in young women who become pregnant. Although experience with these treatments in pregnancy is sparse, no evidence exists for concerns with continued use during pregnancy and the peripartum period. There are several reports of women with indwelling spinal cord stimulators who have had vaginal deliveries with successful epidural analgesia.[173] In this setting, it is important to know the spinal level at which the stimulator leads have been placed, and to avoid them. They are seldom located in the lower lumbar spine. Whether antibiotic prophylaxis is indicated in patients with these devices is controversial.

Prophylaxis

Several studies have evaluated the incidence of the development of new chronic pain after childbirth. The highly variable results of these studies can likely be explained, in part, by study design differences, population differences, and the definition of chronic pain.[7,10,11,17,174–177] In general, earlier retrospective questionnaire-based studies have reported higher incidences,[174] thus raising the suspicion of recall bias, whereas later prospective studies have reported a lower incidence.[10,11] In these studies, although patients were assessed at multiple time points after delivery, follow-up was terminated when the patient reported no pain.[10,11] Thus, patients with intermittent pain received no further follow-up, and this may have contributed to the low reported incidence of persistent pain.

Several factors have been associated with an increased risk for developing chronic pain after delivery, including severe pain in the early postpartum period and preexisting chronic headache, back pain, and pelvic pain.[7,178–180] Quantitative sensory testing, evaluating response to a pain stimulus, and simply asking patients how much pain they anticipate may contribute to better prediction of women at risk for severe acute postdelivery pain.[71,181,182] Genetic factors may explain a small component of post–cesarean delivery pain (see earlier discussion).[183,184]

The risk for progressing to chronic opioid use because of new persistent pain is likely small. However, given that cesarean delivery is the most common major surgical procedure in the world, with over 1 million women undergoing this procedure annually in the United States, an estimated 4000 women annually in the United States may become new chronic opioid users after delivery.[185] This potential public health problem deserves further study.

It is unknown whether aggressive treatment of severe postdelivery acute pain will reduce the development of persistent pain or prevent initiation of chronic opioid use. Several approaches have been tried, but long-term follow-up is lacking. Wound infiltration with local anesthetics, diclofenac, and other NSAIDs improves pain and reduces opioid requirements in the short term but does not prevent the development of chronic pain.[186,187] Similarly, abdominal wall nerve blocks, most commonly transversus abdominis plane blocks, are efficacious for acute pain, but do not improve analgesia when combined with long-acting neuraxial opioids in low-risk patients (see Chapter 27). Whether adjunctive therapy targeted toward patients at high risk for severe postpartum pain and the development of chronic pain will improve long-term pain outcomes remains to be studied (see later discussion).

MANAGEMENT OF INTRACTABLE PAIN AFTER DELIVERY

Most patients with chronic pain syndromes can be maintained on their usual pain medications, supplemented as needed after delivery. Patients who suffer from chronic pain syndromes may report more postdelivery pain than patients without chronic pain because of sensitization and tolerance to systemic opioids. In a study of patients on methadone maintenance therapy, higher post–cesarean delivery pain scores and 70% greater opioid analgesic use were reported compared with opioid-naïve matched controls.[188] Although most postpartum pain in healthy patients can be managed with a single dose of long-acting neuraxial opioid and oral analgesics (see Chapter 27), consideration should be given for continuous postoperative neuraxial analgesia in patients with a history of chronic pain and opioid use. Pain management in these patients may be particularly difficult if neuraxial analgesia is contraindicated. Meticulous planning with the care team, including assessment of the benefits and risks associated with available options, must be discussed with the multidisciplinary team and the patient.

Adjunctive therapies have not been found to be efficacious in healthy patients without chronic pain, likely caused by a floor effect. Most healthy patients have low pain scores and well-controlled pain using the normal multimodal approaches, making it difficult to identify incremental improvements with

additional therapy.[38] However, this may not be true for patients with chronic pain. The best management for these patients, or patients at risk for the development of chronic pain, is not known. Severe acute pain after delivery is both a red flag for, and likely a precipitant to, the onset of chronic pain after delivery. It is likely that single-dose adjuvant regimens will not be effective in preventing progression to chronic pain in those at highest risk. Sustained, individualized treatment with adjuvant medications through the post-delivery period should be considered in this population. Future studies should evaluate longer-term treatment with analgesic adjuvants in patients at risk for chronic pain. Several classes of drugs, including NMDA antagonists and alpha$_2$-adrenergic agonists, have potential to treat persistent pain after cesarean delivery and to prevent progression to chronic pain.

NMDA Antagonists

NMDA antagonists, including **ketamine,** are efficacious for the treatment of neuropathic pain and have been used in the treatment of chronic pain.[149] NMDA antagonists have been used for treatment of acute postoperative pain and prevention or reversal of central sensitization in chronic pain.[189,190] Ketamine is particularly useful for treatment of acute postoperative pain in opioid-tolerant patients. It is also used for intraoperative analgesia as an adjuvant to neuraxial anesthesia in cesarean deliveries; small intravenous doses provide significant analgesia with minimal respiratory depression.[191] It is reasonable to consider using an NMDA antagonist in a patient with chronic pain or to prevent conversion to chronic pain after cesarean delivery. In one study, patients undergoing cesarean delivery with spinal anesthesia and multimodal postoperative analgesia that included spinal morphine were randomized to receive ketamine 10 mg or placebo after delivery.[192] Women who received ketamine reported less pain at 2 weeks postpartum compared with women who received a placebo.

Perhaps the most commonly used NMDA antagonist in obstetric patients is **magnesium,** a medication commonly used for seizure prophylaxis in women with preeclampsia and fetal/neonatal neuroprotection for women at risk for preterm birth.[193] Magnesium has been shown to reduce central sensitization and wound hyperalgesia.[194] A systematic review concluded that magnesium has a positive effect on acute postoperative pain and may be particularly useful as an adjuvant in patients with opioid tolerance.[195] Neuraxial magnesium has also been shown to be effective for postoperative analgesia; however, it has not been adequately evaluated for neurologic complications, and its use cannot be recommended at this time.

Dextromethorphan is another NMDA-blocking drug that has been studied for its effect on postoperative analgesia and chronic pain. A systematic review concluded that perioperative dextromethorphan therapy may contribute to a reduced need for opioid analgesia, although the clinical significance was unclear.[196] In a single study, women undergoing cesarean delivery with multimodal analgesia that included intrathecal morphine were randomized to receive a single dose of dextromethorphan 60 mg[197]; efficacy was not demonstrated. However, the drug has not been studied in women with chronic pain. Memantine, a noncompetitive NMDA antagonist that does not have hallucinogenic side effects, is efficacious for neuropathic and postoperative pain[149,198–200]; it has not been evaluated for post–cesarean delivery analgesia.

Alpha$_2$-Adrenergic Receptor Agonists

Alpha$_2$-adrenergic agonists have been used for the treatment of acute and chronic pain in nonobstetric settings.[201] Both neuraxial **clonidine** and **dexmedetomidine** have been used for post–cesarean delivery analgesia.[202] Clonidine did not appear to add any benefit to intrathecal morphine in healthy women, but it may be useful in the setting of chronic pain.[203] The epidural formulation of clonidine carries a black box warning from the U.S. Food and Drug Administration stating the following:

> *Clonidine hydrochloride injection (epidural clonidine) is not recommended for obstetrical, postpartum or perioperative pain management. The risk of hemodynamic instability, especially hypotension and bradycardia, from epidural clonidine may be unacceptable in these patients. However, in a rare, obstetrical, postpartum or perioperative patient, potential benefits may outweigh the possible risks.*[204]

This statement suggests that neuraxial clonidine may be beneficial in patients who are at risk for the development of neuropathic pain after cesarean delivery. The finding in one study that the combination of intrathecal clonidine (150 µg) and bupivacaine was associated with reduced wound hyperalgesia after cesarean delivery supports this hypothesis.[205] Further study of the use of alpha$_2$-adrenergic agonists in women with chronic pain is warranted.

KEY POINTS

- The prevalence of chronic headache, back pain, pelvic pain, and fibromyalgia is high in women of reproductive age. Thus, these syndromes commonly occur during pregnancy.
- Multimodal pain management, including medication, psychological support, and physical therapy, is key to the support of patients with chronic pain throughout pregnancy.
- Interventional pain injections may contribute to optimal control in the pregnant chronic pain patient and can be guided by ultrasonography to minimize fetal exposure to ionizing radiation.
- Knowledge of the pharmacokinetics and pharmacodynamics of medications used for management of chronic pain, as well as changes induced by pregnancy, are important to tailor management during pregnancy.

- Multidisciplinary management that includes the obstetric care providers and chronic pain physician should start as early as possible, optimally preconception.
- The prevalence of prescription opioid use during pregnancy is increasing and has significant regional variation.
- Management of patients with opioid use disorder throughout pregnancy and parturition can be challenging and requires a multispecialty team that includes an addiction specialist.
- Women who take chronic opioids during pregnancy are at risk for tolerance, and the neonate is at risk for opioid withdrawal syndrome.

Endocrine Disorders

Richard N. Wissler, MD, PhD

CHAPTER OUTLINE

DIABETES MELLITUS

Definition and Epidemiology

Diabetes mellitus (DM) is a common metabolic disorder with a prevalence of approximately 8% in the general adult population worldwide.[1,2] DM results from either an absolute deficiency in insulin secretion (type 1) or a combination of resistance to insulin in target tissues and inadequate insulin secretion (type 2).[3] Although a combination of genetic and environmental factors contributes to both types, type 1 DM is primarily an autoimmune disorder. Type 2 DM occurs primarily in obese individuals and accounts for 90% to 95% of cases of DM in the United States.[3] Gestational DM refers to DM or glucose intolerance that is first diagnosed during pregnancy and occurs in approximately 5% to 20% of pregnancies in the United States, depending on the screening test strategies implemented.[3–5]

Pathophysiology

Insulin is a peptide hormone secreted by the beta cells of the islets of Langerhans in the pancreas that binds to specific cell-surface receptors in insulin-responsive target tissues (e.g., liver, skeletal muscle, fat). The intracellular effects of insulin are mediated by tyrosine kinase in the beta-subunit of the receptor through a cascade of distal protein kinase–mediated phosphorylations.[6,7] Normal hepatic glucose metabolism represents a balance between the effects of insulin and several "counterregulatory" hormones (e.g., glucagon, cortisol, epinephrine [adrenaline], growth hormone).[8] This control system for glucose homeostasis permits rapid adjustments in glucose metabolism in the fed and fasted states. Insulin is also an important anabolic regulator of lipid and amino acid metabolism (Fig. 43.1). Insulin deficiency (absolute or relative) associated with DM results in abnormal metabolism of carbohydrates, lipids, and amino acids.

Acute and chronic complications occur in patients with DM (Box 43.1). The three major acute complications are **diabetic ketoacidosis (DKA), hyperglycemic nonketotic state,** and **hypoglycemia. DKA** occurs predominantly in patients with type 1 DM. It may develop with a new source of insulin resistance (e.g., infection, trauma, stress) and/or as a result of failure to administer usual insulin doses. DKA results from decreased uptake of glucose by insulin-responsive tissues and greater use of free fatty acids as a hepatic energy source. The lack of insulin favors lipolysis, beta-oxidation of free fatty acids in the liver, and hepatic formation of acetoacetate and beta-hydroxybutyrate from the excess acetyl-coenzyme A generated by fatty acid oxidation.[9] These biochemical events result in metabolic acidosis, hyperglycemia, and dehydration secondary to osmotic diuresis. Signs and symptoms of DKA include nausea, vomiting, weakness, tachypnea, hypotension, tachycardia, stupor, and acetone on the breath. The diagnosis of DKA depends on the laboratory findings of hyperglycemia, ketosis, and acidosis.[10]

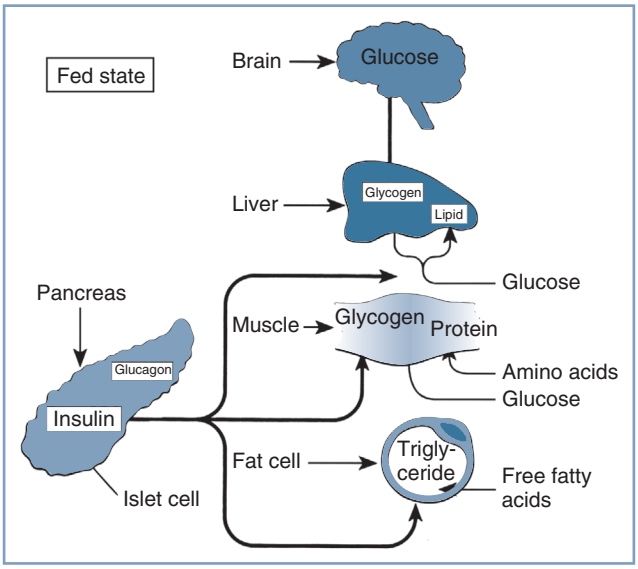

Fig. 43.1 Substrate use in the fed state, showing the role of insulin in the promotion of fuel storage. (From Kitabchi AE, Murphy MB. Diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic coma. *Med Clin North Am.* 1988;72:1545–1563.)

BOX 43.1 Major Complications of Diabetes Mellitus

Acute
- Diabetic ketoacidosis
- Hyperglycemic nonketotic state
- Hypoglycemia

Chronic

Macrovascular (Atherosclerosis)
- Coronary
- Cerebrovascular
- Peripheral vascular

Microvascular
- Retinopathy
- Nephropathy

Neuropathy
- Autonomic
- Somatic

Hyperglycemic nonketotic state (HNS) occurs predominantly in patients with type 2 DM. Laboratory findings in HNS are hyperglycemia (blood glucose level often greater than 600 mg/dL [33.3 mmol/L]), hyperosmolality (greater than 320 mOsm/kg), and moderate azotemia (serum blood urea nitrogen [BUN] often greater than 60 mg/dL), without ketonemia or significant acidosis.[10] The absence of significant ketosis in HNS may indicate an inhibition of lipolysis by hyperosmolality or low levels of insulin. DKA and HNS are probably related conditions; inadequate insulin therapy and infection are the most common precipitating events for both.[10]

BOX 43.2 Criteria for the Diagnosis of Diabetes Mellitus

1. Fasting plasma glucose ≥ 126 mg/dL (7 mmol/L). Fasting is defined as no caloric intake for at least 8 h.[a]
   OR
2. Two-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using an oral glucose load with the equivalent of 75 grams of anhydrous glucose dissolved in water.[a]
   OR
3. Hemoglobin A_{1c} ≥ 6.5%.[a]
   OR
4. A random plasma glucose ≥ 200 mg/dL (11.1 mmol/L) in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis.

[a]In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.

From American Diabetes Association: 2. Classification and diagnosis of diabetes: standards of medical care in diabetes—2018. *Diabetes Care.* 2018;41(Suppl 1):S13–S27.

Hypoglycemia is a continuing health threat in diabetic patients, especially in patients receiving insulin therapy. Hypoglycemia results from an imbalance between insulin or oral hypoglycemic agents and available metabolic fuels. In hospitalized patients with DM, major risk factors for hypoglycemia include renal insufficiency and decreased caloric intake.[11] Symptomatic awareness of hypoglycemia and counterregulatory responses may be inadequate in some diabetic patients with autonomic neuropathy.[12] Problems with hypoglycemia awareness in patients receiving beta-adrenergic receptor antagonists can be minimized by using $beta_1$-adrenergic receptor–selective antagonists.[13] Factitious hypoglycemia results from a deliberate, inappropriate self-administration of insulin or an oral hypoglycemic agent.[14]

In general, the rate of chronic complications increases with the duration of DM.[3,15] The Diabetes Control and Complications Trial, a randomized multicenter study of patients with type 1 DM, demonstrated a positive relationship between tight glucose control and a lower incidence or rate of progression of **retinopathy, nephropathy,** and **neuropathy.**[16] In a similar study of patients with type 2 DM—the UK Prospective Diabetes Study (UKPDS)—intensive glucose control lowered the incidence of microvascular complications but not of macrovascular complications or patient mortality.[17] In contrast, antihypertensive therapy reduced the incidence of macrovascular complications and mortality in patients with both type 2 DM and chronic hypertension.[17] DM may affect **cardiovascular function** as a result of coronary atherosclerosis, autonomic neuropathy, or development of a cardiomyopathy.[18]

Clinical Presentation and Diagnosis

Box 43.2 lists the current diagnostic criteria for DM in *nonpregnant* patients.[3]

Gestational DM is associated with (1) age greater than 35 years, (2) obesity, (3) family history of type 2 DM, (4) prior history of gestational DM, (5) history of polycystic ovarian syndrome, and (6) history of prior stillbirths or macrosomic babies.[19] Several observational clinical studies, including the Hyperglycemia and Adverse Pregnancy Outcome study,[20] have shown that adverse pregnancy outcomes are a continuous function of glucose intolerance in pregnancy. Box 43.3 lists the current recommendations of the American Diabetes Association (ADA) for screening and diagnosis of gestational DM, including one-step and two-step procedures.[3] The choice between one-step and two-step screening strategies for gestational diabetes at 24 to 28 weeks' gestation remains controversial.[3,21,22] As diagnostic thresholds decrease for any disease process, the apparent prevalence in the population increases. The continuing debate over screening protocols for gestational DM centers on whether treatment of an expanded patient population is cost-effective and will improve outcomes.[23–25]

Glycosylated hemoglobin measurements are used as time-integrated estimates of glycemic control, although both analytical and physiologic factors may affect this relationship.[26] The normal range for hemoglobin A_{1c} in nondiabetic pregnant women is 4.0% to 5.5%, compared with 4.8% to 6.5% in nondiabetic nonpregnant women.[27]

BOX 43.3 Screening and Diagnostic Strategies for Gestational Diabetes Mellitus

A. One-step strategy
   1. Perform a 75-gram oral glucose tolerance test, with plasma glucose measurements when the patient is fasting and at 1 hour and 2 hours, at 24 to 28 weeks' gestation in women not previously diagnosed with overt DM.
   2. The oral glucose tolerance test should be performed in the morning after an overnight fast of at least 8 hours.
   3. The diagnosis of gestational DM is made when any of the following plasma glucose values are met or exceeded:
      - Fasting: 92 mg/dL (5.1 mmol/L)
      - 1 hour: 180 mg/dL (10 mmol/L)
      - 2 hours: 153 mg/dL (8.5 mmol/L)

B. Two-step strategy
   1. Step 1:
      - Perform a nonfasting 50-gram oral glucose load test, with a plasma glucose measurement at 1 hour, at 24 to 28 weeks' gestation in women not previously diagnosed with overt DM.
      - If the plasma glucose level 1 hour after the glucose load is ≥ 130 mg/dL (7.2 mmol/L), then proceed to a 100-gram oral glucose tolerance test (Step 2).
   2. Step 2:
      - The 100-gram oral glucose tolerance test should be performed when the patient is fasting.
      - Four blood samples are collected: fasting, 1 hour, 2 hours, and 3 hours.
      - The diagnosis of gestational DM is made if at least two of the four plasma glucose samples exceed the following criteria (either Carpenter-Coustan or National Diabetes Data Group).

Sample	Carpenter-Coustan	Or	National Diabetes Data Group
Fasting	95 mg/dL (5.3 mmol/L)		105 mg/dL (5.8 mmol/L)
1 hour	180 mg/dL (10 mmol/L)		190 mg/dL (10.6 mmol/L)
2 hours	155 mg/dL (8.6 mmol/L)		165 mg/dL (9.2 mmol/L)
3 hours	140 mg/dL (7.8 mmol/L)		145 mg/dL (8.1 mmol/L)

DM, Diabetes mellitus.

Interaction with Pregnancy

How Does Pregnancy Affect Diabetes Mellitus?

Pregnancy is characterized by progressive peripheral resistance to insulin at the receptor and postreceptor levels in the second and third trimesters (Fig. 43.2).[28-30] The presumed mechanism involves an increase in counterregulatory hormones (e.g., placental lactogen, placental growth hormone, cortisol, progesterone) during pregnancy. The change in placental lactogen is a plausible mechanism, given that (1) a graph of serum lactogen level during pregnancy is similar in shape to that of insulin requirement in pregnant women with type 1 DM and (2) placental lactogen has growth hormone–like activity. Also, maternal adipokines probably are important factors in insulin resistance of pregnancy[29]; they facilitate the provision of maternal fuels for the fetus.[30]

Gestational DM develops when a patient cannot mount a sufficient compensatory insulin response during pregnancy. In some patients, gestational DM can be viewed as a preclinical state of glucose intolerance that is not detectable before pregnancy. After delivery, most patients return to normal glucose tolerance but remain at increased risk for DM

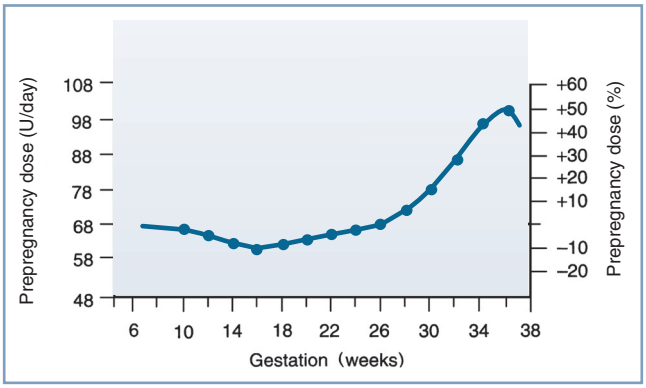

Fig. 43.2 Insulin requirements in euglycemic women with type 1 diabetes mellitus during pregnancy. (From Crombach G, Siebolds M, Mies R. Insulin use in pregnancy: clinical pharmacokinetic considerations. *Clin Pharmacokinet.* 1993;24:89–100.)

(predominantly type 2) in later life.[31] The recurrence rate for gestational DM in a subsequent pregnancy is 35% to 70%.[32]

In patients with **pregestational DM,** insulin requirement progressively increases during pregnancy because of peripheral insulin resistance.[33] At term, the daily insulin requirement is approximately 1.0 insulin unit/kg, compared with 0.7 unit/kg before pregnancy.[33] Insulin requirement may be higher in pregnancies with multiple gestation.[34] During late pregnancy in normal healthy patients, basal and glucose-stimulated plasma insulin levels are twice the postpartum measurements.[30] These changes reflect pregnancy-related increases in pancreatic islet cell mass and glucose sensitivity, probably secondary to the net effect of competing progesterone and lactogenic hormone stimuli in the endocrine pancreas.[35,36] Near term, maternal overnight insulin requirements may decrease, presumably as a result of a "siphoning of maternal fuels" by the growing fetus during the overnight maternal fast.[37]

Endogenous plasma insulin concentration during labor and delivery in nondiabetic parturients differs from exogenous insulin requirement in laboring diabetic women. In nondiabetic parturients, the plasma glucose concentration is only one of many factors that affect endogenous insulin secretion; glucose production and use are markedly higher during painful labor than postpartum.[38] Plasma insulin concentration remains unchanged except for a brief increase during the third stage of labor and immediately postpartum.[38,39] This finding suggests that glucose use during labor is largely independent of insulin. The pattern of plasma insulin concentrations is similar in nondiabetic patients with and without analgesia (e.g., nitrous oxide, meperidine [pethidine]).[39]

In patients with type 1 DM, insulin requirement decreases with the onset of the first stage of labor.[40] These patients may require no additional insulin during the first stage of labor, although insulin requirement is modified by (1) the level of metabolic control before labor, (2) the residual effect of prior doses of subcutaneous insulin, and (3) the glucose infusion rate.[40,41] Insulin requirement increases during the second stage of labor via an unknown mechanism.[40,41] The use of epidural analgesia or oxytocin does not affect exogenous insulin requirement during the first and second stages of labor.[40] After delivery—either vaginal or cesarean—insulin requirement in women with type 1 DM decreases markedly for at least several days, although there is significant variability among individuals (Fig. 43.3).[28,42] Presumably, the decreased insulin requirement results from loss of counterregulatory hormones produced by the placenta. Pituitary growth hormone responsiveness to hypoglycemia is blunted in late pregnancy and may contribute to impaired counterregulatory responses during the postpartum period.[43] Insulin requirement gradually returns to prepregnancy levels within several weeks of delivery in women with type 1 DM.[37]

Before the discovery of insulin in 1921, pregnancies were rare in diabetic patients. Insulin therapy improved the rate of survival in women with severe DM, allowing these women to reach childbearing age and become pregnant. Maternal outcomes improved, but fetal and neonatal morbidity and mortality remained high.[44]

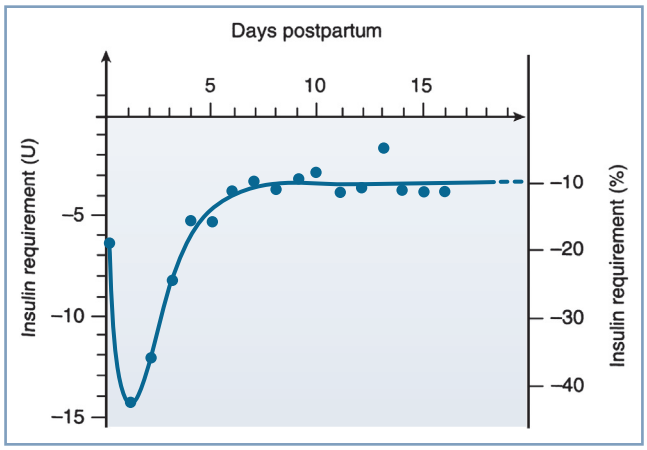

Fig. 43.3 Insulin requirements in the postpartum period. (From Crombach G, Siebolds M, Mies R. Insulin use in pregnancy: clinical pharmacokinetic considerations. *Clin Pharmacokinet.* 1993;24: 89–100.)

