Hepatitis B (HBV) and **hepatitis D (HDV)** are usually transmitted via percutaneous or permucosal exposure to infected body fluids. In high-prevalence areas, HBV infection is most commonly acquired perinatally or in early childhood. In low-prevalence areas, infection is primarily acquired in adulthood through sexual contact or intravenous drug abuse. The incidence is decreasing after implementation of widespread vaccination and safety precautions in health care settings. Postexposure prophylaxis with HBV vaccination alone or a combination of vaccination with hepatitis B immune globulin (HBIG) is highly effective in preventing HBV transmission in adults as well as in infants of HBV-infected mothers and may prevent perinatal transmission in 90% of cases. The majority of acute infections are asymptomatic, with only 30% of adults developing typical symptoms of hepatitis, and less than 0.5% developing fulminant hepatitis. Most cases can be managed with supportive treatment, although nucleoside analogue therapy may improve prognosis in severe cases. Chronic HBV develops in less than 5% of adults but in more than 20% of children, and exacerbations of chronic HBV may occur in the postpartum period. The 5-year cumulative incidence of cirrhosis in those with chronic HBV may be as high as 20%, and once cirrhosis has developed the annual risk for hepatocellular carcinoma may be as high as 5%.[8] Therefore, treatment of chronic HBV is aimed at clearance of virus to prevent the development of cirrhosis and cancer. Vertical transmission to the fetus from hepatitis Be antigen (HBeAg)-positive mothers can be as high as 90% without attempts to prevent transmission.[9] For patients with active disease or high viral loads, oral antiviral therapies (lamivudine, telbivudine, or tenofovir) reduce transmission without apparent increased risk for adverse maternal or fetal outcomes, as does cesarean delivery.[10] Interferon therapy has a finite course of treatment and an increased chance of viral clearance and significantly reduces the risk for cirrhosis and liver cancer; however, it has more side effects and is contraindicated during pregnancy.[11] Current recommendations are to administer HBV vaccination to all neonates, and to administer HBIG to all offspring of infected mothers.[12]

HDV is dependent on HBV co-infection to replicate. Acute co-infection with both viruses can be more severe than acute HBV infection alone and may result in acute liver failure. HDV superinfection in the setting of chronic HBV results in chronic HDV infection in most patients, and these patients have more rapid progression to cirrhosis.[13]

Hepatitis C (HCV) transmission most commonly occurs from transfusion of infected blood products or injection of contaminated drugs (both illicit and iatrogenic). Maternal-fetal and sexual transmission are less common routes of transmission. Initial infection is generally asymptomatic, but up to 30% of patients develop acute hepatitis. In patients with acute HCV infection that has not cleared spontaneously within 12 weeks, treatment with pegylated interferon may be used to prevent chronic infection, with treatment success in up to 98% of patients. In most asymptomatic and untreated cases, infection persists for over 6 months and leads to chronic infection with progression to cirrhosis in up to 30% of patients within 30 years. Thus, HCV is the leading cause of chronic hepatitis, cirrhosis, and liver cancer (which develops in up to 3% of patients per year) and a primary indication for liver transplantation in the developed world. Depending on the severity of liver fibrosis, therapy may be warranted to prevent these complications. Combination treatment with pegylated interferon, ribavirin, and a protease inhibitor can result in a sustained virologic response in up to 80% of patients, but is contraindicated during pregnancy.[14,15] Various second-generation antiviral drugs have been introduced for single-agent or combination regimens to clear HCV infection, but there are insufficient data to endorse their use during pregnancy.[16]

Hepatitis G (HGV) is transmitted parenterally, sexually, or vertically. In the United States, nearly 20% of all blood preparations are infected with HGV. Although there have been reports of acute, fulminant, and chronic hepatitis and hepatic fibrosis, HGV replicates predominantly in the hematopoietic system rather than in hepatocytes. Clinical significance is mostly for those co-infected with HCV or human immunodeficiency virus (HIV) or for individuals with hematologic cancers.[17]

Cholecystitis

Pregnancy may promote gallstone formation. Cholelithiasis is present in up to 3% of pregnant women, although acute cholecystitis occurs in only 0.1% of pregnancies. Patients may have right upper-quadrant pain, fever, and leukocytosis, and diagnosis is generally made by ultrasonography. Serious complications include **cholangitis, pancreatitis, gangrenous cholecystitis,** and **perforation.** To avoid surgery, conservative treatment may be considered in mild cases and includes intravenous hydration, antibiotics, opioid analgesia, bowel rest, and possibly percutaneous cholecystostomy. Although a conservative approach does not seem to be associated with poorer fetal outcomes, treatment failure or disease recurrence during pregnancy are common, so many conservatively managed patients ultimately require surgical treatment.[18] Both open and laparoscopic cholecystectomy (preferably in the second trimester) can be considered, though laparoscopic techniques offer maternal recovery advantages similar to those in the nonpregnant patient and may have slightly lower fetal complication rates. With either technique, the incidence of miscarriage or preterm labor/delivery is over 25%.[18,19]

Liver Abscess

Liver abscess can develop from infection by a range of organisms with various sites of entry. Organisms with a predilection for the liver include parasites such as ***Entamoeba, Echinococcus, Clonorchis,*** and ***Ascaris.*** Direct inoculation during medical instrumentation or hematogenous spread from intravenous drug abuse or endocarditis can occur.

Appendicitis, diverticulitis, or other intra-abdominal infections may spread to the liver. **Fungal infections** are also possible in immunocompromised patients. Management of liver abscess includes antimicrobial agents, percutaneous or open drainage, and possibly surgical resection.[20] The condition is rare during pregnancy, but treatment modalities are similar to those described for the nonpregnant patient.[21]

Autoimmune Diseases

Autoimmune hepatitis, primary biliary cirrhosis, and **primary sclerosing cholangitis** are conditions that may overlap and may also be associated with other extrahepatic autoimmune disorders.[22,23] All may lead to end-stage liver disease, and treatment with corticosteroids, other immunosuppressants, and/or ursodeoxycholic acid is aimed at preventing this progression. For advanced and intractable disease, liver transplantation may be necessary. Pregnancy is associated with a 33% incidence of disease flares (mostly in the postpartum period), one-third of which result in maternal hepatic decompensation, liver transplantation, or death. Risks for preterm birth, gestational diabetes, and low birth weight are also significantly increased.[24] Immunosuppressive therapy during pregnancy is reportedly safe and effective in reducing disease flares.[23]

Vascular Syndromes

Budd-Chiari syndrome involves thrombosis of the hepatic vein or suprahepatic inferior vena cava and may be associated with pregnancy (comprising nearly one-half of all cases) or other hypercoagulable states. Hepatic venous congestion can also result from right-sided heart failure or other cardiopulmonary diseases that increase central venous pressure or from mechanical compression or compartment syndrome that impedes hepatic venous outflow. This congestive hepatopathy can ultimately lead to fibrosis, portal hypertension, and liver failure. **Portal vein thrombosis** may also occur and cause portal hypertension without cirrhosis. Initial therapy is anticoagulation with low-molecular-weight heparin, and endoscopic screening/treatment and beta-adrenergic receptor blockade (propranolol or nadolol) for prophylaxis of variceal bleeding are also recommended. Liver transplantation may ultimately be required in chronic cases. "**Shock liver**" syndrome can occur in the setting of perioperative hypotension, critical illness with septic shock or cardiac arrest, pulmonary embolus, heart failure, or heatstroke caused by disruption of hepatic arterial and/or portal venous inflow, resulting in acute ischemic/hypoxic hepatitis, especially in the setting of other co-existing liver disease.[25–27]

Metabolic Diseases

Wilson disease is a condition of reduced copper excretion. Gradual copper accumulation in the liver can lead to cirrhosis, while rapid accumulation may result in acute liver failure. Patients may also develop neurologic, ophthalmologic, and renal dysfunction. Fertility is generally reduced in women, but treatment with copper-chelating agents during pregnancy can result in positive outcomes for both the mother and fetus.[28] **Hemochromatosis** is a condition of iron accumulation that results in arthropathy, skin pigmentation, diabetes, hypopituitarism, hypogonadism, heart failure, and liver cirrhosis. Phlebotomy (with or without a chelating agent) to deplete iron stores markedly improves survival and prevents most of the complications.[29] **α_1-Antitrypsin deficiency** results in uncontrolled tissue degradation, with effects predominantly in the lungs and liver. This leads to emphysematous changes in the lung as well as liver cirrhosis.[30] Pregnancy can be complicated by fetal growth restriction, preterm labor, and pneumothorax or other respiratory decompensation.[31]

Hepatotoxicity

Hepatotoxicity can result from a variety of exposures. **Acetaminophen (paracetamol),** involved in 20% of drug overdoses during pregnancy, is metabolized by the liver into highly reactive oxides. If their formation exceeds the binding capacity of glutathione, maternal and fetal hepatic injury occurs. Treatment with *N*-acetylcysteine within 16 hours of acetaminophen ingestion may bind toxic metabolites in both the mother and the fetus and improve outcomes.[32] **Alcoholic hepatitis** can result from the acute ingestion of large amounts of alcohol, and chronic alcohol ingestion may lead to cirrhosis.[33] Other agents that have potential to cause hepatotoxicity during pregnancy are **antiretroviral drugs** for HIV infection, **propylthiouracil** for hyperthyroidism, **alpha-methyldopa** and **labetalol** for hypertension, **sevoflurane** (given for status asthmaticus), **isoniazid** for tuberculosis, **statins** for antiphospholipid syndrome or hyperlipidemia, **mushrooms** and **herbal supplements,** and **industrial agents.**[34–38] In one report, liver transplantation was successfully accomplished during pregnancy to treat acquired propylthiouracil-induced hepatotoxicity.[39]

Liver Diseases Specific to Pregnancy

Liver diseases specific to pregnancy are summarized in Table 45.1.

Hyperemesis Gravidarum

Hyperemesis gravidarum occurs in 0.3% to 3% of pregnancies and is characterized by a severe and persistent form of nausea and vomiting that can lead to dehydration and electrolyte imbalances, as well as elevated liver transaminases, mild jaundice, and transient hyperthyroidism (see Chapter 16). The possible etiologies include hormonal, infectious (e.g., *Helicobacter pylori*), mechanical (e.g., gastroesophageal reflux), genetic, and psychogenic causes. Treatment with **ginger,** vitamin supplementation (**pyridoxine**) and antiemetics (e.g., **doxylamine, metoclopramide, promethazine, ondansetron**) is beneficial. Severe cases may require corticosteroids, rehydration, and enteral or parenteral nutrition. Adverse pregnancy outcomes are rare but may occur in women who fail to gain adequate weight during pregnancy.[40]

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy occurs with an incidence ranging from less than 2% in Europe up to 25% in

TABLE 45.1 Liver Diseases Specific to Pregnancy

	Hyperemesis Gravidarum	Intrahepatic Cholestasis of Pregnancy	Preeclampsia/ Eclampsia	HELLP Syndrome	AFLP
Incidence	< 0.3%–3%	0.3%–6%	2%–8%	0.1%–0.6%	< 0.01%
Presentation	First trimester	Second or third trimester	Second or third trimester, or after delivery	Second or third trimester, or after delivery	Third trimester
Symptoms, Signs, and Complications	Nausea/vomiting Ketosis	Pruritus Jaundice	Hypertension Proteinuria Edema Seizures Renal failure Pulmonary edema Hepatic hematoma/ rupture	Abdominal pain Renal dysfunction Hypertension Hepatic hematoma/ rupture Liver infarction	Nausea/vomiting Abdominal pain Jaundice Hepatic failure
Laboratory Findings	Elevated aminotransferase levels	Increased serum bile acid levels Hyperbilirubinemia Mild abnormalities of liver function tests	Low platelet count Proteinuria Increased uric acid level Mildly elevated aminotransferase levels	Low platelet count Hemolysis Markedly elevated aminotransferase levels	Low platelet count Hypoglycemia Mildly/moderately elevated aminotransferase levels
Treatment	Supportive management	Delivery at fetal maturity Ursodeoxycholic acid	Blood pressure control Seizure control Delivery	Prompt delivery	Prompt delivery
Outcome	Benign for mother and fetus	No increase in maternal death rate Increased risk for preterm delivery and fetal loss May recur with subsequent pregnancies Increased risk for subsequent liver and biliary tract disease	Increased risk for maternal morbidity and mortality Increased risk for perinatal morbidity	Maternal death rate 1%–4% Fetal death rate 1%–30%	Maternal death rate up to 10% Fetal death rate up to 20%

AFLP, Acute fatty liver of pregnancy; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count.
Adapted from Schutt VA, Minuk GY. Liver diseases unique to pregnancy. *Best Pract Res Clin Gastroenterol.* 2007;21:771–792.

some populations of South America, with the large variation possibly related to population genetics. Other risk factors include multiple gestation, advanced age, and hepatitis C infection. Proposed causes include genetic canalicular transporter mutations that alter phospholipid or bile salt transport across hepatocyte membranes, as well as abnormal steroid hormone profiles, resulting in pruritus and elevated serum bile acid levels during the second or third trimester. Pruritus, primarily on the palms and soles, is more severe at night, and may lead to excoriations resulting from scratching, though jaundice is unusual.[41]

Intrahepatic cholestasis of pregnancy has minimal impact on maternal health during gestation. By some reports, vitamin K malabsorption may lead to coagulopathy (incidence of abnormal coagulation tests up to 20%) and an increased incidence of postpartum hemorrhage, while others have found no increased risk for obstetric bleeding or neuraxial hematoma.[42,43] While maternal outcome is generally good, the fetus may be at increased risk for prematurity and fetal compromise, with reported incidence of such fetal complications ranging from 19% to 64%.

Ursodeoxycholic acid (possibly in combination with rifampicin) is currently the treatment of choice until fetal lung maturity allows for early delivery.[44] Delivery at 36 weeks' gestation is recommended to minimize fetal complications.[45] Earlier delivery may be warranted in cases of intolerable pruritus or previous fetal demise. Recurrence of the disease is common in subsequent pregnancies.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP), or reversible peripartum liver failure, occurs in up to 1 in 7000 pregnancies. It is more common in twin gestations and has been associated with preeclampsia and HELLP syndrome. The disease is characterized

by microvesicular fatty infiltration of the liver (and possibly kidney) believed to be caused by defective beta oxidation of fat, usually in the third trimester. In AFLP, genetic enzymatic defects in the fetus (e.g., fetal long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency) and placenta are thought to cause toxic free fatty acid metabolites to build up in maternal hepatocytes. Early symptoms are nonspecific and include anorexia, nausea, emesis, malaise, fatigue, and headache. Jaundice, edema, hypertension, hypoglycemia, diabetes insipidus, and encephalopathy may develop. Progression to fulminant hepatic and renal failure, disseminated intravascular coagulation (DIC), and acute respiratory distress syndrome (ARDS) can be rapid. AFLP is commonly misdiagnosed as preeclampsia or HELLP syndrome because of a similar constellation of presenting symptoms. After additional laboratory tests (e.g., renal function), the definitive diagnosis can be made. Rarely, percutaneous or transjugular liver biopsy to identify microvesicular fatty infiltration of hepatocytes may be needed for diagnosis in indeterminate cases. Similarities between AFLP and preeclampsia or eclampsia are intriguing. Both disorders primarily occur near term and are associated with nulliparity and multiple gestation.[46]

AFLP is a medical emergency that demands rapid evaluation and treatment. Hepatic failure and fetal death may occur within days. Once the diagnosis is made, immediate delivery of the fetus or termination of the pregnancy is recommended. Additional supportive care may include transfusion, mechanical ventilation, dialysis, plasmapheresis, antibiotics, and *N*-acetylcysteine. Mode of delivery is not as critical as is doing so expeditiously.[47] Liver transplantation may be indicated in severe cases.[48] The anesthesia provider should anticipate postpartum hemorrhage, establish adequate intravenous access, and ensure that cross-matched blood is immediately available for any parturient with AFLP.[49] The use of neuraxial anesthesia may be limited by coagulopathy, encephalopathy, ascites, respiratory compromise, or other contraindications. Episiotomy is avoided if possible, and abdominal delivery may be complicated by wound dehiscence related to coagulopathy; delayed wound closure may be indicated.[47]

Improvements in diagnosis and management have reduced maternal mortality rates (once as high as 85%) to less than 10% worldwide. Recovery typically occurs within 1 to 3 weeks, though it is unclear if there are significant long-term maternal sequelae. Fetal mortality may be as high as 20% as a result of the maternal milieu as well as preterm delivery.[46]

Spontaneous Hepatic Rupture of Pregnancy

From 2000 to 2010, only 93 cases of hepatic rupture in pregnancy had been published.[50] Hepatic rupture may complicate preeclampsia, eclampsia, HELLP syndrome, and AFLP, or it may be an isolated event. By definition, spontaneous hepatic rupture of pregnancy occurs in the absence of antecedent trauma. Instead, rupture is preceded by an intraparenchymal hepatic hematoma. The strong association with preeclampsia suggests that periportal hemorrhagic necrosis, hypertension, and coagulopathy may lead to hematoma formation. With expansion of the hematoma, the hepatic capsule is progressively distended and dissected from the parenchyma, leading to rupture.[50,51] **Primary hepatic pregnancy** with embryonic implantation on the liver is another rare condition that can result in liver hemorrhage and shock. In the early postpartum period, growth of hepatic hemangiomas, adenomas, or other potentially hemorrhagic masses may occur.

Diagnostic ultrasonography, computed tomography, magnetic resonance imaging, angiography, technetium scintigraphy, and exploratory laparotomy may demonstrate the expanding hematoma before rupture.[52] Hematomas that are contained within the liver may be conservatively managed with intravenous fluids and blood products. More aggressive treatment options include open laparotomy, hepatic artery ligation or embolization, and compression of bleeding points with hepatic packing. Recombinant factor VIIa may be considered in the presence of intractable hemorrhage (although it is controversial),[53] and liver transplantation can be considered as a last resort.[54] Maternal and fetal mortality rates with current therapy are 17% and 38%, respectively.[50]

LIVER FUNCTION AND DYSFUNCTION

Regardless of the disease state and whether it is incidental or unique to pregnancy, the signs and symptoms of acute and chronic liver diseases are similar.

Markers of Liver Dysfunction

The liver performs a variety of physiologic functions, derangements of which are characteristic of liver diseases (Box 45.1). Amino acid metabolism in the liver uses enzymes that include alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Levels of these enzymes are generally normal in pregnancy, but hepatocyte injury leads to their release (commonly called "transaminitis") into the blood, where abnormal serum levels can be detected. The liver also removes bilirubin produced from heme metabolism in the blood. Thus, liver dysfunction can lead to accumulation of bilirubin that becomes symptomatic as jaundice. Gluconeogenesis can be impaired by liver dysfunction leading to hypoglycemia and accumulation of lactate. Synthetic functions of the liver include production of albumin and coagulation factors. Although albumin concentration normally decreases during pregnancy secondary to increased maternal plasma volume, prothrombin time (PT) is unchanged during normal pregnancy; therefore, an increase in PT is an indicator of possible liver disease. Decreased thrombopoietin production in the liver, along with hypersplenism from portal hypertension, may lead to thrombocytopenia. Alkaline phosphatase (ALP) and gamma glutamyl transferase (GGT) are found in biliary tract cells. ALP is normally increased during pregnancy because of fetal and placental production, but an elevated level of GGT is suggestive of biliary disease. Detoxification functions of the liver are responsible for clearance of many toxic metabolites and drugs. Failure of conversion of ammonia to urea in the liver results in accumulation of ammonia and consequent encephalopathy. Decreased clearance of estrogen and progesterone with liver disease may

BOX 45.1 Signs and Symptoms of Liver Disease

Laboratory Findings

- Increased
  - Alanine aminotransferase (ALT)
  - Aspartate aminotransferase (AST)
  - Gamma glutamyl transferase (GGT)
  - Bilirubin
  - Lactate
  - Prothrombin time/international normalized ratio (PT/INR)
  - Ammonia
- Thrombocytopenia
- Hypoglycemia
- Hypoalbuminemia
- Metabolic acidosis
- Respiratory alkalosis
- Immune dysfunction
- Renal dysfunction
- Decreased systemic vascular resistance
- Portal hypertension and varices
- Pulmonary hypertension

Symptoms and Physical Findings

- Jaundice
- Pruritus
- Abdominal pain
- Decreased appetite
- Telangiectases
- Palmar erythema
- Easy bruising
- Gastrointestinal bleeding
- Ascites
- Encephalopathy

cause hyperventilation, and other signs of a hyperestrogenic state such as telangiectases and palmar erythema, although this may occur even in normal pregnancies because of increased production by the placenta. Various antigens and antibodies also show characteristic patterns of abnormalities in autoimmune and infectious forms of hepatitis and can be used for diagnosis and treatment monitoring.[26,55]

Acute Liver Failure

Acute (or fulminant) hepatic failure is an extreme complication of liver disease specific or incidental to pregnancy. Because the liver is responsible for many physiologic processes, liver failure manifests in profound ways that may be life-threatening. A patient's condition can deteriorate in an unpredictable and rapid manner, and the patient may require management in a critical care setting. Treatment is mostly supportive, except in cases with specific anecdotal or proven therapies (e.g., immediate delivery for pregnancy-related causes,[56] *N*-acetylcysteine therapy for acetaminophen toxicity, lamivudine for acute HBV infection, penicillin therapy in *Amanita phalloides* intoxication, chelating agents in Wilson disease, steroid therapy for autoimmune hepatitis). Despite advances in care, maternal mortality in women with acute liver failure still remains as high as 55%.[57]

Encephalopathy results from reduced hepatic ammonia metabolism that leads to astrocytic glutamine accumulation and cerebral edema. Subtle mental status changes are followed by somnolence and disorientation, then by incoherence, and finally by coma. Use of invasive intracranial pressure (ICP) monitoring to determine cerebral perfusion pressure (CPP) is controversial because of questionable usefulness and concerns about intracranial bleeding from the procedure. If monitored, ICP should be maintained below 25 mm Hg, and CPP should be maintained above 50 mm Hg. Jugular bulb oxygen saturation can provide information about cerebral oxygen use, with levels below 55% indicative of cerebral hypoperfusion and levels above 85% suggestive of cerebral hyperemia or inadequate neuronal metabolism.[58]

Patients should be kept in a quiet room with the head of the bed elevated more than 30 degrees. *N*-acetylcysteine given early may decrease cerebral edema and improve survival. Mannitol or hypertonic saline infusion may be used to manage intracranial hypertension. Indications for tracheal intubation include (1) progressive encephalopathy; (2) acute respiratory distress syndrome (ARDS); (3) pulmonary aspiration prevention; (4) sedation for agitation, which can contribute to increased ICP; and (5) hyperventilation for refractory intracranial hypertension. High tidal volumes and levels of positive end-expiratory pressure (PEEP), hypercarbia, and frequent suctioning should be avoided. Hyperthermia should be actively treated, but deliberate hypothermia has not proven beneficial. Phenytoin or propofol can effectively decrease the risk for seizure activity. For patients whose ICP and CPP have been refractory to therapy, a technetium-99m albumin scan can document the absence of cerebral blood flow so that these patients can be removed from the liver transplant waiting list.

Immune dysfunction is related to loss of Kupffer and other immune cell function, and complications of bacterial or fungal infections are a leading cause of mortality. Infection and sepsis have been associated with progression to high-grade encephalopathy and poorer outcomes, though prophylactic antimicrobial therapy does not appear to improve survival compared with surveillance and treatment only as needed.[59]

Coagulopathy results from impaired synthesis of coagulation factors, most of which are produced in the liver, and from thrombocytopenia, which may be caused by reduced hepatic thrombopoietin production, acute portal hypertension with splenic sequestration, and reduced marrow production. DIC may also develop. Mucocutaneous, gastrointestinal, and iatrogenic bleeding can all occur in this setting. Cholestasis leads to malabsorption of vitamin K, an important cofactor required for the synthesis of factors II, VII, IX, and X. A therapeutic trial of vitamin K may be attempted if malabsorption is the primary defect, but women with impaired hepatic synthesis do not respond. Routine use of fresh frozen plasma or platelet transfusion is not recommended except when there is evidence of active bleeding or an invasive procedure is planned. Proton-pump inhibitors may help prevent

gastric stress ulcers and bleeding. Although liver failure is generally thought to be a hypocoagulable state, it can also be a hypercoagulable state, with clinical manifestations that are difficult to predict and cannot be effectively prevented by prophylactic treatment with blood product transfusions.[60]

Circulatory dysfunction is common because of low systemic vascular resistance, and subclinical myocardial injury is common. Fluid resuscitation is the initial treatment for hypotension, but fluid overload can increase the risk for cerebral edema and acute lung injury. Norepinephrine and vasopressin are preferred agents for maintaining CPP. Corticosteroids may be considered for patients unresponsive to vasopressors with suspected relative adrenal insufficiency.

Increased production and reduced hepatic uptake of lactate results in **metabolic acidosis.** In addition, renal function is impaired in up to 40% of patients. **Renal failure,** acidemia, electrolyte disturbances, or volume overload necessitate renal replacement therapy with continuous venovenous hemofiltration with dialysis. Decreased gluconeogenesis can lead to **hypoglycemia,** whereas **hyperglycemia** may worsen neurologic outcome. Enteral feeding is preferred to parenteral nutrition, although parenteral nutrition with hypocaloric, low-glutamine, and normal protein formula appears to be safe.

For patients who are not expected to recover liver function necessary for survival, liver transplantation may be planned. In patients with toxicity from massive liver necrosis, total hepatectomy and temporary portocaval shunting can be performed in the interim, while awaiting a donor organ. Auxiliary partial orthotopic liver transplantation has also been performed, where only one-half of the native liver is resected and transplanted, allowing the native liver time to recover/regenerate and eventually allowing the donor liver to be rejected, avoiding lifelong immunosuppression. Artificial and bioartificial liver-support devices are also under development.[32,56,61–63]

Cirrhosis and Chronic Liver Failure

Any chronic liver disease can progress to cirrhosis, which is characterized by diffuse hepatic fibrosis. Cirrhosis may be asymptomatic until up to 90% of the hepatic parenchyma is destroyed or until a comorbidity causes decompensation. Many manifestations are similar to those of acute liver failure, although gradual in onset and of lesser severity, whereas others are unique to cirrhosis. Pregnancy is rare in patients with cirrhosis (approximately 1 in 6000 pregnancies) because cirrhosis is uncommon in women of reproductive age and because hormonal changes can cause anovulation and infertility in those who are cirrhotic during childbearing age. Risks for preeclampsia, preterm delivery, low birth weight, small for gestational age, and neonatal death appear to be increased in cirrhotic parturients.[64]

Hepatic fibrosis causes increased resistance to portal blood flow, resulting in portal hypertension that promotes blood flow through portosystemic anastomoses such as esophageal, hemorrhoidal, and other intra-abdominal veins. Congestion and dilation of these collateral vessels increases the risk for spontaneous or iatrogenic bleeding. In addition, coagulopathy of cirrhosis resulting from decreased clotting factor production and thrombocytopenia can exacerbate bleeding from many causes. **Esophageal variceal bleeding** has been reported in up to 32% of pregnant women with cirrhosis, 50% of those with known portal hypertension, and 78% of those with preexisting varices, with a mortality rate up to 50%. It most commonly occurs later in pregnancy when maternal blood volume is expanded and fetal growth causes compression of collateral vessels. Bleeding risk theoretically increases during labor because of the repetitive intra-abdominal pressure increases, especially from pushing during the second stage, though few cases of variceal bleeding at the time of delivery have been reported. Elective cesarean delivery for women with known varices has been suggested to avoid Valsalva-related pressure and variceal bleeding, but surgical delivery also carries the risk for bleeding from abdominal wall collateral vessels. Therefore, an attempt at vaginal delivery (possibly with forceps to shorten the second stage of labor) may be considered before cesarean delivery.[65] Screening for varices and prophylaxis against bleeding should be considered early in the pregnancy. Nonselective beta-adrenergic receptor antagonists can decrease the risk for variceal bleeding by reducing portal pressure through reduction of cardiac output and splanchnic vasoconstriction, but have been associated with fetal bradycardia, growth restriction, and hypoglycemia. Prophylactic endoscopic band ligation or surgical portocaval shunting may also be considered in high-risk parturients. For acute esophageal variceal hemorrhage, endoscopic band ligation (after tracheal intubation for airway protection) is the first-line management. Octreotide infusion may also be considered, although its safety has not been proven in pregnant patients. Transjugular intrahepatic portosystemic shunting may be considered for refractory variceal bleeding (see later discussion).[66] Surgical shunt procedures may also be considered in extreme cases.

Splenic artery aneurysms may also develop in cirrhotic parturients, and rupture in late pregnancy carries high maternal and fetal mortality rates.[67] Management options include splenectomy, transcatheter embolization, and stent-graft placement. **Postpartum uterine hemorrhage,** a consequence of coagulopathy, is another potential source of maternal morbidity and mortality, occurring in up to 10% of pregnancies in patients with cirrhosis.

Encephalopathy secondary to ammonia accumulation may occur in cirrhotic patients and may be precipitated or exacerbated by sedative medications, infection, hypoglycemia, gastrointestinal hemorrhage, hypotension, or hypoxemia. Management includes correction of precipitating factors and reducing the nitrogenous load from gastrointestinal tract with oral, nonabsorbed antimicrobial agents such as lactulose and neomycin. Flumazenil may also improve mental status transiently, and bromocriptine may improve extrapyramidal symptoms, although these have not been studied extensively in cirrhotic parturients.

Massive **ascites** appears to be uncommon in pregnancy, possibly because the increased intra-abdominal pressure

from the gravid uterus opposes extravasation of fluid from splanchnic vessels and organs. If therapy is required, sodium restriction and diuretics can be used. Symptomatic ascites refractory to medical treatment may require paracentesis for drainage, although this could potentially increase the risk for bacterial peritonitis and pregnancy complications.

Cardiovascular manifestations of cirrhosis include systemic vasodilation caused by reduced hepatic clearance of endogenous substances regulating vascular tone. Cardiac output is thereby increased, assuming cardiomyopathy is not present, as may occur in the settings of alcoholic cirrhosis or hemochromatosis. **Portopulmonary hypertension,** a progressive disease characterized by increased pulmonary vascular resistance caused by arteriolar medial hyperplasia, thrombosis, or fibrosis, and eventually right-sided heart failure, has been reported as a complication during pregnancy, resulting in postpartum maternal death.[68] **Hepatorenal syndrome,** renal dysfunction secondary to splanchnic and systemic vasodilation of cirrhosis, does not appear to be a common complication in cirrhotic parturients. Similarly, **hepatopulmonary syndrome** caused by intrapulmonary vasodilation and shunting resulting in hypoxemia appears to be rare during pregnancy.[68–74]

LIVER SURGERY

Liver Transplantation during Pregnancy

Fulminant hepatic failure during pregnancy may necessitate liver transplantation if supportive measures prove inadequate and maternal death is likely without transplantation. In second-trimester pregnancies, pregnancy following transplantation has been continued with good maternal and fetal outcomes possible. In third-trimester pregnancies, combined cesarean delivery and liver transplantation have also resulted in positive maternal and fetal outcomes.[75] In some cases, liver failure first develops or worsens postpartum after spontaneous labor and delivery and necessitates transplantation. A cadaveric organ can be used for transplantation or, if unavailable in the required timeframe, a living donor graft can be utilized. Auxiliary grafts may be implanted in parallel with the native liver left *in situ* when the donor graft is too small to work independently, or when eventual native liver recovery is anticipated, after which the graft can be explanted and immunosuppression discontinued.[48,75–81] In patients for whom a matching organ cannot be found, artificial liver systems have been used temporarily while awaiting an organ or spontaneous recovery of the native liver.[82,83]

The literature is insufficient to make evidence-based recommendation about specific anesthetic and surgical techniques (e.g., venovenous bypass versus piggyback/caval preservation) for liver transplantation during pregnancy.