In 1949, White[45] proposed a classification system for DM during pregnancy based on 439 consecutive cases. Physicians caring for pregnant diabetic patients should be familiar with the White system, which has endured with some modifications (Table 43.1). The system emphasizes the relationship among the duration of type 1 DM, vascular complications of type 1 DM, and poor fetal outcome.[46] In the 1950s, fetal survival rates were as follows: class A, 100%; class B, 67%; class C, 48%; class D, 32%, and class F, 3%.[46]

Diabetic ketoacidosis. The incidence of DKA has decreased from 9% to between 0.5% and 3% of diabetic pregnancies,[47,48] probably as a result of improvements in medical care and patient education. Similarly, the incidence of perinatal and maternal mortality from DKA during pregnancy has decreased in the past several decades.[48,49] DKA during pregnancy occurs predominantly in patients with type 1 DM, but also in patients with type 2 DM or gestational DM.[48,50] The higher risk for DKA during pregnancy reflects the metabolic adaptations of pregnancy, including peripheral insulin resistance.[29]

During pregnancy, DKA occurs most commonly during the second and third trimesters.[49] It is associated with (1) emesis, (2) infection, (3) poor compliance or noncompliance, (4) insulin pump failure, (5) use of beta-adrenergic receptor agonists, (6) use of corticosteroids, and (7) poor medical management.[48] The infection rate in pregnant women with pregestational type 1 DM is 3.2 times higher than that in nondiabetic pregnant women.[51] DKA may be the first clinical sign of type 1 DM during pregnancy.[52,53] Beta-adrenergic receptor agonists, which are used to treat preterm labor, and corticosteroids, which are used to accelerate fetal lung maturity, both have counterregulatory pharmacologic effects that oppose insulin action. Beta-adrenergic receptor agonist tocolytic therapy, with or without concurrent corticosteroid therapy, and by any route of administration, can precipitate

TABLE 43.1 Modified White Classification of Diabetes Mellitus during Pregnancy

Class	Age at Onset of Diabetes (Yr)		Duration of Diabetes (Yr)	Vascular Disease	Insulin Required
Gestational Diabetes					
A_1	Any		Any	No	No
A_2	Any		Any	No	Yes
Pregestational Diabetes					
B	> 20		< 10	No	Yes
C	10–19	or	10–19	No	Yes
D[a]	< 10	or	> 20	Yes	Yes
F (nephropathy)	Any		Any	Yes	Yes
R (proliferative retinopathy)	Any		Any	Yes	Yes
T (status post–renal transplantation)	Any		Any	Yes	Yes
H (ischemic heart disease)	Any		Any	Yes	Yes

[a]Vascular disease in D is hypertension or benign retinopathy.
Modified from Landon MB, Gabbe SG. Diabetes mellitus and pregnancy. *Obstet Gynecol Clin North Am.* 1992;19:633–654.

DKA during pregnancy.[54] Beta-adrenergic receptor stimulation worsens glucose intolerance by stimulating glucagon secretion[55]; beta-adrenergic receptor agonists may be well tolerated in pregnant women with DM if higher insulin requirements are anticipated and doses are adjusted in response to frequent blood glucose determinations.[53,54]

Nonreassuring fetal heart rate patterns during episodes of maternal DKA have been described.[48,56] After appropriate medical management of maternal DKA, preterm uterine contractions stopped and fetal heart rate patterns normalized. The mechanism of fetal compromise during DKA is unclear, but it may be related to changes in uterine blood flow. Blechner et al.[57] demonstrated that uterine artery blood flow is reduced by acute maternal metabolic acidosis. A single case report demonstrated reversible redistribution of fetal blood flow during an episode of maternal DKA on the basis of Doppler pulsatility indices of the umbilical and middle cerebral arteries.[58]

There are three case reports of HNS during pregnancy.[59–61] No conclusion can be drawn about HNS and pregnancy, except that HNS rarely occurs during pregnancy.

Hypoglycemia. Hypoglycemia occurs in 33% to 71% of pregnant women with pregestational type 1 DM and is a significant health risk.[62–65] This rate is 3 to 15 times higher than that in similar groups of nonpregnant patients with type 1 DM[62,63]; 80% to 84% of severe hypoglycemia episodes occur before 20 weeks' gestation.[64,65] The risk for hypoglycemia during pregnancy in patients with type 1 DM increases with tight glucose control.[62,64] This pattern mirrors the clinical experience in nonpregnant women with type 1 DM, in which a threefold rise in the occurrence of severe hypoglycemia results from tight insulin control.[66] In both pregnant and nonpregnant patients with type 1 DM, counterregulatory hormone response to hypoglycemia is impaired after intensive insulin therapy.[67,68] Two small series suggest that acute mild to moderate maternal hypoglycemia is not associated with acute alterations in fetal well-being in pregnant women with type 1 DM.[67,69]

Other complications. The relationship between pregnancy and the development of macrovascular complications of DM is largely unknown. Patients with pregestational type 1 DM have higher systolic and diastolic blood pressure during pregnancy, and they are three times more likely than nondiabetic control subjects to have gestational hypertension.[70,71] In women with pregestational type 1 DM, the risk for preeclampsia is increased with increased severity of diabetes (White classification), and proteinuria early in pregnancy is associated with an increased risk for adverse outcomes.[72] Myocardial infarction is a rare complication.[73] The effect of gestational hypertension on the progression of atherosclerotic disease in diabetic patients is unclear.

Pregnancy may accelerate the development of **proliferative retinopathy,** a microvascular complication of DM. Hyperglycemia and hypertension are also associated with the progression of retinopathy.[74,75]

In contrast to diabetic retinopathy, pregnancy does not accelerate the progression of diabetic **nephropathy,** provided that antihypertensive therapy is effective.[75,76] It is unclear whether pregnancy accelerates the progression of **somatic** or **autonomic neuropathy** in diabetic women.

How Does Diabetes Mellitus Affect the Mother and Fetus?

Both pregestational and gestational DM are associated with higher rates of gestational hypertension, polyhydramnios, and cesarean delivery.[47,76–78] The incidence of cesarean delivery is higher in women with pregestational DM than in women with gestational DM.[47,76,78] Trial of labor after cesarean delivery (TOLAC) in patients with gestational DM is associated with rates of operative vaginal delivery and repeat cesarean delivery that are higher than those found in nondiabetic controls.[79] Pregestational DM—but not gestational DM—is associated with a twofold to threefold increase in the incidence of **preterm labor and delivery.**[76,80]

Box 43.4 lists the fetal complications of maternal DM during pregnancy. **Fetal macrosomia** is a well-recognized

complication of maternal DM. Most studies suggest that both pregestational DM and gestational DM result in an increased incidence of fetal macrosomia.[81–83] Depending on the definition of macrosomia (4000 g versus 4500 g), pregestational DM results in fetal macrosomia in 9% to 25% of women—a fourfold to sixfold higher rate than in nondiabetic controls.

Macrosomia results in an increased risk for **shoulder dystocia** and **birth trauma** with vaginal delivery.[77,84,85] Moreover, when comparisons are made within birth weight categories above 4000 g, pregnancies in diabetic women have a higher risk for shoulder dystocia than nondiabetic women.[86] The use of intensive insulin therapy may reduce the risk for birth trauma in women with pregestational DM.[87] Several mechanisms have been suggested for the development of fetal macrosomia in diabetic pregnancy. Maternal hyperglycemia can result in fetal hyperglycemia, with reactive fetal hyperinsulinemia and an anabolic response in the fetus.[88] Shoulder dystocia may reflect the excessive growth of the fetal trunk (relative to the fetal head) in response to fetal hyperinsulinemia.[89]

Women with pregestational DM are at increased risk for **fetal anomalies** (see Box 43.4). The incidence of major anomalies, estimated to be 6% to 10%, is five times higher than in nondiabetic controls.[47,90,91] Overall, cardiovascular anomalies are most common, followed by anomalies of the central nervous system (CNS). Caudal regression syndrome is uncommon, but it is 200 times more likely in diabetic than in nondiabetic pregnancies. The incidence of major congenital anomalies in infants of women with gestational DM is 3% to 8%, which is lower than in infants of women with pregestational DM.[76]

Mechanisms that may be involved in the development of fetal structural malformations in diabetic pregnancies include embryonic apoptosis and yolk sac vasculopathy.[92,93] Most fetal structural malformations that occur during diabetic pregnancies are likely to have a multifactorial etiology. However, hyperglycemia during the period of critical organogenesis before the seventh week after conception is probably the single strongest etiologic factor in diabetic women and may be associated with embryonic oxidative stress.[91,92]

Studies have suggested that patient education and strict glycemic control during the preconception period may reduce the rate of major congenital anomalies from 10% to 1% in patients with pregestational DM.[94] The latter figure is similar to the baseline risk for major structural malformations in the general population. Strict glycemic control initiated during the preconception period also increases the incidence of maternal hypoglycemic episodes. These studies suggest that hypoglycemia is not a significant factor in the etiology of human malformations, because the rate of anomalies decreased 10-fold despite hypoglycemic episodes.[94] Similarly, strict glycemic control before conception also has been associated with a threefold decrease in the incidence of spontaneous abortion in women with pregestational DM.[95] Dicker et al.[96] observed normal induced ovulation, *in vitro* fertilization, and early embryonic development in a small series of infertile patients with pregestational DM who attended a preconception diabetes clinic. However, only 36% of women with known pregestational DM receive appropriate medical care before conception.

During the 1950s to 1970s, the **perinatal mortality rate** in women with pregestational DM was 15% to 18%.[47] Subsequent studies noted a decrease to 2%, a rate similar to that in nondiabetic controls.[76] In contrast, one study noted a rate of 8%, three times greater than in nondiabetic controls.[83] If the entire population is considered, the perinatal mortality rate likely remains higher in patients with pregestational DM than in nondiabetic controls. The rate in patients with gestational DM is intermediate between the rate in women with pregestational diabetes and the rate in nondiabetic controls.[76,83]

Historically, **intrauterine fetal death** was responsible for approximately 40% of the perinatal deaths in women with DM; 68% of the stillbirths occurred between 36 and 40 weeks' gestation.[45,83] In contemporary reports, the ratio of intrauterine deaths to neonatal deaths in diabetic pregnancies has varied from 0 to 1.0. Fetal macrosomia is a risk factor for intrauterine fetal demise in both diabetic and nondiabetic pregnancies. Recurrent episodes of intrauterine hypoxia can occur in diabetic pregnancies that end in stillbirth; episodes of hypoxia may reflect reduced uteroplacental blood flow and changes in fetal carbohydrate metabolism. **Congenital anomalies** have now emerged as the leading cause of perinatal mortality in diabetic pregnancies.[91] This change likely reflects better obstetric care during pregnancy, despite the lack of adequate glycemic control before conception.

BOX 43.4 Fetal Complications of Maternal Diabetes Mellitus

During Pregnancy and the Puerperium

Chronic

- Macrosomia
- Shoulder dystocia
- Birth injury or trauma
- Structural malformations
- Central nervous system: anencephaly, encephalocele, meningomyelocele, spina bifida, holoprosencephaly
- Cardiac: transposition of great vessels, ventricular septal defect, situs inversus, single ventricle, hypoplastic left ventricle
- Skeletal: caudal regression
- Renal: agenesis, multicystic dysplasia
- Gastrointestinal: anal or rectal atresia, small left colon
- Pulmonary: hypoplasia

Acute

- Intrauterine or neonatal death
- Neonatal respiratory distress syndrome
- Neonatal hypoglycemia
- Neonatal hyperbilirubinemia

After Pregnancy

- Glucose intolerance
- Possible impairment of cognitive development

Two series that involved women who delivered between 1950 and 1979 demonstrated an incidence of **neonatal respiratory distress syndrome (RDS)** in diabetic pregnancies that was 6 to 23 times that in nondiabetic controls.[47,97] Respiratory distress is more common among newborns who are delivered preterm or who are surgically delivered without labor. Later studies of patients with both pregestational and gestational DM have not demonstrated a significant difference in the incidence of neonatal RDS between diabetic and nondiabetic pregnancies.[76,98,99]

The level of glycemic control during pregnancy affects the amniotic fluid phospholipid profile. In pregnancies of patients with poorly controlled diabetes, there may be a higher incidence of immature amniotic fluid fetal lung profiles at 34 to 38 weeks' gestation.[99–101]

Neonatal hypoglycemia occurs in 5% to 12% of cases of pregestational and gestational DM.[76] This represents a 6-fold to 16-fold higher risk for neonatal hypoglycemia than in nondiabetic controls. Neonatal hypoglycemia likely results from sustained fetal hyperinsulinemia in response to chronic intrauterine hyperglycemia. Clinical studies have demonstrated higher fetal insulin levels and exaggerated fetal insulin responses to acute maternal hyperglycemia in diabetic pregnancies.[102,103] An acute increase in maternal glucose concentration, as might occur if a dextrose-containing solution is used for intravenous hydration during administration of neuraxial anesthesia, can lead to reactive neonatal hypoglycemia, even in nondiabetic women.[104]

There is a twofold to fivefold higher incidence of **neonatal hyperbilirubinemia** in women with pregestational and gestational DM than in nondiabetic controls.[76] Other associated factors include the severity of gestational DM and excess maternal weight gain during pregnancy.[105,106] Both the etiology and the clinical significance of neonatal hyperbilirubinemia are unknown, although one study noted the absence of long-term morbidity.[76]

Children of diabetic mothers are at increased risk for development of **DM,** likely from a combination of genetic and intrauterine environmental factors. Despite the well-known association of type 1 DM with human leukocyte antigen markers, studies of monozygotic human twins have suggested that genetic factors have a greater role in type 2 DM than in type 1 DM (100% versus 20% to 50% concordance, respectively).[105] In addition, fathers with type 1 DM are five times more likely than mothers with the same disease to have a child with type 1 DM. The intrauterine environment also affects the development of glucose intolerance in offspring.[31]

Some investigators have suggested that **cognitive development** may be impaired in the children of diabetic mothers,[107] but this issue remains controversial.

Obstetric Management

Glycemic Control

Early, strict glycemic control is the best way to prevent fetal structural malformations in women with pregestational DM.[90,94] Determination of hemoglobin A_{1c} concentrations may help the physician determine the adequacy of preconceptional glycemic control.

During pregnancy, the patient should frequently determine capillary blood glucose concentration using a reflectance meter. However, the ideal frequency of these measurements remains under investigation.[108] Continuous glucose monitoring systems (e.g., transdermal, subcutaneous) have been used safely in pregnancy and enable remote monitoring.[109] Glucose determinations guide adjustments in diet and insulin therapy. In general, insulin requirement increases progressively during the second and third trimesters. Both maternal and perinatal outcomes seem to improve when maternal glycemic control approaches that observed in normal pregnancies. Table 43.2 illustrates glycemic targets recommended by the American Diabetes Association for pregnant patients with either pregestational or gestational DM.[4] Of course, strict glycemic control increases the risk for maternal hypoglycemia.

Therapeutic insulin is available in several forms. Initially, insulin was isolated as a natural product from domestic animals (e.g., cattle, pigs). In the past 30 years, synthetic human insulin has become commercially available and has largely replaced beef and pork insulin in human medicine.

The goal of insulin therapy is to provide plasma insulin concentrations that lead to tight glucose control without hypoglycemia. This goal is facilitated by the availability of several insulin preparations with different subcutaneous absorption rates (Table 43.3).[110–112] Regular insulin can be administered by the intravenous or subcutaneous route. Regular insulin administered intravenously has a half-life of approximately 4 minutes.[110] Administering a rapid-acting insulin by the subcutaneous route using a continuous programmable pump is an alternative to intermittent manual injections.[113] It remains controversial whether the use of continuous subcutaneous insulin pumps will improve pregnancy outcomes in diabetic pregnancies.[114,115]

Human insulin therapy has fundamentally changed in recent years through the development of insulin analogues.[110,111,116] These molecules have specific chemical substitutions in portions of the human insulin protein not involved

TABLE 43.2 American Diabetes Association: Glycemic Targets in Pregnancy for Women with Diabetes Mellitus

Parameter	Pregestational DM[a]	Gestational DM[a]
Hemoglobin A_{1c}	6%–6.5%	6%–6.5%
Fasting plasma glucose	60–99 mg/dL (3.3–5.5 mmol/L)	≤ 95 mg/dL (5.3 mmol/L)
One-hour postprandial plasma glucose	100–129 mg/dL (5.6–7.2 mmol/L)	≤ 140 mg/dL (7.8 mmol/L)

DM, Diabetes mellitus.
[a]Assumes patients with low risk for hypoglycemia; otherwise targets should be adjusted higher on an individual basis.
Modified from American Diabetes Association. 13. Management of diabetes in pregnancy: standards of medical care in diabetes—2018. *Diabetes Care.* 2018;41(Suppl 1):S137–S143.

TABLE 43.3 Pharmacokinetics of Subcutaneous Insulin Administration in Nonpregnant Humans

Insulin Preparations	Onset	Peak	Duration
Short-Acting Class			
Regular	30 min	2–4 h	6–8 h
Lispro[a]	5–15 min	30–90 min	4–6 h
Aspart[a]	5–15 min	30–90 min	4–6 h
Glulisine[a]	5–15 min	30–90 min	4–6 h
Intermediate Class			
NPH	1–2 h	6–12 h	18–24 h
Lente	1–3 h	6–12 h	18–24 h
Long-Acting Class			
Glargine[a]	2–4 h	No peak	20–24 h
Detemir[a]	1–4 h	No peak	12–24 h
Degludec[a]	30–90 min	No peak	> 24 h

[a]Insulin analogue.

Pharmacokinetic considerations of new insulin formulations and routes of administration. *Clin Pharmacokinet.* 1997;33:285–301; Gururaj Setty S, Crasto W, Jarvis J, et al. New insulins and newer insulin regimens: a review of their role in improving glycaemic control in patients with diabetes. *Postgrad Med J.* 2016;92:152–164; Gabbe SG, Carpenter LB, Garrison EA. New strategies for glucose control in patients with type 1 and type 2 diabetes mellitus in pregnancy. *Clin Obstet Gynecol.* 2007;50:1014–1024.

in receptor binding. Both short-acting and long-acting insulin analogues are in clinical use. **Lispro, aspart,** and **glulisine** are rapid-acting analogues, with a more physiologic onset and offset than regular insulin. **Glargine, detemir,** and **degludec** are long-acting insulin analogues with a sustained plateau of activity instead of a peak. Lispro, aspart, glargine and detemir have all been used safely during human pregnancy.

Because insulin requirement decreases abruptly at delivery, it is important to verify the times, doses, insulin preparations, and routes of administration in the 24 hours before delivery to avoid maternal postpartum hypoglycemia.

Management of **DKA** is similar in pregnant and nonpregnant women. It involves (1) intravenous hydration, (2) intravenous insulin, (3) treatment of the underlying cause of DKA, (4) careful monitoring of blood glucose and electrolyte levels, and (5) restriction of bicarbonate therapy to cases of extreme acidosis.[9,10,48] In addition, left uterine displacement should be maintained, and supplemental oxygen should be administered. Initial management of the critically ill pregnant woman should focus on the effective management of DKA. Fetal compromise is likely to resolve with appropriate medical management.[48,56,57]

Diet and exercise are the initial therapeutic approaches for glycemic control in women with gestational DM. Pharmacologic therapy with oral hypoglycemic agents and/or insulin is initiated if the lifestyle changes are not clinically effective.[117] In current practice, many women with gestational DM are treated with metformin or the sulfonylureas glipizide or glibenclamide (glyburide).[118,119] In the past, oral hypoglycemic agents were used sparingly during pregnancy because of concerns for fetal effects. These medications are in common use, although the concerns continue to be investigated.[118,119] Concerns about the long-term health implications of gestational diabetes have resulted in national and international initiatives for postpartum metabolic surveillance.[120,121] The goal is to identify and treat postpartum type 2 DM, with an emphasis on lifestyle interventions.

Timing of Delivery

Timing of delivery is important in the management of diabetic pregnancies. White[46] noted, "Our problem must [be] … to prevent premature delivery of the infant of the diabetic mother prior to the period of its viability … and, secondly, the termination of the pregnancy at the point of viability and before the dreaded late intrauterine accident can occur." Typically a nonstress test is performed twice weekly in patients with pregestational DM, beginning at 32 weeks' gestation.[122] A nonreactive nonstress test should prompt the performance of a fetal biophysical profile (see Chapter 6). Risk factors for abnormal fetal testing in diabetic pregnancies include maternal nephropathy, hypertension, and poor glycemic control.[123] Patients with poorly controlled gestational DM should probably undergo antepartum fetal surveillance similar to that in patients with pregestational DM.[117]

In the presence of reassuring fetal testing, delivery can be delayed until after 38 weeks' gestation.[124] If fetal testing is abnormal and amniotic fluid analysis indicates fetal pulmonary maturity, the fetus should be delivered as soon as possible. If fetal testing is abnormal but amniotic fluid analysis suggests that the fetal lungs are immature, decisions about the timing of delivery are more difficult.

The decision regarding the method of delivery requires consideration of estimated fetal weight, fetal condition, cervical dilation and effacement, and previous obstetric history. The obstetrician may choose elective cesarean delivery in the diabetic parturient with evidence of fetal macrosomia to decrease the risk for shoulder dystocia.

Anesthetic Management

There are few studies of the anesthetic management of pregnant women with DM. In general, neuraxial analgesia is the preferred technique for labor and cesarean delivery, but clinical decisions about these patients must be guided by logical extensions of studies of nonpregnant diabetic patients and nondiabetic pregnant patients.

Preanesthetic evaluation of the woman with DM should include a history and physical examination that focuses on the identification of the acute and chronic complications of DM (see Box 43.1). There are no published data on the relationship between the complications of DM and responses to anesthetic agents or on anesthetic outcomes in pregnant patients. In a study of nonpregnant diabetic patients, preoperative evidence of **autonomic cardiovascular dysfunction** was predictive of the need for a vasopressor during general anesthesia.[125] Because of the potential for hypotension during neuraxial anesthesia, noninvasive testing of autonomic

function may be useful in obstetric patients with pregestational DM. For example, in nonpregnant diabetic patients, the corrected QT interval on an electrocardiogram correlates with the severity of autonomic neuropathy.[126] Patients with evidence of autonomic dysfunction may benefit from more frequent blood pressure determinations and more vigorous intravenous hydration before and during the administration of neuraxial anesthesia. **Gastroparesis** is a manifestation of autonomic neuropathy in diabetic patients.[127] In nonpregnant diabetic patients, autonomic neuropathy is associated with a decreased cough reflex threshold and a higher incidence of obstructive sleep apnea.[128,129] Theoretical concerns have been expressed about local anesthetic toxicity in patients with diabetic polyneuropathy undergoing neuraxial or peripheral nerve blocks since diabetic nerves may be more susceptible to injury, but practically, neuraxial anesthesia is still the anesthetic of choice for the diabetic.[130]

Several studies have examined the maternal, fetal, and neonatal effects of **neuraxial anesthesia** for cesarean delivery for women with pregestational DM.[131–134] Datta and Brown[131] observed that spinal anesthesia was associated with a slightly but significantly lower umbilical cord blood pH measurement at delivery in patients with pregestational DM than in similar patients who received general anesthesia for cesarean delivery. Subsequently, these investigators noted an association between fetal acidosis and peripartum maternal hypotension in patients with pregestational DM who received epidural anesthesia for cesarean delivery.[132] In both studies, acute maternal hyperglycemia—secondary to intravenous hydration with 5% dextrose before administration of neuraxial anesthesia—was a potentially confounding factor.[131,132]

Neonatal acidosis is *not* likely to occur during **spinal** or **epidural anesthesia** for cesarean delivery in diabetic parturients, provided that (1) maternal glycemic control is satisfactory, (2) the patient receives aggressive preanesthetic volume expansion with a non–dextrose-containing balanced salt solution, and (3) hypotension is treated promptly and aggressively.[133,134]

Thalme and Engstrom[135] demonstrated normal umbilical arterial blood pH measurements after the administration of **general anesthesia** in a small series of patients with pregestational DM.

After administration of epidural anesthesia for cesarean delivery, Ramanathan et al.[134] observed an increased incidence of neonatal hypoglycemia in patients with pregestational DM compared with nondiabetic controls (35% versus 7%, respectively). In this study, maternal glycemic control was fair (mean fasting plasma glucose level was 127 mg/dL [7.1 mmol/L]), a non–dextrose-containing solution was used for intravenous hydration, and intravenous insulin therapy was adjusted on the basis of frequent blood glucose determinations. This study illustrates the neonate's vulnerability to hypoglycemia after a diabetic pregnancy despite meticulous anesthesia care at the time of delivery.

A single case report describes a parturient who received combined spinal-epidural labor analgesia and subsequently became hypoglycemic. The authors hypothesized that the rapid decrease in catecholamine levels from the resultant analgesia led to hypoglycemia.[136] In a retrospective study, epidural labor analgesia lowered cord blood glucose and improved the acid-base status in newborns after term vaginal delivery in mothers with well-controlled gestational diabetes.[137]

Maternal insulin requirements decrease with the onset of labor, increase again during the second stage of labor, and decrease markedly during the early postpartum period.[40,41] Intravenous insulin therapy is the most flexible method of treatment during this period of rapid change. Absorption of subcutaneous insulin may be unpredictable and may increase the risk for maternal hypoglycemia, especially during the postpartum period.[41] Moreover, strict glycemic control in pregnant women with type 1 DM increases the risk for maternal hypoglycemia as a result of impaired counterregulatory hormone responses (as discussed earlier).

Intravenous glucose and insulin infusions during the peripartum period should be titrated to maintain a maternal blood glucose concentration of 70 to 90 mg/dL (3.9 to 5 mmol/L). During active labor, the glucose requirement is 2.5 mg/kg/min or more.[38] For cesarean delivery in patients using a subcutaneous insulin pump, a preoperative strategy should be formulated for perioperative insulin pump management. This plan should identify the individual(s), other than the patient, who are experienced and knowledgeable in adjusting her insulin pump if the patient is not able to adjust it herself during surgery. Some patients and obstetricians prefer discontinuing the subcutaneous insulin pump preoperatively in favor of an intravenous insulin infusion. The preanesthetic evaluation is an excellent opportunity to discuss with the patient the expected changes in insulin requirement at the time of delivery. The preprocedure and postprocedure "time-outs" are excellent opportunities to discuss the plan for perioperative pump management and other diabetic management concerns with all team members.

Many perioperative strategies have been proposed for metabolic control in nonpregnant patients with DM.[138,139] No convincing evidence suggests that one clinical strategy for perioperative diabetic control is superior in terms of patient outcome. Frequent blood glucose measurements (e.g., at 30- to 60-minute intervals), followed by appropriate adjustment of glucose and insulin infusions, represent the cornerstone of optimal perioperative care in patients with DM.

There are no published data on the effects of DM on the pharmacokinetics and pharmacodynamics of anesthetic agents in pregnant women. In nonpregnant patients, DM may be associated with challenging neuromuscular monitoring because of diabetic polyneuropathy or alterations at the neuromuscular junction.[140,141]

The **diabetic stiff-joint syndrome** has been associated with difficult direct laryngoscopy and tracheal intubation in patients with DM.[142,143] This syndrome occurs in patients with long-standing DM type 1 and is associated with nonfamilial short stature, joint contractures, and tight skin.[144] Limited movement of the atlanto-occipital joint may result in difficult direct laryngoscopy and tracheal intubation. During the preanesthesia evaluation of patients with DM, the anesthesia

provider can screen for the stiff-joint syndrome by looking for the "prayer sign" (Fig. 43.4). Management is controversial. Some authorities recommend preanesthesia flexion-extension radiographic studies of the cervical spine followed by awake tracheal intubation.[143] Others have expressed doubt about the clinical significance of this syndrome and the reported frequency of airway management problems.[145,146] The term **diabetic scleredema** is synonymous with stiff-joint syndrome. There is one case report of a pregnant patient with pregestational DM and diabetic scleredema who experienced anterior spinal artery syndrome after the administration of epidural anesthesia for cesarean delivery.[147] The author suggested that spinal cord vascular compression resulted from a combination of (1) preexisting microvascular disease, (2) an epidural space that was stiff because of connective tissue disease, and (3) administration of a large volume (35 mL) of the local anesthetic agent. In patients with a history and physical examination that suggest diabetic stiff-joint syndrome, the anesthesia provider should consider two potential problems: (1) difficult direct laryngoscopy and tracheal intubation and (2) a noncompliant epidural space.

Infection is an important cause of morbidity in pregnant women with pregestational DM.[49] Strict aseptic technique always should be used during the administration of neuraxial anesthesia.

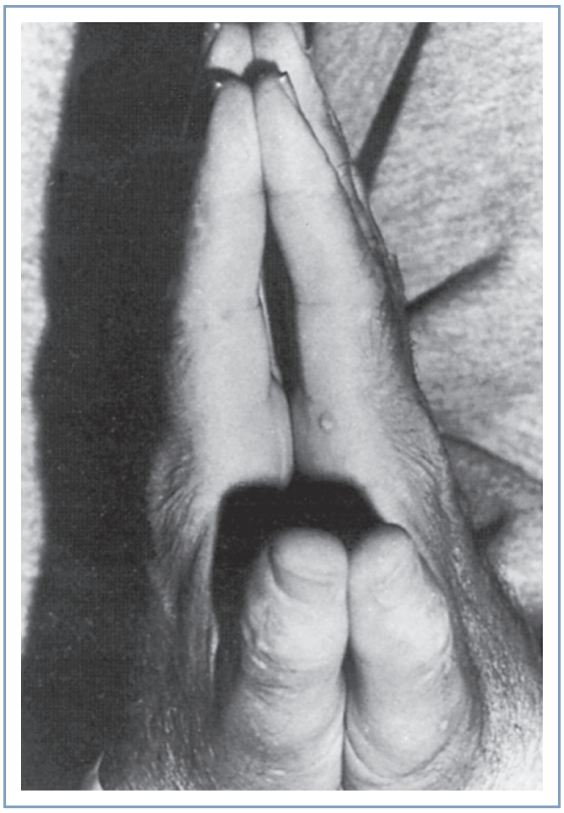

Fig. 43.4 Inability to approximate the palmar surfaces of the phalangeal joints despite maximal effort, secondary to diabetic stiff-joint syndrome. (From Hogan K, Rusy D, Springman SR. Difficult laryngoscopy and diabetes mellitus. *Anesth Analg.* 1988;67:1162–1165.)

THYROID DISORDERS

Thyroid Hormone Physiology

The follicular cells of the thyroid gland sequester iodine and synthesize thyroglobulin, an iodinated precursor protein. Thyroglobulin is secreted into the lumen of the microscopic thyroid follicles before it undergoes reuptake, proteolysis, and transfer to lysosomes, where it undergoes degradation.[148] This process results in the systemic release of the thyroid hormones: thyroxine (T_4) and 3,5,3′-triiodothyronine (T_3). Reverse T_3 (3,3′,5′-triiodothyronine) is a structural variant with much less physiologic potency in most target organs.[149]

Thyroid hormone synthesis and release are controlled primarily by thyroid-stimulating hormone (TSH)—a trophic hormone from the pituitary gland—and the supply of iodine. The thyroid hormones normally participate in a negative feedback loop that regulates TSH secretion (Fig. 43.5) and thyrotropin-releasing hormone production in the hypothalamus.[150]

Thyroid hormones are highly bound to protein in the blood. In euthyroid nonpregnant humans, the normal total serum concentrations of T_4 and T_3 are 50 to 150 nmol/L and

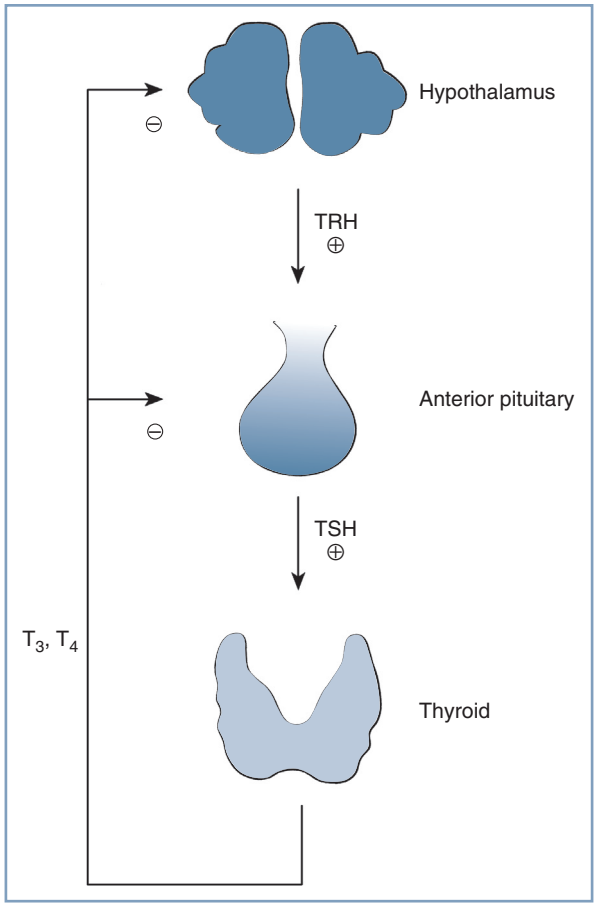

Fig. 43.5 Normal feedback control of thyroid hormone secretion. *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone; T_3, triiodothyronine; T_4, thyroxine. (From Davies PH, Franklyn JA. The effects of drugs on tests of thyroid function. *Eur J Clin Pharmacol.* 1991;40:439–451.)

1.4 to 3.2 nmol/L, respectively.[151] The unbound or free fractions of T_4 and T_3 are 0.03% and 0.3% of total circulating T_4 and T_3, respectively.[152] Similar proportions of T_4 and T_3 are distributed among the three major plasma proteins that bind thyroid hormones, which are (1) thyroxine-binding globulin (70% to 80%), (2) thyroxine-binding prealbumin or transthyretin (10% to 20%), and (3) albumin (10% to 15%).[153,154] The serum concentration of unbound or free T_4 is typically the major determinant of thyroid hormone activity in target tissues. Thyroid hormones are temporarily inert while bound to plasma proteins. Changes in the concentrations of thyroxine-binding proteins can occur during various physiologic states (e.g., pregnancy) and disease processes. Thyroid hormone action does not change with fluctuations in the total concentration of T_4 as long as the concentration of free T_4 remains constant.

Thyroid hormone is an endocrine regulator in many target organs (e.g., liver, kidneys, skeletal and cardiac muscles, brain, pituitary gland, placenta).[155] The defined physiologic effects of thyroid hormones are mediated by regulation of specific gene products. These effects include (1) somatic and nervous system development, (2) calorigenesis, (3) augmented skeletal and cardiac muscle performance, (4) intermediary metabolism, and (5) feedback control.[156]

In target tissues, the molecular actions of T_4 begin with the enzymatic deiodination of T_4 to T_3. Iodothyronine deiodinase is widely distributed in the body and occurs in three molecular forms.[157] Only 20% of the daily T_3 production is secreted by the thyroid gland; the rest is formed by peripheral deiodination.[158] In the classic model of thyroid hormone action, T_3 enters the nuclei of target cells, binds to specific thyroid hormone receptors, and alters genomic transcription of specific proteins.[159] Research has now characterized other mechanisms of action for thyroid hormones and their metabolites, including mitochondrial transcription and cytoplasmic or cell-surface nontranscriptional effects.[160,161] The thyroid hormone receptor belongs to a family of structurally related, intracellular ligand-binding proteins.[160] Variations in the number and types of thyroid hormone receptors, as well as receptor linkage to development- or tissue-specific genomic expressions, provide additional levels of physiologic control and vulnerability to disease processes.[157]

Antithyroid medications may affect single or multiple steps in thyroid hormone synthesis and release, as well as concentrations of plasma-binding proteins, deiodinase activity, and peripheral uptake of thyroid hormones.[153,162,163]

Laboratory evaluation of thyroid function consists of two measurements. First, the serum concentration of free T_4 can be directly measured or indirectly calculated. Second, the serum concentration of TSH is measured to assess the negative feedback loop that controls the thyroid gland. The TSH concentration is judged as appropriate or inappropriate in the context of the serum concentration of free T_4.

During normal human pregnancy, the serum concentration of thyroxine-binding globulin (TBG) steadily increases until it reaches a plateau at 20 weeks' gestation, when it is 50% greater than the nonpregnant level.[151] The greater concentration of TBG results from a prolonged half-life—not higher synthesis—during pregnancy.[154] The normal pregnant woman is euthyroid because the serum concentrations of free T_4 and T_3 are in the normal or low-normal range for nonpregnant humans.[151] However, the increased concentration of TBG means that total serum concentrations of T_4 and T_3 during pregnancy are at or above the upper limit of normal for nonpregnant women.[151,164]

Human chorionic gonadotropin (hCG) is a placental protein that shares some structural features with TSH. The serum concentrations of TSH and hCG have an inverse relationship during normal human pregnancy,[151] reflecting the mild TSH-like activity that results from increased plasma concentrations of hCG during early pregnancy.[165,166]

Maternal iodine availability is decreased during pregnancy because of greater fetal uptake and increased maternal renal clearance.[167] In geographic areas with marginal iodine supplies, the lower availability may predispose the mother to goiter unless she receives dietary iodine supplementation.[151,168,169]

Hyperthyroidism

Definition and Epidemiology

Hyperthyroidism is defined as an abnormal increase in the serum concentration of unbound or free thyroid hormones. The prevalence of hyperthyroidism in the general population is 0.2% to 1.9%, with a female-to-male ratio of 10:1.[170,171] The etiology of hyperthyroidism is shown in Box 43.5. Graves' disease is responsible for 70% to 90% of cases; thyroiditis and the combined category of toxic adenoma and toxic multinodular goiter each account for approximately 5% of cases. There are multiple levels of interaction between the thyroid and reproductive endocrine systems in women, with specific implications for patients with hyperthyroidism and hypothyroidism.[172]

Pathophysiology

Graves' disease is an autoimmune thyroid disease.[170,173] Its etiology is likely multifactorial and includes both

environmental (e.g., stress, hormones) and **genetic** influences. Several autoantibodies against thyroid tissue have been described in patients with this disease. Autoantibodies known as **thyroid receptor antibodies (TRAbs)** directed against the TSH receptor in the thyroid gland may either augment or inhibit TSH action, depending on their binding specificities. The binding specificities of TRAbs in the blood of each patient with Graves' disease affect the net thyroid-stimulating activity. Autoantibodies against thyroid peroxidase, the sodium-iodine cotransporter, and thyroglobulin also have been described in patients with Graves' disease.

Clinical Presentation and Diagnosis

Hyperthyroidism presents as a physiologic state dominated by an increased metabolic rate. A hyperthyroid symptom scale has been developed on the basis of the following 10 clinical factors: nervousness, sweating, heat intolerance, hyperactivity, tremor, weakness, hyperdynamic precordium, diarrhea, appetite, and level of incapacitation.[174] This symptom scale has been useful to follow the clinical course of patients with Graves' disease. Exophthalmos or infiltrative ophthalmopathy is clinically apparent in most patients.[173–175] Other physical signs may occur at low frequency, including pretibial myxedema or dermopathy (1% to 2%) and nail changes or acropachy (< 1%). The infiltrative ophthalmopathy in Graves' disease is caused by enlargement of both the extraocular muscle bodies and intraorbital adipose tissue. The pathogenetic mechanism involves abnormal accumulation of hyaluronic acid and edema within these tissues; the orbital fibroblast appears to be the primary target cell of this autoimmune process.[173]

Hyperthyroidism stimulates the cardiovascular system in excess of the underlying increased metabolic rate, resulting in a hyperkinetic circulatory state.[163,176] Myocardial contractility, heart rate, stroke volume, and ventricular size all increase, and peripheral vascular resistance decreases in skin and muscle. Thyroid hormones can affect the ratio of alpha- and beta-adrenergic receptors in the heart.[176] Cardiomyopathy can be demonstrated during exercise in hyperthyroid patients, independent of beta-adrenergic receptors; it is reversible with normalization of thyroid function.[177]

The diagnosis of hyperthyroidism depends on increased serum concentrations of unbound or free T_4. The more common forms of hyperthyroidism (e.g., Graves' disease, toxic adenoma, toxic multinodular goiter) may be differentiated from the less common forms by a radioiodine uptake study. The identification of TSH receptor autoantibodies may have some role in distinguishing Graves' disease from toxic adenoma or multinodular goiter.[173]

Interaction with Pregnancy

Normal human pregnancy is a euthyroid state, with normal serum concentrations of unbound or free T_4 despite increased serum concentrations of TBG and total T_4. During pregnancy, hyperthyroidism results from the same causes as in nonpregnant patients (see Box 43.5). Graves' disease is the leading cause of hyperthyroidism during pregnancy, with a prevalence of 0.2%, which is lower than in the general population.[178-180] The lower prevalence may reflect a beneficial effect of the immunotolerance of pregnancy on autoimmune disorders such as Graves' disease.[173] Human pregnancy is also associated with a change in the specificity of TSH receptor antibody activity from stimulatory to blocking activity.[181]

Gestational trophoblastic neoplasms are frequently associated with elevated serum hCG concentrations. High concentrations of hCG may possess significant thyroid-stimulating bioactivity because of the structural homology between hCG and TSH.[165,182] Transient hyperthyroidism during pregnancy has been reported in association with hyperemesis gravidarum; hyperthyroidism and hyperemesis gravidarum may be parallel disease processes in pregnancy, with elevated hCG as a shared mechanism.[183] Hyperthyroidism can, on rare occasions, result from two coincident disease processes (e.g., Graves' disease, struma ovarii) in both pregnant and nonpregnant women.[184]

Thyroid nodules occur in 4% to 7% of adults. Pregnancy is associated with increases in the number and size of thyroid nodules.[185] Pregnancy probably does not affect the development or recurrence of thyroid carcinoma, but may enhance the progression of active disease.[186,187] Evaluation of a thyroid nodule that presents during pregnancy should include (1) measurement of serum TSH and free T_4 concentrations, (2) ultrasonographic examination to determine whether the lesion is cystic or solid, and (3) fine-needle aspiration or percutaneous needle biopsy. Malignant lesions, depending on the level of cellular differentiation, can be resected in the second trimester or observed until after delivery.[187] Radioactive iodine therapy should be delayed until the postpartum period.[186]

Medical and Surgical Management

Current therapies for Graves' disease in nonpregnant patients include radioactive iodine, antithyroid medications, and surgery.[170,175,188]

Radioactive iodine is administered orally as iodine-131 (^{131}I) in a dose range of 30 to 75 mCi.[189] All forms of iodine are sequestered by the thyroid gland, and ^{131}I exerts a therapeutic effect in Graves' disease primarily through local emission of beta radiation. In most patients with Graves' disease, hypothyroidism develops after a therapeutic dose of radioactive iodine, necessitating careful follow-up and long-term thyroid hormone replacement therapy. In nonpregnant patients, the long-term health risks of radioactive iodine therapy are minimal.[189] Radioactive iodine therapy is contraindicated in pregnancy, because all forms of iodine readily cross the placenta to the fetus. Currently recommended treatment is to delay pregnancy for 6 months to 1 year after radioactive iodine therapy,[186] although ^{131}I has a half-life of only 8 days.

Propylthiouracil and **methimazole** are the antithyroid medications used to treat Graves' disease.[175,188,190] These drugs interfere with the incorporation of iodine into thyroglobulin and with subsequent coupling reactions in the thyroid gland, and propylthiouracil inhibits iodothyronine deiodinase in

peripheral tissues. Typical oral doses are 5 to 15 mg two times daily for methimazole and 100 to 150 mg three times daily for propylthiouracil. The long-term clinical strategy is to adjust the dose downward as tolerated. Some patients with Graves' disease experience remission after the administration of an antithyroid medication. Asymptomatic agranulocytosis, with an incidence of 0.03% to 0.5%, is a rare complication of antithyroid medications; onset typically occurs within 3 months of initiating therapy. Another rare complication of propylthiouracil, fulminant hepatic necrosis, prompted an FDA safety alert in 2009.[188] If treatment with antithyroid medications is unsatisfactory, nonpregnant patients may receive radioactive iodine.

Surgical therapy for Graves' disease is typically reserved for patients unable or unwilling to undergo treatment with radioactive iodine or antithyroid medications.[188,191] Controversy exists about the choice between subtotal and total thyroidectomy; the surgeon must weigh the risk for recurrent hyperthyroidism against that of permanent hypothyroidism requiring supplementation.[191] Perioperative complications of thyroid surgery include (1) unilateral or bilateral vocal cord paralysis secondary to laryngeal nerve injury, (2) wound hematoma, (3) pneumothorax, (4) hypoparathyroidism, and (5) thyroid storm.[191] Hypocalcemia secondary to acute hypoparathyroidism may manifest as laryngospasm during the postoperative period.[192]

Adjunctive therapies for hyperthyroidism include iodine, radiocontrast agents, lithium, and glucocorticoids.[163,170] Beta-adrenergic receptor antagonists also have been used to decrease cardiovascular responses to higher concentrations of thyroid hormones.

Thyroid storm. Thyroid storm, also known as thyroid crisis, is a life-threatening exacerbation or decompensation of a preexisting hyperthyroid state.[193–196] It is a clinical diagnosis based on the following signs and symptoms: (1) fever, (2) mental and emotional disturbances, (3) tachycardia, (4) tachypnea, (5) diarrhea, (6) congestive heart failure, and (7) atrial fibrillation. Without treatment, thyroid storm may progress to coma, multiorgan system failure, and death. The mortality rate approached 100% in earlier series, but improved therapy has reduced the mortality rate to less than 20%.[195]

In most cases, thyroid storm is associated with a precipitating event in a patient with untreated or incompletely treated hyperthyroidism (Box 43.6). Historically, the precipitating events reflect the common serious medical illnesses of a given era[193–196]; cases of thyroid storm were categorized as "surgical" or "medical" depending on whether the exacerbation occurred during the perioperative period. With improved perioperative management, the incidence of surgical thyroid storm has decreased markedly, and this terminology is rarely used in contemporary medical practice.

In the past, 2% to 7% of patients hospitalized for hyperthyroidism experienced thyroid storm.[193,194,196] The current incidence of thyroid storm in hyperthyroid patients is difficult to determine but appears to be much lower. Akamizu et al.[197] estimated that the incidence of thyroid storm in Japan was 0.2 per 100,000 hospitalized patients between 2004 and 2008.

BOX 43.6 Events Associated with Precipitation of Thyroid Storm

- Surgery
- Childbirth
- Trauma
- Iodinated contrast agents
- Treatment with iodine-131
- Emotional stress
- Pulmonary embolism
- Stroke
- Infection
- Diabetic ketoacidosis
- Hypoglycemia
- Congestive heart failure
- Bowel infarction

From Roth RN, McAuliffe MJ. Hyperthyroidism and thyroid storm. *Emerg Med Clin North Am.* 1989;7:873–883.

The mechanism of the development of thyroid storm is unknown. On the basis of the clinical presentation and known precipitating events, one hypothesis is that it is caused by increases in thyroid hormone and catecholamine secretion. Limited data suggest that total serum concentrations of T_4 and T_3 do not increase during thyroid storm in hyperthyroid patients,[198] although one case report suggests otherwise.[199] Alternatively, the precipitating event in thyroid storm may augment thyroid hormone action by increasing the circulating free fraction of thyroid hormones. This hypothesis is supported by data that demonstrate higher serum concentrations of free T_4 during thyroid storm as well as by observations of changes in thyroid hormone binding during fever or systemic illness.[200]

Catecholamine secretion may also play a role in the development of thyroid storm. In hyperthyroid patients without thyroid storm, the endogenous secretion of epinephrine and norepinephrine is normal, as are the cardiovascular responses to exogenous epinephrine and isoproterenol.[201,202] These parameters have not been measured during episodes of thyroid storm, but symptoms respond well to medications that block the synthesis or receptor binding of beta-adrenergic receptor agonists.[194] The role of the sympathetic nervous system in thyroid storm is supported by historical observations that spinal anesthesia to the fourth thoracic dermatome level is therapeutic.[203] It is unclear whether thyroid storm can develop with baseline catecholamine secretions; a surge of catecholamines may be necessary to trigger this condition.

Box 43.7 outlines the treatment of thyroid storm. Several points merit discussion. Glucocorticoid supplementation is listed as a general supportive measure because endogenous glucocorticoid production is impaired in patients with hyperthyroidism.[204] Glucocorticoids also inhibit both thyroid hormone production and the peripheral conversion of T_4 to T_3.[171] Propylthiouracil and methimazole reduce thyroid hormone production, but only propylthiouracil inhibits the

BOX 43.7 Treatment of Thyroid Storm

General Supportive Measures
- Cooling blanket and ice
- Chlorpromazine (25–50 mg IV) or meperidine (pethidine) (25–50 mg IV) to diminish shivering
- Intravenous hydration
- Glucose and electrolyte replacement
- Acetaminophen (paracetamol)
- Oxygen
- Glucocorticoids: dexamethasone (2–4 mg IV q8h) or hydrocortisone (100 mg IV q8h)
- B-complex multivitamins

Reduction of Synthesis and Secretion of Thyroid Hormones
- Antithyroid medications: propylthiouracil (200–400 mg orally q6–8h) or methimazole (20–25 mg orally q6h)
- Iodine: sodium iodide (1 g IV or Lugol's solution 4–8 drops orally q6–8h) or supersaturated potassium iodide solution (5 drops orally q6h)
- Glucocorticoids

Reduction of Peripheral Conversion of Thyroxine (T_4) to 3,5,3′-Triiodothyronine (T_3)
- Propylthiouracil
- Glucocorticoids
- Radiographic contrast agents
- Propranolol

Decrease in the Metabolic Effects of Thyroid Hormones
- Beta-adrenergic receptor antagonists (propranolol, esmolol)

Other Therapeutic Maneuvers
- Plasma exchange

Diagnosis and Treatment of the Underlying Illness That Precipitated the Thyroid Storm

peripheral conversion of T_4 to T_3 (as discussed earlier). In addition to the relief of many symptoms of hyperthyroidism, several beta-adrenergic receptor antagonists (including propranolol, metoprolol, and atenolol) inhibit the peripheral conversion of T_4 to T_3.[205,206] Esmolol also has been used successfully during the treatment of thyroid storm (see later discussion).[207,208]

Thyroid storm is an acute hypermetabolic state that may be difficult to distinguish clinically from malignant hyperthermia; rhabdomyolysis is one of the few features of the latter disorder that has not also been reported in thyroid storm.[209] Three cases of thyroid storm treated with dantrolene have been reported.[210–212] Two patients survived, but the third succumbed to multiorgan system failure that antedated the dantrolene therapy. In another case, a patient with known Graves' disease undergoing subtotal thyroidectomy had an intraoperative hypermetabolic crisis that was initially diagnosed and treated as thyroid storm. The correct diagnosis of malignant hyperthermia was made on the basis of subsequent blood gas analysis, and the patient was successfully treated with dantrolene.[213] Plasma exchange is another unusual but effective therapeutic option in cases of thyroid storm.[214]

In summary, treatment of thyroid storm consists of general supportive measures and the administration of glucocorticoids, propylthiouracil, sodium iodide, and beta-adrenergic receptor blockade. It is reasonable to delay iodine treatment until 1 hour after the administration of propylthiouracil to avoid increased iodine use by the thyroid gland.