Pregnancy after Liver Transplantation

In 1978, the first pregnancy in a liver transplant recipient was reported.[84] Subsequently, hundreds of such pregnancies have been reported worldwide. Successful pregnancy outcome has even been achieved after triple organ transplantation (small intestine, liver, and pancreas).[85]

Approximately 8% of liver transplant recipients are females of reproductive age, and the hormonal changes of chronic liver disease that disrupt menstruation are usually corrected by transplantation, with 74% of women recovering regular menstrual cycles within 1 year. Still, it is recommended that pregnancy be delayed for 1 to 2 years after transplantation until such time as graft function has stabilized on a low-dose immunosuppression regimen with low teratogenic potential.[86]

Pregnancy after liver transplantation carries an increased risk for preterm birth, fetal growth restriction, and maternal graft dysfunction. Cesarean delivery is commonly necessary for obstetric indications. Posttransplant thrombocytopenia is of particular concern since it is has implications for neuraxial anesthesia during labor and delivery as well as blood loss during cesarean delivery.

Liver Resection

Benign and malignant liver tumors may occur during pregnancy in patients with or without chronic underlying liver disease. Hepatic ectopic pregnancy may also occur. Surgical resection, where feasible, is the definitive treatment.[87] Partial hepatectomy has been reported during pregnancy with favorable maternal outcomes. Management of the pregnancy has ranged from termination,[88] to simultaneous cesarean delivery,[89] to later spontaneous vaginal delivery.[90] There are inadequate data to make specific recommendations about the intraoperative management of liver resection during pregnancy compared with nonpregnant patients, including the role of vascular clamping and maintenance of low central venous pressure to reduce blood loss.[91]

Transjugular Intrahepatic Portosystemic Shunt

Indications for a transjugular intrahepatic portosystemic shunt include variceal bleeding and massive ascites refractory to other therapies. Contraindications include right-sided heart failure, polycystic liver disease, severe hepatic failure, systemic infection, hepatic encephalopathy, hepatic tumors, and portal vein thrombosis. The procedure involves accessing a jugular vein, fluoroscopically guiding an endovascular needle into a hepatic vein, and then perforating the liver parenchyma until the needle tip reaches an intrahepatic portal vein. An endovascular stent is then placed across the liver parenchyma to maintain the shunt. The communication created between the portal and systemic venous systems decompresses the portal system, thereby decreasing the pressure that was causing bleeding and formation of ascites.[92] This procedure has been successfully performed during pregnancy and can be done with radiation-limiting techniques that minimize exposure to the fetus and allow the pregnancy to continue.[66,93]

ANESTHETIC CONSIDERATIONS

Anesthetic management is influenced by the extent of hepatic impairment. If hepatic synthetic and metabolic functions are

BOX 45.2 Anesthetic Guidelines for the Parturient with Liver Disease

- Evaluate the extent of hepatic impairment.
- Recognize and evaluate underlying systemic abnormalities, including coagulation and volume status.
- Assist the obstetric team with stabilization of maternal condition before delivery.
- Plan preferentially for neuraxial analgesia/anesthesia for labor, delivery, and cesarean delivery in the absence of contraindications.
- Exclude coagulopathy before administration of neuraxial anesthesia.
- Prevent further hepatic injury by optimizing hepatic blood flow and oxygenation.
- Recognize altered pharmacokinetics and pharmacodynamics.
- Prevent transmission of viral hepatitis to the health care team.
- Monitor the patient for evidence of postoperative hepatic dysfunction.

intact, the patient may be managed in the same manner as healthy parturients. In contrast, the parturient with evidence of severe hepatic impairment presents the anesthesia provider with many challenges (Box 45.2).

For patients with underlying liver disease, ischemic or other hepatic insults have the potential to exacerbate liver dysfunction. Many retrospective analyses of various types of hepatic and nonhepatic surgery and anesthesia have focused on perioperative outcomes in patients with liver disease, although not specifically during pregnancy. Most studies have shown an association between preoperative liver disease (and its severity) and postoperative morbidity and mortality. Child-Turcotte-Pugh (CTP) scoring and, more recently, model for end-stage liver disease (MELD) scoring (based on international normalized ratio [INR], creatinine, and bilirubin) have both been used to grade severity of liver disease and associated outcomes. In cirrhotic patients undergoing elective surgery, cirrhosis has been independently associated with a 47% increased risk for postoperative complications and an approximately 250% increased risk for in-hospital mortality.[94] Increased duration of anesthesia also predicts poorer outcomes in this population. It is recommended that abdominal surgery should be avoided or deferred, if possible, until full evaluation and optimal treatment have been completed.[95–103] Other studies, however, found no such association.[104–106] The timing of delivery should be based on maternal and fetal considerations. If possible, it is best to fully evaluate the liver disease before delivery, although sometimes this may not be practical. Early delivery should be considered if the liver disease is exacerbated by the pregnancy (e.g., AFLP or cholestasis of pregnancy) or if the pregnancy is limiting the ability to perform a full liver evaluation. Neuraxial techniques have been used safely in asymptomatic chronic hepatitis patients, as well as after liver transplantation, although data specifically on pregnant patients are lacking.[31,106–109]

Hepatic Effects of Anesthesia

Various studies have examined the effects of anesthetics on hepatic blood flow, although these investigations were not in the setting of pregnancy. Volatile anesthetics appear to decrease hepatic blood flow: **isoflurane, sevoflurane,** and **desflurane** reduce hepatic blood flow by less than 20%. **Nitrous oxide** may further decrease hepatic blood flow, whereas propofol or ketamine anesthesia may maintain hepatic blood flow better than inhalational anesthesia.[110–117] **Neuraxial anesthesia** also may reduce hepatic blood flow via the effects of systemic arterial hypotension secondary to sympathetic blockade.[118–120] In one study,[120] this reduction persisted during lumbar epidural anesthesia despite maintenance of normotension by infusion of colloid, but the decrease in hepatic blood flow was reversed by dopamine infusion. These findings suggest that reduced cardiac output, secondary to sympathetic blockade, may be responsible for the observed decrease in hepatic blood flow rather than hypotension. Nevertheless, judicious hydration and avoidance of systemic hypotension should minimize the chances of a clinically significant reduction in hepatic blood flow.

Pharmacokinetic Effects of Liver Failure

The liver's numerous metabolic functions include clearance of drugs as well as synthesis of plasma proteins that bind drugs. Liver disease, therefore, can alter the normal pharmacokinetics of anesthetics and other drugs. Drug clearance may be decreased by hepatocyte dysfunction or reductions in liver blood flow. Impaired hepatic synthesis of plasma proteins can lead to decreased drug binding and increased free fraction of drugs. This makes more drug available for clearance by the liver, but at the same time increases tissue availability and effective volume of distribution, which can alter drug effects and clearance. Overall, severe liver disease can decrease clearance of various agents, and repeated or continuous administration can lead to drug accumulation and adverse effects. Additionally, compared with their effects in healthy individuals, anesthetic agents at any concentration may cause increased sedation or decompensation in patients already compromised by hepatic encephalopathy.

Clearance of some opioids, including **morphine, meperidine,** and **alfentanil** may be decreased in patients with advanced liver disease. Other opioids, including **fentanyl** and **sufentanil,** do not appear to have significantly impaired clearance, although repeated or continuous dosing may be problematic. **Remifentanil** undergoes breakdown by plasma and tissue esterases, and so its pharmacokinetics are not significantly changed. **Methadone** also appears to have nearly normal disposition. **Codeine,** which requires hepatic conversion to morphine for analgesia and clearance, may not be safe or effective, and similar uncertainty exists regarding **tramadol**.[121–124] Prolonged effects can also be seen with **etomidate** and benzodiazepines including **midazolam** and **diazepam,** whereas **propofol, methohexital,** and **thiopental** clearances are unchanged after anesthesia induction doses.[125–129] Neuromuscular blocking agents normally cleared by the liver

(**vecuronium, rocuronium**) or by liver-synthesized enzymes (**succinylcholine**), or that may be present in a larger volume of distribution (**pancuronium**), may have longer durations of action, whereas agents not dependent on liver function (**atracurium, cisatracurium**) should have normal durations of action.[130–134] The half-lives of amide local anesthetics (**lidocaine, bupivacaine, ropivacaine**) may be prolonged and potential for toxicity increased because of decreased liver clearance, whereas ester local anesthetics (**2-chloroprocaine**) have potentially prolonged half-lives because of decreased hepatic pseudocholinesterase synthesis.[135–137] **Acetaminophen (paracetamol)** can be safely administered in routine doses for acute pain in patients with cirrhosis, but chronic administration can provoke hepatic injury, and reduced doses are recommended in those with decompensated liver disease. Although **ketorolac** metabolism may be normal, **nonsteroidal anti-inflammatory drugs (NSAIDs)** can precipitate renal dysfunction and should be avoided.[73,138]

Neuraxial Anesthesia

Neuraxial analgesia/anesthesia is the preferred technique for labor, vaginal delivery, and cesarean delivery and can be offered to patients with liver disease in the absence of significant intravascular volume depletion or a coagulopathy. Before administration of a neuraxial technique, a full coagulation profile and platelet count should be obtained and intravascular volume assessed. Epidural techniques in particular may have added risk in patients with portal hypertension because the epidural venous plexus is engorged even beyond that of normal pregnancy and could predispose to intravascular needle/catheter placement or epidural hematoma.[139] The potential for impaired clearance of local anesthetics and opioids described earlier should also be considered, especially when repeated boluses or continuous infusions are used. There are no data indicating that one local anesthetic is clearly superior to another for epidural analgesia, and we use our standard epidural infusion of bupivacaine with fentanyl for labor analgesia. Single-shot spinal techniques with small-gauge needles may minimize the issues of drug metabolism and bleeding, although with possibly increased risk for acute hypotension and reduced liver blood flow.

General Anesthesia

Coagulopathy, obstetric hemorrhage, altered mental status, and severe fetal compromise may necessitate the use of general anesthesia for cesarean delivery. Intravascular volume should be evaluated before induction. Invasive blood pressure monitoring and pulmonary artery catheterization may be useful in the patient with cardiovascular compromise or portopulmonary hypertension. Large-bore intravenous access should be established, and blood products should be available. Gastric acid neutralization should precede rapid-sequence induction and tracheal intubation. All standard induction agents are safe, and the dose should not be altered. Liver disease and reduced pseudocholinesterase concentrations may delay the metabolism of succinylcholine, but the delay is of negligible clinical importance. Succinylcholine thus remains the muscle relaxant of choice during rapid-sequence induction of general anesthesia, and it should be administered in the same dose as for healthy parturients. For patients with contraindications to succinylcholine, rocuronium may be used. **Sugammadex** may be considered for emergent or routine reversal of rocuronium, but this agent has not been studied in patients with liver dysfunction and may worsen coagulopathy in this setting.[140] Careful gastric tube placement may be considered, even in the presence of esophageal varices.[141] For maintenance of anesthesia, agents that do not undergo significant hepatic metabolism (e.g., **isoflurane, desflurane, atracurium, cisatracurium, remifentanil,** and **nitrous oxide**) may be preferable to other inhalational agents that further reduce liver blood flow or intravenous agents that may accumulate before clearance. Reversal of neuromuscular blockade must be ensured before tracheal extubation. To this end, sugammadex pharmacodynamics in cirrhotic patients appear to be similar to controls.[142]

Postoperative Care

Although clearance is delayed in patients with severe liver disease, intravenous opioids may be administered judiciously to provide postoperative analgesia. Neuraxial opioids, especially a single dose of **morphine**, may obviate any accumulation issues. Advanced liver disease can lead to hepatic encephalopathy. Neurologic deterioration in the postoperative period may result from the residual effects of anesthetic agents, acute liver decompensation, or an intracranial process. Other postoperative complications to be anticipated include paracentesis-induced circulatory dysfunction, decompensation of preexisting liver disease, cirrhotic cardiomyopathy, hepatorenal syndrome, and hepatopulmonary syndromes. Perioperative strategies to avoid these (e.g., administration of **albumin, terlipressin, norepinephrine, midodrine, octreotide, *N*-acetylcysteine**) may be considered.

KEY POINTS

- Liver disease can be either incidental or unique to pregnancy and complicates as many as 3% of all pregnancies.
- Viral hepatitides are the most common cause of jaundice during pregnancy.
- All pregnant women should be screened for hepatitis B virus, and all neonates should be vaccinated against it.
- Acute fatty liver of pregnancy (AFLP) is a rare but life-threatening complication of pregnancy that demands rapid evaluation and prompt delivery.
- AFLP is commonly misdiagnosed as preeclampsia or hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome because of a similar constellation of presenting symptoms.
- Hepatic rupture may complicate preeclampsia/eclampsia, HELLP syndrome, or AFLP, and the mortality rate can be greater than 60%.
- Encephalopathy may result from reduced hepatic ammonia metabolism.

- Coagulopathy may result from impaired synthesis of coagulation factors and from thrombocytopenia. Paradoxically, in some cases, liver failure may result in hypercoagulability.
- Renal failure and cardiovascular, renal, pulmonary, and immune dysfunction may accompany liver failure.
- Women with portal hypertension may develop esophageal varices that are prone to bleed during the third trimester of pregnancy, and this risk increases during labor.
- Successful pregnancy is common after liver transplantation, and pregnancy does not affect the long-term survival of hepatic allografts, though pregnancy complications are more common.
- Liver disease can alter the normal pharmacokinetics of anesthetics and other drugs.
- Both neuraxial and general anesthesia can be administered safely to the parturient with liver disease, with close attention to hemodynamics to preserve hepatic blood flow.
- Neuraxial analgesia/anesthesia is the preferred technique for labor, vaginal delivery, and cesarean delivery and can be offered to patients with liver disease provided significant intravascular volume depletion and coagulopathy have been excluded.
- Hepatic, neurologic, cardiovascular, renal, and pulmonary complications should be anticipated in the postpartum period in patients with significant liver disease.

Malignant Hyperthermia

M. Joanne Douglas, MD, FRCPC

CHAPTER OUTLINE

Malignant hyperthermia (MH) is an inherited disorder of skeletal muscle. On exposure to triggering agents (e.g., succinylcholine, volatile halogenated anesthetic agents), affected individuals demonstrate a hypermetabolic syndrome characterized by hypercapnia, acidosis, muscle rigidity, arrhythmias, and hyperthermia. MH was first described in 1960 by Denborough and Lovell,[1] but may have been responsible for some of the earlier deaths attributed to ether and chloroform anesthesia.[2]

EPIDEMIOLOGY

Ording,[3] reviewing the incidence of MH in Denmark, noted that the incidence of the fulminant syndrome (e.g., muscle rigidity, acidosis, hyperkalemia, arrhythmias, hyperthermia, increased creatine kinase [CK] levels, myoglobinuria) was 1 in 220,000 patients who received general anesthesia and 1 in 62,000 patients in whom succinylcholine was combined with a volatile halogenated agent. MH (either mild or fulminant) was suspected in 1 in 16,000 patients who received anesthesia of any type. The male-to-female ratio was 1.4 : 1.[3] MH appears in all ethnic groups and throughout the world.[4]

There are few reports of development of MH during pregnancy and parturition.[5–12] The infrequent occurrence during pregnancy probably reflects both the low frequency of this disorder in the general population and the widespread use of local and neuraxial anesthetic techniques in obstetric patients.

PATHOPHYSIOLOGY

MH is the result of a disorder in the regulation of intracellular calcium in skeletal muscle. The precise mechanism by which volatile anesthetics and depolarizing muscle relaxants cause an MH crisis is still unknown.[4] In muscle, the sarcoplasmic reticulum is responsible for controlling calcium release and reuptake during muscle contraction.[13] During skeletal muscle excitation-contraction coupling, calcium is released from the terminal sarcoplasmic reticulum via the **ryanodine receptor (RYR1).** Dihydropyridine receptors (DHPR) in the T-tubule membrane also participate in the excitation-contraction coupling. In humans, mutations in both the dihydropyridine and ryanodine receptor genes can result in clinical MH. Dantrolene inhibits excitation-contraction coupling, and succinylcholine, caffeine, and volatile halogenated agents increase it.

GENETICS

MH is a heterogeneous disorder, meaning that more than one gene defect is responsible for expression of the clinical syndrome.[14] It is inherited in an autosomal dominant fashion with variable penetrance, although this pattern has been questioned in some families.[15] Porcine MH is transmitted as a recessive gene. The defective gene in MH-susceptible pigs has been localized to a single point mutation in the ryanodine receptor gene *(RYR1).*[16]

Investigators have found the corresponding point mutation in the human *RYR1* in some families with MH (chromosome 19q12.1–13.2; locus MHS-1), and other mutations in *RYR1* have been linked to MH susceptibility.[17] Other point mutations in *RYR1* are found in patients with central core disease, a myopathy associated with MH.[18] As of 2015, more than 400 *RYR1* variants had been identified,[4] and as of 2017, 36 of these variants were determined to be causal for MH.[19] Mutations responsible for MH in some families are located on chromosomes 5p, 17, 7q, 3q, and 1q.[20] Some 50% to 70% of human MH cases are linked to mutations in *RYR1,* and approximately 1% are linked to the gene encoding the main subunit of the DHPR, the calcium voltage-gated channel subunit alpha-1 S gene *(CACNA1S).*[21] Some cases of MH may not be genetically linked, or the causal genetic mutations have not yet been identified.

Some myopathies may be characterized by a hyperthermic state with muscle damage and metabolic derangements similar to those seen in MH, but their chromosomal abnormality has not been mapped to the same area.[14] A potential association between exertional rhabdomyolysis, exercise-induced rhabdomyolysis (EIR), exertional heat illness, heat stroke, and MH has been identified, with the presence of MH-causative mutations in some of these patients.[22,23]

TRIGGERS

Known triggers of MH include depolarizing muscle relaxants (e.g., succinylcholine) and all the volatile halogenated anesthetic agents (i.e., sevoflurane, desflurane, isoflurane, halothane) (Box 46.1).[24] The dose and duration of exposure to the triggering agent may influence the onset and severity of a reaction. The combination of a volatile agent and succinylcholine worsens the severity of the MH response.[25] Previous uneventful administration of general anesthesia with triggering anesthetic agents does not rule out the diagnosis of MH.[4]

In contrast to the porcine model, reports of stress-induced MH in humans are rare.[26–32] In one report, two cases of fatal, stress-induced MH occurred in unrelated families[30]; both children had a known *RYR1* mutation, and one had a second mutation, possibly suggesting an additive effect.[33] The sympathetic nervous system is active during an episode of acute MH, but there is insufficient evidence to implicate increased sympathetic activity as a cause in humans. Although muscle biopsy contracture testing may help distinguish MH from EIR, exertional heat stroke, and other myopathies, there is some evidence of a link between some cases of heat stroke and EIR and MH susceptibility.[23,34]

Investigators have explored other possible triggers of MH both in the porcine model and in humans. No evidence suggests that exogenous calcium, digoxin, hypercarbia, potassium,[35] or norepinephrine[36] triggers MH. Exercise[37] and environmental temperature[38–40] may intensify an existing reaction or modify a developing reaction. Sodium thiopental and pancuronium delay the onset of MH in susceptible pigs and may modify the reaction in humans.[41] Duke et al.[42] postulated that hypomagnesemia may increase the probability and severity of an MH event in MH-susceptible humans.

There are case reports of the occurrence of MH during regional anesthesia and during general anesthesia with nontriggering agents.[43–47] The cases that occurred during regional anesthesia appeared mild and responded readily to treatment. In some cases, however, the diagnosis was not confirmed with muscle biopsy or appropriate laboratory investigation at the time of the event.

CLINICAL PRESENTATION

Individuals who are MH-susceptible may demonstrate the fulminant syndrome when anesthetized with a triggering agent. During an acute episode, the diagnosis is based on the finding of an elevated end-tidal CO_2 concentration, muscle rigidity (generalized and/or masseter), respiratory and metabolic acidosis, rhabdomyolysis, hyperkalemia, elevated CK concentration, and myoglobinuria (Box 46.2). A dramatic increase in temperature may occur early, but often it is a late sign.[48] Hypoxemia, unstable blood pressure, and evidence of sympathetic hyperactivity (e.g., tachycardia, hypertension, arrhythmias) are other signs. Perioperative rhabdomyolysis, without any of the previously mentioned clinical signs, also may indicate MH susceptibility.[4]

With the advent of routine end-tidal CO_2 monitoring, MH may be detected early, often before the development of rhabdomyolysis and hyperthermia.[48] This situation may lead to

BOX 46.1 Triggers for Malignant Hyperthermia

- Volatile anesthetic agents
  - Sevoflurane
  - Desflurane
  - Isoflurane
  - Halothane
- Succinylcholine

BOX 46.2 Signs and Symptoms of Malignant Hyperthermia

- Tachycardia
- Tachypnea
- Masseter spasm
- Generalized rigidity
- Elevated end-tidal CO_2 concentration
- Cyanosis
- Arrhythmias
- Acidosis
- Hyperkalemia
- Hyperpyrexia
- Myoglobinuria
- Increased creatine kinase level

uncertainty about the clinical diagnosis of MH, given that many of the confirmatory signs and laboratory abnormalities may be absent during the early phase of MH. Thus, early treatment of possible MH could present a dilemma as to whether the patient should undergo diagnostic muscle biopsy or should be assumed to be MH susceptible.

Masseter Muscle Rigidity

Masseter muscle rigidity is one of the early signs of MH.[48] The masseter muscles are sensitive to the action of succinylcholine and respond with increased tension in normal individuals.[49,50] Often this tension is imperceptible, but in some patients it is impossible to open the mouth for laryngoscopy and tracheal intubation. The duration of rigidity parallels the duration of action of succinylcholine. Typically there is no difficulty with mask ventilation. Patients with myopathies and other neuromuscular disorders also may have masseter muscle rigidity after the administration of succinylcholine.[51]

If masseter muscle rigidity is accompanied by generalized rigidity, anesthesia should be discontinued, dantrolene should be administered, and the patient should be monitored closely.[52] However, there is controversy regarding the management of isolated masseter muscle rigidity.[53] Options include (1) discontinuation of the anesthetic agents and administration of dantrolene; (2) continuation of anesthesia with nontriggering, "safe" agents and close attention to the end-tidal CO_2 concentration; and (3) continuation of anesthesia with triggering agents and careful monitoring. In our judgment, the anesthesia provider should either discontinue anesthesia altogether or continue anesthesia with nontriggering agents. If anesthesia is continued, the minute ventilation, end-tidal CO_2 concentration, electrocardiogram (ECG), temperature, and arterial blood gas measurements should be monitored. The anesthesia provider also should look for evidence of rhabdomyolysis by monitoring CK levels and looking for myoglobinuria, and should recommend that the patient undergo muscle biopsy and caffeine-halothane contracture testing (see later discussion).[54]

DIAGNOSIS

Investigators have correlated clinical presentation (i.e., evidence of metabolic and muscle derangements) with abnormal contracture on the caffeine-halothane contracture test.[55–57] The greater the number of clinical signs or abnormal laboratory findings, the greater the risk for MH (Table 46.1).[55] The mortality rate for MH is as high as 80% without dantrolene therapy.[57] Early administration of dantrolene lowers the mortality rate to 4%.[4]

An international group of experts has developed a clinical grading scale to predict MH susceptibility.[58] This scale consists of six processes (rigidity, muscle breakdown, respiratory acidosis, temperature increase, cardiac involvement, family history) and their clinical indicators. Points are assigned for each indicator present in a patient, and the total represents a raw score. A rank is subsequently assigned to this score, which indicates the likelihood of development of MH in the patient.

TABLE 46.1 Risk for Malignant Hyperthermia (MH) with Associated Signs and Symptoms

Type	Symptoms/Signs	Risk
Fulminant/classic	Metabolic acidosis Muscle rigidity Hyperthermia (> 38.5°C) Arrhythmias Hyperkalemia Myoglobinuria Increased creatine kinase level	0.96
Moderate	Inconclusive signs of MH involving metabolic and muscle abnormalities, with MH the probable diagnosis	0.88
Mild	Signs of metabolic derangement (pH > 7.3, body core temperature < 38.5°C)	0.14
Masseter spasm with rhabdomyolysis	Creatine kinase level > 1500 U/L, myoglobinuria	0.76
Masseter spasm with signs of metabolic disturbance	Arrhythmias, rising core temperature	0.57
Masseter spasm only		0.28
Unexplained perioperative death or cardiac arrest		0.66
Other	Postoperative pyrexia or rhabdomyolysis	0.07

MH, Malignant hyperthermia.
Data from Ellis FR, Halsall PJ, Christian AS. Clinical presentation of suspected malignant hyperthermia during anaesthesia in 402 probands. *Anaesthesia.* 1990;45:838–841.

TESTING

Susceptibility to MH is determined by a positive caffeine-halothane contracture test result. During this test, fresh muscle is exposed to halothane and caffeine, and the extent of contraction is measured. The caffeine-halothane contracture test has been standardized in MH testing centers throughout North America (the North American protocol) and Europe (the European protocol is called the *in vitro* contracture test).[4] This test is the "gold standard" for the diagnosis of MH. The sensitivity and specificity of the North American protocol are 97% and 78%, respectively.[4] Patients with a negative caffeine-halothane contracture test result subsequently have received anesthesia with triggering agents without incident.[59–62]

Testing for the known genetic mutations associated with MH is now available. However, because all the genetic mutations responsible for MH have yet to be identified, genetic testing is still not sensitive enough to use for routine screening.[63] In the future, MH may be detected in most MH-susceptible patients with genetic analysis without the need for an invasive muscle biopsy.[63] Meanwhile, investigators are

studying other relatively noninvasive tests (e.g., assessment of metabolism in B-lymphocytes).[64] In the absence of muscle biopsy results, a parturient with a positive family history should be treated as if she were MH susceptible.

PREGNANCY AND MALIGNANT HYPERTHERMIA

In 1972, Crawford[65] wondered "whether or not there was a record of a pregnant or newly born patient or animal having developed hyperpyrexia and … whether hyperpyrexia has been encountered in a patient undergoing an operation under regional block anesthesia." Subsequently there have been few reports of MH during parturition and fewer reports of maternal mortality attributable to MH. Wadhwa[5] reported the death of a woman with a known family history of MH in whom muscle rigidity developed during twilight sleep for parturition. Douglas et al.[6] reported one fatal case of MH in a parturient undergoing general anesthesia for cesarean delivery.

There are three published reports[7–9] of nonfatal MH during cesarean delivery and one report of MH after cesarean hysterectomy performed because of postpartum hemorrhage.[12] The triggering agents were succinylcholine and halothane,[7] succinylcholine and isoflurane,[12] cyclopropane,[8] and succinylcholine alone (without a volatile halogenated agent).[9] There are several reports of the successful administration of epidural and spinal anesthesia during labor and cesarean delivery in MH-susceptible parturients.[5,12,66–73]

Although it is unclear whether pregnancy alters susceptibility to MH, the rarity of MH events during pregnancy suggests that pregnancy protects against the occurrence of MH. However, it also may reflect the widespread use of neuraxial anesthesia for labor, vaginal delivery, and cesarean delivery.

Maternal Physiology

Basal metabolic rate, oxygen consumption, and minute ventilation increase during pregnancy (see Chapter 2). Serum bicarbonate, buffer base, and base excess decrease to maintain normal pH. Thus, the pregnant patient typically has a compensated respiratory alkalosis. The reduced buffering capacity could adversely affect the pregnant woman during an episode of MH.

Oxygen consumption and minute ventilation increase further during labor. Maternal lactate and pyruvate concentrations increase steadily during labor, indicating an increase in both aerobic and anaerobic metabolism. Hyperventilation during contractions may result in periods of hypoventilation between contractions, which may adversely affect the Pao_2 of both the mother and fetus. These metabolic and physiologic responses to pain are similar to the metabolic and physiologic changes that are observed during acute MH. Effective epidural analgesia decreases oxygen consumption and minute ventilation. If tachycardia and hyperventilation occur despite effective analgesia, they are more likely to signal an episode of MH.

Aortocaval compression from the pregnant uterus results in decreased cardiac output, hypotension, and reduced uteroplacental perfusion. Thus, aortocaval compression may accelerate the occurrence of acidosis during an episode of MH. Aortocaval compression hinders resuscitative efforts during cardiac arrest, and evacuation of the uterus (i.e., delivery of the fetus) facilitates maternal resuscitation (see Chapters 41 and 54).[74] The obstetrician may need to deliver the fetus to facilitate maternal resuscitation during a fulminant case of MH.

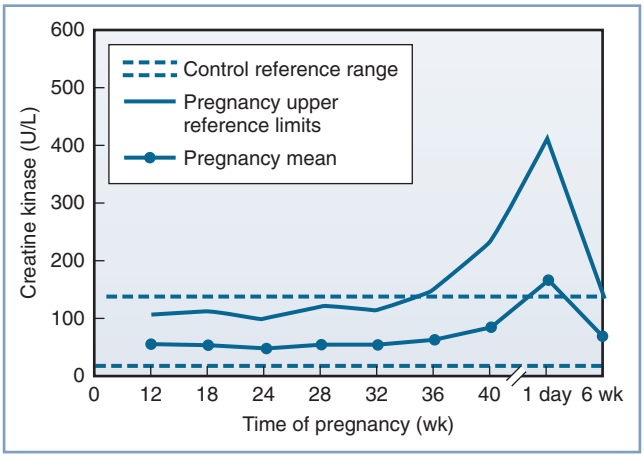

Fig. 46.1 Changes in creatine kinase activity during and after pregnancy. (Modified from Lockitch G, ed. *Handbook of Diagnostic Biochemistry and Hematology in Normal Pregnancy*. Boca Raton, FL: CRC Press; 1993:59.)

CK concentrations are not diagnostic of MH. During pregnancy, there is a slight decrease in CK levels during the first trimester. CK levels remain stable until term, when they increase by approximately 50%. At delivery, there is an abrupt rise in the CK concentration, followed by a return to normal by 6 weeks postpartum (Fig. 46.1).[75] The increased CK concentration results from increases in both the CK-M fraction (skeletal muscle) and the CK-B fraction (myometrium, placenta, and fetal blood). Postpartum CK levels are higher in nulliparous women regardless of differences in duration of labor.[76] Mean plasma CK activity is approximately 50% higher in African Americans than in Caucasians or Asians.[75]

Acute cocaine toxicity may mimic MH. Although cocaine does not induce contractures in MH-susceptible muscle,[77] elevated CK concentrations and myoglobinemia can occur secondary to rhabdomyolysis and renal failure from cocaine intoxication.[78] Umbilical cord blood CK and myoglobin levels are elevated when cocaine metabolites are present in maternal urine.[79]

Effects on the Fetus and Newborn

MH usually is inherited as an autosomal dominant gene. Thus, there is a 50% chance that the infant of an MH-susceptible parent will also be MH susceptible. All anesthetic agents cross the placenta. Small quantities of succinylcholine also cross the placenta. This knowledge should prompt the anesthesia provider to question the choice of anesthetic agents for an MH-negative mother whose fetus has an MH-susceptible

father. In this situation, the anesthesia provider should avoid the use of triggering agents until after delivery.[80]

There is only one published report of suspected MH in a newborn.[81] The condition is rare in infancy, and some reports of infant MH may represent undiagnosed myopathy.[51,82,83]

MANAGEMENT OF THE MALIGNANT HYPERTHERMIA–SUSCEPTIBLE PARTURIENT

Ideally, an anesthesiologist will evaluate every MH-susceptible pregnant patient before she is hospitalized for labor and delivery. Clearly, the obstetrician should consult an anesthesia provider immediately after the admission of each MH-susceptible patient. All hospitals and birthing facilities should be prepared to provide care for MH-susceptible patients. Adequate supplies of dantrolene (at least 36 vials of Dantrium or Revonto, or 3 vials of Ryanodex[84]), sterile water, and sodium bicarbonate should be immediately available.[85]

Analgesia for Labor

Soon after admission, a large-gauge intravenous catheter should be placed in each MH-susceptible patient. Maternal temperature, heart rate, and blood pressure should be monitored throughout labor. During early labor, it may be acceptable to monitor temperature and heart rate intermittently to facilitate maternal ambulation, if desired. Once active labor is established, frequent monitoring of the maternal heart rate and temperature should be initiated. Continuous ECG and axillary temperature monitoring are ideal once the parturient is confined to bed. (Measurement of axillary temperature allows placement of a temperature probe in close proximity to large muscle groups.) Of course, aortocaval compression should be avoided throughout labor and delivery.

Most agents used for intrapartum analgesia are considered safe in the MH-susceptible parturient (Table 46.2). Both the obstetrician and the anesthesia provider should encourage the early administration of neuraxial analgesia. Relief of pain reduces maternal stress (as reflected by decreased catecholamine,[86] cortisol,[87] and adrenocorticotropic hormone [ACTH] concentrations) and decreases maternal metabolism and oxygen consumption.[88] Although experts continue to debate the role of stress in human MH,[89] it is best to diminish stress when possible. Further, the anesthesia provider may extend epidural analgesia for vaginal or cesarean

TABLE 46.2 Common Anesthetic Drugs and Their Safety in Malignant Hyperthermia–Susceptible Women

Drug	Route	Use	Safe in MHS Women
Local Anesthetic Agents			
Bupivacaine	Neuraxial	Analgesia/anesthesia	Yes
Lidocaine	Neuraxial	Analgesia/anesthesia	Yes
	Intravenous	Arrhythmia	Yes
Ropivacaine	Neuraxial	Analgesia/anesthesia	Yes
2-Chloroprocaine	Neuraxial	Analgesia/anesthesia	Yes
Opioids			
Fentanyl, sufentanil, alfentanil, remifentanil	Neuraxial, intravenous	Analgesia	Yes
Meperidine	Neuraxial, intravenous	Analgesia	Yes
Morphine	Neuraxial, intravenous	Analgesia	Yes
Sedative-Hypnotics			
Propofol	Intravenous	Induction of anesthesia	Yes
Sodium thiopental	Intravenous	Induction of anesthesia	Yes
Etomidate	Intravenous	Induction of anesthesia	Yes
Ketamine	Intravenous	Induction of anesthesia, analgesia	Yes
Benzodiazepines	Intravenous	Amnesia, anxiolysis	Yes
Neuromuscular Blocking Agents			
Succinylcholine	Intravenous	Muscle relaxation	No
Rocuronium	Intravenous	Muscle relaxation	Yes
Cis-atracurium	Intravenous	Muscle relaxation	Yes
Vecuronium	Intravenous	Muscle relaxation	Yes
General Anesthetic Agents			
Sevoflurane, desflurane, isoflurane, halothane	Inhalation	Anesthesia, uterine relaxation	No
Nitrous oxide	Inhalation	Analgesia/anesthesia	Yes

MHS, Malignant hyperthermia–susceptible.

delivery if necessary, thus avoiding administration of general anesthesia.

All local anesthetic agents appear safe for MH-susceptible patients. Epinephrine can be safely added to the local anesthetic agent to improve the quality and duration of analgesia, if clinically appropriate.

Anesthesia for Cesarean Delivery

General anesthesia should be avoided for operative delivery if possible. Spinal or epidural anesthesia using either amide or ester local anesthetic agents can be given safely. Phenylephrine is probably the preferred agent for the treatment of hypotension. Ephedrine may exacerbate the catecholamine response during an acute episode of MH. In doses greater than those used clinically, ephedrine exacerbates halothane-induced muscle contractures *in vitro*.[90]

Rarely, the mother may refuse neuraxial anesthesia. In other cases, neuraxial anesthesia may be contraindicated (e.g., maternal hemorrhage, coagulopathy, prolonged fetal bradycardia). When the anesthesia provider encounters an MH-susceptible parturient, the anesthesia machine and delivery circuit should be flushed of volatile agents. Preparation consists of replacing the carbon dioxide absorbent and the delivery tubing, disabling the vaporizers, and purging the machine of residual anesthetic agent with a 10 L/min flow of oxygen through the circuit (including the ventilator).[91] The time required to purge the anesthesia machine is dependent on the specific machine; new-model anesthesia machines with plastic components require longer flushing times.[91] Activated charcoal filters appear to be an effective alternative to the prolonged flushing required to reduce the volatile anesthetic concentration in these new machines.[92]

Nontriggering agents should be administered for induction and maintenance of general anesthesia (Box 46.3; see Table 46.2). Unless difficult tracheal intubation is expected, rapid-sequence induction should be performed with a sedative-hypnotic drug and a nondepolarizing neuromuscular blocking agent. All commonly used induction agents (e.g., propofol, thiopental, ketamine, etomidate) are safe in MH-susceptible patients. Succinylcholine and the volatile halogenated agents (sevoflurane, desflurane, isoflurane, halothane) are contraindicated. For intubation, rapid onset (approximately 60 to 90 seconds) of muscle relaxation can be achieved with rocuronium (0.6 to 0.9 mg/kg, which is two to three times the dose causing 95% twitch depression [ED_{95}])[93] or vecuronium[94] (0.25 mg/kg). Nitrous oxide (delivered via a prepared anesthesia machine), opioids, and propofol are safe agents for the maintenance of anesthesia. Midazolam administered after delivery provides amnesia. It is safe to reverse neuromuscular blockade with glycopyrrolate and neostigmine or edrophonium. Atropine may cause an increase in temperature, which could cause a diagnostic dilemma.

At delivery, determination of maternal and umbilical cord blood gas and pH measurements may provide information about an impending reaction in either the mother or the neonate. As well, if the MH-susceptible mother has a known genetic mutation, umbilical cord blood may be used to assess MH susceptibility in the neonate.[95] If uterine relaxation (tocolysis) is required to assist with delivery of the infant or to facilitate the removal of a retained placenta, we prefer to give 100-µg bolus doses of nitroglycerin intravenously[96]; the action of this agent is brief and easily reversed with oxytocin. Clearly, a volatile halogenated agent should *never* be given to effect uterine relaxation in an MH-susceptible patient.

Concern has been raised about administering triggering agents to a non–MH-susceptible mother who is carrying a fetus whose father is MH susceptible.[97] In this situation, the Malignant Hyperthermia Association of the United States recommends that the mother be treated as if she were MH susceptible to avoid a possible MH reaction in the neonate.[80]

BOX 46.3 General Anesthesia for Cesarean Delivery in the Malignant Hyperthermia–Susceptible Patient

Monitoring
- End-tidal CO_2
- Pulse oximeter
- Electrocardiogram
- Automatic blood pressure monitoring
- Peripheral nerve stimulator
- Temperature (core)

Induction of Anesthesia
- Denitrogenation
- Rapid-sequence induction (propofol 2.0 to 2.8 mg/kg, thiopental 4 mg/kg, ketamine 1 mg/kg)

Muscle Relaxant
- Intubation: rocuronium 0.6 to 0.9 mg/kg
- Maintenance: rocuronium

Maintenance of Anesthesia
- Nitrous oxide/oxygen, propofol, opioid

Amnestic Agent
- Midazolam

Reversal of Neuromuscular Blockade
- Glycopyrrolate and neostigmine

Obstetric Drugs in Malignant Hyperthermia–Susceptible Parturients

Information on use of obstetric drugs in MH-susceptible patients is scant (Table 46.3). The beta-sympathomimetic tocolytic agents (e.g., terbutaline) produce anxiety and tachycardia in normal parturients. Such side effects may be confused with MH, although these agents are safe in the MH-susceptible parturient.

Magnesium sulfate attenuates but does not prevent MH in MH-susceptible swine.[98] There is one report of a fatal adverse interaction between dantrolene and the calcium entry–blocking agent diltiazem,[99] and hyperkalemia has been described after the co-administration of dantrolene and

TABLE 46.3 Drugs Commonly Used for Labor and Delivery and Their Safety in Malignant Hyperthermia–Susceptible Women

Drug	Route	Use	Safe in MHS Women
Tocolytics			
Nitroglycerin	Intravenous, sublingual	Tocolysis, antihypertensive	Yes
Terbutaline	Intravenous, subcutaneous	Tocolysis	Yes
Calcium entry–blocking agents	Oral	Tocolysis, antihypertensive	Yes[a]
NSAIDs	Oral	Tocolysis	Yes
Oxytocics			
Oxytocin	Intravenous, intramuscular	Induction/augmentation of labor, uterine atony	Yes
Prostaglandin $F_{2\alpha}$	Intramuscular, intramyometrial	Uterine atony	Inadequate information available[b]
Misoprostol	Vaginal, rectal	Uterine atony	Inadequate information available[b]
Ergot alkaloids	Intramuscular	Uterine atony	Inadequate information available
Cardiovascular Drugs			
Phenylephrine	Intravenous	Vasopressor	Yes
Ephedrine	Intravenous	Vasopressor	Yes[c]
Epinephrine	Intravenous, neuraxial	Vasopressor, epidural test dose, neuraxial local anesthesia adjunct	Yes
Beta-adrenergic receptor antagonists	Intravenous, oral	Antihypertensive	Yes
Antiemetics			
Metoclopramide	Intravenous	Prophylaxis, therapeutic	Yes
Ondansetron	Intravenous	Prophylaxis, therapeutic	Yes
Other			
Magnesium	Intravenous	Seizure prophylaxis, cerebral palsy prophylaxis	Yes
Histamine$_2$-blocking agents	Intravenous, oral	Aspiration prophylaxis	Yes

MHS, Malignant hyperthermia–susceptible; *NSAIDs,* nonsteroidal anti-inflammatory drugs.
[a]Do not use during an MH crisis (see text).
[b]May cause fever which could be confused with an MH event.
[c]May exacerbate the catecholamine response during an MH crisis (see text).

verapamil.[100] Administration of calcium entry–blocking agents should be avoided during an episode of MH. These agents do not prevent the development of MH.[101]

Oxytocin is safe. Some of the commercial preparations of oxytocin contain a preservative (chlorbutol) that has been shown to reverse the development of MH in susceptible pigs *in vitro*.[102] The ergot alkaloids cause vasoconstriction, which may lead to decreased muscle perfusion and a greater tendency toward lactic acidosis. The prostaglandins may be associated with changes in blood pressure and maternal oxygen desaturation.[103] Prostaglandin E_2, prostaglandin $F_{2\alpha}$, and misoprostol may cause pyrexia, which may lead to confusion in the diagnosis of an MH episode.[104] In one study, fever greater than 38°C occurred in 30.4% of women randomized to receive misoprostol compared with 6.3% in a placebo group.[105] The routine postpartum administration of ergot alkaloids, prostaglandins, or misoprostol probably should not be performed in MH-susceptible patients. However, persistent uterine atony and postpartum hemorrhage may warrant the administration of these agents.

BOX 46.4 Differential Diagnosis of Fever During Parturition

- Infection: chorioamnionitis, urinary tract infection, other infections (e.g., influenza, viral illness)
- Environmental temperature
- Labor epidural analgesia
- Dehydration/labor
- Malignant hyperthermia
- Drug reactions: cocaine, atropine, tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), neuroleptic malignant syndrome, prostaglandins (misoprostol)

ASSESSMENT OF HYPERTHERMIA AND TACHYCARDIA

The hallmark signs of MH may be present during normal labor (Boxes 46.4 and 46.5). Other causes of fever and tachycardia in the MH-susceptible parturient should be excluded.

BOX 46.5 Differential Diagnosis of Tachycardia during Parturition

- Pain
- Fever
- Anxiety
- Blood loss
- Hypotension
- Drug reactions: cocaine, atropine, beta-adrenergic tocolytic agents
- Malignant hyperthermia

Tachycardia and tachypnea are normal responses to pain, anxiety, and fever. Fever may be a sign of dehydration and infection. Pain and infection (e.g., chorioamnionitis, urinary tract infection) are much more common during parturition than MH. Some healthy parturients may have a gradual increase in temperature during epidural analgesia (see Chapter 23).[106] The fever may be accompanied by corresponding increases in maternal and fetal heart rates.

The butyrophenones, phenothiazines, thioxanthenes, and other miscellaneous antipsychotic agents may produce tachycardia, fever, and rigidity (i.e., neuroleptic malignant syndrome).[107] There is one published report of neuroleptic malignant syndrome in a pregnant woman.[108] Drugs capable of increasing serotonin in the central nervous system (i.e., selective serotonin reuptake inhibitors) also can produce a hypermetabolic reaction. Cocaine intoxication causes severe vasoconstriction, fever, and rhabdomyolysis.[109]

TREATMENT

Box 46.6 summarizes the treatment of MH; a more detailed protocol for the management of an MH episode is available online from the Malignant Hyperthermia Association of the United States (https://www.mhaus.org/healthcare-professionals/managing-a-crisis/). The anesthesia provider should call for help, obtain dantrolene, and notify the surgeon. If possible, the surgeon should stop the procedure. All triggering agents must be stopped immediately, and the patient should be hyperventilated with 100% oxygen at 10 L or more per minute. The level of volatile halogenated agent decreases rapidly with flushing of the machine with 100% oxygen. Therefore, substitution with a vapor-free machine is not an immediate priority. Insertion of an activated charcoal filter into the breathing circuit (inspiratory and expiratory limbs) may also be helpful, but administration of dantrolene is the first priority.[110]

The anesthesia provider should give dantrolene intravenously in a dose of 2.5 mg/kg, and repeat every 5 to 10 minutes until the signs and symptoms (e.g., tachycardia, hypercarbia, rigidity, fever) have subsided.[111] A new formulation of dantrolene (Ryanodex) was approved for use in the United States in 2014. In contrast to earlier formulations (Dantrium, Revonto) which contain 20 mg of dantrolene sodium powder and 3000 mg of mannitol per vial, the new formulation contains 250 mg of lyophilized dantrolene with 125 mg of mannitol per vial. The major advantage of Ryanodex is that it dissolves more easily in a smaller volume of sterile water (5 mL/vial versus 60 mL/vial for the older formulations), and therefore it can be administered more quickly (it reconstitutes as a suspension rather than a solution).[84] Although the maximum dantrolene dose is often listed as 10 mg/kg, there are case reports in which higher doses of dantrolene were required to control an MH reaction. If a dose of greater than 10 mg/kg is required, one should consider alternate diagnoses.

Oxygen saturation, end-tidal CO_2, ECG, blood pressure, arterial and venous blood gas measurements, core temperature, potassium levels, lactate concentration, CK levels, coagulation profile, urine output, and urine myoglobin should be monitored. Depending on the patient's condition, implementation of arterial and/or central venous pressure monitoring can be considered.

BOX 46.6 Management of Malignant Hyperthermia Crisis

1. Call for help, and obtain dantrolene.
2. Notify the surgeon to finish surgery as quickly as possible.
3. Discontinue all triggering agents.
4. Hyperventilate with 100% oxygen at high gas flows (≥10 L/min). If available, insert charcoal filters into the breathing circuit.
5. Administer dantrolene 2.5 mg/kg intravenously. Repeat until signs and symptoms resolve.
6. Perform serial blood gas measurements. Treat acidosis with sodium bicarbonate 1 to 2 mEq/kg.
7. Treat hyperkalemia with sodium bicarbonate, glucose, insulin, and calcium.
8. Treat arrhythmias with antiarrhythmics, but avoid calcium entry-blocking agents.
9. If temperature greater than 39°C or rising rapidly, cool patient (administration of cold intravenous solutions, removal of covers, cooling of room temperature, surface cooling with ice and/or cooling blanket, peritoneal lavage with iced saline, use of new cooling devices).
10. Maintain urine output with fluids, mannitol, and/or furosemide.
11. Call the Malignant Hyperthermia Hotline for assistance (1-800-MH-HYPER).
12. Postoperatively, monitor patient in intensive care unit for 24 to 48 hours. Administer maintenance dantrolene for 24 hours or longer. Discontinue when metabolically stable.
13. Counsel patient and family, and refer for caffeine-halothane contracture test.

Modified from Malignant Hyperthermia Association of the United States. Emergency treatment of an acute MH event. September 2011. https://www.mhaus.org/healthcare-professionals/. Accessed March 2018.

The anesthesia provider must initiate treatment of acidosis, hyperkalemia, arrhythmias, and hyperthermia. Metabolic acidosis (base excess greater than –8 mEq/L) is treated by administering sodium bicarbonate in 1- to 2-mEq/kg increments, as guided by blood gas and pH measurements. Hyperkalemia (K^+ greater than 5.9 mEq/L) is treated by administration of calcium chloride (10 mg/kg) or calcium gluconate (30 mg/kg intravenously), sodium bicarbonate (1 to 2 mEq/kg intravenously), and glucose and insulin (10 units regular insulin intravenously; 50 mL of 50% glucose intravenously). Glucose levels should be monitored.

Early administration of dantrolene often prevents or successfully treats arrhythmias. If arrhythmias persist, one should follow standard advanced cardiac life support (ACLS) protocols. Amiodarone, lidocaine, procainamide, and adenosine may be used safely. Calcium entry–blocking agents should be avoided because simultaneous administration of dantrolene and a calcium entry–blocking agent may precipitate cardiovascular collapse.[100]

The operating room care team should actively cool the patient if the core temperature is greater than 39°C (or less, if rising rapidly). Options for doing so include (1) intravenous administration of cold saline; (2) removing blankets and cooling the room temperature; (3) surface cooling with ice and/or a hypothermia blanket; (3) peritoneal lavage with iced saline; and (4) new devices specifically developed for rapid cooling.[112] Cooling should stop when core temperature reaches 38°C.

Myoglobin is excreted in the urine. Thus, diuresis should be maintained by giving adequate volumes of crystalloid and furosemide 1 mg/kg and/or mannitol 0.25 g/kg. Mannitol is present in dantrolene, and separate administration of a diuretic agent may not be required. Ryanodex contains significantly less mannitol than the older formulations of dantrolene. Sedation should be administered as necessary.

After an acute episode of MH, postoperative administration of dantrolene (1 mg/kg or more intravenously every 4 to 6 hours for 24 to 48 hours) is recommended. In addition, the patient should be monitored closely in an intensive care unit for at least 24 to 48 hours. In a retrospective analysis of data from the North American Malignant Hyperthermia Registry, 20% of patients had recrudescence of MH after the initial MH episode.[113] Recrudescence was associated with increased muscle mass and a longer interval between anesthesia induction and intraoperative reaction. Counseling and diagnostic muscle biopsy should be performed after recovery from the acute episode. The Malignant Hyperthermia Association of the United States provides a registry and an informative newsletter for MH-susceptible patients. An MH hotline (800-MH-HYPER [800-644-9737] or, outside the United States, +1-209-417-3722) is available 24 hours a day to assist physicians with questions on treatment, diagnosis, and follow-up.

DANTROLENE IN PREGNANCY

Dantrolene is the drug of choice for the treatment of MH crisis. Dantrolene works by blocking the release of calcium from the sarcoplasmic reticulum of skeletal muscle cells.[114] It crosses the placenta and can be detected in the fetus after maternal administration.[115] Clinical doses do not adversely affect maternal or fetal cardiovascular and acid-base measurements in gravid ewes. Morison[71] reported a fetal-to-maternal serum dantrolene concentration ratio of approximately 0.4 after prophylactic oral administration of dantrolene. In one study in which oral dantrolene was administered prophylactically, there were no adverse effects on the fetus or newborn,[116] but theoretically, dantrolene may cause neonatal hypotonia if administered before delivery.

There is one published report of postpartum uterine atony after the administration of dantrolene.[10] Laboratory testing of the effects of dantrolene sodium on pregnant uterine muscle suggests that the relaxant effect is secondary to the mannitol.[117]

There is no benefit to dantrolene prophylaxis in the MH-susceptible patient when triggering agents are avoided.[114] However, the anesthesia provider should give dantrolene promptly when an MH crisis is suspected.

Fricker et al.[118] reported serial measurements of dantrolene concentrations in breast milk after administration of dantrolene in a patient with suspected MH during cesarean delivery (Fig. 46.2). The authors estimated that the half-life of dantrolene in breast milk is approximately 9 hours. They concluded that "breast-feeding can be expected to be safe for the newborn 2 days after discontinuation of intravenous dantrolene administration in the mother."[118]

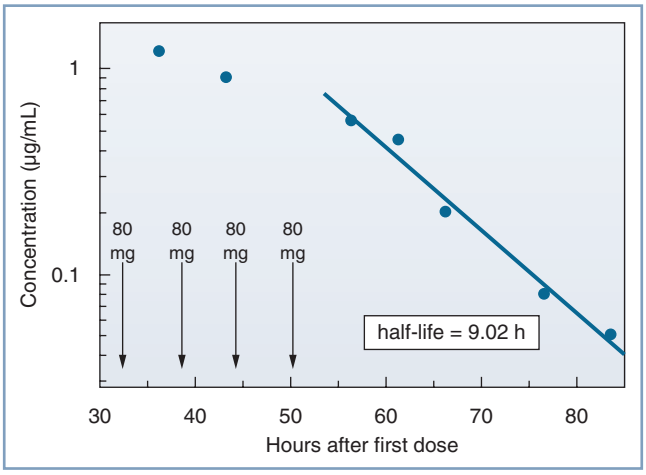

Fig. 46.2 Estimation of the half-life of dantrolene in breast milk by log-linear fitting of the terminal elimination phase (dantrolene measured in breast milk by high-pressure liquid chromatography, reverse-phase high-pressure liquid chromatographic column, by in-line ultraviolet absorption spectrometer; detection limit, 0.02 µg/mL). (From Fricker RM, Hoerauf KH, Drewe J, Kress HG. Secretion of dantrolene into breast milk after acute therapy of a suspected malignant hyperthermia crisis during cesarean section. *Anesthesiology*. 1998;89:1023–1025.)

KEY POINTS

- Malignant hyperthermia is a heterogeneous disorder of skeletal muscle with variable clinical penetrance.
- Affected individuals develop a hypermetabolic syndrome on exposure to triggering agents (succinylcholine, volatile halogenated agents).
- The current diagnostic test is the caffeine-halothane contracture test.
- Current genetic testing has low sensitivity.
- It is unclear whether pregnancy alters susceptibility to MH.
- Both the obstetrician and the anesthesia provider should encourage early administration of neuraxial analgesia during labor in MH-susceptible patients.
- The anesthesia provider may convert epidural *analgesia* to epidural *anesthesia* for emergency cesarean delivery and thus avoid administration of general anesthesia.
- All local anesthetic agents are safe in MH-susceptible patients.
- If general anesthesia is indicated, the anesthesia provider should avoid succinylcholine and volatile halogenated agents in MH-susceptible patients.
- Intravenous administration of dantrolene is lifesaving treatment for MH crisis.
- Dantrolene crosses the placenta and may result in neonatal hypotonia if administered before delivery.
- Dantrolene may cause uterine atony.
- The anesthesia provider need not administer dantrolene prophylactically to MH-susceptible parturients.

Musculoskeletal Disorders

Roanne Preston, MD, FRCPC

CHAPTER OUTLINE

Pregnancy commonly results in musculoskeletal complaints. Although these complaints typically are benign and self-limited, symptoms may be disabling in some women. In addition, preexisting musculoskeletal disorders interact with pregnancy to a variable extent. These interactions range from an ameliorating effect of pregnancy on the course of the disease (e.g., rheumatoid arthritis) to the potential for significant and possibly life-threatening deterioration in maternal condition (e.g., uncorrected severe thoracic scoliosis). The purpose of this chapter is to discuss the most common musculoskeletal disorders encountered in pregnant women and their implications for obstetric and anesthesia providers.

LUMBOPELVIC PAIN OF PREGNANCY

Lumbopelvic pain is the most common musculoskeletal complaint during pregnancy; it comprises two distinct areas of discomfort: (1) the lumbar spine area (low back pain) and (2) the posterior pelvic girdle area (from the sacroiliac joints radiating down into the posterior thighs), which has been termed *pelvic girdle pain.*[1] Pregnancy-related lumbopelvic pain occurs at some time during gestation in more than 50% of pregnant women and impairs at least one normal activity of daily life, including sleep; the prevalence ranges from 25% to 70%. It is the most common reason for sick leave during pregnancy. Women who complain primarily of pelvic girdle pain report more disability during pregnancy than those with isolated lumbar pain.[1,2] Severe pelvic girdle pain is seen in less than 0.5% of women; however, differentiation between pelvic girdle pain and low back pain is important because the management differs and the disability of pelvic girdle pain is more likely to extend into the postpartum period for up to 1 to 2 years. There are indices developed specifically for the pregnant woman to assist in diagnosis and determining the degree of disability; the Pregnancy Mobility Index and Overall Complaints Index are examples.[3] Risk factors for pregnancy-related lumbopelvic pain include a history of low back pain, young age, hypermobile joints, low socioeconomic class, multiparity, and spondylolisthesis; the strongest factors are prior history of lumbopelvic pain, previous non–pregnancy-related low back pain, and strenuous work.[1,4] In addition, there are psychological determinants affecting the

development of lumbopelvic pain. Women who score high on the stress and fear domains are more likely to have significant lumbopelvic pain. Women who have high pain scores on pain threshold testing are also more likely to develop lumbopelvic pain.[3,5]

The etiology includes hormonal and mechanical factors. The corpus luteum synthesizes and releases relaxin, and maternal blood concentrations of this peptide hormone increase 10-fold during gestation. Relaxin induces ligamentous softening and peripheral and pelvic joint laxity, which cause instability of the symphysis pubis and sacroiliac joints; the extent of instability and disability may be related to the maternal concentration of relaxin. There is a correlation between serum levels of relaxin and the occurrence of back pain during pregnancy; women with incapacitating symptoms have the greatest serum concentrations of relaxin.[6]

Mechanical changes have a later onset than hormonal changes. Women with pelvic girdle pain have increased pelvic joint motion, which increases sheer forces across the joints and likely results in pain. In all pregnant women, uterine enlargement results in a forward rotation of the sacrum and an increase in the lumbar lordotic curve, which tends to close the lumbar interlaminar space (see Fig. 2.10). This change exaggerates the mechanical load borne by both the facet joints and the posterior aspect of the intervertebral discs. These mechanical changes also may compromise nerve root foramina. Sciatica occurs in 1% of pregnant women, and most cases occur late in pregnancy. Sciatica is distinguished from pelvic girdle pain by its extension to the ankle or involvement of the foot, and it may be associated with neurologic changes. Disc herniation and sacral stress fractures are rare in pregnancy but do occur.[7,8] Incapacitating pain that radiates below the knee, typically accompanied by progressive neurologic deficits or bowel and bladder dysfunction, distinguishes disc herniation from the more common and benign pregnancy related-lumbopelvic pain.[7]

In summary, hormonal changes cause sacroiliac joint dysfunction, which is responsible for the lumbopelvic pain that occurs early in pregnancy. Mechanical changes are primarily responsible for the pain that manifests during late gestation, although symphysis pubis and sacroiliac joint instability may also continue to cause pain. Disc herniation is uncommon and is characterized by the presence of neurologic findings.

Obstetric Management

Treatment is conservative in the absence of neurologic compromise. The many studies now published on various treatment modalities for lumbopelvic pain have discordant results. Moderate quality evidence from single studies supports the use of structured exercise programs, acetaminophen administration, osteomanipulative therapy, pelvic belts, and acupuncture in the treatment of lumbopelvic pain.[9] However, a 2015 systematic review revealed overall low-quality evidence supporting exercise therapy for low back pain and no effect on pelvic girdle pain.[10] If nonrandomized controlled studies are included in the analysis, the evidence suggests combining modalities is the most effective strategy.[11] Patients with severe neurologic signs or symptoms of disc herniation should be assessed by a consultant neurosurgeon or neurologist who can provide recommendations for intrapartum and postpartum care. In a woman with severe symptoms, the obstetrician may choose to perform elective assisted vaginal delivery to decrease maternal work and back stress during the second stage of labor; however, this strategy does not protect against having postpartum pelvic girdle pain.[9] Because the disability associated with lumbopelvic pain, especially pelvic girdle pain, can impair the woman's ability to function postpartum, it is important to diagnose pregnancy-related lumbopelvic pain and treat it appropriately.

Anesthetic Management

No evidence suggests that epidural or spinal anesthesia is contraindicated in patients with pregnancy-related lumbopelvic pain. The anesthesia provider may administer neuraxial anesthesia, even to patients with sciatica. However, neurologic signs and symptoms should be first identified, delineated, and recorded. It seems prudent to administer a dilute solution of local anesthetic, with or without an opioid, to minimize motor block associated with epidural analgesia during labor to reduce any further stress on relaxed sacroiliac joints. Women with lumbopelvic pain may be reluctant to have neuraxial anesthesia because of concern that it may aggravate symptoms. The literature does not support this fear, and reassurance may be required.

Careful attention to the positioning of the patient with back complaints is critical. The patient must not be placed in a position that she could not tolerate before the administration of neuraxial anesthesia. The lithotomy position puts significant stress on the lower back and should be avoided whenever possible. If it is used, care must be taken to raise and lower both legs simultaneously to prevent injury to the lumbar spine and to avoid extremes when positioning the legs. Finally, caregivers should avoid rotational movements of the spine during transfer of the patient between the bed and the operating table.[1]

CHRONIC LOW BACK PAIN

Approximately 50% of pregnant women with a previous history of back pain or those with chronic low back pain experience a recurrence or exacerbation of their symptoms during pregnancy.[4] Neuraxial anesthesia may be more likely to fail in patients with chronic low back pain and in those who have had back surgery,[12,13,14] although newer data are conflicting.[15] Benzon et al.[12] reported a delayed onset of epidural anesthesia in patients with back pain or sciatica; the affected roots were blocked 10 to 70 minutes later than the contralateral roots at the same level. The delay in block onset most likely results from the inability of the local anesthetic agent to diffuse into the area of the injured root. Luyendijk and van Voorthuisen[16] evaluated 600 epidurograms and confirmed that contrast material failed to reach the nerve root in

33% of patients with uncomplicated disc prolapse and did not move beyond the affected disc space in 5% of cases. This may be caused by epidural space scarring and adhesions that may develop during healing after disc injury. Prolapse of an intervertebral disc may result in relative or total obstruction of the flow of local anesthetic agent within the epidural space.

Sharrock et al.[13] reported a 91.2% success rate of epidural anesthesia in nonobstetric patients with a history of limited spine surgery, as compared with a 98.7% success rate in patients without back surgery. The greater failure rate was postulated to be secondary to the distortion of surface anatomy and the tethering of the dura to the ligamentum flavum by scar formation, which renders the epidural space discontinuous or obliterated. Support for this hypothesis is provided by LaRocca and Macnab's[17] description of the postlaminectomy membrane. They noted the postlaminectomy formation of organized fibrous tissue surrounding the dura and, at times, binding of the nerves to the posterior aspect of the disc and adjacent vertebral body. The fibrous response was proportional to the extent of surgical trauma and was more marked with greater operative exposures. Postlaminectomy spinal stenosis also may lead to attenuation or obliteration of the epidural space, and the most common site of obstructive stenosis is immediately above the fusion mass.[18]

In contrast, Bauchat et al.,[15] in a prospective observational, case-controlled study of 42 women with a history of discectomy and 42 matched control women studied between 2007 and 2010, found no difference in the total bupivacaine consumption (primary outcome), duration of the neuraxial procedure, or need for epidural catheter replacement between the postlaminectomy parturients and the control parturients after combined spinal-epidural (CSE) or epidural labor analgesia. The only difference between groups was the need to attempt more than one interspace more often in the postlaminectomy group. A possible explanation for the difference in the Bauchat et al. study[15] to former studies[13] is that surgical techniques have changed in the past half century, and newer techniques may cause less trauma and scarring in the epidural space.