Preoperative preparation. The risk for thyroid storm during the perioperative period can be minimized by appropriate preparation of the hyperthyroid patient. Most cases of perioperative thyroid storm involve thyroid surgery. The preoperative therapeutic goals are to inhibit thyroid hormone synthesis and secretion in patients with preexisting hyperthyroidism and to decrease the vascularity of the thyroid gland. The four main therapies used in preoperative preparation are administration of (1) an antithyroid medication (primarily propylthiouracil), (2) a beta-adrenergic receptor antagonist, (3) a glucocorticoid, and (4) iodine.[163,191,215] Iodine inhibits thyroid hormone secretion more effectively in hyperthyroid patients than in euthyroid patients because the latter are capable of mounting a compensatory TSH response as serum T_4 levels decrease.[216]

In some patients, beta-adrenergic receptor blockade may be sufficient to prevent perioperative thyroid storm,[217] although thyroid storm has been reported after preoperative preparation with propranolol alone.[218] In some of these cases, patients probably did not receive effective beta-adrenergic receptor blockade. A 25% reduction in exercise-induced heart rate is a better indication of adequate beta-adrenergic receptor blockade than a change in the resting heart rate.[215] One advantage of beta-adrenergic receptor antagonists over antithyroid medications is the shorter time typically required for preoperative preparation (2 weeks versus 6 to 8 weeks, respectively).[217] Several investigators have recommended preoperative preparation with a beta-adrenergic receptor antagonist, with the addition of iodine beginning 10 days before surgery.[215,219] The use of beta-adrenergic receptor antagonists entails a risk for hypoglycemia in hyperthyroid patients, because they have reduced hepatic glucose reserves and nonspecific beta-adrenergic receptor blockade results in a pharmacologic blunting of counterregulatory sympathetic responses.[215]

No prospective randomized studies have compared the efficacy of various methods for preoperative preparation of hyperthyroid patients. A reasonable clinical approach would include the use of multiple therapeutic agents (e.g., a beta-adrenergic receptor antagonist, iodine, glucocorticoid), with the doses titrated to the clinical response of each patient. The clinical parameters may include exercise-induced heart rate, fine tremor, weight gain, and recovery of muscle strength.[163]

Elective surgery should not proceed without adequate preoperative preparation of hyperthyroid patients. In cases of emergency surgery, physicians should use the therapies discussed for the treatment of thyroid storm (as discussed earlier) (see Box 43.7).

Medical and surgical management during pregnancy. All of the therapeutic options used in nonpregnant hyperthyroid patients should be efficacious in pregnant women. However, the potential effects on the fetus dictate modifications in the options for treatment of hyperthyroidism during pregnancy.

Radioactive iodine is contraindicated during pregnancy because iodine readily crosses the placenta to the fetus. Fetal effects of inadvertent maternal administration of ^{131}I vary with gestational age.[189] Before 10 weeks' gestation, the risk to the fetus is less well defined and likely approximates that of a low-level dose of radiation during early development[189]; after 10 weeks' gestation, however, the fetal thyroid gland can sequester iodine, and ^{131}I may destroy or significantly damage the gland.

The mainstays of therapy for hyperthyroidism during pregnancy are the antithyroid medications **propylthiouracil** and **methimazole**,[179,180,220,221] which cross the placenta much more easily than the maternal thyroid hormones, potentially inducing fetal hypothyroidism and goiter. Although these agents are similar in efficacy for treatment of hyperthyroidism during pregnancy,[179,190] propylthiouracil has been used more frequently than methimazole. Propylthiouracil is favored in the first trimester of pregnancy, owing to rare congenital anomalies reported with methimazole (e.g., scalp defects, choanal atresia, tracheoesophageal fistula).[179,180,220] After the first trimester, therapy can be switched to methimazole if there are concerns for hepatotoxicity with propylthiouracil.

Surgical therapy (e.g., subtotal thyroidectomy) is generally reserved for pregnant women in whom medical therapy has failed.[191,220] The pregnant woman should receive preoperative preparation with a beta-adrenergic receptor antagonist, a glucocorticoid, and iodine to minimize the risk for thyroid storm. Clinical data suggest that treating maternal Graves' disease with iodine does not result in fetal hypothyroidism,[222] implying that short-term preoperative maternal treatment with iodine should be safe for the fetus.

One national database study of pregnant women undergoing thyroid or parathyroid surgery demonstrated a threefold increase in general complications compared with age-matched nonpregnant controls.[223] In pregnant patients with Graves' disease, surgical thyroidectomy may lead to fetal hyperthyroidism through a combination of autoimmune and medication effects.[224]

During pregnancy, **thyroid storm** is a rare hypermetabolic event. Prior reports of a 2% to 4% incidence among pregnant patients are probably overestimates of the true incidence.[197] Most contemporary cases of thyroid storm during pregnancy occur in patients with undiagnosed or undertreated preexisting hyperthyroidism.[225–227] Precipitating events for thyroid storm during pregnancy include infection, thyroid cancer, normal labor, hemorrhage, cesarean delivery, and eclampsia.[225–228]

Treatment of thyroid storm is identical for both pregnant and nonpregnant patients (as discussed earlier) (see Box 43.7). Despite an association with fetal growth restriction (formerly called intrauterine growth restriction) or preterm labor,[229] beta-adrenergic receptor antagonists are commonly prescribed during pregnancy.

Several case reports have described the use of the beta-adrenergic receptor antagonist **esmolol** for treatment of hyperthyroidism in both pregnant and nonpregnant patients,[207,208] although laboratory and clinical observations suggest that maternal administration of esmolol may result in fetal bradycardia and acidosis.[230,231] Esmolol may be considered when longer-acting beta-adrenergic receptor antagonists are contraindicated or the patient's hemodynamic status requires the use of a short-acting beta-adrenergic receptor antagonist. Esmolol is preferred for patients with a relative contraindication to nonspecific beta-adrenergic receptor blockade (e.g., asthma). Patients with significant cardiomyopathy from hyperthyroidism, who may be very sensitive to beta-adrenergic receptor blockade,[177,232,233] may benefit from esmolol because the dose can easily be titrated to the desired effect.[234] Hyperthyroid cardiomyopathy during pregnancy or the puerperium may require invasive monitoring and the use of multiple medications that require titration.[225,235,236] Esmolol's short half-life allows a rapid reversal of effect if needed. Untreated hyperthyroidism is associated with secondary pulmonary hypertension.[237]

In general, maternal and fetal interests are best served by optimal maternal therapy. When the physician opts for maternal therapy that could, in theory, adversely affect fetal well-being, the rationale should be documented in the medical record.

Obstetric Management

Poorly controlled hyperthyroidism during pregnancy increases the risk for severe preeclampsia in the mother and for low birth weight in the newborn.[238] Pregnant patients with treated hyperthyroidism have perinatal outcomes similar to those for euthyroid parturients.[239] The presence of hyperthyroidism does not affect the obstetric management of preeclampsia. In a retrospective study, Davis et al.[225] suggested that early diagnosis and treatment of hyperthyroidism during pregnancy is associated with better maternal and fetal outcomes.

The use of a nonselective beta-adrenergic receptor antagonist may precipitate or aggravate preterm labor. In women with Graves' disease, the placental transfer of antithyroid medications or thyroid-stimulating antibodies may result in the development of **fetal goiter**,[240] which can interfere with vaginal delivery or lead to airway obstruction in the newborn. Fetal goiter can be diagnosed with ultrasonography; fetal hypothyroidism can be diagnosed with percutaneous umbilical cord blood sampling and can be treated with intra-amniotic injections of thyroxine.[241] In pregnant women with Graves' disease, maternal serum concentrations of TRAbs during the third trimester may predict neonatal thyroid function.[242]

Normal somatic and intellectual development have been reported in the children of hyperthyroid mothers treated with antithyroid medications[243]; such treatment does not contraindicate breast-feeding.[190]

Anesthetic Management

No prospective randomized studies have evaluated the efficacy or safety of various anesthetic techniques in patients with hyperthyroidism. The following features of hyperthyroidism may affect anesthetic management: (1) the hyperdynamic cardiovascular system and the possibility of cardiomyopathy, (2) partial airway obstruction secondary to an enlarged thyroid gland, (3) respiratory muscle weakness, and (4) electrolyte abnormalities.[163]

Halpern[244] described two patients with uncontrolled hyperthyroidism who required anesthesia for cesarean delivery and suggested that either neuraxial or general anesthesia can be safely administered in these parturients. On the basis of theoretical concerns, he suggested the omission of epinephrine from the epidural solution of local anesthetic agent and the use of an alpha-adrenergic receptor agonist (e.g., phenylephrine) for the treatment of hypotension. Earlier clinical studies in nonpregnant subjects with spontaneous hyperthyroidism, however, have shown normal hemodynamic responses to exogenous epinephrine, norepinephrine (noradrenaline), phenylephrine, and clonidine.[245,246] It therefore appears safe to use epinephrine to minimize local anesthetic uptake and toxicity during the administration of epidural anesthesia in both euthyroid and hyperthyroid patients. One case report described a successful low-dose combined spinal-epidural anesthetic for an urgent cesarean delivery in a patient with uncontrolled hyperthyroidism, thyrotoxic heart disease, and severe preeclampsia.[247]

Hyperthyroid women should receive glucocorticoid supplementation because they have a relative deficiency of glucocorticoid reserves.[204] It seems prudent to avoid medications associated with tachycardia (e.g., ketamine, atropine).[163,244] Patients with Graves' disease may have exophthalmos and therefore may require additional care to prevent corneal abrasions during general anesthesia.[244] Some investigators have emphasized the efficacy of deep preoperative sedation in nonpregnant hyperthyroid patients.[163,203] The routine use of this technique in pregnant patients is not recommended because of the risks for maternal aspiration and neonatal depression.

Adequate preoperative preparation minimizes the risk for perioperative thyroid storm; when time permits, the goal is to make the patient euthyroid. In an emergency, the hyperthyroid patient can be prepared for surgery with oral propylthiouracil, an intravenous glucocorticoid, sodium iodide, and a beta-adrenergic receptor antagonist. The anesthesia provider should be prepared to treat perioperative thyroid storm (see Box 43.7).

Hypothyroidism

Definition and Epidemiology

Hypothyroidism is defined as an abnormal decrease in the serum concentration of unbound or free thyroid hormones. The prevalence of hypothyroidism in the general population is 0.1% to 2%, which is similar to that of hyperthyroidism.[248] Hypothyroidism is more common in women and the elderly. Screening tests for hypothyroidism in asymptomatic nonpregnant adults are not recommended by the American Academy of Family Physicians.[249] When clinically indicated, the preferred screening test is a sensitive assay for serum TSH.

Pathophysiology

The etiology of hypothyroidism can be divided into primary and secondary categories (Box 43.8); primary hypothyroidism is more common than secondary hypothyroidism. The clinical manifestations of hypothyroidism result from withdrawal of thyroid hormone from its many target organs and tissues.

Clinical Presentation and Diagnosis

The clinical presentation of hypothyroidism is dominated by constitutional signs and symptoms such as dry skin, decreased sweating, hoarseness, paresthesia, periorbital edema, and delayed reflexes.[250] A diagnosis of hypothyroidism may be suggested by detection of the following factors during the preanesthetic history and physical examination: (1) a history of neck irradiation or radioiodine therapy; (2) the use of lithium, iodine, amiodarone, antithyroid medications, or thyroid replacement medications; and (3) a history of thyroid

surgery or the presence of a surgical scar overlying the site of the thyroid gland.

By definition, hypothyroidism is diagnosed by measuring a decreased serum concentration of unbound or free T_4. In the presence of an intact feedback loop, the serum concentration of TSH should be increased in patients with primary hypothyroidism. The serum TSH concentration is a more sensitive indicator of primary hypothyroidism than the serum T_4 concentration and is therefore the best initial laboratory test in a patient with suspected hypothyroidism.[248,249]

Interaction with Pregnancy

The prevalence of hypothyroidism during pregnancy is 0.3% to 0.5%.[251] This estimate is based on laboratory screening of all obstetric patients in a given geographic area. Pregnant women likely exhibit overt or symptomatic hypothyroidism at a much lower rate than nonpregnant women. Hypothyroid women have a lower fertility rate than euthyroid women; this difference reflects neuroendocrine and ovarian dysfunction.[172,252] The immunosuppressive effects of pregnancy may lead to a temporary improvement of Hashimoto's thyroiditis during pregnancy.

Medical Management

Hypothyroidism is treated by replacement therapy with oral thyroid hormones. The medication most commonly used in replacement therapy is **levothyroxine**,[253] which has a half-life of 7 days. Numerous studies have shown that the required replacement dose of thyroid hormone in hypothyroid women often increases during pregnancy.[178,180,220] Ideally, the increased dose of thyroid hormone replacement will begin as soon as pregnancy is recognized, and it will be titrated to serum TSH levels at 4-week intervals during the first half of pregnancy.[220,254,255]

Obstetric Management

Hypothyroidism is associated with an increased incidence of the following obstetric complications: anemia, preeclampsia, fetal growth restriction, gestational diabetes, preterm delivery, placental abruption, and postpartum hemorrhage.[178,251,256–258] However, several reports have emphasized successful pregnancy outcomes in some untreated hypothyroid patients.[259,260] Early diagnosis and treatment of hypothyroidism appear to be associated with improved maternal and fetal well-being.

In most instances of maternal hypothyroidism, neonatal thyroid function is normal because fetal thyroid development is typically independent of maternal thyroid function. The fetus, however, depends on maternal thyroxine until the fetal thyroid system is fully functional at approximately 20 weeks' gestation. Therefore, maternal hypothyroidism in the first half of pregnancy may affect fetal brain development. In addition, fetal hypothyroidism during the second half of pregnancy may also affect normal maturation of the CNS.[261] With universal screening of neonates for hypothyroidism, these neonates should be readily identified. Published data suggest that cognitive development is relatively normal in hypothyroid infants who receive timely and appropriate thyroid hormone replacement with an initial dose of 10 to 15 μg/kg/day.[262] Controversy continues on the issue of screening pregnant women for hypothyroidism with serum TSH levels. It is unclear whether screening should be universally applied to all pregnant women or restricted to a high-risk subgroup identified by medical history.[180,220,263–267]

Anesthetic Management

The clinical manifestations of hypothyroidism that may affect anesthetic management include the following:[268–278]

- Reversible myocardial dysfunction
- Coronary artery disease
- Reversible defects in hypoxic and hypercapnic ventilatory drives
- Obstructive sleep apnea
- Paresthesias
- Prolonged somatosensory-evoked potential central conduction time
- Abnormal peripheral nerve conduction
- Increased peripheral nociceptive thresholds
- Hyponatremia
- Decreased glucocorticoid reserves
- Anemia
- Abnormal coagulation factors and platelets

Hypothyroid patients may have an abnormal response to peripheral nerve stimulation that decreases the clinical utility of a nerve stimulator during neuromuscular blockade.[279] Clinical studies of vasopressors in nonpregnant hypothyroid patients show normal responses to exogenous epinephrine and diminished responses to phenylephrine.[280,281]

Whether elective surgery should or should not be delayed to treat hypothyroidism adequately is controversial.[282] Patient safety issues may justify such a delay. For emergency procedures, anesthesia care should include glucocorticoid supplementation. **Myxedema** (hypothyroid) coma is likely the only circumstance in which acute intravenous thyroid hormone replacement is indicated.[195] In most hypothyroid patients, acute intravenous replacement therapy entails a significant risk for myocardial ischemia.[270]

No prospective randomized studies have compared the safety or efficacy of different anesthetic techniques in pregnant or nonpregnant hypothyroid patients. Hypothyroidism is associated with qualitative platelet dysfunction and is a rare cause of acquired von Willebrand's disease.[278,283,284] The anesthesia provider should use findings from the history and physical examination as well as laboratory testing to verify the presence of normal coagulation before administering neuraxial anesthesia to the patient with severe untreated hypothyroidism. Although epidural hematoma represents a theoretical risk in such patients, there are no published reports of this complication in this patient population.

PHEOCHROMOCYTOMA

Definition and Epidemiology

Pheochromocytomas belong to a heterogeneous group of tumors called paragangliomas that develop from neural

crest–derived chromaffin cells and arise in the adrenal medulla (90%) or in the adjacent sympathetic nervous system tissues.[285,286] Extra-adrenal paragangliomas may develop from sympathetic or parasympathetic tissues and include such diverse neoplasms as glomus tumors, chemodectomas, carotid body tumors, and jugulotympanic tumors.[287] Pheochromocytomas occur bilaterally (e.g., in the medulla of both adrenal glands) in 5% to 10% of cases.[288] Approximately 10% of pheochromocytomas are malignant.[288,289] Histopathologic features are not reliable predictors of malignancy[290]; however, large tumor size, extra-adrenal location, and certain tumor susceptibility gene mutations (e.g., succinate dehydrogenase subunit B) are associated with malignant pheochromocytomas.[285]

Pheochromocytomas occur in 0.1% to 0.2% of hypertensive adults.[287] Men and women are affected relatively equally, and the peak incidence varies between the third and seventh decades of life.

Pheochromocytoma is one of the tumors found in two of the **multiple endocrine neoplasia (MEN)** syndromes, **MEN 2A** (e.g., medullary thyroid carcinoma, hyperparathyroidism, pheochromocytoma) and **MEN 2B** (e.g., medullary thyroid carcinoma, mucocutaneous neuromas, pheochromocytoma).[291] Other disease processes associated with pheochromocytoma include von Recklinghausen's disease, von Hippel–Lindau disease, Sturge-Weber syndrome, and tuberous sclerosis. At least 10 distinct genetic mutations have been identified in patients with paragangliomas; the estimated rate of the familial form of pheochromocytoma is 30%.[285,287] There is an evolving concept of combined genotype/biochemical phenotype classifications to predict the clinical behavior of pheochromocytomas, and to guide therapy in individual patients.[292]

Pathophysiology

The pathophysiology of pheochromocytoma is related almost entirely to the systemic effects of its endocrine secretory products, typically norepinephrine and epinephrine. Some pheochromocytomas may, however, secrete other catecholamines (e.g., dopamine, dihydroxyphenylalanine [DOPA]) or peptide hormones. In an individual patient, the clinical manifestations of pheochromocytoma represent the net systemic effects of the tumor's secretory products.

Clinical Presentation and Diagnosis

Patients with pheochromocytoma can have a variety of common or uncommon symptoms.[285–291] Patients typically have **paroxysmal symptoms** because of the episodic nature of hormone secretion by the tumor (Table 43.4). The most common symptoms are sweating, tachycardia, and headaches; one study suggested that the diagnosis of pheochromocytoma can be excluded with 99.9% certainty if a patient does not have these symptoms.[293] The attacks may remain the same, or the symptoms may evolve over time.[289] Pallor is common and flushing is uncommon in patients with pheochromocytoma. Paroxysmal symptoms may be triggered by a wide variety of physical activities that patients learn to avoid.[289] Typically, these activities directly or indirectly increase the pressure around the tumor. As the tumor grows, the attacks may last longer and occur more frequently.[289]

TABLE 43.4 Symptoms of Pheochromocytoma during Paroxysmal Attacks

Symptom	Patients Affected in Previous Series (%)		Patients Affected in Ross and Griffith Series (%)
	MEAN	RANGE	
Headache	59.9	43–80	57
Sweating	52.2	37–71	61
Palpitations	49.2	44–71	63
Pallor	42.9	42–44	43
Nausea	34.5	10–42	33
Tremor	33.5	30–38	13
Anxiety	28.9	15–72	30
Abdominal pain	25.8	5–62	14
Chest pain	25.0	19–50	0
Weakness	19.4	8–58	25
Dyspnea	17.0	15–39	23
Weight loss	16.5	14–23	7
Flushing	14.8	10–19	4
Visual disturbances	12.4	11–22	19

From Ross EJ, Griffith DN. The clinical presentation of phaeochromocytoma. *Q J Med.* 1989;71:485–496.

The ability of pheochromocytomas to mimic other diseases has frustrated and confused many generations of physicians. In one series of patients with pheochromocytoma, 76% of the tumors were not diagnosed before autopsy.[289] Reports include numerous examples of pheochromocytomas that were initially confused with other medical or psychiatric disorders.[294–296] In addition to their systemic endocrine effects, pheochromocytomas can occasionally cause local abdominal symptoms.[297]

Hypertension is a common but not universal finding, occurring in 77% to 98% of patients with pheochromocytoma.[289] Although most patients have paroxysmal episodes of hypertension, one-half may also experience *sustained* hypertension.[287] **Orthostatic hypotension** occurs in 70% of patients.[289,291] The presumed mechanisms for orthostatic hypotension are chronic vasoconstriction with intravascular volume depletion and impaired reflex responses secondary to receptor down-regulation or synaptic effects of circulating catecholamines.[289,291]

The current approach to the diagnosis of pheochromocytoma involves the following four steps: (1) biochemical testing for increased catecholamine secretion, (2) anatomic imaging, (3) functional imaging, and (4) genetic testing.[286,287,292] Catecholamine secretion is evaluated by measuring norepinephrine and epinephrine or concentrations of their metabolites (normetanephrine, metanephrine, or vanillylmandelic acid) in plasma or urine samples. Although the relative merits of these laboratory tests have been debated for years, a consensus has emerged in favor of measuring free metanephrines in

plasma or urinary fractionated metanephrines as the initial laboratory test.[286,298–300]

Conversion of norepinephrine and epinephrine to the respective metanephrines by catecholamine-*O*-methyl transferase occurs to a large extent within the pheochromocytoma before secretion.[298] Several medical conditions may confound the diagnosis of pheochromocytoma by altering the plasma and urinary concentrations of catecholamine metabolites. These conditions include congestive heart failure, acute myocardial infarction, stroke, cocaine abuse, sleep apnea, and ethanol or clonidine withdrawal.[301] Medications that alter normal catecholamine secretion and metabolism include tricyclic antidepressants, acetaminophen (paracetamol), hydralazine, and beta-adrenergic receptor antagonists.[302] Chromogranin-A is a protein found with catecholamines inside secretory vesicles within pheochromocytoma and normal adrenal medullary cells. Originally, chromogranin-A was thought to be a packaging protein in secretory vesicles, but it is now recognized as a prohormone for several peptide hormones, including vasostatin.[303] The measurement of plasma concentrations of chromogranin-A has been used as a confirmatory biochemical test for pheochromocytoma.[304,305]

For patients in whom initial laboratory findings are equivocal, a clonidine suppression test can be performed.[299] The basis of the test is that clonidine fails to suppress catecholamine secretion by pheochromocytoma cells.

After the laboratory diagnosis is confirmed, the pheochromocytoma is localized with anatomic and functional imaging.[306] The major anatomic imaging modalities are computed tomography (CT) and magnetic resonance imaging (MRI). Functional imaging relies on labeled compounds with a high affinity for pheochromocytoma cells. Meta-iodobenzylguanidine (MIBG) is an analogue of norepinephrine, and ^{123}I-MIBG is commonly used for scintigraphic localization. Positron emission tomography (PET) with either fluorine-18 (^{18}F)-fluoro-2-deoxy-D-glucose (^{18}F-FDG) or ^{18}F-fluoro-L-3,4-dihydroxyphenylalanine (^{18}F-DOPA) can be used to localize pheochromocytomas.[306]

Interaction with Pregnancy

Pheochromocytoma is rare during pregnancy, with an overall incidence estimated to be less than 0.2 per 10,000 pregnancies.[307,308] Although pregnancy may accelerate the growth of some tumors, no data suggest that it does so for pheochromocytoma. Both sporadic and familial types of pheochromocytoma, as well as benign and malignant forms, may occur during pregnancy. Case reports have demonstrated specific tumor susceptibility gene mutations in pregnant patients who have familial cases of pheochromocytoma.[309–312]

Clinical signs and symptoms of pheochromocytoma are similar in pregnant and nonpregnant patients.[307,308,313] Noninvasive hemodynamic measurements demonstrated intense vasoconstriction and decreased cardiac output during episodes of hypertension in two pregnant patients with pheochromocytoma.[314,315] The clinical recognition of pheochromocytoma during pregnancy is especially difficult because of its rarity and its similarity to preeclampsia, a common obstetric disease.[316,317] The diagnosis of pheochromocytoma before labor and delivery may reduce maternal mortality from 35% to near zero.[307] Easterling et al.[315] demonstrated that either an inverse relationship between blood pressure and heart rate or an increasing hematocrit during treatment with a beta-adrenergic receptor antagonist in a patient with suspected preeclampsia suggests the presence of pheochromocytoma. Pheochromocytoma may also manifest in the early postpartum period after an unremarkable vaginal delivery.[318,319]

Plasma concentrations of epinephrine, norepinephrine, and dopamine in normal pregnant women do not differ significantly from those in nonpregnant controls.[320] These data suggest that the same threshold levels can be used to interpret most laboratory test results (except urinary norepinephrine and normetanephrine) for the diagnosis of pheochromocytoma in pregnant and nonpregnant patients. During pregnancy, ultrasonography or MRI is most commonly used for anatomic imaging of pheochromocytomas.[307,308] One case report described functional PET/CT imaging of a pheochromocytoma during pregnancy using ^{18}F-FDG.[321] However, this imaging was delayed until 21 weeks' gestation to minimize the fetal radiation effects.

Medical and Surgical Management

Definitive therapy for pheochromocytoma is surgical resection of the tumor.[286,287,300] The greatest challenge in perioperative management is to prevent or effectively treat wide swings in hemodynamic parameters. The patient is at risk for severe hypertension during induction of anesthesia and surgical manipulation of the tumor; severe hypotension frequently occurs after excision of the tumor because of an abrupt decline in circulating concentrations of catecholamines.