Obstetric Management

It is not uncommon for obstetricians to offer pregnant women who have had persistent chronic low back pain the option of cesarean delivery to decrease the potential for further back injury during labor. There are no data to either encourage or discourage this option.

Anesthetic Management

The anesthesia provider may offer epidural or spinal anesthesia to patients with previous lumbar spine pathology or surgery after an appropriate history and screening examination to identify any neurologic deficits. A decreased incidence of successful epidural anesthesia is possible, especially in patients who have had extensive surgery. Nonetheless, the experienced anesthesia provider will likely administer epidural anesthesia successfully in most patients. Subarachnoid anesthesia is likely to be more reliable than epidural anesthesia in this patient population.

POSTPARTUM BACKACHE

Postpartum backache is a common complaint worldwide, occurring in at least 25% of women, with 5% to 7% of women seeking medical help. Evidence emerged in the early 1990s implicating epidural labor analgesia as the cause for postpartum backache.[19,20] These original investigations were based on postal surveys, notably provided to women up to 9 years after childbirth.[19] These studies were followed by several prospective studies to eliminate the potential for reporting bias that may confound retrospective surveys.

Macarthur et al.[21] prospectively studied the association between epidural analgesia and early, new-onset postpartum backache in 329 women. In patients who labored without epidural analgesia, the incidence of postpartum backache was 43% at 1 day, 23% at 7 days, and 7% at 6 weeks. The incidence of symptoms in patients who had received epidural analgesia was greater on the first postpartum day (53%), but this increase did not persist. At 1 year postpartum, 12% of the patients had back pain (9.9% in the epidural group and 13.8% in the control group). Howell et al.[22] performed a randomized controlled trial comparing epidural with nonepidural labor analgesia in 369 nulliparous women. There was no difference in the incidence or characteristics of postpartum backache at 3 and 12 months postpartum. In a follow-up study, there was no difference between the two groups in the incidence of back pain, disability, or movement restriction more than 2 years after delivery.[23]

Both transient and persistent postpartum backaches are common, but there is little evidence that they are related to the provision of epidural analgesia during labor. Similarly, no evidence suggests that denying a parturient epidural analgesia results in a lower incidence of back problems during the postpartum period. Factors associated with persistent postpartum backache include the presence of back pain before pregnancy, the presence of pregnancy-related lumbopelvic pain, cesarean delivery, and performance of physically demanding work.[1] Some evidence supports the use of osteopathic manipulation to help relieve postpartum backache.[24,25]

SCOLIOSIS

Scoliosis is a lateral deviation in the vertical axis of the spine. The severity of scoliosis is determined by measurement of the angle of the spinal curve, the Cobb angle, which is expressed in degrees (Fig. 47.1). The prevalence of minor curves is 4 per 1000 in the North American population; larger curves occur less frequently, predominantly in females. Severe scoliosis is relatively rare in pregnant women, occurring in 0.03% to 0.07% of pregnancies.[26] Although women with moderate to severe scoliosis constitute a small population of obstetric patients, pregnancy in this population is common.[27] Most cases of scoliosis are idiopathic, although some are associated with other conditions, most commonly neuromuscular disorders (Box 47.1).

Scoliotic curves can be divided into structural and nonstructural varieties. **Nonstructural curves** are those seen with

postural scoliosis, sciatica, and leg-length discrepancies. They do not affect the mobility of the spine and are nonprogressive. **Structural curves** are seen in patients with idiopathic scoliosis and with scoliosis resulting from the conditions listed in Box 47.1. Structural curves lead to reduced spinal mobility, and affected patients typically have a fixed prominence (rib hump) on the convex side of the curve. A rotatory component is associated with the structural scoliotic curve. The axial rotation of the vertebral body is such that the spinous processes rotate away from the convexity of the curve toward the midline of the patient (Figs. 47.2 and 47.3).[28] Deformation of the vertebral bodies results in shorter, thinner pedicles and laminae, and a more narrow vertebral canal on the concave side. Vertebral deformation is unusual in patients with a Cobb angle less than 40 degrees.

Scoliosis interferes with the formation, growth, and development of the lungs; the occurrence of scoliosis before lung maturity may reduce the number of alveoli that ultimately form. The pulmonary vasculature develops in parallel with

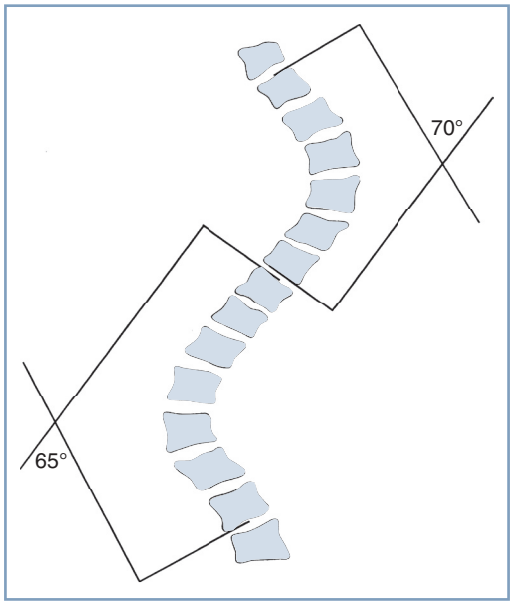

Fig. 47.1 Schematic representation of the Cobb angle. A line is drawn parallel to the superior cortical plate of the proximal end vertebrae and another line parallel to the inferior cortical plate of the distal end vertebrae. A perpendicular line is drawn to each of these lines. The angle of intersection is the Cobb angle of the curve.

BOX 47.1 Conditions Associated with Scoliosis

Congenital (Vertebral) Anomalies
- Hemivertebra
- Spinal dysraphism

Neurologic Disorders
- Cerebral palsy
- Polio
- Neurofibromatosis

Myopathic Disorders
- Myotonic dystrophy
- Muscular dystrophy

Connective Tissue Disorders
- Marfan syndrome
- Rheumatoid disease

Osteochondrodystrophies
- Achondroplasia/hypochondroplasia
- Osteogenesis imperfecta

Infection
- Tuberculosis

Previous Trauma

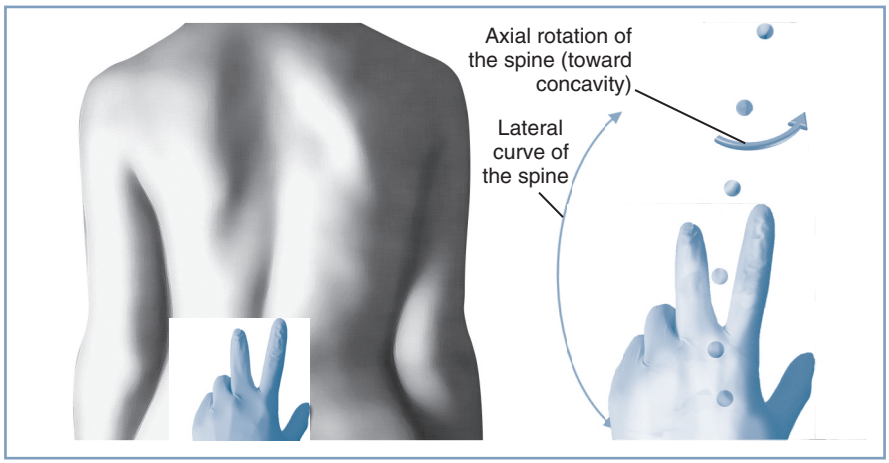

Fig. 47.2 Spinal rotation with scoliosis. *Left,* View of the lumbar spine in a patient with a scoliotic curve to the left demonstrating surface landmark palpation. *Right,* Skeletal anatomy at the same level in the same patient. There is a reduction in the dimensions of the interlaminar space on the concave side of the curve *(to the right)* and an expansion on the convex side. These changes are enhanced with greater severity of the curve. As the curve increases, the spinous processes rotate into the concavity of the curve, further altering the local anatomy. Surface landmark palpation from the view at left superimposed on the skeleton reveals how the palpated midline *(indicated by the white X)* is to the right of the true axial midline. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

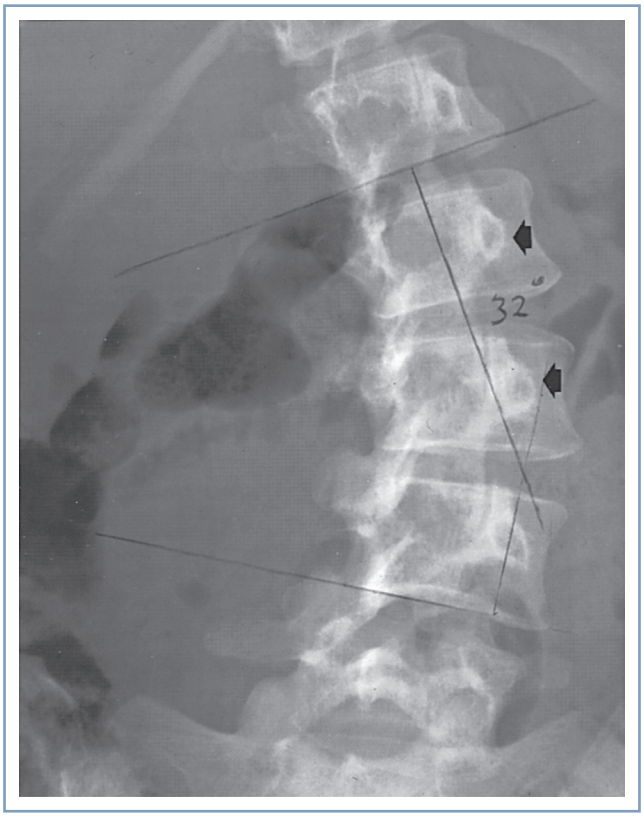

Fig. 47.3 Radiographic study of the lumbar spine in a 26-year-old woman with idiopathic scoliosis. The spinous processes and pedicles *(arrows)* are rotated away from the convexity and into the concavity of the curve. (The epidural space was entered easily with direction of the needle approximately 15 degrees off the perpendicular at the skin level toward the convexity of the curve.)

the alveoli; early-onset scoliosis and severe scoliosis may result in greater pulmonary vascular resistance and eventually lead to pulmonary hypertension. Musculoskeletal deformities also affect the mechanical function of the lungs; anatomic findings in scoliosis that are most commonly associated with respiratory compromise include the presence of a thoracic curve, thoracic lordosis, and a rib cage deformity. The most common pulmonary function abnormality is a restrictive pattern with decreases in vital capacity, total lung capacity, and lung compliance. This pattern occurs in all patients with a thoracic curve greater than 65 degrees. The functional residual capacity is reduced, and airways may close during normal tidal breathing. If the functional residual capacity is reduced to the extent that it falls below the closing capacity, atelectasis may occur in basal alveoli. The most common blood gas abnormality is an increased alveolar-to-arterial oxygen gradient, with reduced Pao_2 and a normal $Paco_2$. It results from both venoarterial shunting and altered regional perfusion. Venous admixture may lead to arterial hypoxemia. The natural history of severe, progressive scoliosis includes early death from cardiopulmonary failure.[29]

Permanent changes of the pulmonary vasculature are common in patients with a curve greater than 65 degrees. Pulmonary hypertension (a resting mean pulmonary artery pressure exceeding 25 mm Hg) occurs in many patients with severe deformity long before the onset of right-sided heart failure and is largely attributable to increases in vascular resistance resulting from chronic alveolar hypoxia, hypoxic pulmonary vasoconstriction, and anatomic changes in the vascular bed. Fixed pulmonary hypertension carries a grave prognosis in pregnancy and may prompt a recommendation to avoid or terminate pregnancy (see Chapter 41).

Scoliosis Associated with Neuromuscular Disease

When scoliosis develops secondary to a neurologic or myopathic disorder, abnormal respiratory function results not only from the skeletal deformity but also from abnormalities in the central control of respiration and the supraspinal innervation of the respiratory muscles, as well as from the loss of muscle function caused by the underlying disorder. Respiratory function may be further compromised by (1) impairment of the defense mechanisms of the airways caused by loss of control of the pharynx and the larynx, (2) an ineffective cough mechanism, and (3) infrequent or reduced large breaths. Recurrent aspiration pneumonitis may result from compromised protective airway reflexes. In general, the prognosis of scoliosis caused by neuromuscular disease is poorer than that of idiopathic scoliosis and is determined predominantly by progression of the primary disorder. Affected patients typically develop irreversible respiratory failure at a younger age, and pulmonary hypertension is common; pregnancy is uncommon in this population.

Interaction with Pregnancy

Pregnancy may exacerbate both the severity of the spinal curvature and cardiopulmonary abnormalities in women with uncorrected scoliosis. Progression of a curve, defined as an increase in the Cobb angle of 5 degrees or more over subsequent assessments, is more likely during periods of rapid growth and in patients with larger curves at the time of diagnosis. Curves that are less than 25 degrees or curves that have been stable before pregnancy typically do not progress during pregnancy.[30] In contrast, more severe curves and those that have not stabilized may worsen. Some investigators have described a correlation between the severity of the curve and maternal morbidity and mortality. However, it is likely that the severity of functional cardiopulmonary impairment before pregnancy is a better predictor of maternal outcome than the severity of the curve.[31] Patients with a severe curve (i.e., Cobb angle greater than 60 degrees) but good cardiopulmonary function tolerate pregnancy well, whereas in those with significant cardiopulmonary compromise, and especially in those with pulmonary hypertension, maternal mortality is high.[32]

The physiologic changes of pregnancy include decreases in both functional residual and closing capacities and increases in minute ventilation and oxygen demand. The thoracic cage normally increases in circumference during pregnancy as a result of increases in both anteroposterior and transverse diameters. If the chest cage is relatively fixed by scoliosis, the

diaphragm is responsible for all increments in minute ventilation. As the enlarging uterus causes elevation of the diaphragm, diaphragmatic activity is restricted and further decreases in residual and closing capacities may occur, which may result in both greater ventilation-perfusion mismatch and decreased arterial oxygen content. The antepartum onset of new symptoms of respiratory compromise or the exacerbation of preexisting symptomatology is associated with higher maternal morbidity and a greater likelihood that assisted ventilation will be required after cesarean delivery.[31] In a retrospective review from Canada of 12 women (15 pregnancies) with restrictive lung disease (defined as forced vital capacity less than 70%), Lapinsky et al.[33] found 20% had deterioration in pulmonary function during the pregnancy. Seven women had an initial forced vital capacity of less than 1 L; four of these women had underlying kyphoscoliosis.

Dyspnea on exertion is uncommon in patients with scoliosis who have curves less than 70 degrees, but it becomes more common as the deformity exceeds 100 degrees. In younger patients with a curve less than 70 degrees, exercise capacity is more likely to be impaired because of the lack of regular aerobic exercise and subsequent deconditioning rather than intrinsic ventilatory impairment.[34] Dyspnea is common in many pregnant women; two features help distinguish physiologic from pathologic dyspnea.[35] **Physiologic dyspnea** tends to occur earlier in pregnancy and often plateaus or even improves as term approaches. The **pathologic dyspnea** of cardiopulmonary decompensation more often begins in the second half of pregnancy and is progressive, often becoming most severe as gestation advances and the physiologic loading is maximal. Second, physiologic dyspnea is rarely extreme, and patients can maintain most daily activities. Dyspnea that is extreme or has a limiting effect on normal activity may signal maternal cardiorespiratory decompensation. Dyspnea at rest is also rare in the absence of cardiopulmonary dysfunction, as is dyspnea that is acute in onset or progressive and intractable.

Minute ventilation typically increases by 45% during pregnancy. Minute ventilation of the unmedicated parturient increases by a further 70% to 140% in the first stage of labor and by 120% to 200% in the second stage. Oxygen consumption increases above prelabor values by 40% in the first stage and 75% in the second stage (see Chapter 2). These levels may be unattainable by the scoliotic parturient with restrictive lung disease, and respiratory failure and hypoxemia may result during labor.

Pregnant women with pulmonary hypertension have a limited ability to increase cardiac output. During normal pregnancy, cardiac output increases 40% to 50% above nonpregnant measurements; during labor and delivery, even greater increases are observed. These increases are achieved with both larger stroke volume and a higher heart rate. These demands may put an excessive burden on the cardiovascular system in parturients who had marginal cardiac reserve before pregnancy. If the right ventricle fails in the presence of pulmonary hypertension, left ventricular filling will decrease and low-output failure and sudden death may occur.[32]

Surgical Management

During spinal fusion and instrumentation, the spinal musculature is reflected off the vertebrae over the course of the curve and the spinous processes and interspinous ligaments are removed. The spine is subsequently extended, correcting the curve. The vertebrae are decorticated throughout the extent of the planned fusion, instrumentation is placed, and bone graft material from the ileum is placed over the decorticated vertebrae. A number of techniques for fusion have been described, but all involve both spinal instrumentation and extensive bone grafting in the axial spine.

Obstetric Management

Pregnant women with corrected scoliosis tolerate pregnancy, labor, and delivery well. In the absence of major lumbosacral deformity, there is little alteration of the pelvic cavity, and malpresentation is not more common than in women without scoliosis. Uterine function is normal, and labor is not prolonged. Spontaneous vaginal delivery is anticipated, and cesarean delivery should be reserved for obstetric indications.

The literature is conflicting as to whether the cesarean delivery rate is greater in women with scoliosis with or without surgery.[26,36] In a retrospective study from Israel, 98 women with idiopathic scoliosis out of a cohort of more than 220,000 were reviewed for birth outcomes.[36] Women with scoliosis (corrected or uncorrected) were not found to have an increased risk for cesarean delivery. Conversely, Chopra et al.[26] reviewed pregnancy outcomes in 22 women with kyphoscoliosis (59% idiopathic) with a total of 34 pregnancies. In this study, 60% of women had severe restrictive lung disease, only one had surgical correction, and the cesarean delivery rate was greater than 75%. The difference in outcomes may be influenced by the severity and etiology of the scoliosis in the populations reviewed or differences in the local practice patterns for managing these patients.

Pelvic abnormalities are more common when scoliosis is associated with neuromuscular disorders and in patients with a severe, uncorrected curve. In addition, abdominal and pelvic muscle weakness predisposes parturients to problems with expulsion of the infant during the second stage of labor and may necessitate instrumental vaginal delivery. The need for instrumental or cesarean delivery is likely related to the severity of skeletal deformity, the resulting maternal compromise, and cephalopelvic disproportion.

In the second stage of labor, the diaphragm has a nonrespiratory function. With expulsive efforts, maximal isometric contractions may be sustained for 20 seconds or more, and diaphragmatic fatigue has been demonstrated even in normal, laboring women. In parturients whose diaphragmatic function is compromised by neuromuscular disease or severe scoliosis, the potential for fatigue and failure is greater; expulsive forces are decreased, the second stage may be prolonged, and a trial of labor may fail, necessitating instrumental or cesarean delivery. In addition, women with severe cardiopulmonary disease (especially those with gestational decompensation)

may require urgent or emergency cesarean delivery because of maternal compromise or nonreassuring fetal status.

Anesthetic Management

Pregnant women who have thoracolumbar scoliosis with a Cobb angle greater than 30 degrees or who have undergone spinal instrumentation and fusion for scoliosis should be referred to an anesthesia provider for antepartum consultation. The anesthesia provider should (1) determine the etiology of the scoliosis, as well as the severity and stability of the curve; (2) obtain a history of maternal musculoskeletal and cardiopulmonary symptoms; and (3) review prior obstetric and anesthetic experiences. For patients with scoliosis secondary to neuromuscular disorders, the anesthesia provider should also become familiar with anesthetic considerations specific to the underlying disorders.

Women with suspected or evident pulmonary compromise should undergo evaluation by a pulmonologist, and pulmonary function studies and arterial blood gas measurements should be obtained. These patients must be reevaluated periodically to ensure that they are tolerating the increasing physiologic demands of pregnancy. Echocardiography is useful to assess right-sided heart function in patients with one or more of the following: (1) a curve of 60 degrees or more, (2) hypoxemia on arterial blood gas measurement, (3) moderate or greater reductions in predicted lung volumes or flows, (4) pulmonary hypertension, and/or (5) evidence of decompensating cardiopulmonary status. Radiographic studies performed before pregnancy and operative notes describing spinal surgical procedures should be reviewed before neuraxial anesthesia is initiated in any patient with significant scoliosis or previous spinal surgery. The anesthesia provider should also examine the spine and note the surface landmarks and interspaces that are least affected by the deformity. Modes of analgesia and anesthesia for labor and delivery can be discussed during antepartum consultation.

Invasive hemodynamic monitoring is rarely indicated during labor and delivery. Pulmonary function studies that suggest significant respiratory compromise or clinical evidence of impending respiratory failure warrant placement of an arterial catheter and serial assessment of blood gas measurements. Echocardiographic demonstration of significant right-sided heart dysfunction may warrant invasive or noninvasive cardiac function monitoring.

The anesthesia provider may offer neuraxial analgesia for labor and delivery to patients with severe thoracolumbar scoliosis. Identification of the epidural space is more difficult in such patients, and the anesthesia provider should anticipate a greater incidence of complications. It is useful to remember the presence of the vertebral rotation during the performance of neuraxial anesthesia in a patient with a significant lumbar curve, which results in the spinous processes (which often may be structurally deformed) rotating into the concavity of the curve. Therefore, the midline of the epidural space is deviated toward the convexity of the curve relative to the spinous process palpable at the skin level (see Figs. 47.2 and 47.4). The extent of lateral deviation is determined largely by the severity of the deformity.[37] One method of placing an epidural or spinal needle is to direct the needle from a palpated spinous process toward the convexity of the curve, often at a significant angle. The experienced anesthesia provider can track the resistance of both the interspinous ligament and the ligamentum flavum to maintain the correct course into the epidural space. The extent of the local anatomic distortion is the limiting factor, and the selection of spaces that are least involved with the curve is advised. Huang[38] suggested a modified paramedian approach based on work by Boon et al.[39] in cadavers. The needle is placed lateral to the spinous process on the convex side of the curve (taking advantage of the wider interlaminar spaces on that side) and aimed directly perpendicular to the skin. The intent is to find lamina with the needle tip and then "walk up or down" the lamina to enter the epidural space (Fig. 47.4).

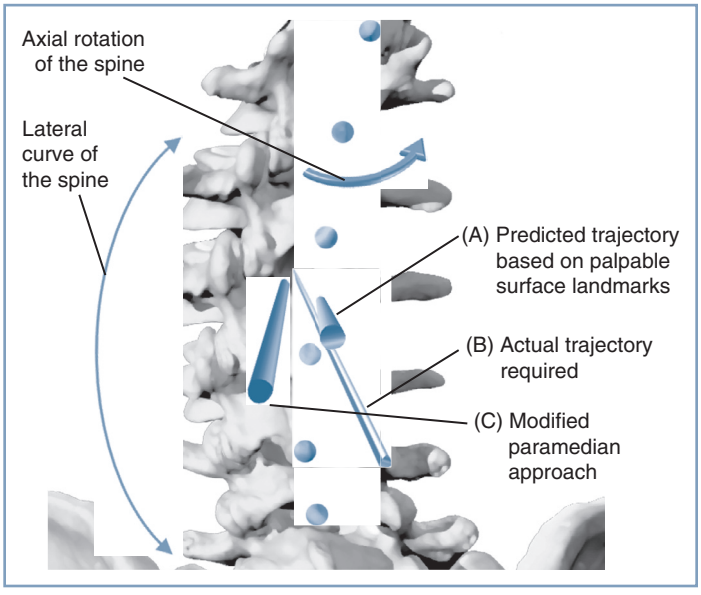

Fig. 47.4 Image of the lumbosacral vertebrae affected by a scoliotic curve to the left. Note the axial and lateral rotation of the vertebral bodies, and the rotation of the affected spinous processes *(blue dots)* into the concavity of the curve; these spinous processes are frequently anatomically abnormal. The apparent midline *(trajectory A)* suggested by palpated surface landmarks is to the right of the true axial midline. The figure demonstrates two approaches to enter the epidural/subarachnoid space: one where the needle is directed along the line of a spinous process toward the convexity of the curve *(trajectory B),* and the other a modified paramedian approach where needle entry starts on the convex side of the curve and is directed perpendicular to the skin *(trajectory C).* (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

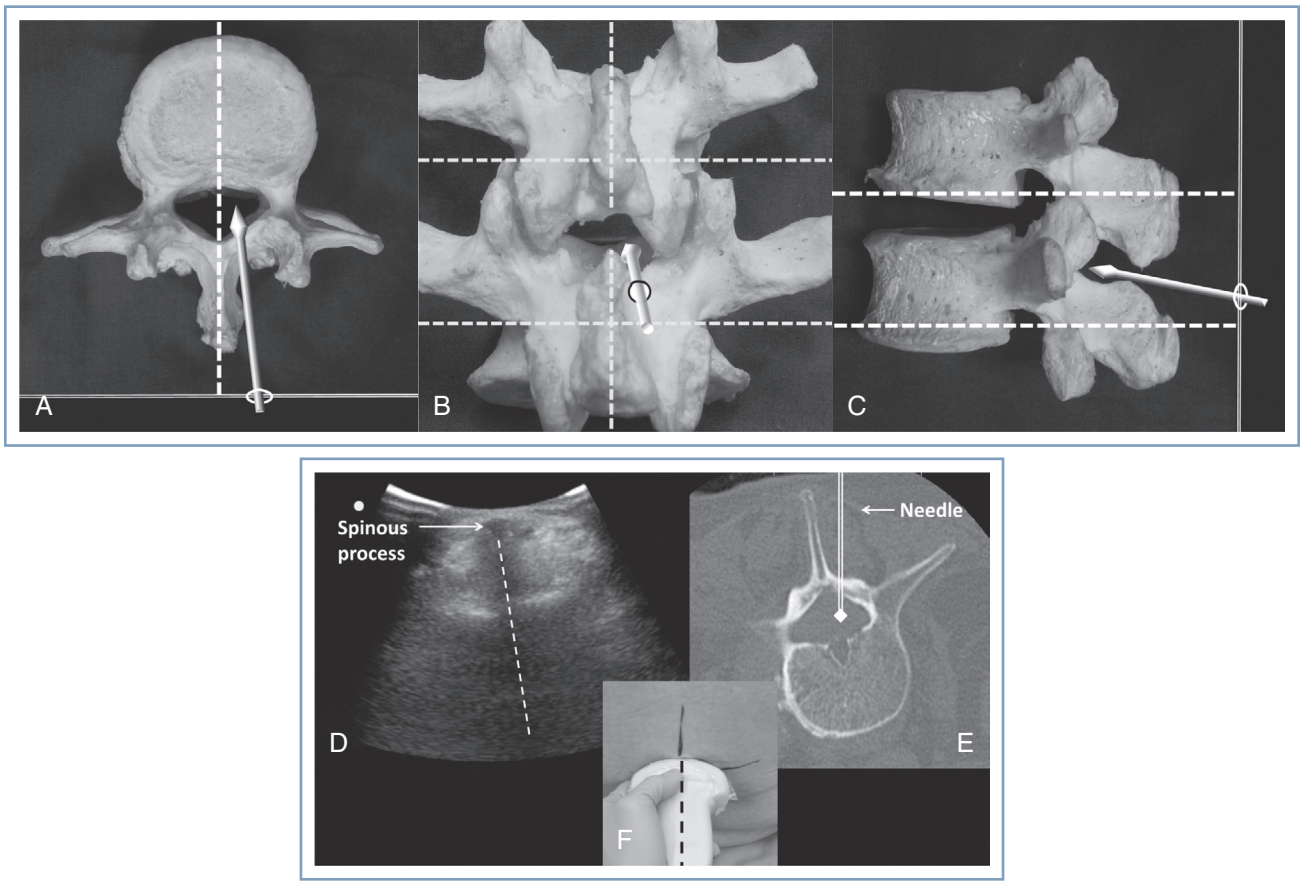

Fig. 47.5 Ultrasonography-assisted paramedian approach to neuraxial blockade in patients with difficult anatomy. An illustration of needle trajectory in the paraspinous approach in (A) the axial view, (B) the anterior-posterior view, and (C) the lateral view of the spine. The white rectangle in (B) shows the transverse ultrasound probe position used to establish the position of the neuraxial midline and spinous processes *(white dotted lines)*. Ultrasonography (D) and computed tomography (E) axial images of spine rotation in a patient with lumbar scoliosis. When the ultrasound probe is placed perpendicular to the patient's back (F), the rotation is evident from the angulation of the acoustic shadow of the spinous process. Paraspinous needle insertion should be performed 1 cm lateral to the midline (defined by the tip of the spinous process), but without medial angulation. (Reprinted with permission from Chin KJ, Perlas A, Chan V. The ultrasound-assisted paraspinous approach to lumbar neuraxial blockade: a simplified technique in patients with difficult anatomy. *Acta Anaesthesiol Scand.* 2015;59:668–673.)

Ultrasonography is a useful technique to facilitate administration of neuraxial anesthesia in parturients with challenging spinal anatomy, including those with scoliosis.[40–43] Asymmetry of the spine is not difficult to appreciate; learning how to use the information and determine the optimal space and needle direction requires more experience.[44] The paramedian view may provide the best information with respect to the widest interlaminar space, and the transverse view shows presence of rotation and asymmetry.[39,42] There are a few studies on the use of preprocedural ultrasonography to identify the best space and angle of approach in parturients with difficult surface anatomy. Ekinci et al.[43] and Creaney et al.,[45] in two separate studies, randomized patients with poor palpable surface landmarks into ultrasonography-facilitated and landmark palpation-only groups. Both studies found fewer needle passes in the ultrasonography group with no increase in procedural time. Chin et al.[42] described a simplified technique for facilitating neuraxial anesthesia in patients with difficult anatomy, including scoliosis. Using a transverse view, the anesthesia provider can visualize the rotation of the spinous process and use this information to perform a more precise version of the paramedian technique described by Huang (Fig. 47.5).[38]

Local anesthetic dose requirements for epidural and spinal anesthesia in the patient with scoliosis are variable. Moreover, during administration of spinal anesthesia in a patient with a severe scoliotic curve, hyperbaric local anesthetic solution may pool in dependent portions of the spine, resulting in an inadequate block.[46] Thus, it may be preferable to use a continuous technique in women with severe scoliosis so that the dose of local anesthetic agent can be titrated to the desired segmental level of anesthesia.

When offering neuraxial anesthesia to patients with a history of corrective spine surgery, the anesthesia provider must consider the following potential problems:

- Persistent back pain occurs in many patients with corrected scoliosis and correlates with both the extent of fusion and the time since surgery.[47]
- Degenerative changes occur in the spine below the area of fusion, and there is a higher incidence of both retrolisthesis and spondylolisthesis.[47]
- Twenty percent of patients undergo fusion to the lowest lumbar levels, limiting the potential for neuraxial anesthesia.[41,48,49]
- Insertion of an epidural needle in the fused area may not be possible because of the presence of instrumentation, scar tissue, and bone graft material.
- Intraoperative trauma to the ligamentum flavum may result in adhesions in or obliteration of the epidural space, and these changes may interfere with the spread of injected local anesthetic.[17]
- Obliteration of the epidural space may increase the incidence of unintentional dural puncture.
- These patients often manifest a high level of anxiety about their backs and may be reluctant to have neuraxial anesthesia.