Preoperative Preparation

The preoperative preparation of a patient with pheochromocytoma relies on pharmacologic therapy to return the patient to a near-normal physiologic state. Patients with a norepinephrine-dominant pheochromocytoma have intense peripheral vasoconstriction and severe intravascular volume depletion. In these patients, preoperative preparation includes alpha-adrenergic receptor blockade and intravascular volume repletion.[286,287,322] The most commonly used alpha-adrenergic receptor antagonist is **phenoxybenzamine,** at an initial dose of 10 mg orally twice a day, titrated upward to 40 to 50 mg twice a day. **Doxazosin, prazosin,** and **phentolamine** are other alpha-adrenergic receptor antagonists that have been used successfully.[323–325] Beta-adrenergic receptor antagonists may be added to treat arrhythmias, but their use must be preceded by effective alpha-adrenergic receptor blockade to prevent a paradoxical hypertensive response.[323,324] Beta-adrenergic receptor blockade must be individualized because patients with pheochromocytoma are at risk for catecholamine-induced cardiomyopathy.[326]

The administration of **nicardipine,** a calcium entry–blocking agent, is an alternative approach in the preoperative preparation of these patients.[324,327] **Metyrosine** is another

therapeutic option that interferes with catecholamine synthesis; it has been used as an adjunct to preoperative alpha-adrenergic receptor blockade at a dose of 250 to 1000 mg orally twice a day.[323,328] Patients whose symptoms or early responses to alpha-adrenergic receptor blockade suggest an epinephrine-dominant pheochromocytoma may need beta-adrenergic receptor blockade as primary preoperative therapy.[329]

Alpha-adrenergic receptor blockade with phenoxybenzamine is the most commonly used technique for preoperative preparation of the patient with pheochromocytoma.[286,322] Administration of a long-acting alpha-adrenergic receptor antagonist (e.g., phenoxybenzamine) may be desirable before tumor excision but can contribute to hypotension after tumor removal.[330] Prospective randomized studies comparing different methods of patient preparation have not been performed. A retrospective review of patients with pheochromocytoma who were treated preoperatively with phenoxybenzamine, prazosin, or doxazosin suggests that all of these agents are effective and safe.[331] Regardless of the method chosen, the patient must be prepared adequately for surgery. Adequate preparation could be the major reason for the decline in operative mortality over the past several decades in patients with pheochromocytoma. Hull[329] stated, "Emergency surgery to remove a phaeochromocytoma from an unprepared patient should never be contemplated." However, recent authors have suggested that "perioperative management may actually be more critical for achieving good clinical outcomes than administration of preoperative hypotensive drugs."[322] It is likely that meticulous preoperative and perioperative medical care both contribute substantially to patient safety with pheochromocytomas.

Fleischer and Mythen[332] have described four widely accepted criteria for adequate preoperative alpha-adrenergic receptor blockade in patients with pheochromocytoma (Box 43.9). Most patients require 7 to 14 days of treatment to meet these criteria.[320,322] Individual reports of rapid preoperative patient preparation techniques for pheochromocytoma resection (e.g., intravenous urapidil plus magnesium) will need additional confirmation before they become mainstream clinical practices.[333]

BOX 43.9 Criteria for Adequate Preoperative Alpha-Adrenergic Receptor Blockade in Patients with Pheochromocytoma

1. No in-hospital blood pressure reading higher than 165/90 mm Hg should be evident for 48 hours before surgery.
2. Orthostatic hypotension is acceptable, as long as arterial blood pressure on standing is not less than 80/45 mm Hg.
3. The electrocardiogram should be free of ST-segment/T-wave changes that are not permanent.
4. No more than one premature ventricular contraction should occur every 5 minutes.

Modified from Fleischer LA, Mythen M. Anesthetic implications of concurrent diseases. In Miller RD, Cohen NH, Eriksson LI, et al., editors. *Miller's Anesthesia*. 8th edition. Philadelphia, Elsevier, 2015:1156–1225.

Intraoperative Management

Intraoperative management includes the treatment of episodic **hypertension** and **tachycardia** *before* excision and treatment of profound **hypotension** *after* excision. Many medications have been used successfully to manage intraoperative hypertension and tachycardia, including calcium entry–blocking agents, nitroprusside, nitroglycerin, esmolol, magnesium sulfate, dexmedetomidine, and adenosine.[322,327,334–339] Because of the episodic nature of catecholamine secretion and the change in cardiovascular status that occurs after tumor excision, the use of agents with a short duration of action may be advantageous. The successful use of various regimens implies that the intraoperative treatment of hypertension and tachycardia depends more on the vigilance and skill of the anesthesia provider than on the specific medication used.

Intraoperative monitoring of a patient with pheochromocytoma should include the use of standard monitors, an intra-arterial catheter, and a urinary catheter. Ongoing assessments of cardiac contractility and cardiac filling pressures and volumes facilitate the successful treatment of catecholamine-induced cardiomyopathy or postexcision hypotension. This information may be acquired via a pulmonary artery catheter or transesophageal echocardiography.[340] Laparoscopic resection of pheochromocytomas has almost completely replaced open surgical approaches, except for very large or malignant tumors.[300,341] Laparoscopic resection is associated with a shorter hospitalization and greater patient satisfaction.[342] In a small study, patients undergoing laparoscopic resection of a pheochromocytoma were randomized to receive one of two different intra-abdominal pressures during the carboperitoneum (either 8 to 10 or 15 mm Hg).[343] Patients with lower intra-abdominal pressure had less perioperative catecholamine release and fewer hemodynamic fluctuations than patients with higher intra-abdominal pressure. A retrospective review of 143 patients who underwent predominantly open resection of pheochromocytoma or paraganglioma at the Mayo Clinic from 1983 to 1996 showed a 25% incidence of sustained intraoperative hypertension but very few serious perioperative complications.[344]

Hypoglycemia may also be a serious problem after the resection of a pheochromocytoma.[345,346] Insulin secretion is inhibited by alpha-adrenergic receptor stimulation, and removal of the tumor may result in a rebound of insulin release. Blood glucose concentration should be measured frequently after pheochromocytoma excision.

Medical therapy for pheochromocytoma is used only as a temporizing measure during pregnancy or in patients with inoperable or metastatic disease. Pheochromocytoma recurs in 6.5% of patients who have undergone complete surgical resection.[347]

Management during Pregnancy

When pheochromocytoma presents during pregnancy, surgical resection of the tumor is the preferred therapy.[307,308,348] A

variety of clinical strategies have been associated with successful obstetric and surgical outcomes. They include (1) open or laparoscopic tumor resection at 16 to 23 weeks' gestation followed by vaginal or cesarean delivery at term,[349–352] (2) cesarean delivery with concurrent open tumor resection,[353] (3) cesarean delivery with open or laparoscopic tumor resection 2 to 8 weeks later,[313,354,355] and (4) vaginal delivery with laparoscopic tumor resection 6 weeks later.[349] A number of case reports have described successful laparoscopic resection of abdominal pheochromocytoma during pregnancy between 12 and 23 weeks' gestation with good maternal and fetal outcomes.[350–352] These reports included one robotic case and one set of twins. Before 24 weeks' gestation, surgery should proceed as soon as the patient is adequately prepared with adrenergic blockade.[322,356] After 24 weeks' gestation, the gravid uterus represents a mechanical obstruction to surgery for most abdominal pheochromocytomas. Women with pregnancy at this gestational age should receive adrenergic receptor blockade for the remainder of the pregnancy, or until the tumor is removed.[322]

Phenoxybenzamine, the most widely used medication for preoperative preparation of the pregnant woman with pheochromocytoma, easily crosses the placenta.[356] A case series suggested that neonates should be monitored closely in an intensive care nursery after intrauterine exposure to phenoxybenzamine.[357] Other alpha-adrenergic receptor antagonists have been used successfully in pregnant patients with pheochromocytoma, including phentolamine, prazosin, and doxazosin. Beta-adrenergic receptor blockade may be added if needed to control tachycardia or arrhythmias or to treat an epinephrine-dominant pheochromocytoma. Beta-adrenergic receptor antagonists that have been used successfully in pregnant patients with a pheochromocytoma include propranolol, atenolol, and metoprolol.[307,356,358] Clinical experience with metyrosine during pregnancy is very limited. Pending further assessment of safety during pregnancy, the use of metyrosine in pregnant women with pheochromocytoma should be restricted to those whose tumors are resistant to adrenergic receptor blockade.

Medications that have been used successfully to control intraoperative hypertension and tachycardia in pregnant patients with pheochromocytoma include phentolamine, nitroprusside, nitroglycerin, magnesium sulfate, propranolol, remifentanil, esmolol, and hydralazine.[313,358–360] Esmolol, however, may not be an ideal medication during pregnancy (as discussed earlier).[230,231] The safety of maternal administration of nitroprusside has also been questioned because of possible fetal cyanide toxicity.[361] Adverse effects were noted in fetal lambs when high doses of nitroprusside were administered in pregnant ewes in which tachyphylaxis had developed.[361] Clinical case reports suggest that a low-dose maternal infusion of nitroprusside (approximately 1 μg/kg/min) should be safe during the peripartum period.[362,363] If maternal tachyphylaxis develops, nitroprusside should be discontinued and a different vasodilator used. Nitroprusside reduces uteroplacental vascular resistance in hypertensive sheep, and it antagonizes norepinephrine-induced uterine artery vasoconstriction in humans and guinea pigs.[364–366] These data suggest theoretical advantages for the perioperative use of nitroprusside in pregnant women with pheochromocytoma.

In summary, early diagnosis of pheochromocytoma during pregnancy and adequate adrenergic receptor blockade are essential to optimize maternal and fetal safety. Phenoxybenzamine is used for preoperative preparation of the pregnant patient. If beta-adrenergic receptor blockade is necessary, metoprolol can be used unless specifically contraindicated. During surgery, short-acting, titratable cardiovascular medications are preferred. Monitoring and therapy should be directed toward optimization of preload, afterload, and cardiac contractility for a patient with rapid changes in circulating concentrations of catecholamines. Attention to detail is likely more important than the choice of specific medications.

Obstetric Management

Pheochromocytoma during pregnancy is associated with an increased incidence of fetal death and fetal growth restriction. The presumed mechanism is decreased uterine blood flow secondary to catecholamine secretion by the tumor; the metabolic activity of the placenta is an effective barrier to the transplacental passage of maternal catecholamines.[367] When pheochromocytoma is diagnosed and effective maternal alpha-adrenergic receptor blockade is instituted before delivery, the fetal death rate declines from 50% to near zero.[307,308]

Placental abruption has been reported in patients with pheochromocytoma.[368] From a hemodynamic standpoint, this process may be analogous to the occurrence of placental abruption in patients with acute cocaine intoxication.[369] Pheochromocytoma and preeclampsia may have overlapping clinical presentations; proteinuria, for example, occasionally occurs in patients with pheochromocytoma.[370]

To avoid the increased abdominal pressure on the tumor that can occur during active labor, cesarean delivery is preferred in patients with an unresected pheochromocytoma.[307,308]

Anesthetic Management

Preoperative preparation and intraoperative monitoring and management have already been discussed. A variety of general anesthetic agents as well as spinal and epidural anesthesia have been successfully used in nonpregnant patients with pheochromocytoma.[324,329] Box 43.10 lists perioperative medications that should be avoided to minimize hormone secretion by a pheochromocytoma. A case series of nonpregnant patients suggested that exogenous glucocorticoids can unpredictably trigger a pheochromocytoma crisis,[371] but this observation requires further confirmation. There are two published cases of nonpregnant patients with pheochromocytoma who were incorrectly diagnosed intraoperatively with malignant hyperthermia.[372,373] Manipulation of a pheochromocytoma during resection may result in a small increase in end-tidal carbon dioxide[374]; it is unlikely, however, that the modest magnitude of this effect would be confused with malignant hyperthermia.

In pregnant women with pheochromocytoma, analgesia during labor is not usually a concern because cesarean

BOX 43.10 Perioperative Medications to Avoid in Patients with Pheochromocytoma

- Atracurium
- Droperidol
- Glucocorticoids
- Metoclopramide
- Morphine
- Pancuronium
- Pentazocine
- Succinylcholine
- Vancomycin

These medications may, either directly or indirectly, increase the release of catecholamines by the tumor.

Data from Hull CJ: Phaeochromocytoma. Diagnosis, preoperative preparation and anaesthetic management. *Br J Anaesth.* 1986;58:1453–1468; Rosas AL, Kasperlik-Zaluska AA, Papierska L, et al. Pheochromocytoma crisis induced by glucocorticoids: a report of four cases and review of the literature. *Eur J Endocrinol.* 2008;158:423–429.

delivery is preferred. Cesarean delivery, with or without concurrent tumor resection, has been accomplished safely with **general anesthesia**,[313,353,359,360] **epidural anesthesia**,[354,358,375] and **combined epidural-general anesthesia**.[355] One case report of bupivacaine spinal anesthesia for cesarean delivery in a patient with an unsuspected and undiagnosed pheochromocytoma described refractory intraoperative hypotension, but satisfactory maternal and neonatal outcomes.[376] There are no prospective randomized studies of the anesthetic management of pregnant women with pheochromocytoma. It seems reasonable to avoid abrupt hemodynamic changes and to avoid the medications listed in Box 43.10. Either neuraxial or general anesthesia for cesarean delivery should be selected on the basis of factors other than the presence or absence of a pheochromocytoma. The care with which anesthesia is administered is probably more important than the specific technique selected.

KEY POINTS

- Pregnancy is characterized by a progressive increase in peripheral insulin resistance.
- Insulin requirement decreases during the first stage of labor, increases during the second stage, and decreases again after delivery.
- Maternal diabetes mellitus is associated with a higher incidence of polyhydramnios, preterm labor, preeclampsia, fetal macrosomia, neonatal hypoglycemia, and cesarean delivery.
- Fetal structural malformations are the leading cause of perinatal mortality in diabetic parturients; strict glycemic control before conception reduces the risk.
- Normal pregnancy is a euthyroid state because serum concentrations of unbound or free thyroid hormones are within the normal nonpregnant range.
- Thyroid storm is a rare but life-threatening disorder during pregnancy. It is best prevented by effective treatment of preexisting hyperthyroidism and adequate preparation of the patient for surgery.
- The required dose of thyroid hormone replacement medication increases during pregnancy; neonatal thyroid function is normal in most cases of maternal hypothyroidism.
- Maternal and fetal safety is enhanced by early diagnosis of pheochromocytoma and effective adrenergic receptor blockade before resection.
- At the time of pheochromocytoma resection, the anesthesiologist should anticipate the potential for (1) episodic hypertension and tachycardia during manipulation of the tumor and (2) severe hypotension after tumor resection.
- For women with an unresected pheochromocytoma, cesarean delivery is preferred.[375]

Hematologic and Coagulation Disorders

Jill M. Mhyre, MD

CHAPTER OUTLINE

ANEMIA

Normal Hemoglobin Morphology

Normal adult hemoglobin consists of four polypeptides (two alpha and two beta chains) and an iron-containing prosthetic group (heme or ferriprotoporphyrin IX). In the early embryo, theta (θ) and zeta (ζ) chains are present instead of the alpha (α) chains, and epsilon (ε) chains are present instead of the beta (β) chains. After early embryogenesis, pairs of alpha chains are linked with pairs of either beta, gamma (γ), or delta (δ) chains to form adult hemoglobin (Hgb A = $\alpha_2\beta_2$), fetal hemoglobin (Hgb F = $\alpha_2\gamma_2$), or hemoglobin A_2 (Hgb A_2 = $\alpha_2\delta_2$). By term gestation, the ratio of hemoglobin F to hemoglobin A is approximately 1 : 1. By 1 year of age, hemoglobin F typically constitutes less than 1% of total hemoglobin. Although hemoglobin A_2 is present, it constitutes less than 2.5% of total adult hemoglobin.

The sequence of amino acids (141 amino acids for alpha chains and 146 for beta chains) defines the **primary structure;** the three-dimensional shape of each chain defines the **secondary structure;** the relationship between the four chains and the heme prosthetic group defines the **tertiary structure;** and the binding of the ligands 2,3-diphosphoglycerate (2,3-DPG) and oxygen defines the **quaternary structure** of the hemoglobin molecule. The physiology of oxygen transport in the fetus is described in Chapter 5.

Anemia in Pregnancy

During normal pregnancy, plasma volume increases by approximately 50%, but red blood cell (RBC) mass increases by only 30%; this differential increase results in the **physiologic anemia of pregnancy** (see Chapter 2). If the hemoglobin concentration decreases below 10.5 g/dL, the physician should consider other causes of anemia.[1,2]

Iron deficiency is the most common cause of anemia in pregnancy. It becomes more prevalent as pregnancy advances; in a population-based sample of women in the United States, the prevalence increased from 7% in the first trimester to 14% in the second trimester and 30% in the third trimester of pregnancy.[3] The global incidence is estimated at 19.2%.[4] In addition to reduced hematocrit, iron-deficiency anemia is characterized by low mean corpuscular volume (MCV) and low total serum iron, ferritin, and transferrin saturation.

Iron-deficiency anemia during the first trimester of pregnancy increases the risk for preterm delivery and low birth weight, but evidence is inconclusive for any association

between anemia in the second and third trimester and adverse perinatal outcomes.[5] In the United States, the risk for iron deficiency is increased by advanced parity, short interpregnancy interval, Mexican-American ethnicity, and African race.[3,6] Daily oral iron treatment in pregnancy reduces the risk for maternal anemia, but likely only improves birth outcomes in populations with high rates of anemia and preterm birth.[7–9] A 2013 meta-analysis of randomized controlled trials identified a dose-response relationship between total daily dose of iron (up to 66 mg/day) and birth weight, but found insufficient evidence of any benefit on the incidence of preterm birth or small-for-gestational age infants.[7] Doses of oral iron also correlate directly with side effects, including nausea, vomiting, constipation, and abdominal cramps.[10] Antepartum anemia is a leading risk factor for postpartum blood transfusion[11]; however, no study has evaluated the impact of antepartum iron supplementation on the risk for postpartum maternal blood transfusion.

Parenteral (intramuscular or intravenous) iron enhances hematologic response compared with oral iron, but formulations that contain dextran may increase risk for venous thrombosis and allergic reactions.[10]

An elevated hemoglobin concentration (greater than or equal to 14.5 g/dL) has been associated with adverse pregnancy outcomes, including preterm delivery, small-for-gestational-age infants, and stillbirth.[5] In the third trimester of pregnancy, iron overload, as demonstrated by high serum ferritin and low soluble transferrin receptor concentrations, is associated with smaller birth size; consequently, the association between polycythemia and decreased fetal growth can be explained partially, but not exclusively, by inadequate plasma expansion.[5]

Thalassemias

The thalassemias are a group of microcytic, hemolytic anemias that result from the reduced synthesis or dysfunction of one or more of the polypeptide globin chains.[12] This reduced synthesis leads to (1) an imbalance in globin chain ratios, (2) defective hemoglobin, and (3) erythrocyte damage resulting from excess globin subunits. In α-thalassemia, alpha-chain production is reduced, and in β-thalassemia, beta-chain production is reduced. Clinically, thalassemia is divided between transfusion-dependent thalassemia and non–transfusion-dependent thalassemia.[13] Patients with transfusion-dependent thalassemia require ongoing transfusion therapy for survival, but even patients with non–transfusion-dependent thalassemia may require blood transfusions during periods of stress such as infection or pregnancy.[13]

α-Thalassemia

There are two alpha-chain loci on each chromosome 16; therefore, there are four genes that can produce alpha chains.[12] Because deletions or mutations can affect any or all of these genes, four types of α-thalassemia exist: (1) **silent carrier** (three functioning genes), (2) **α-thalassemia trait** (two functioning genes), (3) **hemoglobin H disease** (one functioning gene), and (4) **α^0-thalassemia** or **Bart's hydrops** (no functioning genes). As the number of functioning genes decreases from three to zero, the ratio of alpha to beta chains decreases from 0.8 : 1 to 0.6 : 1 to 0.3 : 1 to 0 : 1. More than 120 specific genetic mutations have been identified in cases of α-thalassemia, including deletional and nondeletional mutations of the α-globin genes, and mutations in regulatory genes that enhance genetic transcription (e.g., MCS-R2).[12] As beta (or beta-like) chains accumulate, they can form tetramers *in utero* (hemoglobin Bart's = γ_4) or after delivery (hemoglobin H = β_4) and appear as Heinz bodies on the peripheral blood smear.

In the United States, 25% to 30% of black women are silent carriers and have slightly smaller (78 to 85 fL) mean corpuscular volume (MCV) than women without thalassemia.[14,15] A chromosome lacking one alpha gene is common in Africa, the Mediterranean basin, the Middle East, India, Southeast Asia, Indonesia, and the South Pacific Islands.[16] Silent carriers are not at increased risk for adverse outcome during pregnancy or surgery.

The **α-thalassemia** trait affects 2% to 3% of black women in the United States[14,15] and is almost exclusively due to homozygous α+-thalassemia, in which one functional α-globin gene is preserved on each chromosome (α–/α–). These women have an MCV of 70 to 75 fL and mild anemia. They typically are asymptomatic and, beyond the effects of mild anemia, experience no additional risk for adverse outcomes during pregnancy or surgery. Heterozygous α^0-thalassemia trait (—/αα) is common among individuals of Southeast Asian descent. It is phenotypically indistinguishable from homozygous α+-thalassemia trait but introduces the risk for bearing an offspring with hemoglobin H disease or Bart's hydrops.

Patients with **hemoglobin H disease** experience moderately severe microcytic anemia, splenomegaly, fatigue, and generalized discomfort. Hemoglobin H (β_4) constitutes 2% to 15% of the total hemoglobin in these patients. Affected patients generally do not have a decreased life span, and hospitalization for the treatment of their anemia rarely is required. However, disease severity and prognosis vary, depending on the specific mutations present[17]; some patients have transfusion-dependent thalassemia and require lifelong transfusion and chelation therapy.

Hemoglobin Barts, or **α^0-thalassemia,** is generally incompatible with life. The disease is found predominantly in Southeast Asia, China, and the Philippines. Affected individuals die *in utero* or shortly after birth of hydrops fetalis; mothers carrying these fetuses are prone to develop hypertension or peripartum hemorrhage, or both.[18] Intact neonatal survival has been reported with intrauterine transfusion therapy and postnatal hematopoietic stem cell transplantation.[19,20] Antenatal screening for the disease is possible (see later discussion).

β-Thalassemias

In β-thalassemia, the production of beta chains is reduced. There are more than 250 genetic causes for ineffective

beta-chain production, including gene deletion, transcription mutations, RNA-processing mutations, and mutations that affect protein stability.[12] Unlike the alpha chains, which have four genes (two on each chromosome 16), beta chains have only one gene on each chromosome 11. Severity depends on the combination of mutations present. **β^0-thalassemia,** also called **β-thalassemia major** or **Cooley's anemia,** is a transfusion-dependent thalassemia characterized by a complete absence of beta-chain formation. With **β^+-thalassemia**, beta-chain production exists, but either production or function is impaired. For example, **Hemoglobin E** is a variant of β^+-thalassemia in which a point mutation on the β-globin gene both decreases mRNA transcription and decreases affinity between the resulting α- and β-globin proteins. Individuals who receive β-thalassemia genes from both parents but with mutations of different types often develop **thalassemia intermedia,** and depending on the combination of mutations, may have transfusion-dependent or non–transfusion-dependent thalassemia. Finally, **β-thalassemia minor** refers to the heterozygous carrier of β-thalassemia, a condition that is not transfusion dependent.

β-thalassemia is found most often in persons from the Mediterranean basin, the Middle East, India, Pakistan, and Southeast Asia and less often among persons from Tajikistan, Turkmenistan, Kyrgyzstan, and China.[21]

Individuals with β-thalassemia have a relative excess of alpha chains that cumulate in RBC precursors. Excess alpha chains undergo auto-oxidation and precipitate to form inclusion bodies called α-hemocromes. Oxidized ferric iron and reactive oxidative species in the α-hemocromes trigger a cascade of events leading to ineffective erythropoiesis and splenic hemolysis.[21] In the fetus, the gamma chain is unaffected; therefore, anemia only develops as gamma-chain production ceases during the first year of life.[21] In some patients, gamma-chain production continues to a variable extent. Thus, the ongoing production of hemoglobin F (even in adults) may minimize the effects of decreased beta-chain production.[12]

β-thalassemia major. In patients with β-thalassemia major, progressively severe anemia develops beginning in the first few months of extrauterine life.[21] Untreated anemia results in tissue hypoxia, increased intestinal absorption of iron, and increased erythropoietin production. The resulting expansion of marrow cavities causes skeletal abnormalities, extramedullary hematopoiesis, leg ulcerations, osteopenia, and pathologic fractures. Splenomegaly leads to thrombocytopenia and leukopenia. Ineffective erythropoiesis and chronic hemolysis increase the risk for thrombotic complications including venous thrombosis and pulmonary hypertension, with risk particularly elevated among those who have undergone splenectomy.[22,23] Similar pathology may develop in individuals with thalassemia intermedia, particularly in cases of compound hemoglobin E/β^0-thalassemia.[13]

RBC transfusions can restore normal childhood development, but the resulting iron load leads to iron accumulation, first in Kupffer's cells (noncirculating macrophages found in the liver), then in liver parenchymal cells, and finally in endocrine and myocardial cells. Clinical effects of iron overload typically present by the end of the first decade of life. Deposition of iron in endocrine tissues may result in short stature, diabetes mellitus, adrenal insufficiency, hypothyroidism, hypoparathyroidism, and infertility.[24] Pulmonary fibrosis with restrictive disease, and renal dysfunction have been attributed to iron deposition.[23] Myocardial accumulation of iron can lead to conduction abnormalities and intractable heart failure, which are exacerbated by anemia-induced tachycardia. Heart failure and infection are the most common causes of death.

Patients with β-thalassemia major who present when younger than 2 years of age often have hepatomegaly and a hemoglobin concentration as low as 2 g/dL. Patients who present later in life (2 to 12 years of age) typically have a hemoglobin concentration between 4 and 10 g/dL, with marked anisopoikilocytosis and numerous target cells, nucleated RBCs, and inclusion bodies. Levels of hemoglobin F range from 10% to 90% of the total hemoglobin, and hemoglobin A_2 constitutes the remainder of the hemoglobin present.