In 2009, Ko and Leffert[50] published a qualitative literature review on neuraxial anesthesia in the parturient with scoliosis. The review describes 117 attempted neuraxial procedures, the majority (93) in surgically corrected patients. Overall, 71% had a successful neuraxial block; however, the corrected patients proved to be more challenging, with a 69% success rate versus 79% for the uncorrected group. The challenges in corrected patients included (1) inability to place the needle (22%), (2) multiple attempts (13%), (3) patchy analgesia (10%), (4) excessive local anesthetic dose requirements (9%), (5) unintentional dural puncture (4%), and (6) inadequate analgesia (4%). In the uncorrected group, the issues included (1) patchy, asymmetric, or unilateral blocks (8% of each) and (2) multiple attempts or failed placement (4% of each). There were also two cases of persistent low back pain of unknown etiology. Complications occurred more frequently in patients with fusion that extended to the lower lumbar and lumbosacral interspaces than in those with fusions that ended in the upper lumbar spine. These findings were corroborated by Bauchat et al.[41] in a prospective case-matched study in which 41 women with previous corrective surgery were compared with 41 healthy matched controls. The rate of neuraxial analgesia failure was higher (12% versus 0%) and the mean time to placement longer (by 41%) in the surgical correction group; however, there was no difference in local anesthetic requirements to maintain analgesia.

Thus, in patients with severe or corrected scoliosis, both the anesthesia provider and the patient should anticipate the possibility that neuraxial analgesia may fail with or without ultrasonography. Alternative modes of intrapartum analgesia include administration of single-shot technique spinal analgesia (may be repeated), caudal analgesia, patient-controlled intravenous opioid analgesia, and inhalation analgesia especially with nitrous oxide.[50] Continuous spinal analgesia or anesthesia is a reasonable alternative to epidural analgesia or anesthesia for labor or cesarean delivery in parturients who have undergone major spinal surgery with instrumentation. The dural-puncture epidural (DPE) technique may also be considered as the presence of cerebrospinal fluid (CSF) confirms the epidural needle tip location and may enhance spread of epidural local anesthetic (see Chapter 12).[50,51]

CHRONIC INFLAMMATORY ARTHRITIDES

This group of diseases includes rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and undifferentiated arthritis. Of these, rheumatoid arthritis is most affected by pregnancy and has been studied most extensively with respect to the immunologic relationship between mother and fetus. The most common arthritides seen in pregnancy are rheumatoid arthritis and ankylosing spondylitis.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic disorder characterized by synovial proliferation that leads to joint destruction and subsequent deformity. It is becoming increasingly a disease of older people. From 1985 to 2005, the overall prevalence in the United States fell from 1.07% to 0.6%; the greatest decline in prevalence occurred among people younger than 55 years of age.[52] The disease occurs approximately two times more frequently in women than in men.[52]

The lumbosacral spine is affected in only 5% of patients with rheumatoid arthritis. In contrast, the cervical spine is commonly involved, and atlantoaxial subluxation occurs in 30% to 45% of patients with rheumatoid arthritis.[53,54] Although atlantoaxial subluxation may occur early in the course of the disease, it most often occurs in patients with a history of 5 years or more of highly active and erosive disease.[55] Atlantoaxial subluxation occurs as a result of an attenuation or disruption of the transverse ligament, which allows anterior movement of C1 on C2 during neck flexion. Radiographically, atlantoaxial subluxation is marked by an increase in the atlas-dens interval, which is best demonstrated on the lateral cervical spine radiograph with the neck flexed (Fig. 47.6).

Vertical subluxation of the odontoid process is associated with a scoliotic deformity of the trachea and larynx.[56] The deformity is complex, involving both rotation and deviation of the larynx from the midline, and it may make laryngoscopy and tracheal intubation difficult. However, vertical subluxations occur primarily in older patients with severe, long-standing disease and are unlikely to be seen in women of childbearing age. Other airway issues such as cricoarytenoiditis and temporomandibular joint (TMJ) dysfunction may occur earlier in the disease and may complicate airway management of the parturient.[57]

Extra-articular features are common in patients with rheumatoid arthritis. Anesthesia providers have a special interest in abnormalities that affect the airway and the cardiovascular and respiratory systems (Box 47.2). Although

Fig. 47.6 Lateral radiographic study of the cervical spine (in flexion) in a 32-year-old woman with rheumatoid arthritis. There is isolated atlantoaxial subluxation (6 mm) in the absence of other radiologic changes of rheumatoid arthritis. She presented with neck pain, and a wire was placed between the occiput and the spinous process of C2 to limit the subluxation.

BOX 47.2 Extra-articular Features of Rheumatoid Arthritis

Cardiovascular
- Pericarditis
- Pericardial effusions
- Endocardial vegetations
- Myocardial nodules—conduction disturbance
- Arteritis/vasculitis

Airway
- Mandibular hypoplasia
- Cricoarytenoiditis
- Temporomandibular joint dysfunction
- Laryngeal deviation and rotation

Pulmonary
- Pleural effusion
- Pulmonary fibrosis
- Pulmonary nodules

Chest Wall
- Costochondritis

Neurologic
- Peripheral nerve compression
- Cervical nerve root compression

Hematologic
- Anemia
- Felty's syndrome

Ophthalmic
- Keratoconjunctivitis

these complications occur more typically in patients with long-standing disease, it is prudent to inquire about those with more significant anesthetic implications. Cardiovascular mortality is especially high in patients with rheumatoid arthritis. Similar to patients with type 2 diabetes mellitus, cardiovascular disease often presents atypically.[57]

Interaction with Pregnancy

Rheumatoid arthritis is associated with a higher incidence of preterm birth, small-for-gestational-age infants, preeclampsia, and elective cesarean delivery compared with reference populations of women in North America and Europe.[58] In the absence of vasculitis, fetal outcome is good, although as a group, the chronic inflammatory arthritides are associated with higher perinatal morbidity.[58] Although earlier evidence consistently showed that pregnancy has a beneficial, ameliorating effect on the activity of rheumatoid arthritis, more recent prospective studies using objective and validated disease scoring systems have shown less benefit. Remission occurs in only 16% to 39% of patients, and improvement in symptoms in 39% to 65% of patients, rather than the previously quoted 75%.[59] The improvements in disease activity (pain, swelling, stiffness) occur despite the discontinuation of effective but teratogenic disease-modifying antirheumatic drugs and a substantial reduction in the dose of safe drugs (e.g., corticosteroids). Relapse occurs postpartum in approximately 35% to 75% of women, beginning as early as the second week after delivery. It appears that most women return to a disease status comparable to their prepregnant state. Current emphasis is on continuing appropriate medications during pregnancy, as a substantial number of women will have moderate to high disease activity.

Medical Management

Drug therapy for rheumatoid arthritis is divided into (1) symptom-modifying drugs, (2) disease-modifying antirheumatic drugs, and (3) biologic drugs.

Symptom-modifying therapies include nonsteroidal anti-inflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors and glucocorticoids. **NSAIDs** and **glucocorticoids** have been the mainstay of therapy in rheumatoid arthritis during pregnancy for many years.[60] A small study of COX-2 inhibitors revealed an increase in congenital anomalies; hence, they are best avoided in pregnancy.[61] In a population-based cohort study, NSAID use in early pregnancy, especially around the time of conception, was associated with an increased incidence of early pregnancy loss.[62] When used later in pregnancy, NSAIDs are associated with premature closure of the ductus arteriosus and increased risk for neonatal bleeding. Although a large multicenter epidemiologic study did not find an association between NSAID consumption during pregnancy and pulmonary hypertension of the newborn,[63] the current recommendation is that all NSAIDs except low-dose aspirin be discontinued at 32 weeks' gestation.

Nonfluorinated glucocorticoids (prednisone, prednisolone) are considered safe in pregnancy after the first trimester,

but early use is associated with a small increase in the incidence of cleft palate.[60] High doses and use later in pregnancy increase the risk for gestational diabetes, gestational hypertension, and premature rupture of the membranes.

Disease-modifying antirheumatic drugs reduce flares, prevent joint erosions, and have proven efficacy in decreasing morbidity and mortality from rheumatoid arthritis. This drug category includes sulfasalazine, azathioprine, methotrexate, leflunomide, gold salts, and antimalarial agents. **Methotrexate** is considered a first-line treatment for rheumatoid arthritis and is typically started at diagnosis, but unfortunately it and **leflunomide** are highly teratogenic and must be stopped several months before conception.[60] **Sulfasalazine** inhibits folate synthesis, and therefore additional folate supplementation is required during pregnancy. **Azathioprine** may be used during pregnancy at doses less than 2 mg/kg/day, although other options are preferable.

The **biologic drugs,** which are proving as effective as methotrexate in preventing erosions and reducing long-term disability, include **the anti–tumor necrosis factor therapies (anti-TNF)** (e.g., etanercept, certolizumab). Experience with these drugs has grown considerably as they are also used in inflammatory bowel disease; overall they appear safe in pregnancy.[59,64,65] A 2016 analysis of data from health registries in Denmark and Sweden identified 683 women who had received TNF inhibitor therapy in early pregnancy; the odds ratio for any birth defect was not significantly greater than in women with chronic inflammatory disease who were not treated with anti-TNF therapy.[66] In contrast, there is little collective evidence on the use of other biologic drugs (e.g., **abatacept, rituximab, tocilizumab**) in pregnancy, or they have been associated with adverse fetal effects. Thus, the recommendation is to discontinue these drugs before conception.[64] There is insufficient information on the newest class of drug, the **JAK-1 inhibitors,** to make any recommendations.[60]

Avoiding disease flares by optimal medical management with acceptable therapies is becoming the standard, rather than the preconception discontinuation of successful antirheumatic drugs that have been shown to be safe for use in pregnancy.

Obstetric Management

Vaginal delivery is preferred for parturients with rheumatoid arthritis, and cesarean delivery should be reserved for obstetric indications. A major concern is maternal positioning during labor. Rheumatoid joints are unstable because of ligament loosening associated with chronic swelling and because of the destruction of ligaments and cartilage. It is important to determine the permissible range of motion and activity for affected joints. Special emphasis should be given to the hips, knees, and neck. Physicians and nurses should be aware of the potential risks associated with forcing motion beyond the disease-imposed limits.

Anesthetic Management

The preanesthetic evaluation should include a careful evaluation of the airway. Patients with rheumatoid arthritis may have a small mandible, TMJ dysfunction, cricoarytenoid arthritis, and laryngeal deviation, all of which may complicate direct laryngoscopy.[57] In particular, these findings may be present in parturients with juvenile rheumatoid arthritis. Cervical spine involvement is not common in young patients but may occur in patients with disease of long duration and in those with severe, deforming disease—typically, patients with juvenile rheumatoid arthritis. Although there is no guideline or consensus on the need to obtain cervical spine radiographs in patients with rheumatoid arthritis, it would be reasonable even in the pregnant woman if her rheumatoid arthritis includes severe erosive disease, neck symptoms, or a history of disease of 10 or more years' duration.[57] The cardiac and pulmonary features of rheumatoid arthritis are not common in young patients, but signs and symptoms of pleural and pericardial effusions and pulmonary parenchymal involvement should be sought.

No evidence contraindicates the administration of spinal or epidural anesthesia in patients with rheumatoid arthritis. However, evidence in the nonpregnant population has indicated that spinal blocks rise higher than expected in patients with rheumatoid arthritis, independent of body mass index.[67,68] Care should be taken to avoid excessive manipulation of the neck during administration of general anesthesia. Finally, joints should be padded and protected appropriately during labor and delivery.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic inflammatory arthropathy characterized by infiltration of granulation tissue into the bony insertions of ligaments and joint capsules, with subsequent fibrosis, ossification, and ankylosis. The disease is a major subtype of an interrelated group of rheumatic disease called the spondylarthritides, which are linked by the major histocompatibility complex (MHC) Class 1 tissue antigen HLA B27.[69] Ankylosing spondylitis primarily affects the sacroiliac, facet, and costovertebral joints; sacroiliitis is pathognomonic. There is progressive flexion and fusion of the spine and fixation of the rib cage; however, the clinical spectrum is wide, and only a small proportion of patients progress to total spinal ankylosis.

The global prevalence of ankylosing spondylitis is estimated to be 0.86%.[69] Onset is common during the second and third decades of life, a period of peak childbearing potential. The disease is milder in women than in men, but women are more likely to have peripheral arthritis and involvement of the cervical spine and symphysis pubis.[70] Although clinically significant lesions of the cervical spine may occur early in the course of the disease, they are far more common in patients with long-standing ankylosing spondylitis (Fig. 47.7).[56,71] Ultimately, 21% of patients with ankylosing spondylitis develop clinically significant atlantoaxial subluxation. TMJ involvement causes limited mouth opening in 10% of patients early in the disease, increasing to 30% to 40% as the disease progresses.[70] A slower development of radiologic changes of the dorsolumbar spine occurs in women, and spinal rigidity or deformity and extra-articular manifestations are rare in

Fig. 47.7 Lateral radiographic study of the cervical spine in a 31-year-old woman with ankylosing spondylitis. There is evidence of facet joint ankylosis *(arrowheads),* although the lordotic curve remains well preserved.

young patients (Box 47.3).[57,69] Individuals with ankylosing spondylitis are at risk for vertebral fractures. The prevalence ranges from 10% to 17%, the most common level is C5–C6, and the fractures are most likely to occur by the third decade.[72]

The mainstays of therapy for ankylosing spondylitis are NSAIDs and exercise programs; however, TNF inhibitors and interleukin-17 inhibitors are used in patients unresponsive to NSAIDs. As in rheumatoid arthritis, NSAID therapy should be discontinued by 32 weeks' gestation.[49]

Interaction with Pregnancy

In contrast to rheumatoid arthritis, pregnancy does not seem to reduce the symptoms or slow the progression of disease in patients with ankylosing spondylitis, and many patients experience an aggravation of morning stiffness and back pain.[69] However, a retrospective review of 35 case-control matched pregnancies identified improvement in pain and stiffness in 51% of women in early pregnancy, although unfortunately there was some return of pain as pregnancy progressed.[73] Pregnancy may ameliorate the extra-articular features of this disease (e.g., psoriasis, inflammatory bowel disease, small joint arthritis), but it appears that women with ankylosing spondylitis are more likely than women with rheumatoid arthritis to enter pregnancy with active disease and, hence, to have higher levels of pain at the beginning of pregnancy.[69] Two retrospective case-control studies from Turkey and Sweden reported that the mean maternal age was higher in women with ankylosing spondylitis than in healthy counterparts.[74,75] Jakobsson et al.,[74] in the largest study assessing ankylosing spondylitis and pregnancy to date, compared 388 women with ankylosing spondylitis with 1082 healthy women. After adjustment for confounding factors, women with ankylosing spondylitis were more likely to deliver prematurely and by elective cesarean. The overall incidence of preeclampsia was not increased.

Care should be taken when positioning women with ankylosing spondylitis, as the biomechanics of the spine are altered by decoupling of bone formation and resorption that occurs as part of the disease. Holding a flexed trunk for prolonged periods while pushing may result in vertebral fractures, as demonstrated in a case report in which a 33-year-old woman with a 5-year history of ankylosing spondylitis suffered a T12 to L1 fracture dislocation with subsequent neurologic compromise during attempted vaginal birth.[72]

Anesthetic Management

An anesthesia provider should review the patient's history with respect to the duration of the disease, the presence of extra-articular features, and the recent use of analgesics. TMJ disorders, cervical spine involvement, and cardiopulmonary complications are rare early in the disease course; however, difficult tracheal intubation has been reported in parturients.[76] Severity of back symptoms is often out of proportion

to the radiographic appearance of the spine, and calcification of the spinal ligaments is typically not advanced in young patients. Neuraxial anesthesia is acceptable in parturients with ankylosing spondylitis; however, even in young patients it may be technically challenging. Calcification of the interspinous ligaments and osteophyte formation may limit the parturient's ability to flex forward, making midline needle placement difficult.[70] A paramedian approach can be considered in this instance.[77] Additionally, the epidural space becomes narrowed in patients with ankylosing spondylitis, and there have been reports of unexpectedly high blocks,[78] as well as failed blocks despite confidence that the catheter was in the epidural space. After multiple failed attempts to provide epidural analgesia in a parturient with advanced ankylosing spondylitis, Hoffman et al.[79] suggested that a highly calcified posterior longitudinal ligament may limit rostral spread of local anesthetic in the epidural space. Preprocedural ultrasonography may be helpful, either to identify the best interlaminar space, or to indicate that administration of neuraxial anesthesia may be impossible.[80]

SPINAL DYSRAPHISM

The term *dysraphism* refers to a neural tube closure defect; however, use of the term has expanded to include all congenital dorsal midline spinal disorders. The old and confusing terms of *spinal bifida occulta* and *spina bifida cystica* were based on clinical findings and plain films. With vastly improved neuroradiologic imaging available, a mixed clinical-neuroradiologic classification system of spinal dysraphism has been proposed that discourages use of the term *occult spinal dysraphism* for the reasons described in the following sections.[81]

Spinal dysraphisms fall into two main categories: **open spinal dysraphism** and **closed spinal dysraphism** (Box 47.4). Open spinal dysraphisms are neural tube defects that are open to the environment and contain malformed spinal cord. Closed spinal dysraphisms include all midline neural tissue abnormalities that are covered by skin; they are not necessarily occult as their presence is usually suspected by cutaneous stigmata such as hairy nevus, hairy tufts, dimples, discolored patches, capillary hemangioma, and subcutaneous masses.[81] Finally, the finding of an isolated failed fusion of the bony neural arch, found typically at L5 or S1 (80%), is common enough (occurring in 5% to 36% of the population) that it can be considered a normal variant.[82] Overall, spinal dysraphism is one of the most common birth defects, with a prevalence of 0.2 to 10 per 1000 births[83]; the incidence is higher in regions that do not advocate for folate supplementation during pregnancy.

Open spinal dysraphisms are relatively uncommon, occurring in 3.7 per 10,000 births in the United States, typically at the lumbar or lumbosacral level.[83,84] Early and aggressive surgical treatment of open spinal dysraphisms has improved survival from 45% in the early 1970s to 70% to 90% by the mid-1980s. Obstetric and anesthesia providers can expect to encounter a growing number of pregnant women with surgically-closed open spinal dysraphisms.[85]

BOX 47.4 Clinical-neuroradiologic Classification of Spinal Dysraphism

Open Spinal Dysraphism
- Myelomeningocele
- Myelocele
- Hemimyelomeningocele
- Hemimyelocele

Closed Spinal Dysraphism
- With a subcutaneous mass
- Without a subcutaneous mass
  - Simple dysraphic states
    - Posterior spina bifida
    - Intradural and intramedullary lipoma
    - Filum terminale lipoma
    - Tight filum terminale
    - Abnormally long spinal cord
    - Persistent terminal ventricle
  - Complex dysraphic states
    - Dorsal enteric states
    - Neurenteric cysts
    - Split cord malformations
    - Dermal sinus
    - Caudal regression syndrome
    - Segmental spinal dysgenesis

Modified from Tortori-Donati P, Rossi A, Cama A. Spinal dysraphism: a review of neuroradiological features with embryological correlations and proposal for a new classification. *Neuroradiology*. 2000;42:471–491.

Neurologic deficits involving the lower extremities and sphincters occur in almost all patients with open lesions, although the deficits vary in severity. Many patients have significant residual neurologic impairment and ongoing orthopedic and genitourinary complications. Hydrocephalus is present in many patients, and shunting of the ventricular system is common, with revisions often required during childhood. By puberty, as many as 50% of patients who have received shunts no longer require them.[86] Kyphoscoliosis, which is common in patients with a thoracic lesion, occurs in 20% of patients with a lumbosacral defect.[87] Paralytic scoliosis is the most common type and results from an imbalance of paravertebral muscle tone.

Closed spinal dysraphisms are further divided into those with or without a subcutaneous mass. The lesions are usually in the lumbosacral region, and the skin covering these defects is frequently abnormal. Meningoceles are herniated sacs of CSF lined by dura and arachnoid; the sacs do not contain parts of the spinal cord, although nerve roots may pass through the sac.[81] Closed spinal dysraphisms *without* a subcutaneous mass comprise an intermediate group of conditions in which the bony defect is associated with one or more anomalies of the spinal cord, some simple and others complex. Complex closed spinal dysraphisms usually have cutaneous markers. Dermal sinus tracts should not to be confused with pilonidal cysts; dermal cysts are frequently connected to the intradural space and therefore pose a risk for developing meningitis.[81]

Affected patients may have no neurologic symptoms or may have minor sensory, motor, and functional deficits of the lower limbs, bowel, and bladder[88]; they also may have orthopedic issues such as scoliosis, limb pain, and lower extremity abnormalities.[89] Fifty percent of patients with spinal cord abnormalities have cutaneous stigmata, and 70% have a tethered spinal cord, which has implications for neuraxial anesthesia.[86,90,91] The malformations may not be clinically evident at birth and present later in life with tethered cord syndrome. Magnetic resonance imaging (MRI) is the preferred imaging method to diagnose these lesions.[81]

Tethered Cord Syndrome and Arnold-Chiari Malformation

Tethered cord syndrome is characterized by neurologic deterioration secondary to traction on the conus medullaris, which typically, but not invariably, is low lying (L2 to L4).[90,91] Congenital abnormalities of the spinal cord such as lipoma, tight filum terminale, dermal sinus, and split cord malformations are found in more than 50% of patients with adult-onset tethered cord syndrome.

A new classification of tethered cord syndrome in adults has been proposed to differentiate tethered cord occurring secondary to open spinal dysraphism from the adult-onset neurologic syndrome associated with closed spinal dysraphism.[92] MRI studies suggest that tethering is present in virtually all patients with open spinal dysraphism.[86] Although many patients with closed spinal dysraphism do not have obvious neurologic impairment secondary to the tethering, adults with tethered cord syndrome often have a long history of minor neurologic or orthopedic issues.[90,92] Others present with acute symptoms after a precipitating event that stretched the spinal cord, such as heavy lifting or placement in the lithotomy position.[93] Of note, more than 50% of adults with tethered cord syndrome present only with a history of low back and leg pain before a precipitating event that leads to the diagnosis.[86,90] The common isolated finding of a defective laminar arch (spina bifida) is not associated with a low-lying or tethered cord.[90]

Low-lying spinal cords and the possibility of undiagnosed tethered cord syndrome have come to the attention of obstetric anesthesia providers with the publication of several case reports of neurologic injury after spinal or epidural anesthesia in women subsequently diagnosed with closed spinal dysraphism, in whom typically there was no obvious history or cutaneous stigmata.[88,89,94] An important feature of adult tethered cord syndrome is that the low-lying cord is located more posteriorly than a normal cord, increasing the likelihood of direct needle trauma during administration of spinal or epidural anesthesia (Fig. 47.8).[95]

Open spinal dysraphism is usually associated with **Arnold-Chiari malformation,** which is characterized by cerebellar herniation through the foramen magnum and descent of the pons and medulla. Tethered cord from a tight filum terminale has also been deemed causal in the development of syringomyelia and subsequent Arnold-Chiari syndrome.[96] Symptoms are more common if the cerebellar herniation exceeds 12 mm or if syringomyelia is present.[97,98]

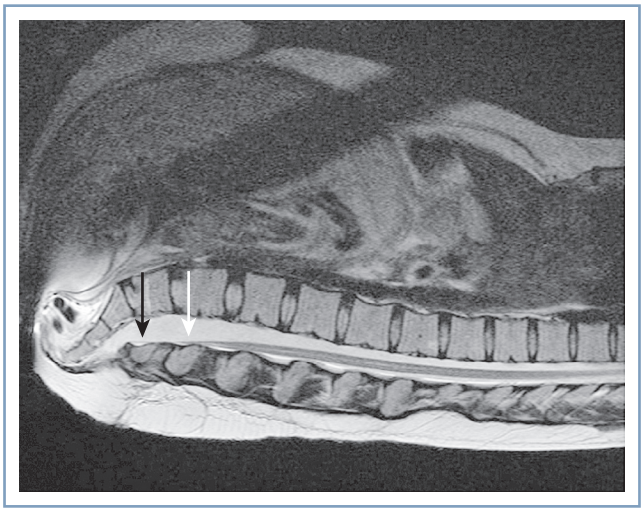

Fig. 47.8 Magnetic resonance image of the spine in a 27-year-old woman with history of a lumbar myelomeningocele excised as a neonate, with residual bladder dysfunction. A tethered spinal cord is present with a typical posterior low-lying position. The *white arrow* indicates the termination of the conus medullaris at L4 to L5, and the *black arrow* indicates the filum terminale located at L5 to S1. (This patient had a vaginal delivery at term, requiring only nitrous oxide for analgesia.)

Obstetric Management

Recurrent urinary tract infection is the most common antenatal complication in patients with open spinal dysraphism and is associated with preterm labor.[85] Intestinal and urinary tract obstruction, as well as problems related to ileal conduits and stomas, are common during pregnancy, as are pressure sores resulting from greater immobility.[85] The enlarging uterus may compromise pulmonary function, especially in patients with kyphoscoliosis.

Cesarean delivery is reserved for obstetric indications, and its incidence is increased and proportionate to the severity of the underlying defect and its consequences. Vaginal delivery is more common in women who are independently mobile and is less common in wheelchair-dependent patients.[85] Sterling et al.[99] found a 60% cesarean delivery rate in a series of 32 women with spinal cord injury—69% secondary to spinal dysraphism. Pelvic and lower limb anomalies and contractures may obstruct the pelvic outlet and warrant cesarean delivery. Cesarean delivery is complicated by the presence of stomas and conduits; postoperative complications and prolonged hospital stays are common.[85] Women with known tethered cord syndrome should avoid both the squatting position and a prolonged lithotomy position for delivery.

Anesthetic Management

Administration of epidural or spinal anesthesia may be considered in women with various forms of spinal dysraphism and stable neurologic function. Imaging studies provide valuable information on neural anatomy and facilitate anesthetic management. A neurologic examination, as well as a full

discussion with the patient of the risks and benefits of neuraxial anesthesia, including risk for inadequate block, should be performed and documented before the administration of neuraxial anesthesia.

An isolated laminar arch defect rarely causes issues for administration of neuraxial anesthesia. First, the lesion typically occurs at the L5 to S1 segments, below the level at which most epidural and spinal anesthetics are administered. Second, the most common anomaly is a simple midline split in the lamina, and this defect rarely seems to interfere with either the performance or the development of spinal or epidural anesthesia. The epidural space may be incomplete or discontinuous across the level of an isolated laminar arch defect because of the variable formation of the ligamentum flavum at this site. An attempt to identify the epidural space at the site of this lesion may result in unintentional dural puncture, although successful epidural analgesia has been reported with the catheter placed within the zone of the lesion.

In patients with surgically corrected open spinal dysraphism, the anesthesia provider should be aware that the terminal portion of the spinal cord typically lies at a vertebral level lower than normal; detethering surgery in the patient with open spinal dysraphism does not usually result in the conus ascending to a normal position.[93] Closed spinal dysraphism without a subcutaneous mass is of concern because of the possibility of a low-lying, posteriorly located, and tethered spinal cord, potentially with no cutaneous stigmata. A neurologic history should be taken and a screening neurologic and lower limb examination should be performed in all women with a known defective laminar arch, preferably antenatally, to determine whether MRI for spinal dysraphism is necessary.[89,100] The presence of skin dimpling (greater than 2.5 cm from the anal margin), hair tufts, pseudotails and midline lumbosacral hemangiomas should raise suspicion that an underlying cord abnormality exists.[82] In our judgment, in women with a known low-lying cord, epidural anesthesia performed by an experienced anesthesia provider is safer than spinal anesthesia. If spinal dysraphism is suspected but no imaging studies are available, it may be prudent to avoid neuraxial anesthesia.

In the patient with an open spinal dysraphism lesion, the anesthesia provider should determine the level of the lesion and whether the patient has residual spinal cord function below it. Patients with a complete lesion at or above T11 are likely to experience painless labor. However, the risk for autonomic hyperreflexia should be evaluated in patients with thoracic lesions, and neuraxial anesthesia should be provided if the patient is deemed to be at risk; this issue is especially important if the lesion is between T5 and T8 (see Chapter 48). If the patient has undergone ventricular shunt placement, the current status of the shunt should be determined. Neurosurgical consultation should be obtained if questions remain about the requirement for, or function of, the shunt. Baseline renal function should be assessed as well as pulmonary function, especially in patients with scoliosis.

There are published reports of the use of epidural and spinal anesthesia in patients with open spinal dysraphism.[101–103] However, experience is limited, and most published series of pregnant women with open spinal dysraphism report neither the type of anesthesia nor complications. Tidmarsh and May[102] reported the management of intrapartum analgesia in 16 patients with spinal dysraphism, 8 of whom had myelomeningocele. Five of the eight patients with open spinal dysraphism received epidural analgesia for labor and delivery. Three patients had a "normal" block, one patient had a sensory level that was higher than expected (T3 after the administration of 10 mL of 0.25% bupivacaine), and one patient had poor sacral analgesia. In the UK Registry of High-Risk Obstetric Anesthesia, the period from 1997 to 2002 included 23 cases of parturients with spinal dysraphisms among 102 cases of neurologic conditions.[104] Of those, the extent of the lesion was defined further in only 10 cases, and 8 had only a bony arch defect. Neuraxial anesthesia was provided in 8 cases. Only epidural anesthesia was used owing to concern about a low-lying or tethered cord; only 5 patients had MRI performed before delivery. Murphy et al.[82] authored a comprehensive review of spinal dysraphism in the parturient, including a summary of reported obstetric anesthesia care. Of the published 139 cases (some only abstracts), epidural anesthesia was used in 52 cases, and spinal or CSE anesthesia was used in 15 cases. There were numerous complications ranging from difficult block placement; rapid onset of anesthesia; and asymmetric, high, and failed blocks, certainly at a rate far higher than in typical obstetric patients. However, no patient had neurologic sequelae.

Asakura et al.[105] demonstrated the use of ultrasonography to detect a bony arch defect. Ultrasonographic imaging of the terminal portion of the cord is difficult, however, and although it has been shown to be feasible in children, it is unlikely to be helpful in determining the safety of neuraxial anesthesia in adults.[106] Spinal anesthesia should be performed below the known level of the conus medullaris or avoided in favor of epidural anesthesia. If possible, epidural analgesia should also be initiated below the level of cord termination in case of unintentional dural puncture. It should be noted that the epidural space is often abnormal, which increases the likelihood of inadequate epidural anesthesia. In our judgment, spinal anesthesia is not contraindicated in women with negligible function of the lower extremities and sphincters, given that the concern for direct neural trauma to a low-lying spinal cord is not clinically relevant.

Limited data exist on the obstetric anesthesia experience in parturients with Arnold-Chiari malformation. Chantigian et al.[97] described their experience with 12 parturients who delivered a total of 30 infants. Nine deliveries were accomplished with neuraxial anesthesia, including six vaginal deliveries with epidural analgesia, two cesarean deliveries performed with single-shot spinal anesthesia, and one cesarean delivery performed with a spinal catheter. No patient experienced postprocedural neurologic sequelae related to the use of neuraxial anesthesia.