Treatment includes (1) lifelong transfusion of leukocyte-poor RBCs every 2 to 3 weeks to maintain a hemoglobin concentration greater than 10 g/dL, thus preventing endogenous erythropoiesis; (2) splenectomy; and (3) iron chelation therapy to prevent hemosiderosis. Deferoxamine was the first available chelation agent; it has a long record of successful use, but it requires continuous subcutaneous infusion or intermittent intramuscular injection.[22] Deferiprone and deferasirox are oral chelation drugs. Deferiprone may reduce cardiac iron levels more quickly than other chelation agents, but no studies have demonstrated improved clinical cardiac outcomes.[25,26] Hematopoietic stem cell transplantation may be curative if a human leukocyte antigen (HLA)-matched family donor without β-thalassemia major is found.[22] Research exploring the potential of gene therapy is underway.[22,27,28]

It is unusual for patients with β-thalassemia major to become pregnant; nonetheless, transfusion and chelation regimens improve fertility, and assisted reproductive technologies facilitate conception in women with hemosiderosis-related infertility.[29] The metabolic demands of pregnancy increase transfusion requirements. Mordel et al.[30] reviewed reports of these patients and suggested that up to 8 L of transfused RBCs may be required over the course of pregnancy to maintain the hemoglobin concentration above 10 g/dL.[30] Usually chelation agents are discontinued in pregnancy, given evidence of teratogenicity in animal models and fetal iron depletion described in case reports[31]; nevertheless, successful pregnancies have been described despite inadvertent use during the first trimester,[32] and some experts suggest resuming chelation therapy in the second and third trimesters among women who develop cardiac symptoms or rapid increase in ferritin.[33,34]

Historically, these patients had an increased incidence of spontaneous abortion, intrauterine fetal death, and fetal growth restriction (also known as intrauterine growth

restriction).[30] A systematic review of case reports and case series identified more than 400 pregnancies complicated by transfusion-dependent β-thalassemia; among women with normal cardiovascular function, careful transfusion therapy and multidisciplinary care appears to facilitate uneventful pregnancy.[34] Although severe skeletal defects and short stature increase the risk for cesarean delivery, trial of labor is usually appropriate, and operative delivery should be reserved for obstetric indications.[35]

In preparation for delivery, careful history and physical examination for the cardiac, pulmonary, hepatic, skeletal, renal, and endocrine manifestations of the disease and complications of iron overload are indicated.[23] Maternal cardiac iron deposition may be quantified using modified magnetic resonance imaging (MRI). Telemetry may be indicated for dysrhythmia surveillance.[34] Heart failure and pulmonary hypertension may be identified using echocardiography.[34,36] Chronic transfusions increase the risk for alloimmunization, which prolongs the time required to identify compatible allogeneic blood products in the event of peripartum hemorrhage. Intraoperative blood salvage has been safely performed during cesarean delivery in a parturient with thalassemia.[37] Postpartum pharmacologic thromboprophylaxis is indicated.[34,35]

Craniofacial abnormalities (e.g., maxillary hypertrophy, high arched palate) that increase the risk for difficult airway management may be evident on airway examination.[23] Extramedullary hematopoiesis can result in vertebral cortical weakening, pathologic fractures, and, rarely, paraplegia. However, in the absence of a major pathologic process of the spine, neuraxial anesthesia can be safely administered.[38] Patients with splenomegaly may develop thrombocytopenia; therefore, anesthesia providers should exclude a history of spontaneous hemorrhage and determine the platelet count before initiating a neuraxial procedure.

β-thalassemia intermedia and minor. The clinical course is usually benign in patients with β-thalassemia minor and with β-thalassemia intermedia when it is not transfusion dependent.[23] The anemia is typically mild (hemoglobin concentration of 9 to 11 g/dL) and is characterized by microcytosis and hypochromatosis. Levels of hemoglobin F range from 1% to 3%, and levels of hemoglobin A_2 range from 3.5% to 7%.

Moderate anemia develops only during periods of stress, such as pregnancy and severe infection. Most patients with non–transfusion-dependent β-thalassemia tolerate pregnancy well, although the incidence of oligohydramnios and fetal growth restriction are greater than in nonthalassemic women.[39] Because of an increased rate of RBC turnover and an increased risk for neural tube defects, high-dose folate supplementation is recommended in the first trimester. Transfusions are reserved for patients with hemorrhage or a hemoglobin concentration below 8 g/dL. Infection, which can cause bone marrow suppression, must be treated promptly. Non–transfusion-dependent β-thalassemia typically does not affect anesthetic management during labor or cesarean delivery.

Antenatal Thalassemia Screening

Among populations at risk for α- or β-thalassemia, antenatal screening can identify couples at increased risk for offspring with a serious hemoglobinopathy. Low maternal and paternal MCV (≤ 80 fL) or mean corpuscular hemoglobin (MCH ≤ 27 pg/cell) with normal serum iron and ferritin should prompt peripheral smear analysis for inclusion bodies, or hemoglobin electrophoresis, or both.[13,16] The latter test may reveal elevated hemoglobin A_2 or hemoglobin F, suggesting β-thalassemia or another hemoglobinopathy (sickle cell trait [AS], sickle cell anemia [SS], or hemoglobin C trait [SC]). Decreased hemoglobin A_2 suggests hemoglobin H disease; however, α-thalassemia cannot be detected by electrophoresis alone.[13,16] Focused genetic testing targets known mutations in the population, but rare variants require genome scanning techniques.[13] For β-thalassemia, cell-free fetal DNA obtained from maternal plasma can be used to screen for a paternally inherited mutation that would indicate a 50% risk for fetal disease.[40] Counseling for fetal genetic testing should be offered if both parents carry at least one abnormal hemoglobin gene.[16]

Prenatal diagnosis can be accomplished with the use of fetal cells obtained by means of chorionic villus sampling or amniocentesis and subjected to DNA analysis.[16,35] In the future, cell-free fetal DNA obtained from maternal plasma may provide an alternative source of material for fetal genetic analysis.

Sickle Cell Disorders

A **sickle cell disorder** refers to a state in which erythrocytes undergo sickling when they are deoxygenated.[41] Normal erythrocytes have a biconcave shape, whereas sickle cells are elongated and crescent shaped, with two pointed ends. Sickling is attributed to polymorphisms in the β-chains of the hemoglobin molecule. In hemoglobin S, valine is substituted for glutamic acid as the sixth amino acid in the β-chains.[42] This substitution results in a propensity for hemoglobin molecules to aggregate when the hemoglobin is in the deoxygenated state. The hemoglobin molecules stack on top of one another and form microtubules. Hemoglobin C, D, and E are other hemoglobin variants, all characterized by point mutations in the genes that encode the β-chains, and all less prone to sickling than hemoglobin S.

Sickle cell disease refers to disorders in which sickling results in clinical signs and symptoms; it includes hemoglobin SS disease (i.e., sickle cell anemia) and several heterozygous hemoglobinopathies (e.g., sickle cell β^0-thalassemia, hemoglobin SC disease).[16,42] Sickle cell disease variants are discussed in the following sections.

Sickle Cell Anemia

Epidemiology. Table 44.1 lists the prevalence of sickle cell anemia and the other common hemoglobinopathies in the adult black population in the United States. Sickle cell disease is less commonly identified among Hispanic, Middle Eastern, or Asian Indian ethnic groups.[45] The current number of individuals with sickle cell disease in the United States may

TABLE 44.1 Prevalence of Hemoglobinopathies in the United States in Persons of African Descent

Type	Estimated Prevalence
Traits	
Hemoglobin AS	1:12.5
Hemoglobin AC	1:33

BOX 44.1 Factors That Increase Sickling in Women with Sickle Cell Anemia

- Hemoglobin S concentration more than 50% of the total hemoglobin concentration
- Dehydration leading to increased blood viscosity
- Hypotension causing vascular stasis
- Hypothermia
- Acidosis

approach 100,000; high-quality surveillance data are not available.[43,44]

Pathophysiology. Oxygen tension is the most important determinant in sickling; other factors that affect sickling are listed in Box 44.1. Hemoglobin S begins to aggregate at a Po_2 of less than 50 mm Hg (6.7 kPa), and all of the hemoglobin S is aggregated at a Po_2 of approximately 23 mm Hg (3.1 kPa). The formation of hemoglobin S aggregates is time dependent[45]; the proportion of sickled hemoglobin increases with decreasing cardiac output and prolonged venous transit time. If an erythrocyte sickles, it can return to its normal shape once the hemoglobin becomes oxygenated.[42,45] However, repeated sickling cycles produce erythrocyte metabolic abnormalities and membrane damage, eventually leading to irreversible sickling regardless of oxygen tension.[42,45] Sickled cells are cleared rapidly from the circulation by the reticuloendothelial system; as a result, the erythrocyte life span is reduced to approximately 12 days.[42,45]

Sickled cells can form aggregates and lead to vaso-occlusive crises and end-organ injury. Repeated cycles of sickling, vaso-occlusion, reperfusion injury, and acute inflammation can lead to chronic inflammation and inflammatory vascular disease. Elevated levels of cell-free hemoglobin deplete nitric oxide, activate the endothelium, and further exacerbate inflammation.[41,42] The reduced erythrocyte life span results in anemia, jaundice, cholecystitis, and a hyperdynamic hemodynamic state.

Marked ventricular hypertrophy can occur in pregnant women with sickle cell disease secondary to increased cardiac output. This may lead to a decrease in ventricular compliance and a deterioration in ventricular diastolic function.[46] Anemia also leads to erythroblastic hyperplasia, expansion of medullary spaces, and a loss of cortex in long bones, vertebral bodies, and the skull.[42] Vaso-occlusive events can give rise to **infarctive crises** (which most often occur in the chest, abdomen, back, and long bones), **cerebrovascular accidents,** and rarely **peripheral neuropathy.**[47] Aggregate formation in the spleen can result in microinfarcts.

Functional asplenia and abnormal neutrophil responses both contribute to susceptibility to infection. Consequently, the incidence of pneumonia and pyelonephritis is higher in pregnant patients with sickle cell disease than in healthy pregnant patients. **Aplastic crises** can occur from depression of erythropoiesis secondary to infection (especially parvovirus) or from marrow failure secondary to folate deficiency during pregnancy.[42] During an aplastic crisis, the hemoglobin concentration can decrease rapidly, leading to high-output cardiac failure and death. **Sequestration crises** can result from the massive pooling of erythrocytes, especially in the spleen. This event occurs more frequently in patients with hemoglobin SC disease or sickle cell β-thalassemia than in patients with other forms of sickle cell disease. In general, a major sequestration crisis is one in which the hemoglobin concentration is less than 6 g/dL and has decreased more than 3 g/dL from the baseline measurement.[42]

The long-term clinical course of sickle cell disease is highly variable. Higher fetal hemoglobin expression and coincident α-thalassemia were among the first genetic modulators described.[48] Subsequent work has identified a complex network of single nucleotide polymorphisms associated with specific complications of sickle cell disease, most prominently the transforming growth factor-beta (TGF-β) family of membrane-bound receptors. These receptors play a role in fibrosis, cell proliferation, hematopoiesis, osteogenesis, angiogenesis, nephropathy, wound healing, and immune response.[48]

Diagnosis. In the adult, sickle cell anemia is characterized by (1) a hemoglobin concentration of 6 to 8 g/dL, (2) an elevated reticulocyte count, and (3) the presence of sickle cells on a peripheral blood smear. The diagnosis is confirmed by electrophoresis, thin-layer isoelectric focusing, or high-pressure liquid chromatography.[42] Because most hemoglobinopathies are inherited as autosomal recessive conditions, prenatal screening for abnormal hemoglobin is recommended in couples at high risk for sickle cell disease.[16] *In utero*, the diagnosis can be made through the use of restriction endonucleases specific for the sickle mutation applied to fetal cells obtained during amniocentesis or chorionic villus sampling.

Interaction with pregnancy. Pregnancy typically exacerbates the complications of sickle cell anemia. Maternal

mortality from sickle cell disease composes as many as 1% of all maternal deaths in the United States.[49] Thromboembolic complications, infection, cardiomyopathy, and pulmonary hypertension are the most serious maternal medical complications.[49,50] Patients with sickle cell anemia have an increased incidence of preterm labor, placental abruption, fetal growth restriction, preeclampsia, and eclampsia.[49,50] Intensive fetal surveillance may reduce the risk for intrauterine fetal death.[49]

Medical management. Sickle cell anemia is a chronic anemia; blood transfusions are given only when they are specifically indicated (e.g., acute anemia, aplastic crisis, acute chest syndrome, pneumonia with hypoxemia, before or during surgery).[42,43] The goals of transfusion are to achieve a hemoglobin concentration greater than 8 g/dL and to ensure that hemoglobin A represents more than 40% of the total hemoglobin present. Systematic review of cohort studies suggests that prophylactic blood transfusions during pregnancy decrease perinatal and maternal mortality, preterm birth, and maternal vaso-occlusive pain episodes, pulmonary complications, and pulmonary embolism[51]; randomized trials confirm a decrease in the frequency of maternal pain crises, but more evidence is needed to evaluate the other outcomes.[52,53] If the patient's baseline hemoglobin concentration is less than 6 to 7 g/dL, simple transfusions with buffy-coat–poor, hemoglobin S–free, washed RBCs should be adequate to meet treatment goals. Otherwise, partial exchange transfusions[54] may be necessary.

Hemoglobin F does not form aggregates with hemoglobin S. Hydroxyurea enhances the production of hemoglobin F, and reduces vaso-occlusive crises and other complications of sickle cell anemia.[43] It is unclear whether hydroxyurea is safe in pregnancy; the drug is known to be carcinogenic, mutagenic, and teratogenic in animals.[55] However, among a small series of pregnancies conceived at the time of maternal or paternal hydroxyurea administration, there was no evidence of abnormal pregnancy outcomes or teratogenicity among surviving offspring.[55] L-glutamine powder was approved by the U.S. Food and Drug Administration in 2017 to reduce acute complications of sickle cell disease, on the basis of a trial that demonstrated decreased rates of vaso-occlusive crisis.[56] Bone marrow transplantation is a potentially curative therapy for individuals with complicated sickle cell disease, although HLA-matched donors can be difficult to locate and the procedure is associated with significant morbidity and mortality.[57,58]

Obstetric management. During prenatal visits, the obstetrician should monitor maternal weight gain, blood pressure, urine protein content, and uterine and fetal growth. Antenatal aspirin therapy reduces the risk for preeclampsia (see Chapter 35).[59] Maternal surveillance for the complications of sickle cell disease continues throughout pregnancy,[54] and antepartum fetal surveillance begins at the time of extrauterine viability. Finally, pharmacologic thromboprophylaxis is indicated.[54]

Anesthetic management. Principles of anesthetic management include (1) close surveillance for the complications of sickle cell disease, (2) use of crystalloid to maintain intravascular volume, (3) transfusion of RBCs to maintain oxygen-carrying capacity, (4) administration of supplemental oxygen, (5) maintenance of normothermia, (6) prevention of peripheral venous stasis, and (7) provision of appropriate venous thromboembolism prophylaxis.[41,60] Preoperative evaluation should focus on recent sickle cell disease exacerbations, the degree of anemia, and chronic end-organ injury.[41,54] Pulmonary hypertension and high-output heart failure should be excluded with echocardiography. Preoperative blood transfusion to achieve a hemoglobin concentration of 10 g/dL improves perioperative outcomes for nonobstetric sickle cell patients undergoing medium-risk surgery with general anesthesia,[61] but no trial has evaluated prophylactic blood transfusion before cesarean delivery. Early preparation of cross-matched blood products should be considered because alloimmunization, and the antigen cross-matching procedures recommended to prevent its development, can prolong cross-matching procedures.[41] Pain control during labor is essential; continuous neuraxial analgesia is recommended.[41] Although general anesthesia for cesarean delivery has been associated with postoperative sickling complications, either neuraxial or general anesthesia is acceptable, and the choice of anesthetic technique ultimately depends on the time available to induce anesthesia and the patient's preference and physical status.[60]

Sickle Cell Disease Variants

If a patient carries one hemoglobin S gene and another gene for a hemoglobin that has a propensity to sickle, that patient is considered to have sickle cell disease. Patients with hemoglobin SD disease tend to have the mildest form, and patients with SC disease or sickle cell β-thalassemia tend to have more severe disease.[42]

As with the hemoglobin S gene, hemoglobin C is most prevalent among persons of West African descent, whereas hemoglobin D is distributed among persons of African, northern European, and Indian descent, and hemoglobin E is most prevalent among persons of Southeast Asian descent.[42] Patients with hemoglobin SC and hemoglobin SD disease tend to be asymptomatic during childhood with only mild anemia. Typically, these individuals do not develop symptoms until the second half of pregnancy. During late pregnancy, they may have severe anemia (secondary to splenic sequestration) and splenomegaly. Patients with hemoglobin SC disease also have a tendency to develop bone marrow necrosis, which predisposes to fat emboli. The other clinical manifestations are similar to those observed in patients with sickle cell anemia.[62]

Blood transfusion is recommended only when the hemoglobin concentration is less than 7 to 8 g/dL. Obstetric and anesthetic management are similar to the management of patients with sickle cell anemia.

Patients who are homozygous for hemoglobin C, D, or E typically have mild anemia. Target cells often are observed, and splenomegaly is common. The diagnosis is confirmed with electrophoresis, thin-layer isoelectric focusing, or high-pressure liquid chromatography.[42] Pregnancy typically is well

tolerated, and no specific change in obstetric or anesthetic management is required.

Sickle Cell Trait

Sickle cell trait (i.e., hemoglobin SA) occurs in approximately 8% of African-American women in the United States. The RBCs of patients with sickle cell trait do not sickle until the Po_2 decreases below 15 mm Hg (2.0 kPa); therefore, RBC life span is normal.[63] Patients with sickle cell trait are not at increased risk for adverse outcome during surgery or the peripartum period.[64] Nevertheless, sickle cell trait is associated with higher rates of thromboembolic complications,[65] and may contribute to long-term adverse outcomes among African Americans, including renal failure and diabetes.

Likewise, patients who are heterozygous for other hemoglobin variants (i.e., one gene for hemoglobin C, D, or E and one hemoglobin A) are asymptomatic. The heterozygous state for both the thalassemias and the structural hemoglobinopathies appears to protect against malaria, which may explain their geographic distribution and continued presence in the gene pool.[41]

Autoimmune Hemolytic Anemia

Patients with autoimmune hemolytic anemia produce antibodies to their own RBCs, resulting in hemolysis and varying degrees of anemia. The annual incidence of new cases of autoimmune hemolytic anemia is approximately 1 in 80,000 persons, but the prevalence approaches 1 in 5000.[66] Warm antibodies react with RBCs at a temperature of 35° to 40° C, whereas cold antibodies react optimally at a temperature lower than 30° C. Table 44.2 lists the characteristics of the four main types of autoimmune hemolytic anemia. Approximately one-half of cases are idiopathic, with the remainder attributed to malignancies, autoimmune diseases, infections, or drugs.[67]

Patients with **warm-reacting antibodies** typically respond to treatment with corticosteroids; splenectomy and the anti-CD20 antibody rituximab are second-line therapies.[66] After splenectomy, relapses and blood transfusions may lead to the continued requirement for intermittent or continuous corticosteroid therapy. The presence of the antibody and the requirement for extended phenotyping may delay matched blood product availability. In acute hemorrhage, the rapid transfusion of body-temperature, ABO-compatible and Rh-negative blood can be lifesaving, with the expectation that the half-life of transfused red blood cells will be shortened; this practice will allow time to procure compatible blood products.[66]

In patients with **cold-reacting antibodies,** the anemia typically is mild, and maintenance of normal body and ambient temperatures typically is all that is required to prevent hemolysis.

COAGULATION

Thrombotic and Thrombolytic Pathways

Hemostasis depends on the normal function of vascular tissue, platelets, and coagulation factors. During the initial response to loss of vessel integrity, platelets adhere to exposed collagen, facilitated by the von Willebrand factor (vWF) (primary hemostasis). Platelet activation results in the release of substances that constrict the injured vessels and cause other platelets to adhere and form a hemostatic plug. The platelet plug is not stable, and initiation of the coagulation cascade, followed by deposition and stabilization of fibrin, is

TABLE 44.2 Characteristics of Autoimmune Hemolytic Anemias

Disease	Immunoglobulin (Ig)	Complement Involved	Site of Red Blood Cell Destruction	Treatment	Transfusion Requirements
Incomplete warm autoantibodies	Typically IgG Rarely IgA Rarely IgM	No No C4b and C3b	Spleen Spleen Liver	Corticosteroids, splenectomy, immune globulin	Rarely needed; if given, combined with corticosteroids
Complete warm autoantibodies					
Type 1	IgM	C4b and C3b	Liver	Corticosteroids, splenectomy	Rarely needed
Type 2	IgM	C1–C9	Intracellular	Plasma exchange, corticosteroids	Frequently needed
Cold autoagglutinins and hemolysins	IgM	No	Intracellular	Corticosteroids, keeping patient warm	Very rarely needed
Biphasic hemolysins					
Acute	IgG	Yes	Intracellular agglutination	Treatment of underlying infection	Occasionally needed
Chronic	IgG	Yes	Intracellular hemolysis	Plasmapheresis, chlorambucil	Frequently needed

necessary for definitive hemostasis (secondary hemostasis). Most coagulation factors circulate in the blood as zymogens, which are converted to active enzymes that in turn convert other zymogens to active enzymes. For example, factor X (a zymogen) is converted to factor Xa (an enzyme), which converts prothrombin (factor II) to thrombin (factor IIa).

In its original conception, the coagulation cascade (Fig. 44.1) was believed to propagate within plasma. Subsequent work has located the enzymatic reactions of the **extrinsic system** primarily to the surface of subendothelial cells and those of the **intrinsic system** to the activated platelet surface.[68] Currently, a widely used model divides the coagulation cascade into three phases: (1) an **initiation phase** (classical extrinsic pathway), in which small amounts of active coagulation factors are generated; (2) an **amplification phase,** in which the level of active coagulation factors is boosted; and (3) a **propagation phase,** in which coagulation factors bind to the membrane of activated platelets, leading to the formation of fibrin clots.[68]

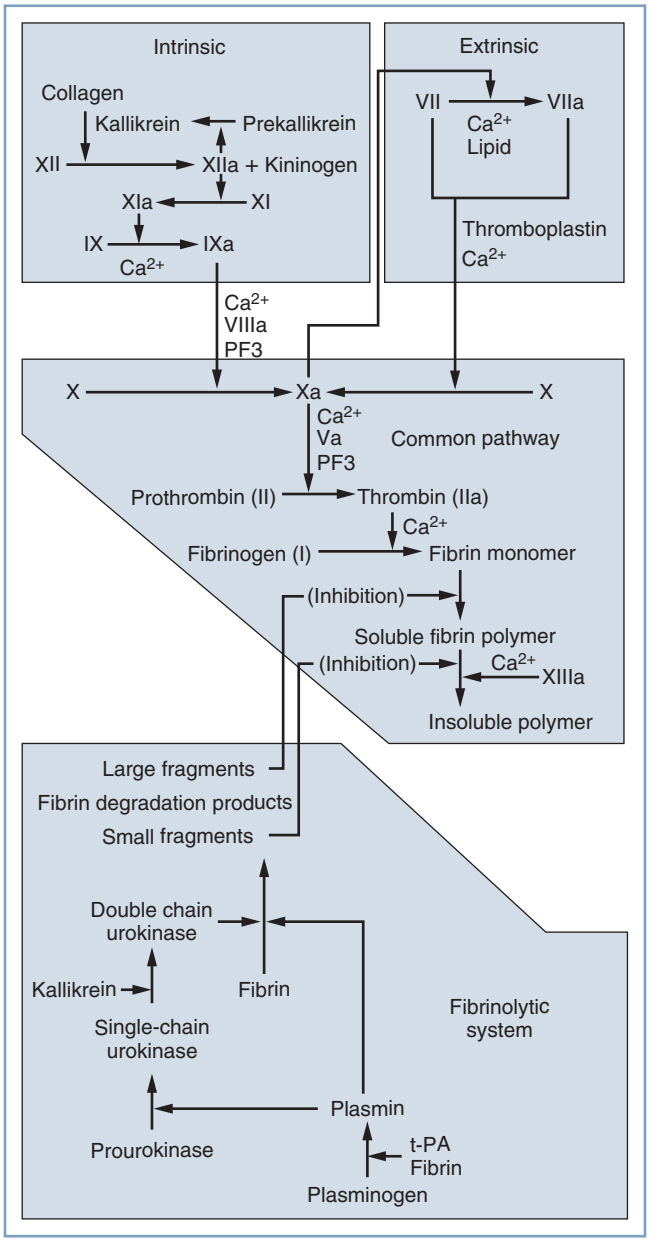

Fig. 44.1 Components of the extrinsic, intrinsic, and common pathways and the fibrinolytic system. The term *cascade* is a misnomer that stems from the presence of positive and negative feedback loops in both the coagulation and fibrinolytic systems. *PF3,* Platelet factor 3; *t-PA,* tissue plasminogen activator.

In the classic extrinsic pathway, tissue damage activates tissue factor (TF) (also known as factor III or thromboplastin) on the surface of extravascular cells (e.g., fibroblasts, smooth muscle cells), which are exposed to the bloodstream after tissue damage. TF has also been identified on the surfaces of syncytiotrophoblasts,[69] adhered leukocytes, circulating monocytes, and circulating microparticle membrane vesicles released by inflammatory and tumor cells.[68] TF binds factor VII and promotes proteolysis and activation to factor VIIa. On the membrane surface, the TF/VIIa complex converts factor X to Xa and small amounts of factor IX to IXa. Factor Xa amplifies conversion of factor VII to VIIa in the first of many positive feedback loops, and factor Xa forms a complex with factor Va. The membrane-bound prothrombinase complex (i.e., Xa/Va) converts small amounts of soluble prothrombin to thrombin. This thrombin diffuses to the activated platelet surface, where it amplifies the intrinsic coagulation pathway.