ACHONDROPLASIA

Achondroplasia, an inherited disorder of bone metabolism, is the most common cause of disproportionate dwarfism, with a prevalence of 1 in 26,000 live births. Although it is inherited in an autosomal dominant mode, most cases arise from spontaneous mutation.[107] The range of cervical motion may be decreased, lumbar lordosis and thoracic kyphosis are increased, and thoracic kyphoscoliosis occurs.[108] The vertebral pedicles are short, and reduced length of the neural arch leads to shortened anteroposterior and transverse diameters of the vertebral canal, resulting in foramen magnum and spinal stenosis.[109] Although it may occur earlier, symptomatic spinal stenosis often does not present until the fourth or fifth decade, when kyphosis, scoliosis, osteophytes, and herniated discs typically cause further narrowing of the spinal canal. There is considerable interindividual variation in the clinical and radiographic characteristics, and skeletal abnormalities often show more variation than consistency.[109,110]

Obstetric Management

The uterus is an abdominal organ in the achondroplastic patient.[111] With advancing pregnancy it may encroach on the small thoracic cage and lead to decreases in the functional residual and closing capacities; severe dyspnea may occur with advancing gestational age. Back discomfort is common during pregnancy, and the reported incidence of sciatica is greater than in healthy pregnant women,[112] most likely owing to the underlying spinal abnormalities. Typically, an inadequate maternal pelvis combined with a normal-sized (nonachondroplastic) fetus results in cephalopelvic disproportion. Imaging techniques may be used to confirm this situation, and the obstetrician should anticipate the need to deliver most patients with achondroplasia by cesarean delivery.[108,109]

Anesthetic Management

The short, obese limbs of the patient with achondroplasia may make it difficult to obtain measurements of blood pressure with a noninvasive cuff, and an intra-arterial catheter may be necessary. Prominent paraspinal muscles and marked lumbar lordosis may complicate attempts to palpate landmarks during the administration of spinal or epidural anesthesia; the use of ultrasonography may help identify landmarks.[108,113] Scoliosis of the spine also may cause technical difficulties with neuraxial anesthesia attempts. The small stature and spinal stenosis reduce the dose of local anesthetic required for major neuraxial anesthesia.[108,110,111,114] It is difficult to estimate the appropriate dose of local anesthetic for single-shot spinal anesthesia. Continuous epidural anesthesia or CSE anesthesia is preferable because it allows the anesthesia provider to titrate the dose of local anesthetic to the desired level of anesthesia. Local anesthetic dose requirements are typically smaller than those in parturients of normal stature; this is not always the case, however, supporting the use of a neuraxial anesthetic technique that may be titrated to the desired effect.[112,113,115]

Difficult tracheal intubation has been reported in patients with achondroplasia and should be anticipated. A case report noted that use of a video laryngoscope did not allow visualization of the vocal cords, and flexible fiberoptic bronchoscopy was required to intubate the trachea in an achondroplastic dwarf undergoing cesarean delivery.[116]

Multidisciplinary team planning is vital, as all anesthetic options may prove challenging and time-consuming. Anesthetic drug-dosing, mechanical ventilation strategies, and postdelivery pain management need to be considered carefully as the disproportion between truncal size and limb size may lead to errors.[117]

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is an inherited condition that occurs with an incidence between 1 in 10,000 and 1 in 25,000.[118,119] The genetic defect is within the genome that encodes for type I collagen, the major collagen in tissues that require structural strength. The disease is a generalized connective tissue disorder, and expression ranges from mild osteoporosis to the classical clinical stigmata characterized by multiple bone fractures and skeletal deformities, blue sclera, and middle ear deafness (otosclerosis). There are now eight types classified by genetic mutations, although clinical features are still the primary differentiation.[119] Type I is the prototype disease. It is inherited as an autosomal dominant trait and is the most common and mildest form of this disease. It typically manifests in childhood as multiple fractures after minor trauma. Types II and III are inherited as autosomal dominant traits and are characterized by extreme bone fragility. Type II is uniformly lethal, and stillbirth or early neonatal death is common; death *in utero* is caused by skeletal collapse, and early neonatal death typically results from chest wall failure and respiratory insufficiency. Infants with type III disease may have fractures at birth and may have progressive skeletal deformities during the first two decades of life; it is the most severe form of osteogenesis imperfecta that survives beyond the newborn period. Type IV, also autosomal dominant, is much less common and the most clinically diverse. Types V to VIII are recent additions, and do not result from genetic mutations of collagen I, nor do they exhibit the typical findings of osteogenesis imperfecta such as blue sclerae and hearing loss. Type V formerly was a subset of Type IV and is characterized by the tendency to develop hypertrophic calluses following surgery or trauma. Type VI varies from moderate to severe deformities secondary to a mineralization defect; it is inherited as an autosomal recessive disease. Types VII and VIII represent less than 10% of all cases of osteogenesis imperfecta, and clinically present with moderate to severe deformities and fragility (VII) or severe growth abnormalities (VIII).[119]

The majority of pregnant women with osteogenesis imperfecta have type I disease, although pregnancy has been reported in more severe forms of the disease.[120,121] There is considerable variability among affected patients in age at

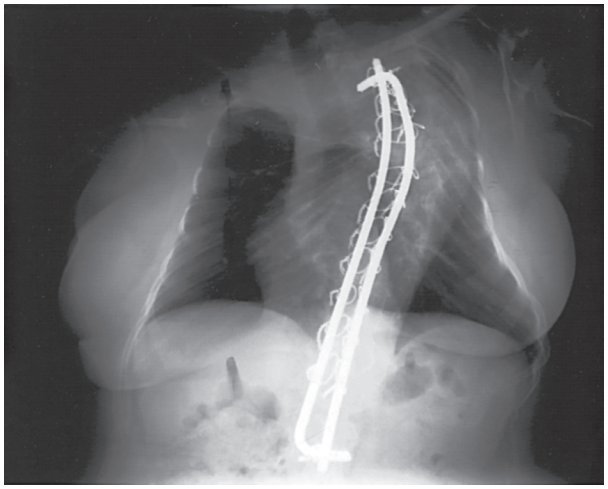

Fig. 47.9 A chest radiograph of a 30-year-old woman with osteogenesis imperfecta type I. Generalized osteoporosis, corrected thoracic kyphoscoliosis, a restricted thoracic cage, and multiple old fractures are demonstrated. (General anesthesia was provided for cesarean delivery and tubal ligation.)

onset and frequency of fractures. Dwarfism is typical, and kyphoscoliosis is common, as are other chest wall abnormalities. These chest and spinal abnormalities result in restrictive lung disorders (Fig. 47.9). Other abnormalities include a decrease in the range of motion of the shortened cervical spine, micrognathia, and malformed, brittle teeth.[121] The abnormal bleeding and early bruising seen in patients with osteogenesis imperfecta is multifactorial; platelet dysfunction, vessel wall fragility, and reduced factor VIII are all potential contributors. Hyperthyroidism occurs in 40% of patients; an elevated concentration of thyroxine leads to increases in both oxygen consumption and heat production.[121] Although there is one published case of a patient with osteogenesis imperfecta who developed malignant hyperthermia, there is no known association between the two diseases.[122] Intraoperative hyperthermia has often been reported; however, a retrospective cohort study of 49 patients with osteogenesis imperfecta undergoing noncardiac surgery revealed no difference in intraoperative temperature changes compared with matched controls.[123] This information should allay ongoing concerns about risk for developing malignant hyperthermia.

Obstetric Management

Pregnancy results in transfer of calcium from the mother to the fetus, which in the patient with osteogenesis imperfecta can lead to increased maternal fracture risk.[124] Platelet dysfunction and vessel fragility in osteogenesis imperfecta as well as abnormal uterine function result in a higher incidence of uterine atony and postpartum hemorrhage.[125] Additionally, the incidence of cesarean delivery and pregnancy complications, including preterm birth, preeclampsia, bleeding, bone fractures, and other musculoskeletal issues, are greater in patients with osteogenesis imperfecta.[125] A retrospective cohort study using a U.S. database containing more than 7 million births found 295 births to women with osteogenesis imperfecta.[124] Compared with women without osteogenesis imperfecta, parturients with the disease were more likely to have antepartum hemorrhage (odds ratio [OR], 2.01; 95% confidence interval [CI], 1.04 to 3.91) and placental abruption (OR, 2.50; 95% CI, 1.24 to 5.03), and less likely to have a spontaneous vaginal birth (OR, 0.19; 95% CI, 0.15 to 0.25).[124] In addition, there was an increased risk for preterm birth, blood transfusion, and venous thromboembolism.[124] Finally, it is important to recognize the increased incidence of chronic pain, and the risk for developing acute musculoskeletal pain during pregnancy in these women.[125]

Anesthetic Management

The anesthesia provider must be aware of the fragility of the bones, the potential for difficult tracheal intubation, and the presence and severity of restrictive lung disease. Transfers, positioning, and any invasive intervention must be accomplished with extreme care. Blood pressure cuffs and tourniquets to facilitate placement of intravenous catheters should be applied gently to prevent fractures. Alternatives to direct laryngoscopy, such as video laryngoscopy, may be considered to reduce the applied forces necessary for direct laryngoscopy. Authors of a case report raised the theoretical concern that fasciculations following succinylcholine administration may be harmful.[126]

Before administration of neuraxial anesthesia, the anesthesia provider should consider the technical difficulties inherent in performing neuraxial anesthesia in patients with spinal deformities and consider using preprocedural ultrasonography to facilitate needle placement. The possibility of platelet dysfunction is best evaluated by obtaining a thorough bleeding history. In the setting of a reassuring history, neuraxial anesthesia need not be withheld. Small stature and spinal abnormalities reduce the local anesthetic dose requirements and increase the risk for both misplaced injection and local anesthetic systemic toxicity. It may be difficult to estimate the appropriate dose for single-shot spinal anesthesia in these patients. Thus, continuous epidural, continuous spinal, or CSE anesthesia is the neuraxial anesthetic technique of choice, barring other contraindications.[127] Yeo and Paech[128] reported the successful use of both epidural and subarachnoid blocks for cesarean delivery on five occasions over 9 years in a single patient with type I osteogenesis imperfecta. Dinges et al.[129] described twin sisters with type III osteogenesis imperfecta, one who received a general anesthetic because of severe corrected kyphoscoliosis and predicted difficult airway, for cesarean delivery at 32 weeks' gestation for increasing respiratory compromise. The second twin, who had only mild scoliosis and a reassuring airway, developed respiratory compromise and was delivered urgently by cesarean with CSE anesthesia at 28 weeks' gestation for a nonreassuring fetal heart rate tracing.

KEY POINTS

- Lumbopelvic pain is the most common musculoskeletal complaint during pregnancy. It results from both hormonal and mechanical factors.
- Low back pain does not contraindicate the administration of spinal or epidural anesthesia.
- Corrected idiopathic thoracolumbar scoliosis is the most common major musculoskeletal disorder seen in pregnant women. Prepregnancy pulmonary function is a better predictor of maternal outcome than the severity of the curve.
- Neuraxial anesthesia is technically challenging in patients with scoliosis, and the anesthesia provider should anticipate a greater incidence of complications and inadequate anesthesia.
- Preprocedural ultrasonography is a useful tool to facilitate neuraxial needle placement in patients with difficult surface anatomy and challenging spinal anatomy.
- Maternal rheumatoid arthritis is associated with preterm delivery and low birth weight, but ankylosing spondylitis does not adversely affect the outcome of pregnancy.
- Pregnancy may mitigate the symptoms of rheumatoid arthritis; however, many women require medical therapy during pregnancy and may require medical management of disease flares.
- *Spinal dysraphism* is the overall term for neural tube defects, encompassing the older terms of *spina bifida occulta* and *spina bifida cystica.*
- An isolated posterior spinal bony defect does not contraindicate the administration of spinal or epidural anesthesia.
- Adult tethered cord syndrome secondary to spinal dysraphism is important to diagnose, as it may preclude the use of spinal anesthesia.
- Cephalopelvic disproportion often mandates cesarean delivery in parturients with achondroplasia or osteogenesis imperfecta.

Neurologic and Neuromuscular Disease

Grace Lim, MD, MS, Angela M. Bader, MD, MPH

CHAPTER OUTLINE

The choice of anesthetic technique for pregnant women with neurologic disease requires knowledge of the pathophysiology of the disorder and an understanding of controversies involved in the diagnosis and management of the disease. If a patient's neurologic condition deteriorates postpartum, the cause may be unclear and the anesthetic technique may be blamed unfairly. There are limited published data on specific neurologic and neuromuscular disorders in pregnant women. However, few of these disorders contraindicate the use of neuraxial anesthesia. In most cases, the obstetrician should obtain early antepartum consultation from an anesthesia provider. Early consultation allows accurate antepartum documentation of the extent and pattern of the neurologic deficit as well as discussion and formulation of the anesthetic plan with the patient, her obstetrician, and a neurologist or neurosurgeon.

Because patients with a wide variety of neurologic disorders will present for preoperative evaluation, the following thought process will assist the clinician with completing a proper evaluation and formulating an anesthetic plan.

What is the basic pathophysiology of the neurologic disorder? Neurologic disorders may be stable, progressive, or relapsing/recurrent. It is important to understand the common disease patterns. The potential for progression of the disease after delivery will depend on the pattern of progression and underlying pathophysiology, and on the effect of pregnancy on disease progression.

What is the patient's history and current findings after neurologic examination? A history should include the onset date and current course of the disorder. Symptoms related to neurologic issues should be documented (e.g., seizure type and frequency, deficits after cerebrovascular events, cognitive deficits). A basic physical examination should be conducted to document existing deficit patterns, including cognitive dysfunction (e.g., ability to understand and cooperate), deficits involving vision, hearing, speech, and swallowing; respiratory symptoms; and weakness and sensory deficits in the head and neck, trunk, and extremities. Motor and sensory deficits are classified as mild, moderate, or severe, with a description of the affected area. Special attention should be directed to limitations in ambulatory ability (e.g., bed-bound, wheelchair, walking with assistance) or positioning.

What are the current treatments, and what testing results are available? Documentation of medical and nonmedical therapies is essential. For some disorders (e.g., myasthenia gravis), documentation of the timing of treatment is also critical. In most cases, specific laboratory testing will not influence anesthetic management and outcome. However, pulmonary function testing should be considered in patients with neurologic disorders that result in significant respiratory compromise; the findings may assist the anesthesia provider in making recommendations about anesthetic management.

What is the impact of the neurologic disorder on other organ systems (e.g., cardiac, respiratory, airway)? The patient's neurologic disease may affect organ systems that are relevant to the anesthetic plan. For example, central core disease is associated with a risk for malignant hyperthermia. In addition, progressive neurologic disorders may significantly compromise the patient's respiratory status, thereby increasing the risks associated with neuraxial and general anesthesia.

What are the potential impacts, risks, and benefits of anesthetic options based on the disease's pathophysiology, symptoms, and treatment? Can treatment be initiated antepartum or before delivery that will improve outcome? For most rare neurologic disorders, there is limited evidence on which to base decisions about anesthetic management. In these cases, the anesthesia provider should consider the disease's basic pathophysiology and its possible direct and indirect interactions with specific anesthetic techniques. Encouraging the obstetrician to send these patients for early antepartum consultation will enable the anesthesia provider to obtain formal input from a neurologist or other consultant if necessary. A multidisciplinary discussion that includes the patient and her family may be necessary to weigh the risks and benefits of specific obstetric and anesthesia plans. A team approach to peripartum care in patients with complex neurologic disorders is essential.

What are the plans for postpartum management of the patient's disease? Will the intrapartum anesthetic management or postpartum analgesia management influence outcomes? Some conditions, such as multiple sclerosis, can have significant implications for the postpartum period. The anticipated progress of the disease and planned postpartum management should be discussed with the patient in the antenatal period.

In all cases, accurate documentation of the responses to the previous questions will greatly assist the team providing peripartum care for these patients. Some of the more common neurologic conditions are addressed in this chapter, and the existing literature is surveyed relative to the peripartum management of these patients. This knowledge allows the anesthesia provider an opportunity to formulate a safe and rational anesthetic plan as well as enable an appropriate discussion with the patient regarding the risks and benefits of anesthetic options.

MULTIPLE SCLEROSIS

Multiple sclerosis is a major cause of neurologic disability in young adults, and it is at least two to three times more common in females than in males.[1] First-time symptoms typically manifest in the second or third decade of life; therefore, the disease typically presents in females in their reproductive years.[2] The prevalence of the disorder varies with the population, and may be as high as 300 per 100,000 in some parts of North America, although the accuracy of epidemiologic estimates have been limited by heterogeneous methods for identifying people with disease and by different data analytic strategies.[1]

The disease is characterized by variable neurologic disabilities with two general patterns of presentation: (1) **exacerbating remitting,** which accounts for 85% of cases, in which attacks appear abruptly and resolve over several months; and (2) **chronic progressive,** in which continued deterioration occurs over time.[3] The relapse rate varies significantly among patients, averaging approximately 0.4 attacks per year; this rate reflects the large proportion of patients with relapsing/remitting disease. The deficits tend to become more progressive and debilitating over time. Environmental factors (e.g., stress, infection, increased body temperature) may provoke a relapse. Most relapses reproduce previously experienced neurologic deficits, which can manifest as pyramidal, cerebellar, or brainstem symptoms. It is estimated that about one-half of affected individuals with exacerbating remitting disease will eventually convert to chronic progressive.[3]

The etiology remains unclear, although it is widely believed to be autoimmune in nature.[4] There is a clinically significant heritable component, and alleles in the HLA locus have been identified as risk factors for multiple sclerosis.[5] Pathologic findings include local inflammation, demyelination, gliotic scarring, and axonal loss; on magnetic resonance imaging (MRI), the formation of gray and white matter plaques is

seen.[4] It is possible that the disease results from a yet undetermined combination of genetic predisposition and exposure to specific environmental factors. The more common symptoms include motor weakness, impaired vision, ataxia, bladder and bowel dysfunction, and emotional lability.

Although there is no cure, over the last two decades relapsing/remitting multiple sclerosis has become a treatable disease as a result of advancements in disease-modifying therapies.[2] Immunosuppressive therapies may hasten recovery from a relapse, but no evidence suggests that these agents influence the progressive course of the disease. Administration of interferon-beta may significantly reduce the relapse rate and retard disability; however, an increased risk for fetal loss and low birth weight (LBW) has been observed with the use of this therapy during the first trimester of pregnancy. In contrast, administration of intravenous immunoglobulin or plasmapheresis for severe relapses has no known adverse effects on pregnancy outcome.[2] Acute relapses during pregnancy are treated with short courses of high-dose corticosteroids, although longer-term use may be associated with maternal glucose intolerance, neonatal adrenal suppression, cleft palate if used in the first trimester, and an increased risk for premature rupture of membranes.[3]

Interaction with Pregnancy

The effects of multiple sclerosis and long-term use of disease-modifying therapies on fertility are poorly studied. Findings from a prospective study in Finland suggest that multiple sclerosis is associated with increased requirement for assisted reproductive techniques.[6] A large Danish national cohort study found that multiple sclerosis was associated with having no or fewer children[7]; however, it is not known whether this finding is explained by the disease itself or if it is caused by altered reproductive behaviors among diseased individuals. In one study of women with multiple sclerosis undergoing assisted reproductive techniques, failed assisted reproductive attempts were associated with increased annual relapse rates.[8] These findings may be explained by the stress of infertility, temporary interruption in disease-modifying therapy, and increases in inflammatory cytokines associated with hormonal therapies.

Pregnancy and obstetric outcomes in women with multiple sclerosis are likely no different from individuals without disease. One cohort study compared 198 affected women with 1584 healthy women; the number of maternal complications was not higher in women with multiple sclerosis.[9] However, infants delivered of women with multiple sclerosis were at greater risk for meconium aspiration.[9] This finding may reflect an intrauterine environment in patients with multiple sclerosis that is more susceptible to acute hypoxic events.[7,9] A subsequent cohort study of 649 pregnancies in women with multiple sclerosis concluded that infants of these women were more likely to be small for gestational age, attributed to a suboptimal intrauterine environment.[10] Moreover, this study found that mothers with multiple sclerosis were more likely to undergo induction of labor and operative delivery, possibly as a result of neuromuscular weakness and spasticity. These findings have not been reproduced in other studies. A 2017 United Kingdom case-controlled study of 181 pregnancies in 98 mothers with multiple sclerosis and 244,573 pregnancies in 124,830 mothers without multiple sclerosis did not find any associations with neonatal birth weight, gestational age at birth, mode of delivery, stillbirth, or neonatal death.[11] A 2011 meta-analysis did not find significant associations between multiple sclerosis and adverse obstetric and neonatal outcomes.[12] The relapse rate was lower during pregnancy than before or after pregnancy.

Data from prospective studies suggest that the rate of relapse increases during the first 3 months postpartum in comparison with the year before pregnancy.[13] Relapses during this period were more likely in women who had higher relapse rates in the year before pregnancy or during pregnancy. Stress, exhaustion, infection, the loss of antenatal immunosuppression, and the postpartum decline in concentrations of reproductive hormones may account for the higher postpartum relapse rate. Treatment with immunologically active agents (e.g., interferon-beta) may result in a decreased postpartum relapse rate, but data are limited.[13]

Pregnancy does not negatively affect the long-term outcome of multiple sclerosis. Rather, at least one study has suggested that parturition may have a slightly favorable effect on long-term disease activity.[14] Data are conflicting as to whether exclusive breast-feeding is associated with a lower risk for relapse than partial or no breast-feeding.[15,16] A 2015 prospective study in 201 German women found a modestly protective effect against relapses among women with multiple sclerosis who exclusively breast-fed for at least 2 months (first postpartum relapse adjusted hazard ratio, 1.70; 95% confidence interval [CI], 1.02 to 2.85; $P = .04$).[17]

Anesthetic Management

The anesthesia provider should assess the patient's level of compromise, document the pattern of deficits, and give special attention to respiratory involvement, in particular the ability to cough, clear secretions, and take vital capacity breaths. Historically, the optimal mode of anesthesia in patients with multiple sclerosis has been controversial. Most anesthesia providers have considered general anesthesia to be safe. Many anesthesia providers have been reluctant to administer neuraxial anesthesia because the effect of local anesthetic drugs on the course of the disease is unclear. Some anesthesia providers have expressed concern that neuraxial anesthesia may expose demyelinated areas of the spinal cord to potentially neurotoxic effects of local anesthetic agents. Several animal studies have investigated the histologic effects of local anesthetic agents on the normal spinal cord. In one study, subarachnoid injection of small doses of a local anesthetic agent produced no histologic changes in the spinal cord or meninges.[18] Injection of very large doses caused reversible inflammatory and degenerative changes, but all changes resolved within 14 days of injection.

Diagnostic lumbar puncture is not associated with a higher rate of relapse. Two small reports have implicated spinal anesthesia in the exacerbation of multiple sclerosis.[19,20]

Bamford et al.[19] described one case of relapse after the administration of spinal anesthesia in 9 patients, and Stenuit and Marchand[20] identified two cases of relapse after the administration of spinal anesthesia in 19 patients. The relationship of these relapses to spinal anesthesia or other postoperative conditions (e.g., stress, infection, hyperpyrexia) known to exacerbate multiple sclerosis is unclear.

There are few published data on the use of epidural anesthesia in patients with multiple sclerosis. Warren et al.[21] reported minor exacerbations after the administration of epidural anesthesia for two separate vaginal deliveries in one patient. Crawford et al.[22] reported one postoperative relapse in 50 nonobstetric and 7 obstetric patients who received epidural analgesia. Confavreux et al.[23] reported a study of 269 pregnancies in 254 women with multiple sclerosis, of whom 42 received epidural analgesia; epidural analgesia did not have an adverse effect on the rate of relapse or on the progression of disability in these patients. Bader et al.[24] retrospectively evaluated 32 pregnancies in women with multiple sclerosis; they observed that women who received epidural anesthesia for vaginal delivery did not have a higher incidence of relapse than those who received only local infiltration anesthesia. The Pregnancy in Multiple Sclerosis (PRIMS) study followed 227 women who had multiple sclerosis for at least 1 year before conception, of whom 42 received epidural analgesia during labor; no adverse effect of epidural analgesia on the rate of postpartum relapse or the progression of disability was identified.[13] Similarly, a 2012 prospective study followed 349 patients for 5 years postpartum and did not find an increased risk for relapse associated with labor epidural analgesia.[25] A 2013 record linkage study comparing 431 deliveries in women with multiple sclerosis who received peripartum neuraxial analgesia or anesthesia to 2959 deliveries in women from the general population in British Columbia did not find an association between the use of neuraxial techniques and increased disability.[26]

Bader et al.[24] observed that all of the women who experienced a relapse after epidural anesthesia had received a concentration of bupivacaine greater than 0.25%. The concentration of local anesthetic in the CSF progressively increases during prolonged administration of epidural anesthesia, and the authors suggested that the higher concentration may overwhelm the protective effect of dilution within the CSF. An alternative explanation is that women who require a higher concentration of neuraxial local anesthetic may have more stressful labor. However, these observations suggest that anesthesia providers should use a dilute solution of local anesthetic for epidural analgesia during labor, when possible.

The administration of neuraxial anesthesia for cesarean delivery is considered safe. Because the operation is of limited duration, multiple doses of local anesthetic are typically not needed, so a progressive increase in CSF concentration of local anesthetic over time is less likely. The 2013 record linkage study from British Columbia compared spinal anesthesia use in cesarean deliveries in 128 women with multiple sclerosis and 846 women in the general population, and did not find a link between spinal anesthesia and increased disability.[26] Although there are limited data on spinal and general anesthesia for cesarean delivery in patients with multiple sclerosis, they are both considered safe, and prior concerns over these techniques are attributable to recall bias associated with postpartum relapses after regional anesthesia.[3] No data suggest harmful effects of neuraxial opioids in women with multiple sclerosis. In light of the significant benefits of neuraxial techniques for intraoperative anesthesia and postoperative analgesia, either spinal or epidural anesthesia is the principal anesthetic technique used for cesarean delivery in patients with multiple sclerosis in many institutions, including our own.

In summary, published data do not contraindicate the use of neuraxial anesthetic techniques for labor analgesia or operative anesthesia. The patient should be aware that there is a higher incidence of relapse during the postpartum period, even without the use of neuraxial analgesia or anesthesia. In addition, when anesthetic techniques are used, the type of anesthesia selected does not appear to influence the relapse rate. Neither pregnancy nor anesthesia appear to have a negative influence on the long-term course of the disease. The willingness of anesthesia providers to use neuraxial techniques in pregnant patients with multiple sclerosis is reflected in a survey of obstetric anesthesia providers published in 2006.[27] The majority (91%) of respondents had seen fewer than 10 cases of multiple sclerosis in the past 10 years; 79% and 98% of anesthesia providers indicated they would perform a neuraxial anesthetic technique for labor and elective cesarean delivery, respectively.

HEADACHE DURING PREGNANCY

Headaches are among the most frequently observed neurologic symptoms during pregnancy (Table 48.1). Tension headaches, migraine headaches, and headaches associated with hypertensive disorders of pregnancy are commonly observed during pregnancy. *De novo* primary headaches (e.g., tension and migraine) are very common during pregnancy, particularly in the first few months of pregnancy; however, new headaches in the third trimester and puerperium should prompt closer evaluation for secondary causes.[28] A pregnant patient with a history of chronic headaches who reports new or different symptoms should be closely evaluated to exclude serious causes such as preeclampsia, tumor, or intracranial vascular malformation. Symptoms of concern include sudden onset, intense severity, altered mental status, meningeal signs, fever, vomiting, changes in vision, pulsatile tinnitus, headache in a woman with prior malignancy or HIV infection, and any localizing or lateralizing abnormality. All imaging modalities may be used to assist in the diagnosis of secondary headaches in pregnancy, although measures should be taken to minimize maternal and fetal exposure to ionizing radiation.[28]

Tension Headache

Tension or muscle contraction headaches are the most common type of headache observed during pregnancy. The

TABLE 48.1 Headache during Pregnancy

Etiology	Symptoms	Pattern	Treatment
Tension headache	Dull, widespread headache	Increased incidence during peripartum period	Analgesics Tricyclic antidepressants
Migraine headache	Frontotemporal throbbing Prodrome of scotomata	Improvement in 79% of patients during pregnancy	Ergotamine contraindicated during pregnancy Promethazine Beta-adrenergic receptor antagonist for prophylaxis
Preeclampsia	Generalized headache Occasional scotomata and/or blurred vision	Occurrence during pregnancy and occasionally postpartum	Blood pressure control Delivery
Meningeal irritation (subarachnoid hemorrhage, meningitis)	Generalized headache	Increased risk for subarachnoid hemorrhage during pregnancy	Based on etiology
Brain tumor	Variable	No increase in incidence during pregnancy; possible increased growth rate	Based on etiology
Idiopathic intracranial hypertension	Generalized headache Visual symptoms	Increased incidence and worsened symptoms during pregnancy	Typically remits within 1 to 3 months or after childbirth

symptoms typically consist of dull, persistent pain that extends over the entire head. The onset is usually gradual, but the symptoms may persist for long periods. Although the etiology is unknown, this type of headache is believed to be associated with stress rather than hormonal changes. These headaches are more common in women, are frequently associated with anxiety, and may be a symptom of postpartum depression.[29]

Treatment

Acetaminophen should be used as a first-line analgesic in the pregnant patient. Caffeine and butalbital may be contained in combination analgesic products (e.g., Fioricet, Fiorinal). The American College of Obstetricians and Gynecologists (ACOG) has concluded that there is no clear evidence that caffeine exposure increases the risk for fetal growth restriction.[30] Because a definitive conclusion regarding high caffeine intake and the risk for miscarriage cannot be made, the ACOG recommends caffeine be limited to moderate consumption (less than 200 mg/day) during pregnancy. Butalbital is sometimes prescribed for treatment of migraine and tension headaches, but its appropriateness has been questioned given increased risks for abuse, overuse headache, and withdrawal. Emerging data from the National Birth Defects Prevention Study, an ongoing case-control study, suggest that butalbital exposure in pregnancy is associated with an increased risk for congenital heart abnormalities, including tetralogy of Fallot, pulmonic stenosis, and atrial septal defect.[31] Butalbital use, however, was rare; only 73 case mothers and 15 control mothers reported periconceptional use.[32]

Ergot alkaloids (e.g., ergotamine) are contraindicated during pregnancy; these agents may cause marked increases in uterine tone, which may compromise placental perfusion and fetal oxygenation.[32] Use of nonsteroidal antiinflammatory drugs (NSAIDs) should be limited during the third trimester because of risk for premature closure of the fetal ductus arteriosus, oligohydramnios, and prolongation of pregnancy. Although a 2013 review did not find evidence that first-trimester exposure to benzodiazepines is associated with an increased risk for congenital malformations,[33] these drugs are not usually used to treat headache during pregnancy. Opioids have a long record of safe use during pregnancy, but because of escalated use and abuse, and their association with neonatal opioid withdrawal syndrome with long-term maternal exposure, their prescription during pregnancy and the puerperium is undergoing increased scrutiny.[34] Tricyclic antidepressants similarly have a record of safe use during pregnancy. Although earlier studies reported links between tricyclic antidepressant use during pregnancy and congenital malformations, most subsequent larger studies have been negative.[35] Findings from one study suggest that tricyclic antidepressants do not have detrimental effects on the neurodevelopment of children exposed *in utero*.[36]

Obstetric and Anesthetic Management

Pregnancy is not likely to reduce the frequency or severity of tension headaches because they are not hormonally mediated. Obstetric and anesthetic management are rarely affected by the presence of tension headaches, although a history of chronic tension headaches has been associated with an increased risk for placental abruption (adjusted odds ratio [OR], 1.60).[37] The frequency and severity of tension headaches should be assessed and documented in the preanesthetic assessment to better differentiate preexisting symptoms from new or changing symptoms in the postpartum period.

Migraine Headache

Migraine headaches are classically described as unilateral, throbbing headaches sometimes accompanied by nausea and vomiting. The duration varies from hours to days. Visual disturbances (e.g., scotomata) typically precede the onset of these headaches, and focal neurologic symptoms (e.g., aphasia, hemiplegia) may also occur. Most investigators favor neurovascular vasospasm, followed by cerebral vasodilation, as a cause of these headaches; a primary vascular disorder or a disturbance in the noradrenergic nervous system also may be involved. Patients appear to be more susceptible to symptoms when serotonin levels are low.