In the intrinsic pathway, factor XII binds to a negatively charged substrate (e.g., collagen, platelet phosphatidylserine) and may undergo autolysis to form factor XIIa, or it may be converted to XIIa by trace amounts of XIIa. In addition to activating its own zymogen, factor XIIa converts prekallikrein to kallikrein and factor XI to XIa. High-molecular-weight kininogen can bind factor XI and facilitate its conversion to XIa by XIIa. Kallikrein and high-molecular-weight kininogen also can convert factor XII to XIIa. Factor XIa converts factor IX to IXa, which, with factor VIIIa, converts factor X to Xa.

Factor Xa promotes platelet aggregation, and it converts factors V and VIII to factors Va and VIIIa, respectively. Factor Xa, combined with factor Va, converts factor II (prothrombin) to factor IIa (thrombin), a process termed the *thrombin burst.* Activated platelets provide the primary surface for conversion of factor X to Xa and prothrombin to thrombin. Thrombin converts factors I (fibrinogen), V, VIII, and XIII to factors Ia (fibrin), Va, VIIIa, and XIIIa, respectively. Thrombin also causes platelet activation. Factor XIIIa is required to cross-link fibrin strands, which helps form a stable clot.

Clot formation is limited by the natural anticoagulants antithrombin III, proteins C and S, and tissue factor pathway inhibitor (TFPI). Antithrombin III, whose activity is enhanced by heparin, inhibits factor IXa, factor Xa, and thrombin. Protein C is activated by a thrombin-thrombomodulin complex. With protein S as a co-factor, protein C breaks down factors Va and VIIIa. TFPI is produced by endothelial cells and inhibits coagulation by simultaneously binding factor Xa and the TF/factor VIIa complex.

The final component of the coagulation system is the **fibrinolytic system,** in which plasmin breaks down fibrin. Tissue-type plasminogen activator (t-PA) circulates as an active protease; however, its activity increases dramatically when it binds to fibrin, at which time it converts plasminogen to plasmin. Urokinase-like plasminogen activator (u-PA) is secreted as the relatively inactive pro-urokinase; it is converted to the active form (single-chain urokinase) by plasmin. Single-chain urokinase is converted to its most active form (double-chain urokinase) by kallikrein, which is released during activation of the coagulation cascade.

Plasmin-mediated fibrinolysis is confined to the clot by the local availability of fibrin and by plasminogen activator inhibitor-1 (PAI-1), which is secreted by many cells, and by plasminogen activator inhibitor-2 (PAI-2), which is secreted primarily by the placenta. Thrombin-activatable fibrinolysis inhibitor (TAFI) is synthesized in the liver, is activated by the thrombin-thrombomodulin complex, and inhibits fibrinolysis by eliminating the binding sites on fibrin for plasminogen and t-PA. The antifibrinolytic drugs **tranexamic acid** and **aminocaproic acid** inhibit fibrinolysis by binding to plasminogen and plasmin and preventing their binding to fibrin.

Changes in the concentrations of coagulation factors during pregnancy are outlined in Chapter 2 (see Box 2.2). The levels of most procoagulants increase during pregnancy, while anticoagulant levels remain stable or decrease.[69] Although t-PA levels decrease and antifibrinolytic proteins (i.e., PAI-1, PAI-2, TAFI) increase, plasminogen and fibrin degradation product levels increase, suggesting that fibrinolysis continues unabated during pregnancy.

Placental syncytiotrophoblasts promote coagulation by presenting tissue factor and phospholipids to maternal blood coursing through the intervillous space.[69] The concentrations of the thrombin-antithrombin complex and fibrin degradation products are elevated in blood from the uterine vein compared with peripheral blood, suggesting that many of the hemostatic changes of pregnancy originate in the placental bed.[70]

Deficiencies in procoagulant factors or an increase in fibrinolytic factors cause **hemorrhagic disorders.** Deficiencies in antithrombin III, protein C or S, or the fibrinolytic system cause **thromboembolic disorders.**

Assessment of Coagulation

Routine Hematology

The increase in the concentration of most coagulation factors is associated with a shortening of the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) during normal pregnancy. Similarly, fibrinogen and fibrin degradation products are increased. These changes may mask the early diagnosis of **disseminated intravascular coagulation (DIC),** so serial laboratory parameters are indicated if the diagnosis is suspected.[69] Thrombocytopenia is a sensitive, but not specific, indicator of DIC. For women with severe preeclampsia, a platelet count is a clinically useful screening test; a result below 100,000/μL suggests the possibility of impairment of other coagulation parameters.[71,72] In the healthy parturient with no history or clinical signs of bleeding, the routine laboratory assessment of hemostasis parameters, including platelet count, is not indicated.[71]

Whole-Blood Viscoelastic Testing

Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) measure whole-blood coagulation and provide information about the adequacy of platelet function and other coagulation factors. In both technologies, a pin connected to a strain gauge and suspended in a cup of blood records the clot kinetics and strength over time. In the case of TEG, a cup of blood oscillates around the torsion pin, and as clot strength increases, the pin records greater torque. In the case of ROTEM, the cup is still, and a pin connected to the strain gauge spins within the blood. Torque is translated to a graphic representation of clot strength (Fig. 44.2) in which specific parameters are interrelated and reflect activities of coagulation proteins, platelets, and their interaction.[73] Commonly used thromboelastography and thromboelastometry parameters are defined in Table 44.3. Activators added to the whole blood can be used to accelerate clotting and to isolate specific components of coagulation (Table 44.4).

Investigations using viscoelastic monitoring confirm that pregnancy is a hypercoagulable state.[73,74] Reference ranges for normal values likely vary over the course of pregnancy and into the postpartum period.[73,74] TEG and ROTEM have been proposed to assess coagulation status in normal and high-risk pregnant women,[75] to assess hemostasis before the initiation of neuraxial anesthesia in high-risk patients,[76] and to monitor the efficacy of venous thromboembolism prophylaxis.[77,78] Whether viscoelastic monitoring improves clinical outcomes in these contexts is unknown.

Observational data suggest that viscoelastic monitoring may reduce consumption of blood products when used to guide resuscitation for postpartum hemorrhage[79] (see Chapter 37). In general, deficits in clotting factor activation, amplification, and fibrin cross-linkage may be corrected with plasma. Deficits in clot strength reflect the need for platelets or fibrinogen (either cryoprecipitate or fibrinogen concentrate). The FIBTEM and functional fibrinogen assays add a platelet inhibitor (cytochalasin D or abciximab) to isolate the need for fibrinogen. For example, a FIBTEM A5 value less than 10 mm corresponds to a fibrinogen concentration below 200 mg/dL. Evidence of clot lysis (LY30 > 3% or ML > 15%) supports the need for antifibrinolytic therapy.

Platelet Function Analyzer

The PFA-100® (Siemens Healthcare Diagnostics, Deerfield, IL) measures platelet function *in vitro,* especially platelet activation and aggregation. This simple test evaluates the capacity of a sodium-citrated whole-blood sample to form a platelet plug at the aperture situated on a collagen/adenosine phosphate or collagen/epinephrine surface under high-shear conditions. The time required for full occlusion of the aperture by the platelet plug is designated as the *closure time.* PFA-100 measurements do not correlate with platelet counts

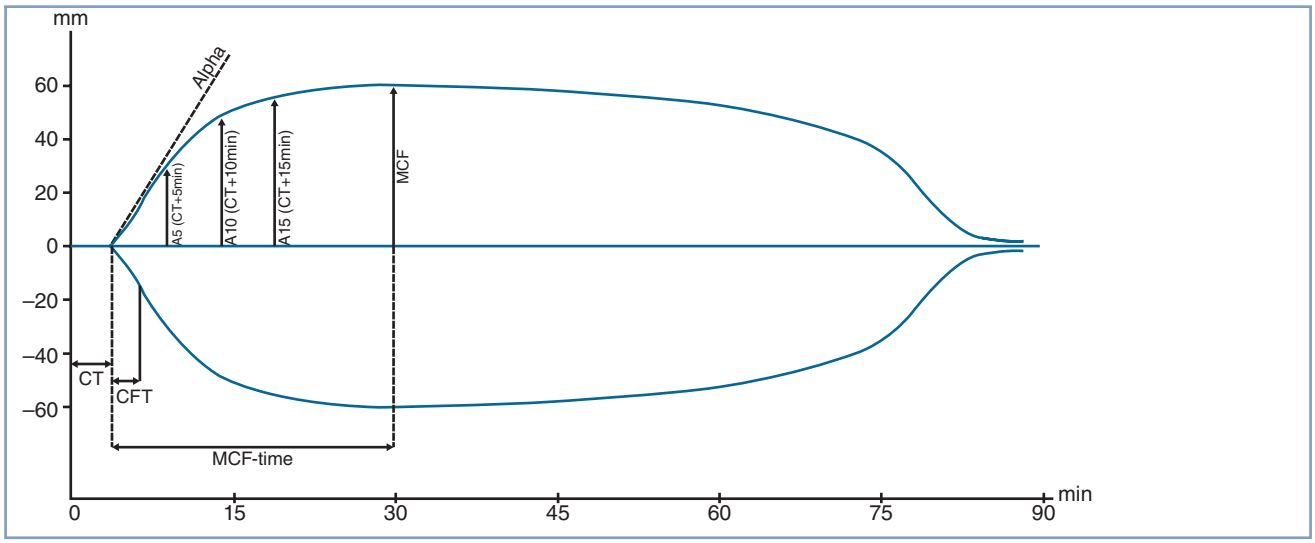

Fig. 44.2 Normal thromboelastomeric tracing using the ROTEM EXTEM assay. *A,* current amplitude; *Alpha,* α-angle; A5, A10, and A15, amplitude at specific minute interval; *CFT,* clot formation time; *CT,* clotting time; *MCF,* maximum clot firmness. (From Katz D, Beilin Y. Disorders of coagulation in pregnancy. *Br J Anaesth.* 2015;115[Suppl 2]:ii75–ii88.)

TABLE 44.3 Commonly Used Thromboelastography and Thromboelastometry Parameters

Coagulation Process	Key Components Tested	TEG	ROTEM	Definition
Clotting factor activation	Soluble coagulation factors, tissue factor	R (reaction time, minutes)	CT (clotting time, minutes)	Time to amplitude of 2 mm
Factor amplification and fibrin cross-linkage		K (kinetics time, minutes)	CFT (clot formation time, minutes)	Time for amplitude to increase from 2 to 20 mm
		α-angle (degrees)	α-angle (degrees)	Angle between the line in the middle of the graph and the tangential line of the body of the graph
Clot strength	Fibrinogen, platelets, Factor XIII	A5, A10, A15 (mm)	A5, A10, A15 (mm)	Amplitude measured at specific time points after CT or R (e.g., A5 is at 5 minutes)
		MA (maximum amplitude, mm)	MCF (maximum clot firmness, mm)	Maximum amplitude reached
Clot lysis	Fibrinolytic enzymes, fibrinolysis inhibitors, Factor XIII	LY30 (lysis)	LI30 (lysis index)	% of decrease in MA or MCF 30 minutes after MA or MCF has been reached
		EPL (estimated percent lysis)	ML (maximum lysis, %)	Maximal reduction in clot firmness after MA or MCF

in healthy parturients,[80] but they may demonstrate impairment in platelet function with severe preeclampsia.[81]

THROMBOCYTOPENIC COAGULOPATHIES

Thrombocytopenia is defined as a platelet count less than 150,000/μL, and affects 5% to 10% of the pregnant population, becoming more frequent as pregnancy advances.[82] **Gestational thrombocytopenia** (also known as essential thrombocytopenia) is the most common cause of thrombocytopenia in the second half of pregnancy (Table 44.5). Platelet count rarely decreases below 80,000/μL, and no changes in clinical management are indicated. When platelet count decreases below 100,000/μL, pathologic thrombocytopenic conditions should be considered, including: (1) **autoimmune thrombocytopenic purpura,**[83] (2) **preeclampsia,** (3) **DIC,** (4)

thrombotic thrombocytopenic purpura, (5) **acute fatty liver of pregnancy,** (6) **drug-induced thrombocytopenia,** (7) **post-transfusion purpura** (in individuals who have received a blood transfusion in the previous 1 to 2 weeks),[84] and (8) **inherited platelet disorders (e.g., Bernard-Soulier syndrome).**[82]

Pseudothrombocytopenia is a laboratory artifact in which chelation of calcium ions by ethylene-diamine-tetraacetic acid (EDTA) exposes antigenic sites that react with antibodies, causing clumping that artificially lowers the platelet count.[85] In these cases, the automated platelet count is normal if citrate anticoagulant is used.

Autoimmune Thrombocytopenic Purpura

Although autoimmune thrombocytopenic purpura (ATP) (previously called immune thrombocytopenic purpura and idiopathic thrombocytopenic purpura) is rare, with an incidence of between 0.01% and 0.1%, it composes the majority of cases of thrombocytopenia in the first trimester of pregnancy, and a sizable percentage of cases with profound thrombocytopenia later in pregnancy[82,86] (see Table 44.5). In this condition, immunoglobin G (IgG) antibodies directed against platelet antigens are produced primarily in the spleen, where phagocytosis by macrophages occurs. The liver and bone marrow are secondary sites of antibody production and phagocytosis. The binding of complement to platelets can facilitate their clearance, and antibody binding to megakaryocytes can result in ineffective production of platelets.[87] In ATP, the blood smear often reveals the presence of higher platelet volume and greater platelet diameter, and a bone marrow biopsy identifies normal or increased numbers of megakaryocytes.

TABLE 44.4 Additives Used in Common Viscoelastic Assays to Isolate Components of the Coagulation System

TEG-Based Tests		ROTEM-Based Tests		
Test	**Activators**	**Test**	**Activator**	**Purpose**
Kaolin-activated TEG	Kaolin	INTEM	Ellagic acid	Reveals defects in intrinsic pathway
Rapid TEG	Kaolin + tissue factor			Reveals defects in intrinsic and extrinsic pathways; tissue factor accelerates results
		EXTEM	Tissue factor	Reveals defects in intrinsic pathway; reveals platelet deficiency when compared with FIBTEM
Functional Fibrinogen Test	Tissue factor + abciximab	FIBTEM	Tissue factor + cytochalasin D	Addition of a platelet inhibitor reveals fibrin-based clot defects—fibrinogen deficiency
		APTEM	Tissue factor + aprotinin	Aprontinin blocks fibrinolysis; comparison with EXTEM confirms fibrinolysis

Although maternal IgG can cross the placenta and affect fetal platelets, ATP should not be confused with **neonatal alloimmune thrombocytopenia,** in which maternal antibodies specific to a fetal platelet antigen cause perinatal thrombocytopenia.

Interaction with Pregnancy

Conservative management is typically sufficient if ATP is diagnosed during pregnancy, but risk for postpartum hemorrhage appears to correlate with the degree of platelet deficit.[86] Symptoms (e.g., gingival bleeding, hematuria, gastrointestinal bleeding) suggest profound thrombocytopenia[86,88]; corticosteroids are indicated if the platelet count is less than 20,000 to 30,000/μL before the onset of labor or less than 50,000/μL at the time of delivery.[83,89] High-dose intravenous immune globulin (IVIG) produces a rapid but transient increase in the platelet count and is administered if there is no response to corticosteroid therapy.[83,89] In some women with preexisting ATP who become pregnant, thrombocytopenia becomes sufficiently severe that administration of high-dose corticosteroids and immune globulin is inadequate. Rituximab, thrombopoietin receptor agents, and recombinant human thrombopoietin (not currently available in the United States) are alternative second-line treatments; however, pharmacokinetics, dosing, and safety in pregnancy have not been established.[82] Splenectomy is another second-line treatment; women who have undergone splenectomy are at increased risk for infection with encapsulated organisms.[83]

Obstetric Management

Maternal IgG can cross the placenta and cause fetal thrombocytopenia, which increases the risk for neonatal hemorrhage.[86,88] Although there is a correlation between maternal platelet-associated IgG and fetal thrombocytopenia,[90,91] it is not possible to predict the degree of fetal thrombocytopenia based on maternal platelet count[91,92] or serology.[83,93] No study has demonstrated a correlation between the fetal platelet count and intrapartum fetal risk. Neonatal intracranial hemorrhage is rare and is not related to the method of delivery.[94] Thus, current guidelines recommend that cesarean delivery should be reserved for obstetric indications.[83,94] Current guidelines do not recommend attempts to measure the fetal platelet count before delivery.[83] Both periumbilical blood sampling and fetal scalp blood sampling introduce additional risks, and the measured platelet counts are not always accurate.

Operative wounds, including episiotomies, increase risk for peripartum bleeding. Bleeding occurs less often from the placental implantation site, where contraction of the uterus represents the primary mechanism for postpartum hemostasis.[90] After delivery, the platelet count often returns to normal in these patients.[91]

Thrombotic Thrombocytopenic Purpura

The classic pentad that defines the syndrome of thrombotic thrombocytopenic purpura (TTP) includes (1) thrombocytopenia (platelet count as low as 20,000/μL); (2) microangiopathic hemolytic anemia; (3) fever; (4) neurologic signs such as photophobia, headache, and seizures; and (5) renal failure. Only the first two elements are essential for diagnosis.[95] Disseminated platelet aggregation is a hallmark of TTP.[95,96] Neurologic and renal changes result from the deposition of platelet emboli and may be of variable intensity in the acute presentation and during recurrences. Diseases that share some of the clinical findings of TTP include DIC, preeclampsia, and hemolytic-uremic syndrome.

TTP is associated with either a congenital or acquired deficiency of the enzyme ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). ADAMTS13 is responsible for cleaving vWF multimers. These multimers promote systemic platelet aggregates and microemboli.[95] Decreased levels of the large multimeric forms of vWF are seen in the acute phase of TTP[97] but return to normal during remission. In contrast, in hemolytic-uremic syndrome the large multimeric forms of vWF are present in normal amounts.[98] The affinity of vWF for platelet membrane glycoprotein IIb/IIIa is also increased in TTP.[96] The presence of vWF (but not fibrinogen) in platelet aggregates helps differentiate TTP from DIC.[99] (In patients with DIC, fibrinogen but not vWF is found in platelet aggregates.)

Approximately 40% of patients who achieve remission have at least one recurrence, but relapse is rare in patients without severe ADAMTS13 deficiency.[100] Pregnancy appears to be a precipitating event for both initial and recurrent episodes of TTP, particularly among women with congenital ADAMTS13 deficiency, also known as Upshaw-Schulman syndrome.[100,101] ADAMTS13 activity declines progressively through normal pregnancy, while vWF levels increase.[102]

Prompt diagnosis and effective treatment for TTP appear to improve both maternal and fetal survival,[89,103,104] although perinatal loss remains significant if the disease develops in the first and second trimesters.[103] Diagnosis of TTP may be delayed because of a misdiagnosis with the hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; concurrent diagnoses have been reported.[103] Clinical signs that suggest TTP include microangiopathic anemia with thrombocytopenia in the first half of pregnancy, concomitant fever or neurologic signs, and a high ratio of lactate dehydrogenase to aspartate aminotransferase.[103]

Plasma exchange is the mainstay of therapy for treating symptomatic TTP, with an exchange volume of 1.0 to 1.5 times the predicted plasma volume of the patient.[95,103,105] For congenital ADAMTS13 deficiency, low-dose aspirin combined with regular plasma infusions may limit disease recrudescence, and should be resumed in subsequent pregnancies.[104] Human plasma–derived factor VIII concentrate, which contains vWF, is an alternative to plasma infusion. Acquired TTP frequently requires immunosuppressant therapy (e.g., with corticosteroids, IVIG, rituximab, or azathioprine) to reduce antibodies to ADAMTS13.[104,106] Platelet transfusions are usually avoided but may be safe if administered immediately before or after plasma exchange therapy begins.[106] Because of the coagulopathy present in patients with TTP, neuraxial anesthesia is not recommended. One case report described

spinal anesthesia administered for cesarean delivery in a woman with familial ADAMTS13 deficiency treated with fresh frozen plasma.[107]

Inherited Platelet Disorders

A large number of inherited platelet disorders impact either platelet quantity or function or both, and can increase the risk for both peripartum and perioperative bleeding.[108]

Bernard-Soulier syndrome is a rare autosomal recessive disorder characterized by (1) thrombocytopenia, (2) large platelets on the peripheral blood smear, and (3) defects of the platelet membrane glycoprotein Ib-IX-V complex.[109] Laboratory diagnosis includes prolonged bleeding time and prolonged closure time on PFA-100. Treatment during labor and delivery may require tranexamic acid, desmopressin, human leukocyte antigen (HLA), and platelet antigen–matched platelet transfusion, if available, or unmatched platelet transfusion, if necessary.[109,110]

Patients with **Glanzmann thrombasthenia** have a deficiency in platelet surface glycoprotein IIb/IIIa receptors, the major receptor for fibrinogen; this deficiency results in abnormal platelet aggregation.[111] These patients have a normal platelet count, but bleeding time and closure time on PFA-100 are prolonged. The treatment for Glanzmann thrombasthenia during labor and delivery is similar to that for Bernard-Soulier syndrome.[108,111]

Drug-Induced Platelet Disorders

Drugs can accelerate platelet destruction through immunologic mechanisms.[112,113] Drugs used in obstetric patients that are known to trigger antibodies against platelet receptors include antibiotics (e.g., beta-lactam drugs, trimethoprim-sulfamethoxazole, vancomycin), nonsteroidal anti-inflammatory drugs, and abciximab.[113] Most penicillins and some cephalosporins also impair platelet activity directly.[114] Likewise, heparin impairs platelet function via immunologic and nonimmunologic mechanisms. Nonimmunologic mechanisms are expected; heparin reduces thrombin production, and thereby prevents thrombin from amplifying platelet activation during the thrombin burst. Heparin-induced thrombocytopenia refers to an immunologic reaction that causes both profound platelet destruction, and a prothrombotic state, usually within 5 to 10 days of starting heparin therapy.[115,116] In postoperative patients, the risk for heparin-induced thrombocytopenia (HIT) is lower with low-molecular-weight heparin (LMWH) than unfractionated heparin.[117]

Drugs that *impair* platelet function are often used in obstetric patients. Aspirin irreversibly inactivates cyclooxygenase, and *in vitro* platelet function tests can remain abnormal for as long as 1 week.[118] However, low-dose aspirin (i.e., 60 to 80 mg) does not significantly prolong the bleeding time in pregnant women.[119] Moreover, a large number of women receiving low-dose aspirin therapy for the prevention or treatment of preeclampsia have received neuraxial analgesia for labor and delivery without complications.[59] Therefore, in the absence of a co-administered anticoagulant (e.g., LMWH) or preexisting hemostatic defect (e.g., von Willebrand's disease, hemophilia A, uremia) in which aspirin's effect is more pronounced,[120,121] recent ingestion of aspirin does not contraindicate the administration of neuraxial anesthesia.

Other nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, indomethacin, naproxen) reversibly inhibit cyclooxygenase.[122] These drugs have only a transient effect on the bleeding time[123,124] and have been given to patients with hemostatic diseases (e.g., hemophilia A) without deleterious effect.[125] Maternal ingestion of these drugs is not a contraindication for neuraxial blockade, and should not affect anesthetic management for delivery.

Drugs that increase platelet cyclic adenosine monophosphate (cAMP) levels decrease platelet responsiveness.[122] This increase in cAMP levels can occur after the administration of prostaglandin E_1 or prostacyclin (which stimulates adenyl cyclase)[126] or after the administration of drugs that decrease the destruction of cAMP (e.g., caffeine, theophylline).

Dextran, which is absorbed onto platelet membranes, can reduce platelet aggregation, secretion, and procoagulant activity.[122] Because platelet membranes are a substrate for steps in the coagulation system, clot formation may also be impaired by dextran. Hydroxyethyl starch also appears to worsen platelet function.[122] A diet rich in omega-3 fatty acids or fish oil can reduce the platelet concentration of arachidonic acid and prolong bleeding time.[122]

The use of **herbal medications** such as garlic, ginkgo, or ginseng alone may not increase the risk for spinal hematoma; however, concurrent use of an oral anticoagulant or heparin may increase the risk for bleeding complications in these patients.[127]

CONGENITAL COAGULOPATHIES

von Willebrand's Disease

The hemostatic disorder, von Willebrand's disease, was named for Erich von Willebrand, who first described it in 1926.[128] vWF is synthesized by endothelial cells and megakaryocytes.[129] The vWF subunit is 260 to 275 kDa. A dimer is formed by a combination of two subunits, and variable numbers of the dimers are combined to form multimers that range from 500 to 200,000 kDa. vWF plays two primary roles in coagulation: (1) it forms a complex with factor VIII, which decreases the excretion of factor VIII; and (2) it mediates platelet adhesion by binding to collagen and platelets (a reaction enhanced by ristocetin).[129,130]

von Willebrand's disease can be divided into several subtypes based on quantitative and qualitative defects in vWF (Table 44.6).[131,132] **Type 1 von Willebrand's disease** is the most common congenital bleeding disorder, which typically is inherited as an autosomal dominant trait that affects up to 1% of the population, and is diagnosed more frequently in women than in men.[129,133] In this subtype, vWF functions normally but its levels are reduced. Both vWF and factor VIII increase in normal pregnancy, so antenatal bleeding is rare in women with type 1 disease.[134] **Type 2 von Willebrand's disease** is less common and includes a family of disorders

TABLE 44.6 Classification of von Willebrand's Disease

Type	Description
1	Partial quantitative deficiency of vWF
2	Qualitative vWF defects
2A	Decreased vWF-dependent platelet adhesion and a selective deficiency of high-molecular-weight vWF multimers
2B	Increased affinity for platelet glycoprotein Ib
2M	Decreased vWF-dependent platelet adhesion without a selective deficiency of high-molecular-weight vWF multimers
2N	Markedly decreased binding affinity for factor VIII
3	Virtually complete deficiency of vWF

vWF, von Willebrand factor.
From Sadler JE, Budde U, Eikenboom JC, et al. Update on the pathophysiology and classification of von Willebrand disease: a report of the Subcommittee on von Willebrand Factor. *J Thromb Haemost*. 2006;4:2103–2114.

characterized by qualitative dysfunction of vWF, with normal plasma concentrations. Although types 2A and 2M lead to decreased platelet aggregation, type 2B results from a gain-of-function mutation in which vWF increases binding between platelets, leading to accelerated platelet turnover and thrombocytopenia. Finally, **type 3 von Willebrand's disease** is caused by a severe quantitative deficiency in vWF and is inherited in an autosomal recessive pattern.