The 1-year period prevalence of migraine headache in the United States is 3.9% for men and 5.1% for women.[38] Prevalence is higher in middle life, between 30 and 59 years of age. Hormonal influences have a strong association with these headaches; estrogen withdrawal is associated with an exacerbation of symptoms. After delivery, the reduction in hormonal concentrations coincides with an increase in migraine symptoms.

Treatment

In nonpregnant patients, therapy centers around prevention, abortive treatments, and rescue treatments. Preventive medications are typically avoided during pregnancy; beta-adrenergic receptor antagonists (e.g., propranolol) may be used for prophylaxis, however, owing to their ability to cross the placenta, these agents should be used only when a patient's symptoms are severe. Antidepressants such as selective serotonin reuptake inhibitors can be used off-label for migraine prevention, although fetal exposure to some antidepressants has been controversially linked to congenital anomalies and adverse neonatal outcomes (see Chapter 50).[35,39,40] Abortive treatments often involve triptans or ergotamine tartrate, typically in combination with caffeine (e.g., Cafergot, Migergot). However, ergot alkaloids are contraindicated during pregnancy because of associated uterotonic effects and possible (but unproven) teratogenic effects.[32,41] The use of sumatriptan or other selective serotonin receptor agonists is controversial. A higher incidence of congenital anomalies was observed after administration of high doses of sumatriptan in animals[41]; however, in a review of human studies, no evidence of any specific adverse effect of sumatriptan on pregnancy outcome was found.[42] A prospective study also showed no relationship between triptan use for migraine and teratogenicity.[43]

Rescue treatments are given when abortive therapies fail and include acetaminophen, antiemetics, and NSAIDs. In general, acetaminophen is considered the first-line treatment during pregnancy. Combination therapy with agents containing caffeine and/or butalbital should be used with caution, as should therapy with NSAIDs (see earlier discussion). Occasionally, calcium entry–blocking agents are used.

Obstetric and Anesthetic Management

Women with a lifetime history of migraine have been reported to have a twofold higher risk for placental abruption. Pregnant women with migraines are at four times higher risk for developing preeclampsia, as well as at higher risk for stroke during pregnancy and the puerperium.[44–46]

Cerebral ischemia has been reported after the administration of terbutaline in pregnant patients with migraine. Rosene et al.[47] recommended that physicians avoid the administration of terbutaline in pregnant women with a history of vascular headache.

Although there are no published data on the relationship between intrapartum anesthesia and postpartum migraine headaches, one cohort study suggested that patients with a prior history of migraine may be more likely to present with atypical symptoms of post–dural-puncture headache, including nonpostural headache; cervical, thoracic, or lumbar vertebral stiffness and pain; and vertigo.[48]

SPINAL CORD INJURY

Worldwide, there are large geographic differences in the incidence, prevalence, and lethality of spinal cord injuries.[49] In the United States, traumatic spinal cord injuries occur with an incidence of 23.7 to 77.0 per million population per year; the prevalence per million inhabitants is 473 to 1800.[49] Improved handling and stabilization of victims at the site of an accident and the availability of extensive rehabilitation services have resulted in more women who present for obstetric care after spinal cord injury than in the past.

Patient disability and residual function depend on the anatomic location of the injury.[50] Cord injuries below S2 involve mainly bladder, bowel, and sexual functions. Affected patients have relaxed perineal muscles, and women with such injuries experience labor pain. Women with a lesion above T10 do not experience labor pain. Patients with a lesion above T6 have varying levels of respiratory compromise and are at risk for autonomic hyperreflexia (see later discussion).

Spinal shock, defined as immediate and temporary areflexia/hyporeflexia and transient sensorimotor dysfunction resolving within 24 to 48 hours after injury, may develop in about one-half of spinal cord–injured patients.[51] Patients with injuries at or above the T6 level are at risk for **neurogenic shock** caused by loss of signals from the sympathetic nervous system. It is characterized by hemodynamic and sensorimotor abnormalities, and flaccid paralysis with loss of tendon and autonomic reflexes.[51] Patients experience loss of vasomotor tone, temperature regulation, sweating, and piloerection in the parts of the body below the lesion. Pulmonary edema, hemodynamic instability, and circulatory collapse can develop in the absence of brainstem regulation of vasomotor tone. Patients are at risk for aspiration, infection, and other pulmonary complications. Paraplegic patients may have a compensatory tachycardia, whereas quadriplegic patients may have bradycardia caused by unopposed vagal tone.

After a variable period, the spinal cord-injured patient progresses to a chronic stage in which reflex activity is regained. In most cases, this return of reflex activity occurs within 1 to 6 weeks after the injury; rarely, return of reflex activity may take several months. This stage is characterized

by disuse atrophy, flexor spasms, and an exaggeration of reflexes. The **mass reflex** is a phenomenon in which a stimulus that normally would cause the contraction of a few muscle units leads to the widespread spasm of entire muscle groups. It results from the absence of central inhibitory mechanisms. The mass reflex can occur with any level of spinal cord injury. It may occur with autonomic hyperreflexia in a patient with a lesion above T6.

Approximately 85% of patients with chronic spinal cord injuries at or above T6 experience the syndrome of **autonomic hyperreflexia.**[51] This is a life-threatening complication that results from the absence of central inhibition on the sympathetic neurons in the cord below the injury. Noxious stimuli, including bladder or bowel distention and uterine contractions, result in afferent transmission by means of the dorsal spinal root (Fig. 48.1).[52] These afferent neurons synapse with sympathetic neurons, and the impulse is propagated both cephalad and caudad in the sympathetic chain, without central inhibition. The propagation results in extreme sympathetic hyperactivity and severe systemic hypertension secondary to vasoconstriction below the level of the lesion. In response, the reflex arcs involving the baroreceptors of the aortic and carotid bodies lead to bradycardia and vasodilation above the level of the lesion. In patients with lesions at T6 and above, these compensatory mechanisms are insufficient to compensate for the severe hypertension. Intracranial hemorrhage, arrhythmias, and myocardial infarction occur in some cases. A variety of agents have been used for control of the hypertension of autonomic hyperreflexia (Fig. 48.2).

Obstetric Management

Approximately 2000 women in the United States with spinal cord injury become pregnant each year.[53] Pregnancy may aggravate many of the medical complications of spinal cord injury (Box 48.1).[52] The loss of both functional residual capacity and expiratory reserve volume during pregnancy may increase the likelihood of respiratory compromise associated with spinal cord injury, with worsening of respiratory function occurring as early as 20 weeks' gestational age. Patients may require tracheal intubation and mechanical ventilatory support, and cesarean delivery may be indicated to avert the fetal risks associated with maternal hypercapnia and to improve maternal respiratory mechanics.

Pregnancy increases the risks for thromboembolic phenomena and urinary tract infection. Loss of sympathetic tone below the level of the lesion renders pregnant patients with spinal cord injury particularly prone to orthostatic hypotension, which may result in reduced uteroplacental perfusion. In pregnant women, autonomic hyperreflexia occurs most commonly during labor; uterine contractions, vaginal and cervical examinations, speculum insertion, and urethral catheterization may trigger autonomic hyperreflexia. Autonomic hyperreflexia may affect uteroplacental blood flow, necessitating careful monitoring of the fetal heart rate (FHR).

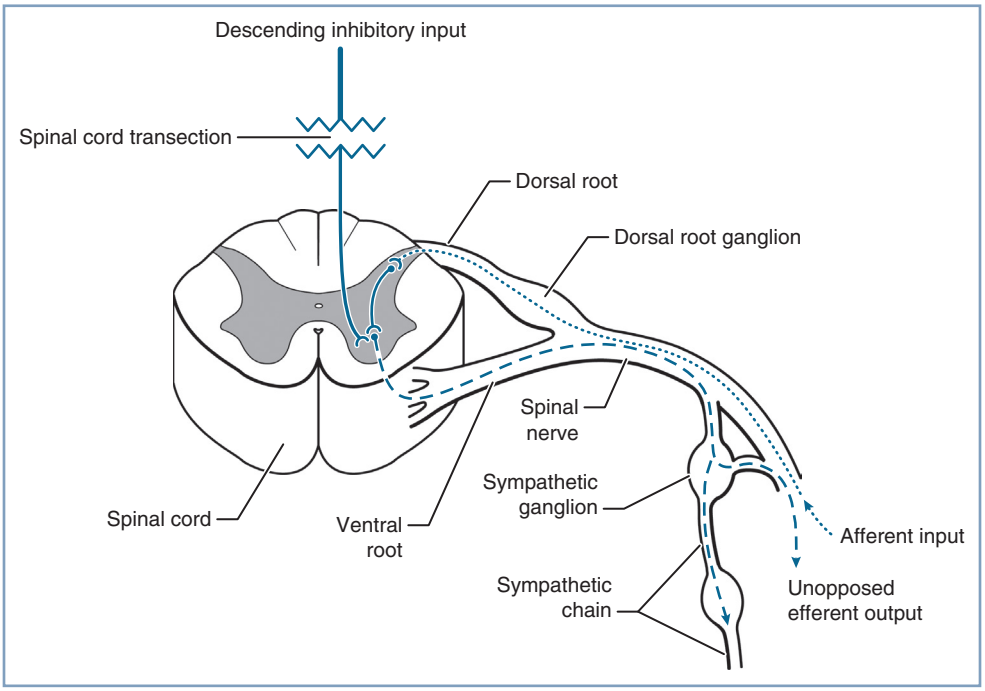

Fig. 48.1 Noxious stimuli enter the dorsal horn of the spinal cord through the dorsal spinal root *(dotted line)*. These afferent neurons synapse either directly or by means of interneurons *(solid line)* with sympathetic neurons in the intermediolateral columns of the lateral horns, which then project through the anterior roots to the paraspinal sympathetic chain *(dashed line)*. The impulse is propagated peripherally at that spinal level and travels both cephalad and caudad in the sympathetic chain, exiting at multiple thoracic and lumbar levels *(dashed line)* and resulting in sympathetic hyperactivity. BOX 48.1 Medical Complications of Spinal Cord Injury Aggravated by Pregnancy

Pulmonary
- Decreased respiratory reserve
- Atelectasis and pneumonia
- Impaired cough

Hematologic
- Anemia
- Deep vein thrombosis
- Thromboembolic phenomena

Urogenital
- Chronic urinary tract infections
- Urinary tract calculi
- Proteinuria
- Renal insufficiency

Dermatologic
- Decubitus ulcers

Cardiovascular
- Hypertension
- Autonomic hyperreflexia

From Crosby E, St. Jean B, Reid D, Elliot RD. Obstetric anaesthesia and analgesia in chronic spinal cord-injured women. *Can J Anaesth.* 1992;39:487–494.

Symptoms of autonomic hyperreflexia are also common in the immediate postpartum period, possibly triggered by postpartum pain, urethral catheterization, and uterine contractions.[54]

Women with a lesion above T11 may be at higher risk for preterm labor.[50] Because these women do not experience labor pain, obstetric management includes weekly cervical examinations during the third trimester, and patients are instructed on uterine palpation techniques to detect contractions at home. Although vaginal delivery is preferred, the development of autonomic hyperreflexia in the second stage of labor may necessitate expedited instrumental delivery. Assisted vaginal delivery may also be necessary because of the inability of the mothers to push during the second stage.[50] In a study of 52 pregnancies in spinal cord–injured women, 9 of 12 patients with lesions above T5 had symptoms of autonomic hyperreflexia. The cesarean delivery rate was 47% for women with lesions above T5 and 26% for women with lesions at T5 or below.[55] Preterm delivery occurred in 19% of patients.

Anesthetic Management

The ACOG recommends continuous hemodynamic monitoring during labor for all patients at risk for autonomic hyperreflexia.[56] This syndrome can be distinguished from other causes of intrapartum hypertension by the occurrence

of cyclic hypertension (i.e., blood pressure increases during contractions and decreases between contractions).

Early neuraxial anesthesia is preferred for the prevention or treatment of autonomic hyperreflexia during labor and delivery.[56] Although neuraxial labor analgesia may attenuate the risk and symptoms of autonomic hyperreflexia, it may not ablate the phenomenon entirely, particularly when low doses of local anesthetics are used.[54] Spinal anesthesia has effectively controlled blood pressure in paraplegic patients undergoing general surgical procedures.[57] Although some anesthesia providers contend that distortion of the vertebral column in paraplegic patients makes it more difficult to predict and control the level of spinal anesthesia, published data do not lend support to this assumption.[57] If spinal anesthesia is chosen, insertion of an intrathecal catheter and use of a continuous technique may be appropriate; this approach may allow careful titration of the resulting neuroblockade. Assessment of level of blockade in an insensate patient may be accomplished by assessing for loss of lower extremity deep tendon reflexes and meticulous monitoring for acute hypertension and bradycardia.

Most obstetric anesthesia providers prefer the use of epidural analgesia for the prevention or treatment of autonomic hyperreflexia during labor and vaginal delivery. Consideration also should be given to providing epidural analgesia after vaginal delivery to minimize the possibility of autonomic hyperreflexia, which has been reported to occur in response to pain as late as 5 days after delivery.[58]

Case reports have described the successful epidural administration of 0.25% or 0.5% bupivacaine, or the administration of combined spinal-epidural (CSE) anesthesia for the mitigation of autonomic hyperreflexia.[59,60] Baraka[61] reported the successful use of epidural meperidine, an opioid with local anesthetic qualities, in avoiding the signs of autonomic hyperreflexia. Abouleish et al.[62] observed that epidural fentanyl alone did not effectively treat the hypertension of autonomic hyperreflexia, but the addition of 0.25% bupivacaine led to a decrease in blood pressure to baseline levels. Maehama et al.[63] described the successful use of magnesium sulfate for management of autonomic hyperreflexia during labor.

Patients with spinal cord injury often have a low baseline blood pressure and some hemodynamic instability. Placement of an intra-arterial catheter before induction of anesthesia allows the continuous assessment of blood pressure. In patients with a history of autonomic hyperreflexia, continuous hemodynamic monitoring with an intra-arterial catheter will permit early detection and treatment of symptoms. Pulse oximetry is particularly useful in patients with respiratory compromise, and the anesthesia provider should always be available to provide ventilatory assistance if necessary.

Positioning for neuraxial block may be difficult; the anesthesia provider should consider performing the block with the patient in a lateral position because the sitting position may cause hypotension from venous pooling in the lower body. Therapeutic doses of a local anesthetic agent should be administered cautiously with the understanding that the cephalad level of the sensory block can be fully assessed only if it is higher than the level of the spinal cord lesion. As a result, the typical epidural test dose may not identify unintentional subarachnoid injection in a patient with spinal cord injury. Neuraxial blockade can be partially assessed by evaluating segmental reflexes below the level of the lesion. For example, the anesthesia provider can lightly stroke each side of the abdomen above and below the umbilicus, looking for contraction of the abdominal muscles and deviation of the umbilicus toward the stimulus. Reflexes are absent below the level of the block. In some patients with spastic paresis at baseline, the level of anesthesia may be confirmed by the conversion of spastic paresis to flaccid paresis.[59] A decline in blood pressure may also herald the onset of neuraxial blockade.

Alternative means of treating autonomic hyperreflexia should be available at the bedside if neuraxial analgesia or anesthesia is inadequate or not successful. Antihypertensive medications such as magnesium sulfate or arteriolar vasodilators may be effective, recognizing that hypotension can result in decreased uterine blood flow.[55] Careful titration of sodium nitroprusside, noting the potential for fetal/neonatal cyanide intoxication, or beta-adrenergic receptor blockade, may also be useful. The anesthesia provider should recognize that increased vagal activity during autonomic hyperreflexia can result in electrocardiographic changes including first- and second-degree atrioventricular block and sinus arrest.[64]

If cesarean delivery is necessary, epidural or spinal anesthesia can be administered. Spinal anesthesia is generally associated with more rapid onset and greater need to treat hypotension.[65] The effect of neuraxial blockade on respiratory function may be less severe with epidural anesthesia than with spinal anesthesia.

Severe respiratory insufficiency or technical difficulties with neuraxial anesthesia may necessitate the use of general anesthesia.[66] If general anesthesia is required, a depolarizing muscle relaxant such as succinylcholine should not be given during the period of denervation injury. By a conservative definition, this period begins 24 hours after the injury and lasts for 1 year. The use of succinylcholine during this period of denervation injury may cause severe hyperkalemia[67]; therefore, a nondepolarizing muscle relaxant should be used to facilitate laryngoscopy and tracheal intubation.

MYASTHENIA GRAVIS

Myasthenia gravis is an autoimmune disorder characterized by episodes of skeletal muscle weakness that are made worse by activity. Its prevalence is 150 to 250 per million.[68] Women are twice as likely to have the disease as men, and the onset is earlier. Subgroups are defined based on autoimmune and antibody disease mechanisms, skeletal muscle target molecules, thymic status, genetic characteristics, response to therapy, and disease phenotype.[68]

Myasthenia gravis results from an abnormality in autoimmune regulation, which leads to the production of antibodies against the nicotinic acetylcholine receptor or to

functionally related molecules on the neuromuscular end plate of skeletal muscle. The result is receptor destruction as well as antibody-induced blockade of the remaining acetylcholine receptors.[68] Smooth muscle and cardiac muscle are not affected. The diagnosis is based on characteristic symptoms and positive antibody tests, and in the absence of antibodies, on neurophysiologic tests or response to therapy. Thymic hyperplasia is common, and thymic tumors occur in approximately 10% of patients. Weakness is confined to the ocular muscles in 15% of patients. There is an association between myasthenia gravis and other autoimmune disorders, such as rheumatoid arthritis and polymyositis. In general, an early age at onset and an extended duration of purely ocular myasthenia are good prognostic signs.

Medical Management

Anticholinesterase drugs, which inhibit the breakdown of acetylcholine, are the mainstay of therapy for all subtypes of the disease. Pyridostigmine, a quaternary ammonium compound that does not cross the blood-brain barrier, is the preferred maintenance drug because it has less severe muscarinic side effects than other anticholinesterase drugs.[68] The treatment goal is full or nearly full remission; most patients will also require immunosuppressive therapy to meet this goal. Prednisone or prednisolone combined with azathioprine are the usual first-line immunosuppressants. Mycophenolate mofetil may also be added; other drugs include rituximab, methotrexate, cyclosporine, tacrolimus, and cyclophosphamide. Monotherapy with glucocorticoids may prevent progression of ocular myasthenia gravis to generalized disease. Thymectomy is performed in all patients with thymomas; however, there is also a benefit of total thymectomy for patients with early-onset symptoms without thymoma.[68]

Myasthenia gravis can manifest in two types of crises. A **cholinergic crisis** is rare, especially if the daily dose of pyridostigmine is less than 960 mg.[69] It results from an excess of the muscarinic effects of anticholinesterase medications combined with a poor response to anticholinesterase therapy. In contrast, a **myasthenic crisis** results from a worsening of the disease; its symptoms include worsening muscle weakness, especially muscles of respiration. Admission to an intensive care unit, ventilatory support, and rapid therapies such as plasma exchange and intravenous immune globulin are indicated.[68,69]

Many drugs can cause a worsening of myasthenic symptoms. These patients are extremely sensitive to drugs that potentiate muscle weakness. These agents include neuromuscular blocking agents, quinidine, propranolol, aminoglycoside antibiotics, and tocolytic agents such as magnesium sulfate[70] and terbutaline. One case report noted worsened symptoms after the maternal administration of betamethasone.[71]

Obstetric Management

The course of myasthenia gravis during pregnancy varies. In general, approximately 30% of cases improve, 30% worsen, and 30% show no change.[72] Retrospective data are inconsistent, suggesting that the course of the disease during pregnancy is highly variable. The baseline clinical state does not predict the course of the disease during pregnancy, and the course during one pregnancy does not predict the course in a subsequent pregnancy. Because disease exacerbations occur more frequently in the first year after diagnosis of myasthenia gravis, women should be counseled to delay pregnancy for 1 to 2 years after the initial disease diagnosis.[73] The is no consistent evidence that myasthenia gravis has adverse effects on pregnancy, although complications of pregnancy and their treatment (e.g., preeclampsia) may contribute to worsening myasthenia gravis symptoms.[72] For example, magnesium therapy has been reported to precipitate a myasthenic crisis.[70,72]

The maternal physiologic changes of pregnancy, including alterations in drug absorption, increases in blood volume, and changes in renal clearance, may require adjustments in the doses of anticholinesterase drugs. Each patient should be monitored carefully for progressive respiratory compromise secondary to diaphragmatic elevation during pregnancy. Vital capacity can be measured to monitor fatigue during labor. The treatment of the myasthenic patient with preeclampsia or preterm labor is problematic because the use of magnesium sulfate for maternal seizure prophylaxis or fetal neuroprotection reduces acetylcholine release and may be associated with a significant increase in maternal and fetal muscle weakness, and even maternal death.[74] In those cases, seizure prophylaxis with anticonvulsants has been described.[75]

The uterus consists of smooth muscle; therefore, myasthenia gravis should not affect the first stage of labor. However, the second stage of labor often requires the use of striated muscle, and consequently an assisted (e.g., vacuum or forceps) vaginal delivery may be required.

Maternal IgG antibodies to the acetylcholine receptor are transferred across the placenta. Transient neonatal myasthenia gravis occurs in approximately 10% to 20% of infants of mothers with myasthenia gravis.[72] Notably, the risk and severity of neonatal myasthenia is not related to the severity of maternal disease; therefore, all neonates of mothers with myasthenia gravis must be closely monitored. The symptoms, including poor sucking, generalized hypotonia, difficulty feeding, feeble cry, ptosis, and respiratory distress, usually develop within the first 12 to 48 hours after birth and abate as the antibodies are metabolized, with resolution typically occurring within 2 to 4 weeks. Arthrogryposis multiplex congenita is a rare and severe disease, occurring in about 6.2 per 100,000 live births. In this condition, infants have multiple joint contractures from reduced movement *in utero;* the condition is associated with stillbirth, spontaneous abortion, and neonatal death.

Anesthetic Management

Myasthenia gravis patients should undergo early antepartum consultation with an anesthesia provider. This evaluation should assess the extent of bulbar and respiratory involvement and overall baseline muscle strength. Pulmonary function testing should be performed in patients with evidence of respiratory compromise. In a study of surgical patients, the

presence of bulbar symptoms, a preoperative serum level of antiacetylcholine receptor antibody greater than 100 nmol/L, and intraoperative blood loss greater than 1000 mL were risk factors for having a postoperative myasthenic crisis.[76]

Patients with respiratory compromise may be more susceptible to opioid-induced respiratory depression, and consideration should be given to minimizing or avoiding opioids when possible. Neuraxial techniques are the preferred method for labor analgesia in patients with myasthenia gravis, and early labor neuraxial analgesia is recommended to attenuate stress and preserve maternal strength and reserve for the second stage of labor.[3] The use of anticholinesterase drugs may prolong the half-life of ester local anesthetic agents.

Neuraxial anesthetic techniques are preferred for cesarean delivery unless the patient has significant bulbar involvement or respiratory compromise. The use of bilevel positive airway pressure for ventilatory support in patients with moderate respiratory compromise may improve the safety of neuraxial anesthesia.[77]

In the patient with severe bulbar involvement or respiratory compromise, it may be prudent to secure the airway before surgery. Depolarizing muscle relaxants (e.g., succinylcholine) have an unpredictable effect in these patients, with affected and unaffected muscles being more sensitive and resistant to these agents, respectively.[78] However, the commonly administered dose of succinylcholine (1 to 1.5 mg/kg), which is three to five times the dose required to depress neuromuscular function by 95%, will most likely provide adequate relaxation even for resistant muscles. Anticholinesterase agents and plasmapheresis cause decreases in the activity of plasma cholinesterase and may cause delays in succinylcholine hydrolysis.

Myasthenic patients are extremely sensitive to nondepolarizing muscle relaxants. If a nondepolarizing muscle relaxant must be given, the anesthesia provider should administer a small amount of an agent with a short half-life (e.g., rocuronium, atracurium, vecuronium).[78] Mivacurium is metabolized via plasma pseudocholinesterase, which may be inhibited by pyridostigmine. In general, greater disease severity corresponds with enhanced sensitivity to nondepolarizing muscle relaxants, necessitating the use of clinical judgment and neuromuscular monitoring to determine the amount and timing of drug doses. Myasthenia may prevent a full-strength contraction with nerve stimulation; therefore, a control train-of-four stimulus test should be performed before paralysis for later comparison. For nondepolarizing agents, approximately 50% of the standard dose may be adequate, and a prolonged recovery should be anticipated. Sugammadex, a cyclodextrin that works by encapsulating nondepolarizing neuromuscular blocking agents, may be preferred for neuromuscular blockade reversal in patients with myasthenia gravis. The limited available data on its use in pregnancy suggest that it is safe.[79,80]

After delivery, fluid shifts and decreased maternal alpha-fetoprotein concentrations may necessitate an adjustment of anticholinesterase drug doses. Some patients who receive general anesthesia require postoperative ventilation. The following factors are predictive of an increased risk for postoperative ventilation: (1) female gender; (2) $FEF_{25\%–75\%}$ (forced expiratory flow during the middle half of the forced vital capacity) less than 3.3 L/sec and less than 85% of that predicted; (3) FVC (forced vital capacity) less than 2.6 L/sec and less than 78% of that predicted; and (4) $MEF_{50\%}$ (maximal expiratory flow at 50% of expired vital capacity) less than 3.9 L/sec and less than 80% of that predicted.[81]

EPILEPSY

Epilepsy is a condition characterized by recurrent seizure activity in the absence of metabolic disorders or acute brain disease. The classification scheme for epilepsy[82] and seizure types[83] was updated in 2017 by the International League Against Epilepsy. The first level of classification is one of three seizure types: focal onset, generalized onset, and unknown onset.[83] The second level of classification is epilepsy type; these are generalized, focal, combined generalized-focal, and unknown.[82] In focal seizures, the excess neuronal discharge is limited to one hemisphere of the brain; in generalized seizures, the discharge occurs bilaterally and involves the entire cortex.

Medical Management

A variety of antiepileptic agents are used for seizure therapy, depending on the type of seizure and clinical response (Table 48.2).[84–86] A variety of adverse effects have been reported with these agents, including early-onset events (e.g., somnolence, dizziness, hypersensitivity, rash, gastrointestinal symptoms) and late-onset events (e.g., depression, leukopenia, aplastic anemia, thrombocytopenia, megaloblastic anemia, hyponatremia).[85]

Prognosis for medical control of seizures is good for patients with generalized seizure disorders; as many as 20% to 40% of newly diagnosed epilepsy patients become seizure-free without or with minimal antiepileptic drug therapy.[87] Two in three newly treated epilepsy patients will eventually enter long-term remission (5 years or more without a seizure).[87] However, about one-third of patients will have an intermittent pattern (early remission with late recurrence or late remission). Finally, the standard mortality ratio for patients with epilepsy (observed number of deaths in the study compared with the general population) is consistently increased in the first several years after the diagnosis of epilepsy.

Interaction with Pregnancy

Epilepsy is common in pregnancy, affecting about 1 in 200 parturients.[88] Maternal mortality is greater in women with epilepsy.[89] Pregnancy may increase the frequency of seizures in 1 in 3 epileptics; this may be secondary to increases in plasma volume and higher drug clearance, which reduces serum levels of antiepileptic drugs.[90] Women who are free of seizures for at least 9 months to 1 year before pregnancy have a probability of 84% to 92% of remaining seizure-free during pregnancy.[91]

TABLE 48.2 Epilepsy Drugs

Antiepilepsy Drug	Enzyme Inducer[a]	Enzyme Inhibitor[b]	Target Dose (mg/day)	Target Plasma Concentration (mg/L)[c]
Carbamazepine	Yes	No	600–1200 bid or tid	3–12
Clobazam	No	No	10–20 bid	–
Ethosuximide			500 qd	40–100
Felbamate	No	No	2400–3600 bid or tid	20–45
Gabapentin	No	No	900–2400 bid or tid	2–20
Lamotrigine	Yes	Yes	100–400 qd or bid	2–15
Levetiracetam	No	No	1000–3000 bid	12–46
Oxcarbazepine	Yes	No	800–1800 bid or tid	7.5–20 (MHD)
Phenobarbital	Yes	No	50–200 qd or bid	10–40
Phenytoin	Yes	No	200–300 bid or tid	5–25
Pregabalin[d]	No	No	150–600 bid or tid	–
Primidone	Yes	No	500–750 tid	10–40 (PHB)
Tiagabine	No	No	36–60 tid	–
Topiramate	Yes[e]	No	100–400 bid	5–20
Valproate	No	Yes	600–1500 bid (slow release) or tid	40–120
Vigabatrin[d]	No	No	500–3000 bid	–
Zonisamide[d]	No	No	300	10–40

bid, twice daily; *MHD,* monohydroxy derivative; *PHB,* phenobarbital; *qd,* daily; *tid,* three times daily.
[a]Enzyme inducer of the CYP cytochrome P450 system.
[b]Enzyme inhibitor of the CYP cytochrome P450 and uridine diphosphate glucuronyl transferase systems.
[c]Dash (–) indicates not relevant.
[d]Dose should be reduced in patients with renal dysfunction.
[e]For doses > 200 mg/day.

TABLE 48.3 Possible Causes of Increased Seizure Frequency during Pregnancy

Mechanism	Examples
Hormonal	Changes in levels of estrogen (proconvulsant) and progesterone (anticonvulsant)
Metabolic	Increased water and sodium retention
Psychologic	Stress, sleep deprivation
Pharmacokinetics	Increase in liver metabolism, renal clearance, or volume of distribution
Physiologic	Decreased gastrointestinal absorption

Optimizing antiepileptic therapy before and during pregnancy is critical to maintain prepregnancy serum antiepileptic drug levels. Because of the teratogenic aspects of many antiepileptic agents, some physicians consider withdrawal of these drugs after 2 years without seizures and recommend waiting at least 6 additional months after withdrawal before attempting to conceive. Substituting new antiepileptic agents after conception is not recommended because of increased risk for teratogenicity associated with polytherapy.[90]

A variety of causes have been proposed for the increase in seizure frequency observed in some pregnant women (Table 48.3). Higher estrogen concentrations in pregnancy lower the seizure threshold.[92] Greater sodium and water retention, alkalosis secondary to hyperventilation, sleep deprivation, and increased stress and anxiety also have been suggested as mechanisms.[93] In addition, anticonvulsant drug levels can decrease during pregnancy, often despite the administration of a larger dose; this may be partially explained by the decreased plasma protein binding and greater drug clearance observed during pregnancy.[94] The American Academy of Neurology and American Epilepsy Society concluded that monitoring of lamotrigine, carbamazepine, and phenytoin levels should be considered during pregnancy. Monitoring of levetiracetam and oxcarbazepine (and its active metabolite, monohydroxy derivative) may be considered, and monitoring of other antiepileptic agents should not be discouraged despite limited data regarding their pharmacokinetic behavior during pregnancy.[95]

Maternal seizures can have devastating consequences. Hypoxia and acidosis that occur during a generalized seizure can result in fetal compromise or intrauterine fetal death. Placental abruption may occur during a seizure. During the past three decades, the overall risk for obstetric complications in epileptic women has declined. Although some studies have suggested an increased risk for hypertension in pregnancy (including preeclampsia), bleeding, and preterm birth, a systematic review concluded that evidence is inconclusive.[91] However, women with epilepsy may have a moderately increased risk for cesarean delivery.[91]

Fetuses and neonates of women with epilepsy are approximately twice as likely to have adverse pregnancy outcomes, including intrauterine fetal death, cesarean delivery, 1-minute

Apgar score less than 7, neonatal and perinatal death, LBW, and abnormal development.[96] Antiepilepsy drugs taken in the first trimester of pregnancy are associated with an increased risk for major congenital malformations.[96,97] Data are insufficient to judge whether intrauterine exposure to antiepileptic agents in general increases the risk for cognitive impairment in the offspring of women with epilepsy, although there is some evidence that the risk may be increased for specific drugs.[97] Specifically, intrauterine exposure to valproate has been associated with maladaptive childhood behavior and autism.[32,97]

The risk for congenital malformations in women with epilepsy receiving antiepileptic drug monotherapy is 4% to 6%.[89,97] Malformations have been associated with all currently used therapeutic modalities; those most often observed are cleft lip and palate, and cardiac, neural tube, and urogenital defects (hypospadias).[97]

Certain drugs have been associated with a higher relative risk for congenital defects than others. Data from prospective studies indicate that valproate in particular is associated with significantly higher rates of major malformations.[89,97] Newer agents (e.g., lamotrigine, gabapentin, felbamate, topiramate, tiagabine, levetiracetam, pregabalin) have fewer teratogenic effects. A systematic review and meta-analysis of 31 studies on antiepileptic drug therapies in pregnant women concluded that lamotrigine and levetiracetam carried the lowest overall risk for malformation, although data on specific malformations were insufficient.[98] Several studies suggest that maternal folic acid supplementation before conception may decrease the risk for major congenital abnormalities in the offspring of women with epilepsy who are receiving antiepileptic therapy.[95]

Tomson and Battino[97] reviewed data from the International Registry of Antiepileptic Drugs and Pregnancy (EURAP) and made the following suggestions: (1) before conception select the most appropriate agent for the woman's type of epilepsy; (2) select the drug with the lowest teratogenic potential; (3) aim for monotherapy with the lowest effective dose; (4) whenever possible, avoid valproate; and (5) if possible, avoid valproate at doses of 700 mg/day and higher.