Patients with von Willebrand's disease have variable levels of both vWF and factor VIII.[130] Thus, some patients with von Willebrand's disease are asymptomatic. Because vWF aids in platelet binding to sites of vascular damage, symptoms of von Willebrand's disease (e.g., bleeding from skin and mucosae) can mimic those of platelet disorders.[129] vWF slows the clearance of factor VIII; therefore, a deficiency can result in decreased factor VIII levels, and patients with severe disease can present with hemorrhages into muscles and joints similar to those seen in patients with classic hemophilia.

Patients with von Willebrand's disease usually have decreased platelet aggregation in response to ristocetin. Levels of factor VIII and vWF ristocetin co-factor should be determined during pregnancy, at least during the third trimester. Prophylactic treatment is reserved for patients with a factor VIII level below 50 IU/dL.[129] For patients with von Willebrand's disease type 1 or 2A, 0.3 μg/kg of desmopressin (l-desamino-8-D-arginine vasopressin [DDAVP])[110] is administered intravenously as labor begins, and the dose is repeated every 12 to 24 hours.[129] For patients who are unresponsive to desmopressin, commercial preparations of plasma concentrates that contain both vWF and factor VIII are administered.[129] The usual dose is 40 to 60 IU/kg. For acute bleeding, fresh frozen plasma (FFP) or cryoprecipitate (500 to 1500 units of factor VIII activity) may be administered.

During labor, factor VIII and vWF ristocetin co-factor levels should each be maintained at greater than 50 IU/dL.[131] When considering anesthetic and analgesic options, the balance between risks and benefits of a neuraxial procedure should be evaluated for each patient.[135] In women with untreated type 1 von Willebrand's disease, factor VIII and vWF levels measured in the third trimester of pregnancy reflect intrapartum levels; for example, vWF activity peaks at 2.5 times the baseline values within the first 4 hours after delivery, and falls rapidly in the first postpartum week.[134] Postpartum hemorrhage rates are increased for up to 1 month after delivery.[131] The factor VIII level should be checked daily during the postpartum period, and treatment should be initiated if the factor VIII level decreases below 50% of normal levels or if significant bleeding occurs.[129,136]

Other Coagulation Factor Deficiencies

In males, the two most common coagulation factor deficiencies are factor VIII (**hemophilia A**) and factor IX (**hemophilia B**). Both occur as X-linked traits. It is possible for a female to have hemophilia if her father is a hemophiliac and her mother is a carrier for hemophilia and passes the abnormal X chromosome to her daughter.[137] A female can also have hemophilia if she is a carrier (i.e., she received one abnormal gene from a carrier mother or an affected father) and she has either a new mutation of the other gene for factor VIII or IX, or another X-chromosome abnormality.[137]

In early embryogenesis, half of the X chromosomes are inactivated.[138] Of the gene population, half of the abnormal genes and half of the normal genes are inactivated in females who are heterozygous for hemophilia A or B. On average, these women have half of the normal concentration of factor VIII or IX, which typically is adequate for coagulation. Because the chromosome inactivation is random, more abnormal genes are inactivated in a certain percentage of carriers, and these women have a normal concentration of factor VIII or IX. However, if most of the normal genes are inactivated, the individual can have severely depressed levels of factor VIII or IX. If such a patient becomes pregnant, factor supplementation with pooled human plasma concentrate (antihemophilic factor/vWF concentrate [hemophilia A] or prothrombin complex concentrate [PCC] [hemophilia B]) may be necessary before or during delivery.

On average, one-half of the male children of heterozygous carriers for hemophilia A or B will have hemophilia. These infants have an increased incidence of excessive bleeding after circumcision, and cephalohematoma with instrumental vaginal birth.[139] Cesarean birth reduces, but does not eliminate the risk for cephalohematoma, when compared with spontaneous vaginal birth; decisions about mode of delivery should be individualized to optimally balance maternal and perinatal risk.[139,140] During any trial of labor and vaginal delivery, the following procedures should be avoided: (1) placement of a fetal scalp electrode, (2) fetal scalp blood pH determination, and (3) instrumental vaginal delivery. One report has described the administration of epidural analgesia during labor in a patient with severe hemophilia A after factor replacement.[141]

Acquired hemophilia is an autoimmune disease resulting from antibodies to factor VIII and is associated with

pregnancy and the postpartum period.[142] Both recombinant factor VIIa (rFVIIa) and factor eight inhibitor bypassing activity (FEIBA) have been used to treat bleeding in patients with acquired hemophilia, but both agents are associated with thromboembolism.[142] Immunosuppression is necessary to treat the underlying cause of the disease.

Other congenital factor deficiencies occur as autosomal recessive traits and cause symptoms only in the homozygous state.[73] Table 44.7 lists the plasma concentrations of coagulation factors that are required for hemostasis. The patient whose liver disease or vitamin K deficiency is responsible for the coagulopathy may benefit from intramuscular administration of vitamin K. In an emergency, factors may be rapidly replaced by administration of the appropriate pooled human plasma product or FFP (10 to 15 mL/kg).

ACQUIRED COAGULOPATHIES

Coagulopathies associated with hypertensive disorders of pregnancy and obstetric hemorrhage are discussed in Chapters 35 and 37, respectively. Pharmacologic anticoagulation to prevent and treat venous thromboembolism is discussed in Chapter 38.

Disseminated Intravascular Coagulation

DIC results from an abnormal activation of the coagulation system, which leads to (1) formation of large amounts of thrombin, (2) activation of the fibrinolytic system, (3) depletion of coagulation factors, and (4) hemorrhage. In severe cases, diffuse microvascular thrombosis can lead to end-organ injury.[143] In the obstetric population, the most frequent causes of DIC are preeclampsia, placental abruption, sepsis, retained dead fetus syndrome, postpartum hemorrhage, acute fatty liver of pregnancy, and amniotic fluid embolism (Fig. 44.3).[69]

Laboratory findings consistent with DIC include (1) decreased platelet count, (2) decreased fibrinogen concentration, (3) variable increases in PT and aPTT, and (4) increased concentrations of D-dimer, fibrin monomer, and fibrin degradation products.[69] Viscoelastic monitoring confirms delayed clot activation, decreased clot strength, and evidence of fibrinolysis.[73]

TABLE 44.7 Minimum Coagulation Factor Levels

Coagulation Factor	Plasma Concentration Required for Hemostasis (U/dL)
I	10–25
II	40
V	10–15
VII	5–10
VIII	10–40
IX	10–40
X	10–15
XI	20–30
XIII	1–5

There is no gold standard for diagnosing DIC. A scoring system that incorporates standard laboratory measures has been established by the International Society on Thrombosis and Haemostasis (ISTH) (Table 44.8), and has been shown to predict adverse outcomes in nonpregnant women. Physiologic changes in the hemostatic system in pregnancy decrease the sensitivity of this scoring system to detect DIC. To improve accuracy in pregnant populations, some experts recommend serial laboratory assessment, and to follow trends in the ISTH score.[69] Erez[143a] analyzed laboratory values from 87 women who developed DIC, and compared them against 24,693 control patients to modify the cut-points of the ISTH. Preliminary validation of the modified ISTH scoring system (see Table 44.8) among the 684 women with abruption in the original sample demonstrated superior sensitivity and specificity to detect clinically significant DIC compared with the standard ISTH scoring system.

Therapeutic goals for these patients are to (1) treat or remove the precipitating cause, (2) replace depleted coagulation factors, (3) stop ongoing proteolytic activity (i.e., both the coagulation and fibrinolytic pathways), and (4) provide multisystem support as required.[144] In obstetric patients, evacuation of the uterine contents often results in removal of the precipitating cause (see Fig. 44.3).[145] Vaginal delivery can be attempted if the mother is stable and delivery can be

TABLE 44.8 Scoring Systems to Detect Disseminated Intravascular Coagulation during Pregnancy

Parameter	ISTH Score	Modified ISTH Score
Platelet count, 100,000/μL	> 100 = 0 < 100 = 1 < 50 = 2	> 185 = 0 101–185 = 1 51–100 = 2 < 50 = 3

achieved in a timely manner. If delivery cannot be achieved quickly, cesarean delivery may be required. Rarely, cesarean delivery may be necessary to deliver a dead fetus.

Blood product transfusion is the cornerstone of hemostatic support for patients with DIC. In the presence of active bleeding or when an invasive procedure is required, the physician should transfuse FFP (15 to 30 mL/kg) to maintain the PT and aPTT within 1.5 times normal values, cryoprecipitate or fibrinogen concentrate to maintain the fibrinogen concentration above 200 mg/dL, and platelets to maintain a platelet count above 50,000/μL.[69,144]

The use of heparin is controversial. No trials have demonstrated improved clinical outcomes with heparin treatment,[144] but experts suggest that heparin at therapeutic doses may be helpful in cases of DIC complicated by thromboembolism or extensive fibrin deposition.[144,146,147] Both unfractionated heparin and LMWH are effective only in the presence of an adequate concentration of antithrombin III.[146] Patients with DIC may have a depleted concentration of antithrombin III,[146] and administration of FFP, lyophilized antithrombin III, or both may be necessary.[69,148]

Patients with DIC often have multiorgan system failure and require mechanical ventilatory support and care in the intensive care unit (see Chapter 54). DIC almost always mandates administration of general anesthesia in patients who require cesarean delivery. Given the increased risk for venous thromboembolism among patients with DIC, thromboprophylaxis with unfractionated heparin or LMWH (as soon as active bleeding is controlled), mechanical methods, or a combination of multiple methods is indicated.[144,147]

NEURAXIAL ANESTHESIA IN THE PATIENT WITH COAGULOPATHY

Concern exists that an epidural hematoma may develop after the administration of neuraxial anesthesia in patients with coagulopathy (see Chapter 31). There are few published case reports of epidural or spinal subdural hematoma after the administration of neuraxial anesthesia in pregnant patients. Similarly, multicenter survey studies have not reported this complication in obstetric patients.[149,150] However, in view of

the serious consequences of an epidural hematoma, the risks and benefits of performing neuraxial anesthesia should be carefully assessed in a patient with either clinical or laboratory evidence of coagulopathy.

Frank coagulopathy represents an absolute contraindication to the administration of neuraxial anesthesia. For patients receiving pharmacologic anticoagulation, professional societies have developed evidence-based guidelines to optimize the safety of neuraxial blockade[127,151] (see Chapter 38). For nonbleeding patients with diagnoses that increase the risk for coagulopathy (see Fig. 44.3), the anesthesia provider can use standard laboratory testing (i.e., the platelet count, PT/INR, aPTT, and fibrinogen) or viscoelastic testing, or both to exclude hemostatic derangements before neuraxial blockade. If use of a neuraxial anesthetic technique is considered in a patient with a congenital coagulopathy, results of relevant factor assays should be within the normal range before neuraxial needle placement.[131,141,152]

Thrombocytopenia develops in 5% to 10% of healthy women by the end of pregnancy, normally with little clinical consequence, particularly when thrombocytopenia is mild (100,000 to 149,000/uL).[82] However, the combination of both quantitative and qualitative platelet deficits presents a more serious risk for epidural hematoma and may develop in the context of severe preeclampsia (see Chapter 35), ATP, and congenital platelet disorders. A number of groups have reported the safe administration of epidural anesthesia—without any neurologic complications—in healthy pregnant women with thrombocytopenia, preeclampsia, and ATP.[153,154] A retrospective cohort study from the Multicenter Perioperative Outcomes Group identified no cases of epidural hematoma requiring surgical decompression among 573 parturients with a platelet count less than 100,000/μL.[154] Combined with an additional 951 parturients identified by systematic review, the authors calculated an upper bound of the 95% confidence interval for risk of epidural hematoma to be 11% for a platelet count less than 49,000/μL, 3% for 50,000 to 69,000/μL, and 0.2% for 70,000 to 100,000/μL.[154]

Although there is no widespread consensus about the minimum platelet count needed to ensure safe neuraxial procedures, several experts have reviewed the available evidence and concluded that a minimum platelet count of 80,000/μL is usually sufficient for the safe initiation of neuraxial analgesia/anesthesia and removal of a neuraxial catheter.[153,155] Under selected circumstances, neuraxial procedures may be appropriate in a well-counseled patient with a platelet count between 50,000 and 80,000/μL.[153] When determining whether neuraxial anesthesia is safe in a thrombocytopenic patient, the anesthesia provider should consider the following factors: (1) clinical evidence of bleeding; (2) time interval since the platelet count was measured; (3) any recent change in the platelet count (e.g., downward trending); (4) quality of platelet function; (5) adequacy of coagulation factor level and function; and, perhaps most importantly, (6) the **risk versus benefit of performing neuraxial anesthesia**. The bleeding time measurement is *not* helpful in determining the risk for epidural hematoma. Although viscoelastic monitoring shows some promise, its usefulness in predicting the risk for epidural hematoma is unproven. The use of single-shot spinal anesthesia may be associated with a lower risk for epidural vein trauma than epidural catheter insertion and removal.

Clinical judgment represents the most important means of assessing the risk for epidural hematoma in an individual patient. Clearly, the anesthesia provider would not want to perform neuraxial anesthesia in a patient with clinical evidence of coagulopathy (e.g., bleeding from nasal or oral mucosae or venipuncture sites, presence of petechiae or ecchymoses). In contrast, a surgical patient with severe preeclampsia, severe upper airway edema, a platelet count of 70,000/μL, and no clinical evidence of coagulopathy may be an appropriate candidate for spinal anesthesia. The risk for airway complications with general anesthesia is greater than the risk for an epidural hematoma in such a patient.[156] Neuraxial analgesia may be offered to such a patient after a thorough discussion of the risks and benefits. However, some anesthesia providers advocate a more conservative approach in such cases and recommend alternative methods of analgesia during labor, followed by awake laryngoscopy and tracheal intubation if cesarean delivery should become necessary.

Several modifications of the neuraxial technique may decrease the risk for venous injury during the administration of epidural analgesia: (1) administration of epidural analgesia early in labor before the platelet count or platelet function declines, (2) needle and catheter placement with the patient in the lateral rather than sitting position, (3) the use of a wire-embedded polyurethane rather than polyamide epidural catheter, (4) limiting catheter insertion length to 6 cm or less, and (5) administration of saline through the needle to distend the epidural space before insertion of the catheter.[157] The epidural catheter may be sited several hours before the patient requires analgesia. This interval allows the anesthesia provider to observe for symptoms and signs of epidural hematoma formation (e.g., back pain, radicular pain, leg weakness) before the administration of an analgesic or anesthetic solution. This last recommendation is impractical in most circumstances. Furthermore, it is unclear that any of these recommendations reduces the likelihood of epidural hematoma in patients with platelet dysfunction or coagulopathy.

During the administration of epidural analgesia, the anesthesia provider can minimize motor blockade, which might confuse the diagnosis of epidural hematoma, by administering a dilute solution of local anesthetic with an opioid. Lower-extremity motor function should be verified at 1- to 2-hour intervals, and the epidural solution adjusted as needed to maintain lower-extremity strength. In addition, all clinical staff should be aware of the signs and symptoms of epidural hematoma, including (1) severe, unremitting backache; (2) neurologic deficit, including bowel or bladder dysfunction or radiculopathy; (3) tenderness over the spinous or paraspinous area; and (4) unexplained fever.[158] If clinical findings raise concern for epidural hematoma, immediate steps should be taken to obtain appropriate diagnostic imaging and to consult a neurosurgeon (see Chapter 31).

In some cases, severe thrombocytopenia and coagulopathy may develop *after* the placement of an epidural catheter. Epidural hematomas have been reported after epidural catheter removal in obstetric patients with coagulopathy. It is possible that movement or removal of the catheter may dislodge a clot, resulting in fresh bleeding and an epidural hematoma. As such, recommended hemostatic conditions for epidural catheter removal parallel those recommended for neuraxial block administration.[153]

HYPERCOAGULABLE STATES

Effective hemostasis is maintained by an appropriate balance of procoagulant and anticoagulant activity. A congenital deficiency in anticoagulant activity occurs in more than 50% of women with pregnancy-related venous thrombosis.[159,160] Factor V Leiden mutation, prothrombin mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency are the most common thrombophilias diagnosed in pregnancy.[160] Venous thromboses are more common than arterial thromboses[161]; the incidence increases with surgery, pregnancy, oral contraceptive use, and immobilization. Although the results of small case-control studies have suggested that patients with thrombophilias may have an increased incidence of fetal growth restriction, intrauterine fetal death, preeclampsia, and placental abruption, these associations have not been replicated in large prospective cohorts.[160,162] There is insufficient evidence that screening for thrombophilias improves birth outcomes for women with a history of pregnancy complications.[163]

The American College of Obstetricians and Gynecologists (ACOG) and the American College of Chest Physicians (ACCP) have recommended thromboprophylaxis for pregnancies complicated by inherited thrombophilias (see Chapter 38).[163,160] Commonly used anticoagulation regimens during pregnancy are listed in Table 38.2.

Factor V Leiden Mutation

Factor V Leiden is a genetic disorder attributable to genetic mutation resulting in a single amino acid substitution in the factor V protein. The mutant protein persists longer in the circulation owing to its slower degradation by activated protein C, leading to a hypercoagulable state.[160] Although heterozygous factor V Leiden affects less than 15% of the childbearing population, these women experience as many as 40% of all obstetric thromboembolic events. Among women with factor V Leiden heterozygosity, a personal history of a venous thromboembolism increases the risk from 1% among those without previous thrombosis to 10% for those with previous thrombosis.[160] A homozygous state is found in 1 in 1600 individuals; these patients have at least a 25-fold higher risk for thrombosis.[86,159]

Prothrombin Gene Mutation

The prothrombin *G20210A* gene mutation results in elevated circulating prothrombin levels.[159] This gene mutation is present in 2% to 3% of the general population and accounts for up to 17% of cases of venous thromboembolism in pregnancy.[159,160] For women who are heterozygous for the prothrombin mutation, a personal or family history of venous thrombosis increases the risk for a subsequent venous thromboembolism in pregnancy from less than 0.5% to approximately 10%.[160] Further, the combination of factor V Leiden and prothrombin mutations has synergistic hypercoagulable effects.[160]

Antithrombin III Deficiency

Antithrombin III is synthesized in the liver and endothelial cells. It inactivates thrombin and factors IXa, Xa, XIa, and XIIa[164]; its activity is potentiated by heparin. Deficiency of antithrombin III occurs in 0.02% to 0.4% of the general population[160,165]; the risk for thrombosis in pregnancy is increased up to fivefold.[159,165] The risk for thrombosis during pregnancy increases from 3% to 7% among those with antithrombin III deficiency and no prior thromboembolism to more than 40% among those with a prior venous thromboembolism.[160] Quantitative (type I) and qualitative (type II) deficiencies exist[166]; thus, both immunologic and functional assays are required to detect abnormalities.[167]

Heparin acts by potentiating the activity of antithrombin III. If antithrombin III levels are decreased, heparin may not ensure effective thromboprophylaxis. Antithrombin III replacement, with or without co-administration of heparin, has been proposed for perioperative or peripartum therapy for patients with antithrombin III deficiency and a history of venous thromboembolism.[164] Although long-term antithrombin III replacement is expensive, its use may be indicated for women who experience venous thrombosis despite thromboprophylaxis with LMWH.[168] Warfarin is an alternative option for women in the second or third trimester of pregnancy, remote from delivery.[168]

Protein C Deficiency

Protein C is produced in the liver and acts by inhibiting activated factors V and VIII. Deficiency is defined by an activity level less than 50%. The incidence of protein C deficiency is approximately 0.3% in the general population; the risk for thrombosis in pregnancy is increased up to fivefold.[159] Protein C levels normally increase by 35% during pregnancy, but this increase is attenuated in patients with protein C deficiency.[169] Among women with protein C deficiency, the risk for venous thromboembolism during pregnancy increases from less than 1% among those without previous thrombosis to between 2% and 17% for those with a previous thrombosis.[160]

Protein C is a vitamin K–dependent protein with a short half-life (8 hours). If warfarin is administered without prior heparin anticoagulation, protein C levels decrease before the levels of factors II, VII, IX, and X decrease. Thrombosis with skin necrosis can result.[166]

Protein S Deficiency

Protein S acts as a co-factor for protein C. In contrast to protein C, the plasma levels of protein S normally *decrease*

during pregnancy.[169] The prevalence of protein S deficiency is less than 0.2% in the general population; the risk for venous thromboembolism during pregnancy is increased up to 2- to 4-fold.[159] Protein S is also produced in the liver and depends on vitamin K for its synthesis.[166] Circulating protein S binds to C4b-binding protein (a protein of the complement system), but it is the free fraction of protein S that acts as a co-factor for protein C.[166] Immunologic assays measure total protein S concentration; therefore, a diagnosis of protein S deficiency is made either by using a functional assay (less than 50% activity) or by calculating the percent of protein S bound to C4b-binding protein.[166] The risk for antepartum and postpartum venous thromboembolism is low in patients with protein C or protein S deficiency; hence thromboprophylaxis is not indicated unless the patient has a history of venous thromboembolism or additional risk factors are present.

Lupus Anticoagulant

The term *lupus anticoagulant* is a misnomer. Patients with lupus anticoagulant do *not* have a coagulopathy; rather, they are at risk for thromboembolic events. The hypercoagulable state associated with lupus anticoagulant is discussed in Chapter 40.

KEY POINTS

- Blood product preparation is frequently delayed for patients with hemoglobinopathies because of high rates of alloimmunization and extended cross-matching procedures to limit future alloimmunization.
- Lifelong transfusion dependence increases the risk for hemosiderosis, causing primarily cardiac, pulmonary, and hepatic toxicity.
- Neuraxial anesthetic techniques can be used safely during labor and delivery in patients with a hemoglobinopathy.
- Routine laboratory assessment of the platelet count and coagulation status is not indicated before the initiation of neuraxial procedures in healthy parturients.
- The first goal in the treatment of disseminated intravascular coagulation is to treat or remove the precipitating cause. In pregnant patients, evacuation of the uterine contents often results in removal of the precipitating cause.
- Uncorrected, frank coagulopathy represents an absolute contraindication to the administration of neuraxial anesthesia.
- In a patient with an isolated laboratory abnormality and no clinical evidence of coagulopathy, the anesthesia provider should assess the risks and benefits of performing neuraxial anesthesia.

Liver Disease

David B. Wax, MD, Yaakov Beilin, MD

CHAPTER OUTLINE

LIVER DISEASES

Liver diseases can be either incidental or unique to pregnancy and complicate as many as 3% of all pregnancies. The more common conditions are addressed in this chapter, and the hepatic aspects of preeclampsia/eclampsia and HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome are discussed in Chapter 35.

Liver Diseases Incidental to Pregnancy

Various hepatobiliary diseases are not unique to pregnancy but may affect pregnant patients. Some of these diseases may have been preexisting before pregnancy, while others may be provoked by pregnancy and may have different clinical courses during pregnancy compared with nonpregnant patients. They can lead to acute or chronic liver failure and have important implications for obstetric and anesthetic management as discussed in the following sections.

Viral Hepatitis

The presentation of viral hepatitides ranges from mild, nonclinical illness to fulminant hepatic necrosis. Viral hepatitis is the most common cause of jaundice and most frequent reason for gastroenterology consultation during pregnancy.[1] Six types—hepatitis A, B, C, D, E, and G—have been identified and are associated with specific viruses. Types A, B, and C are the most common. Infrequently, hepatitis can also be caused by herpes simplex virus (HSV), yellow fever virus, rubella virus, Epstein-Barr virus (EBV), or cytomegalovirus (CMV).

Hepatitis A (HAV) and **hepatitis E (HEV)** are viral infections of hepatocytes that typically spread by oral ingestion of food or water contaminated with feces from infected individuals. Although endemic in other countries, the current all-time low incidence of HAV of 0.4 per 100,000 in the United States is attributed to good sanitation.[2] Despite its prevalence, it has been infrequently reported among pregnant women. In a study from Ireland, there was only one case of HAV in 13,181 consecutive deliveries.[3] The incidence of HAV infection has also been reduced by vaccination for preexposure prophylaxis; immune globulin is available for postexposure prophylaxis to prevent or attenuate infection. Clinically, a preicteric phase typically occurs with nonspecific viral symptoms, followed by an icteric phase with jaundice and acholic stools. Acute treatment is supportive. Increased risk for preterm labor, premature rupture of membranes, and placental abruption have been associated with HAV during pregnancy, and vertical transmission to the fetus has been reported.[4] Chronic HAV infection does not occur, but a prolonged or relapsing course occurs in up to 20% of patients, and an acute fulminant course occurs in less than 1% of patients.[5]

HEV infection may be largely asymptomatic. In symptomatic patients, the disease is usually self-limited. Pregnant women and patients already infected with another hepatitis virus, however, have more severe presentations. A mortality rate of 27% has been reported in pregnant women with HEV, a consequence of fulminant hepatic failure. Pregnancy complications such as premature rupture of membranes, fetal growth restriction, placenta previa, retained placenta,

and preterm delivery are also more common. Chronic HEV infection may occur in immunosuppressed patients, and vertical transmission can occur.[6] Pegylated interferon and/or ribavirin treatment for chronic HEV infection has shown moderate success, and HEV vaccines are under development.[7]