Neonates of mothers undergoing long-term antiepileptic therapy may be at risk for deficiencies in vitamin K–dependent clotting factors or other coagulation defects, despite the absence of clinically evident maternal coagulation abnormalities.[95] Enzyme-inducing antiepileptic agents (e.g., phenytoin, phenobarbital, carbamazepine) can cross the placenta and may increase the rate of oxidative degradation of vitamin K in the fetus. Affected infants are at risk for neonatal hemorrhage and respond to typical vitamin K doses (1 mg) given intramuscularly at birth. The administration of prenatal vitamin K to epileptic women with long-term exposure to these antiepileptic agents has not been conclusively shown to reduce the risk for neonatal hemorrhage.[95]

Anesthetic Management

There are significant interactions between antiepileptic drugs and anesthetic agents.[99] Carbamazepine, phenytoin, phenobarbital, and primidone are potent inducers of the cytochrome P450 enzymes in hepatic metabolism (see Table 48.2), which may result in decreased plasma concentrations of many medications, including neuromuscular blockers, beta-adrenergic receptor antagonists, and calcium entry–blocking agents.[85]

Serum levels of antiepileptic drugs should be checked if therapeutic levels are known (see Table 48.2). Drug doses should not be missed during the peripartum period. If the patient experiences a seizure during labor, airway protection and support of ventilation are essential. Small doses of a benzodiazepine or propofol arrest most seizures. Fetal bradycardia may necessitate immediate delivery.

Oral antiepileptic therapies should be continued whenever possible throughout the peripartum period. Unfortunately, many of the agents are not available in parenteral forms. If oral agents cannot be taken, conversion to a parenteral agent such as phenytoin may be required. In general, antiepileptic agents have sedating properties.

The presence of epilepsy is not a contraindication to the administration of neuraxial analgesia or anesthesia. Although antiepileptic drugs have been associated with adverse effects on the coagulation system, Manohar et al.[100] observed no abnormal clotting parameters or platelet counts preoperatively in a series of patients with epilepsy undergoing surgery.

If general anesthesia is necessary, it seems prudent to avoid opioids, particularly meperidine, as these drugs have been associated with seizures, even after low to moderate doses.[94] Sevoflurane has stronger epileptogenic properties than isoflurane, but limiting the concentration to less than 1.5 minimum alveolar concentration minimizes risk, and co-administration of nitrous oxide and hyperventilation both counteract this effect.[101] The highest incidence of seizure activity with induction of anesthesia is believed to occur with etomidate. Ketamine may also facilitate seizures at low doses, but at high doses each of these induction agents acts as an anticonvulsant.[99] One study noted that some patients who receive phenytoin are resistant to vecuronium but not to atracurium.[102]

MYOTONIA AND MYOTONIC DYSTROPHY

Myotonia is the general term used to describe a prolonged contraction of certain muscles after stimulation, which is followed by a delay in relaxation. **Myotonic dystrophies** are a genetically and phenotypically heterogeneous group of neuromuscular disorders caused by expansion defects in nucleotide sequences, principally on chromosome 19.[103] Based on clinical ascertainment, the estimated prevalence of myotonic dystrophy is about 1 in 8000; however, prevalence estimates vary widely.[103] As the most common form of myotonic disorders, myotonic dystrophies manifest in two distinct forms with different nucleotide sequences, DM1 and DM2. Both DM1 and DM2 are multisystem disorders characterized by skeletal muscle weakness and myotonia, cardiac conduction abnormalities, cataracts, hypogammaglobulinemia, and insulin resistance. DM1, also known as Steinert disease, is generally more severe and exists in congenital, juvenile, and adult forms, whereas only an adult form has been identified for DM2.[103]

Myotonias can involve specific muscles, typically the hand, facial, masseter, and pretibial muscles, which become dystrophic or wasted. The disorder is slowly progressive with continual deterioration and gradual involvement of pharyngeal and laryngeal muscles, proximal limb muscles, and the diaphragm. Uterine smooth muscle is affected, and cardiac conduction abnormalities are often present. Patients typically succumb to either pulmonary or cardiac failure.

Congenital myotonic dystrophy is a severe form of myotonic dystrophy (DM1) that manifests early in infancy with hypotonia and feeding difficulties.[104] Myotonia becomes apparent during the first few years of life. In most cases, the mother has myotonic dystrophy. Sudden cardiac death is possible, due to atrioventricular block and ventricular arrhythmias.[105]

Myotonia congenita is a milder familial disorder characterized by myotonia of the skeletal muscles; multisystem involvement does not occur.[106] Unlike myotonic dystrophy, cardiac abnormalities are not present, and smooth muscles are not affected. In some cases, muscle hypertrophy rather than wasting occurs. This disorder can be compatible with long life. It is distinguished from DM1 and DM2 by characteristic clinical features and an absence of significant histopathology in the muscle biopsy specimen. Myotonia congenita is characterized by dysfunction of the chloride channel.

Central core disease is a rare disorder in which muscle biopsies demonstrate the absence of oxidative enzyme activity in the longitudinal axis of the muscle fiber (i.e., the "central core").[107] Affected individuals have proximal muscle weakness and often scoliosis. This disease is caused by mutations in the skeletal muscle ryanodine receptor gene *(RYR1)* at chromosome 19q13.1, which has been associated with malignant hyperthermia.[107] Many patients with central core disease test positive for the malignant hyperthermia susceptibility trait on the caffeine-halothane contracture test (*in vitro* contracture test) (see Chapter 46); these patients should be considered at risk for malignant hyperthermia and should not be exposed to triggering agents (i.e., succinylcholine, volatile halogenated agents).[107] Some patients with multi-minicore and nemaline rod myopathy may also be at risk for malignant hyperthermia.[108]

Drugs such as quinine and mexiletine are most commonly used to relieve myotonic symptoms.[103,104,106] Corticosteroids, phenytoin, and tocainide also have been prescribed.

Obstetric Management

In patients with myotonic dystrophy, symptoms of weakness and myotonia usually remain unchanged during pregnancy; however, in a minority of women, symptoms worsen during pregnancy but generally resolve after delivery.[109] Antepartum evaluation should include pulmonary function testing, to assess the severity of restrictive lung disease caused by muscle wasting, and an electrocardiogram, which may reveal conduction abnormalities.

There may be a higher risk for preterm labor in patients with myotonic dystrophy. Other complications of pregnancy include polyhydramnios (secondary to reduced fetal swallowing) and an increased risk for placenta previa and accreta.[109] Magnesium sulfate has been reported to cause respiratory compromise.[110] Poor uterine contractions may result in prolonged labor, uterine atony, and an increased risk for postpartum hemorrhage.[111,112] Skeletal muscle weakness increases the risk for prolonged second stage of labor and operative delivery.[109] The neonate also may have respiratory distress if affected by congenital myotonic dystrophy.

There are reports of patients with myotonia congenita who experience temporary worsening of symptoms during pregnancy.[113] Obstetric problems have not been described, most likely because this disease involves skeletal muscle only; uterine smooth muscle is not affected in these patients.

Anesthetic Management

Many reports of anesthetic management of patients with myotonic dystrophies were published before the distinction between DM1 and DM2 was appreciated, and before the era of modern anesthesia management; therefore, generalization from these reports may not be valid.[114] Reports suggest that patients with myotonic disorders may be especially sensitive to the respiratory depressant effects of opioid analgesic and general anesthetic agents.[114] Sedative-hypnotic agents should be used with caution; in some cases, opioids or sedatives may precipitate apnea. Thus, neuraxial anesthesia is preferred for labor and vaginal or cesarean delivery. Both spinal and epidural anesthesia have been used successfully in patients with myotonic dystrophy.[115–117] Although the clinical characteristics of myotonic dystrophy DM2 are generally more benign than DM1, anesthesia providers should be aware that both may be associated with dysphagia, cardiomyopathy, and cardiac conduction abnormalities.[118] Two case reports described atrial flutter and fibrillation resulting in shock after tracheal intubation in myotonic dystrophy patients receiving general anesthesia for cesarean delivery.[119,120]

The prolonged contractions witnessed in patients with myotonia are caused by an intrinsic muscle disorder that is not relieved by spinal or epidural anesthesia; however, infiltration with a local anesthetic agent may partially release contractions. Cold external temperatures and shivering are known triggers of myotonia, so the patient should be kept warm. Patients with myotonic dystrophy have a high incidence of pulmonary complications after general anesthesia.[121]

If general anesthesia is required, it may be prudent to limit the use of opioids and carefully titrate muscle relaxants to mitigate the risk for postoperative pulmonary complications.[122] Depolarizing agents such as succinylcholine should be avoided because fasciculations trigger myotonia,[123] thereby making ventilation and tracheal intubation difficult. In contrast, patients with myotonic dystrophy appear to have a normal response to nondepolarizing muscle relaxants.[114] Regardless, careful neuromuscular monitoring is essential, particularly in those with significant baseline muscle weakness. Reversal of neuromuscular blockade with sugammadex has been described.[124] In a review of dystrophic myotonias and their possible association with malignant hyperthermia, Parness et al.[125] concluded that susceptibility to malignant

hyperthermia in this group of patients is similar to that of the general population. Patients with central core disease should be assumed to be susceptible to malignant hyperthermia.[107]

MUSCULAR DYSTROPHY

Muscular dystrophy is a group of disorders characterized by a progressive degeneration of skeletal muscle with intact innervation.[126] Research on the subsarcolemmal muscle fiber protein dystrophin has led to a reclassification of these disorders. Analysis of dystrophin quality and quantity can be used diagnostically before and during pregnancy, and can identify carriers in some cases.

Duchenne and **Becker muscular dystrophies** are transmitted as X-linked recessive disorders and occur almost exclusively in males. However, female carriers may have electrocardiographic and/or echocardiographic abnormalities. The most common muscular dystrophies affecting females are fascioscapulohumeral dystrophy and limb-girdle dystrophies. **Fascioscapulohumeral dystrophy** is an autosomal dominant, slowly progressive disorder that primarily involves the muscles of the shoulders and face.[126] Over time, the pelvic and pretibial muscles may be affected. Tachycardia and arrhythmias have been infrequently reported. **Limb-girdle dystrophies** involve slow degeneration of the shoulder and pelvic muscles; exacerbations are common during pregnancy, and risk for cesarean delivery is increased because of weakness in the trunk and pelvic muscles.[126] The inheritance pattern and severity of these diseases are variable. Cardiac conduction disorders and cardiomyopathies occur in some affected patients.

Obstetric Management

The presentations of dystrophinopathies are variable, and the overall management is guided by the presence and severity of symptoms. If significant weakness is present, pulmonary function testing should be obtained to assess the extent of restrictive disease. An antepartum electrocardiogram and echocardiogram should be considered. Pregnant women with muscular dystrophies may have an increased incidence of operative delivery; the presence of severe pelvic wasting may necessitate instrumental vaginal or cesarean delivery.[127] A study of the course of pregnancy in women with hereditary neuromuscular disorders reported a high rate (27%) of abnormal fetal presentation in women with limb-girdle muscular dystrophy, especially in chair-bound patients. Muscle weakness worsened during and after pregnancy in one-half of patients with limb-girdle dystrophy.[109]

Anesthetic Management

Limb-girdle muscular dystrophy is associated with various cardiac abnormalities, including cardiomyopathies and conduction abnormalities. Reduced lung function and respiratory compromise can be exacerbated by the physiologic changes of pregnancy; one report of a parturient with limb-girdle muscular dystrophy noted the requirement of noninvasive positive-pressure ventilation for progression of severe restrictive pulmonary disease during the third trimester of pregnancy.[128] Neuraxial techniques are preferred for labor analgesia and cesarean delivery anesthesia. Severe disease may result in both airway abnormalities and spinal deformities, which may complicate the administration of either general or neuraxial anesthesia.

Whereas most females are asymptomatic carriers of the abnormal gene for muscular dystrophies, approximately 2.5% of female carriers have mild symptoms of the disease.[129] Cardiac manifestations may be significant; one report described a female carrier of Becker's muscular dystrophy who had peripartum cardiomyopathy; general anesthesia was associated with intraoperative respiratory insufficiency, hemodynamic instability, and cardiac arrest.[130] There are reported cases of muscular dystrophy associated with "malignant hyperthermia–like" reactions. In a systematic review, Gurnaney et al.[131] summarized reported cases of patients with muscular dystrophy who developed hyperthermia, tachycardia, rhabdomyolysis, and hyperkalemia after exposure to succinylcholine and/or volatile anesthetic agents. However, none of these patients had other classic signs of malignant hyperthermia or evidence of hypermetabolism. The mechanism for this response may be related to the ability of these agents to exacerbate instability and permeability of dystrophin-deficient muscle membranes.[131] Although muscular dystrophy does not increase risk for malignant hyperthermia, volatile anesthetic agents should be used cautiously because of the risk for severe rhabdomyolysis. Succinylcholine may lead to life-threatening hyperkalemia because of upregulation of extrajunctional acetylcholine receptors or because of rhabdomyolysis. Thus, succinylcholine should not be administered to patients with known muscular dystrophy. In general, these patients have a normal response to nondepolarizing muscle relaxants, but careful neuromuscular monitoring is needed, especially in patients with severe muscle wasting.

THE PHAKOMATOSES (NEUROCUTANEOUS SYNDROMES)

The phakomatoses are congenital disorders that manifest as CNS and cutaneous abnormalities. Structures of ectodermal origin such as skin, nervous system, and eyes are commonly affected.[132] The diseases are classified into three main groups: neurofibromatoses, tuberous sclerosis, and angiomatoses with CNS abnormalities (Box 48.2).[133] The most common phakomatoses are neurofibromatosis types 1 and 2, tuberous sclerosis, Sturge-Weber disease, and von Hippel-Lindau disease. Abnormalities of the brain and spinal cord can have significant implications for anesthetic management.

Neurofibromatosis

Neurofibromatosis occurs as a result of excessive proliferation of neural crest elements such as Schwann cells, melanocytes, and fibroblasts. Clinical manifestations include hyperpigmented lesions (*café-au-lait* spots) accompanied by a variety of cutaneous and subcutaneous tumors. This disorder is now believed to exist in two distinct forms with gene abnormalities

BOX 48.2 The Congenital Neuroectodermoses

True Phakomatoses
- Tuberous sclerosis
- Neurofibromatosis
  - Type 1 (classical)
  - Type 2 (acoustic)
  - Familial schwannomatosis

Cutaneous Angiomatosis with Abnormalities of the Central Nervous System
- Sturge-Weber syndrome (meningofacial or encephalofacial angiomatosis with cerebral calcification)
- Dermatomal hemangiomas and spinal vascular malformations
- Epidural nevus (linear sebaceous nevus) syndrome
- Osler-Rendu-Weber disease (hereditary hemorrhagic telangiectasia)
- von Hippel-Lindau disease
- Ataxia-telangiectasia (Louis-Bar disease)
- Fabry disease

Modified from Ropper AH, Samuels MA, Klein JP. *Adams and Victor's Principles of Neurology*. 10th ed. New York, NY: McGraw Hill; 2014: online version Chapter 38.

on two different chromosomes. Neurofibromatosis type 1, the "classic" form, has an incidence of approximately 1 in 3000.[134] The severity and progression of the disease are variable, with the neurologic symptoms depending on the location of the tumors. Intracranial tumors and paraspinal neurofibromas are a cause of concern and may require surgical excision. The risk for pheochromocytoma is greater in these patients.[135] Neurofibromatosis type 2 is a less common form of the disease with fewer cutaneous lesions. Acoustic neuromas as well as other cranial or spinal neurofibromas, meningiomas, and gliomas may be present.

Obstetric Management

Pregnancy may exacerbate the disease by increasing tumor growth.[135] Regression occurs after delivery in some women. A population-based cohort study of 1553 pregnancies associated with neurofibromatosis type 1 found increased risks for gestational hypertension, preeclampsia, fetal growth restriction, cerebrovascular disease, and cesarean delivery.[135] Pelvic neurofibromas may necessitate cesarean delivery. Risk for thromboembolic events, stillbirth, cardiac events, or maternal death were not elevated compared with the general population.[135] The presence of intracranial masses may be problematic during labor and vaginal delivery, particularly with the increased intracranial pressure (ICP) that occurs with the Valsalva maneuver during the second stage of labor.

Anesthetic Management

An anesthesia provider should thoroughly assess the patient's current symptoms and known lesions, particularly if they involve neck and laryngeal tumors; these tumors are common, particularly in patients with neurofibromatosis type 1.[136] Antenatal evaluation for concomitant pheochromocytoma and potential neuraxial, intracranial, and peripheral nerve tumors should be considered.

Neuraxial anesthetic techniques can be used for labor analgesia and operative anesthesia in most patients with the disorder. However, severe kyphoscoliosis owing to the presence of paraspinal tumors may complicate the administration of neuraxial anesthesia. The presence of asymptomatic paraspinal and intracranial tumors has prompted some anesthesia providers to suggest that neuraxial anesthesia should be administered only after careful clinical and radiographic evaluations.[137]

The use of muscle relaxants in these patients is controversial, because both increased and decreased sensitivity to succinylcholine has been reported; increased sensitivity to nondepolarizing agents has been reported as well.[138–140] However, a number of investigators observed only minimal alterations in dose response to both depolarizing and nondepolarizing muscle relaxants in these patients and have recommended no alterations in the dose of drug.[138]

Tuberous Sclerosis

Tuberous sclerosis is a phakomatosis characterized by epilepsy, mental retardation, and adenoma sebaceum.[141] The brain shows abnormal growth of glial cells in hamartomas called tubers. Hamartomatous tumors can occur in multiple organs, including the heart, kidneys, liver, and lungs. The inheritance pattern is autosomal dominant with a variable expression, and the disease is slowly progressive.

Obstetric and Anesthetic Management

A retrospective cohort study using the Nationwide Inpatient Sample from 1998 to 2008 found that tuberous sclerosis may be associated with increased rates of preterm labor (adjusted OR, 2.1) and preeclampsia (adjusted OR, 2.8).[142] The obstetrician and anesthesia provider should know the locations of lesions in an individual patient. Hemorrhage into the tumors, renal failure, and hypertension may complicate pregnancy.[143] Renal involvement appears to represent an important prognostic factor during pregnancy, and spontaneous rupture of a renal angiomyolipoma has been reported.[144] Factors that could potentially impact anesthetic management of these patients include the presence of cardiac and renal tumors (angiomyolipomas), spinal and intracranial tubers, epilepsy, pharyngeal tumors, and pulmonary involvement.[145] Cardiac rhabdomyosarcomas have been reported to occur in over 60% of children with this disorder. These tumors generally regress with age, but arrhythmias and cardiac failure from ventricular obstruction may occur. In the presence of known elevated ICP from cerebral lesions, some anesthesia providers believe that neuraxial anesthesia is contraindicated. Imaging should be considered before administration of neuraxial blockade if intracranial or spinal lesions are suspected. In addition, the airway should be assessed closely for the presence of oral tubers, which have been described in approximately 15% of these patients.

Cutaneous Angiomatosis with Central Nervous System Abnormalities

One group of phakomatoses consists of disorders in which a cutaneous vascular anomaly is accompanied by CNS abnormalities (see Box 48.2).[133] There are few reports of pregnancy in patients with these disorders. Patients may have neurologic problems related to hemangiomas of the CNS. Epidural and spinal anesthesia have been reported in only a few patients with spinal hemangiomas; epidural anesthesia may be preferable to spinal anesthesia as von Hippel-Lindau hemangioblastomas are not present in the epidural space.[146] The presence of widespread varicosities in these disorders may result in a chronically low ventricular preload; if a significant increase in preload occurs during the peripartum period, cardiac overload and peripartum cardiomyopathy may occur.[147]

ACUTE IDIOPATHIC POLYNEURITIS (GUILLAIN-BARRÉ SYNDROME)

Acute idiopathic polyneuritis, also known as Guillain-Barré syndrome, is an inflammatory demyelinating illness with a reported incidence of approximately 1 case per 100,000 persons per year.[148] In 60% of patients, a viral illness precedes neurologic symptoms by 1 to 3 weeks. Zika virus is a newly identified antecedent infection. Cases also have occurred after the administration of antirabies and influenza vaccines.

Patients with this disorder initially have weakness in the limbs, followed by the trunk, neck, and facial muscles. Loss of reflexes, total motor paralysis, and respiratory failure can occur. Symptoms peak at 2 to 3 weeks. The majority of patients recover completely; approximately 10% of patients have severe residual disability, and in 3% the syndrome is fatal.[148] Autonomic nervous system involvement and dysfunction may occur.

Treatment is largely supportive and may include mechanical ventilatory support. Plasmapheresis reduces the duration of illness when instituted during the evolution phase and has been used safely during pregnancy.[149]

Obstetric Management

The incidence of this syndrome appears unchanged in pregnant women, but increases in the first 3 months postpartum.[149] There is no evidence that pregnancy affects the natural history of the disease, and termination of pregnancy does not appear to improve its course.[149]

Anesthetic Management

Anesthetic management depends on patient status at the time of delivery; epidural and spinal techniques have been described in patients with Guillain-Barré syndrome.[150,151] However, some anesthesia providers have expressed concern regarding the use of neuraxial techniques in these patients, citing the theoretical potential for adverse neurologic effects as a result of anesthetic toxicity or immunologic modulation. Steiner et al.[152] implicated epidural anesthesia as a trigger of Guillain-Barré syndrome in four patients; Wiertlewski et al.[151] reported the immediate worsening of neurologic status after delivery in a pregnant patient with Guillain-Barré syndrome who had received epidural anesthesia. These authors did not establish a causal relationship between the disease and neuraxial anesthetic techniques, nor did they properly acknowledge the increased frequency of Guillain-Barré syndrome in the postpartum period.[149]

If general anesthesia is necessary, succinylcholine should be avoided because of the risk for hyperkalemia in patients with acute muscle wasting. Careful titration of nondepolarizing muscle relaxants is also necessary.

The parturient with a history of remote Guillain-Barré syndrome may have persistent diminished respiratory reserve, even in the absence of obvious residual disability. Pulmonary evaluation should be considered before the administration of anesthesia. Approximately 5% of patients experience a relapse, with a small number of cases progressing to a chronic disorder.

POLIOMYELITIS

Poliomyelitis is a disease caused by a picornavirus that is transmitted by the fecal-oral route. Most cases are asymptomatic or are accompanied by mild systemic symptoms. More severe symptoms and nervous system involvement occur in approximately 1% of patients.[153] Motor neurons in the cerebral cortex, brainstem, and spinal cord are affected. Asymmetric flaccid paralysis develops over several days. Bulbar paralysis is more common in young adults. The CSF findings are consistent with viral meningitis. Recovery occurs 3 to 4 months after onset, most likely from motor axon terminal sprouting that reinnervates the previously denervated muscle fibers; however, residual deficits often persist. A slowly progressive syndrome called **postpoliomyelitis muscular atrophy** (postpolio syndrome) may develop as many as 40 years after the acute illness as a result of death or dysfunction of the enlarged, surviving motor neurons.[154]

Obstetric Management

Although the poliovirus vaccine has been available since the 1950s, the last phase of poliomyelitis eradication has been difficult; in 2014, the World Health Organization declared the worldwide transmission of polio virus to formerly polio-free countries to be a public health emergency.[155] The oral form of the vaccination does not appear to have harmful effects on fetal development and can be used if vaccination is required during pregnancy.[156] A history of poliomyelitis may increase the risk for preeclampsia, maternal renal dysfunction, LBW infants, perinatal death, and cesarean delivery in poliomyelitis survivors.[157] Some of these adverse outcomes may be related to chronic pulmonary issues or mechanical obstruction during labor.

Anesthetic Management

A complete preanesthetic evaluation should be performed for the presence of respiratory impairment, sleep apnea, swallowing difficulties, and other neurologic and motor deficits in

all parturients with a history of poliomyelitis. Some anesthesia providers have feared that administration of neuraxial anesthesia in patients with a history of poliomyelitis might cause reactivation of the virus or postpolio syndrome. However, there is no evidence that neuraxial analgesia or anesthesia worsens symptoms in these patients. Rezende et al.[158] reported a series of 123 patients with a history of poliomyelitis undergoing 162 surgical procedures and observed postoperatively for 22 months; neuraxial blockade was used in 64% of cases, with no patients exhibiting worsening of neurologic symptoms. Anesthetic considerations in these patients should include assessment for pulmonary restrictive disease as well as anatomic issues that may make neuraxial techniques difficult.[159] For the patient with postpolio syndrome in whom general anesthesia is needed, some anesthesia providers have suggested the use of a decreased dose of a short-acting nondepolarizing muscle relaxant in lieu of succinylcholine, which may provoke severe acute hyperkalemia.[160]

BRAIN NEOPLASMS

Intracranial neoplasms vary in incidence, histology, clinical presentation, and prognosis (Table 48.4).[161] Brain neoplasms in pregnant women appear to occur with the same relative frequency as in nonpregnant women; however, the physiologic alterations that occur during pregnancy can have profound implications for symptomatology and management.

Gliomas are the most common intracranial neoplasms, accounting for approximately 39% of all primary intracranial tumors.[162] These tumors, which result from anaplasia of astrocytes, exhibit diversity in invasive potential and include glioblastoma multiforme, astrocytomas, ependymomas, and oligodendrocytomas. Glioblastoma multiforme is the most lethal, whereas oligodendrocytomas have a better prognosis.

Meningiomas account for approximately one-third of all primary brain tumors.[162] These benign tumors originate from the dura mater or arachnoid. Surgery typically is curative.

Pituitary adenomas account for 7% of diagnosed primary brain neoplasms.[162] Only a small fraction of these tumors cause symptoms (e.g., visual field deficits). These tumors may secrete prolactin, growth hormone, or adrenocorticotropic hormone. Tumor growth is physically limited by the sella turcica of the sphenoid bone and the hypothalamus. The resulting compression of the hypothalamus or pituitary gland may cause decreases in the production or release of vasopressin, leading to diabetes insipidus. The pituitary gland normally enlarges during pregnancy, and this additional growth may cause symptoms in a woman who was previously asymptomatic.[162] Women with known microadenomas should be carefully monitored during pregnancy to detect symptoms of pituitary compression.[163] Growth of pituitary tumors can be triggered by breast-feeding.

Bromocriptine often provides effective medical therapy for prolactin-secreting adenomas and has a track record of use during pregnancy; its continued use during breast-feeding must be balanced against its suppressive effect on lactation. Surgery is indicated for tumors that do not respond to medical management.

Schwannomas, also called **neurinomas,** account for 7% of all brain tumors.[162] These lesions originate in the Schwann cells surrounding the nerve. Clinical presentation depends on the location of the tumor. Acoustic neuromas result when the eighth cranial nerve is involved; these lesions are often seen in patients with neurofibromatosis. The treatment is surgical excision.

Metastatic carcinomas account for a significant number of brain neoplasms.[162] Common primary cancers include those of the lung, breast, and colon. Prognosis and therapy depend on the tumor of origin.

Brain tumors share several pathophysiologic features. Neurologic deficits can result from a mass effect or increased ICP, even if the tumor is benign. Brain edema, which may result from a combination of vasogenic and cytotoxic mechanisms, is a prominent feature of cerebral neoplasms.

The potential for herniation must be considered in any patient with a mass lesion. The brain is divided into three basic compartments. The falx cerebri separates the cerebrum into right and left halves, and the tentorium isolates the cerebellum. High pressure from a mass can cause shifts from one compartment to another with devastating effects.

TABLE 48.4 Classification of Brain Tumors in Women

Histologic Type	Percentage of All Diagnosed Tumors
Benign	
Meningioma	35
Schwannoma	7
Pituitary neoplasms	7
Malignant	
Gliomas:	
Low-grade astrocytoma	3
Glioblastoma multiforme (plus high-grade astrocytoma)	23
Other astrocytoma	8
Other	5
Lymphoma	2
Medulloblastoma	2
Other brain neoplasms	8

Modified from Swensen R, Kirsch W. Brain neoplasms in women: a review. *Clin Obstet Gynecol.* 2002;45:904–927.

Obstetric Management

The incidence of primary brain tumors first manifesting in pregnancy does not appear to be greater than that in age-matched, nonpregnant women.[162] However, pregnancy may affect existing tumor biology; in one case series, 44% of pregnant women with an existing history of grade II or III gliomas experienced tumor progression during pregnancy or within 8 weeks postpartum.[164] Approximately 9% of patients

with **choriocarcinoma** have brain metastases at the time of diagnosis.[165] In one epidemiologic study, patients with primary brain tumors had a higher incidence of spontaneous abortion, possibly because of hormonal factors.[166] A 2012 study using a retrospective cohort from the National Inpatient Sample reported an increased rate of maternal mortality, cesarean delivery, and preterm labor in patients with malignant brain tumors, and an increased rate of preterm labor and cesarean delivery in patients with benign brain tumors.[167] Pregnancy complications were significantly more likely to occur in patients having a neurosurgical procedure during their admission.

Although pregnancy does not affect the incidence of brain tumors, some of these lesions appear to grow faster during pregnancy. Visual field defects from pituitary adenomas worsen as a result of tumor enlargement during pregnancy, and symptoms have been observed to improve during the postpartum period.[168] Edema and the increased blood volume may account for some of these symptoms. Pregnancy-induced hormonal changes also may play a role because estrogen and progesterone receptors are present in meningiomas and some gliomas.[162]

Diagnosis during pregnancy requires intracranial imaging. In general, MRI is preferred because it avoids the use of ionizing radiation. MRI may require the use of gadolinium-based contrast agents. Gadolinium has the advantage compared with other contrast agents of not containing iodine, and studies demonstrating adverse fetal effects are lacking in humans. However, gadolinium appears rapidly in the fetal bladder and amniotic fluid, from where it may be swallowed by the fetus and absorbed from the gastrointestinal tract. Its fetal half-life is unknown. The American College of Radiology has stated that in pregnant patients, gadolinium-based contrast agents "…should only be used if their usage is considered critical and the potential benefits justify the potential unknown risk to the fetus."[169]

Management during pregnancy depends on the nature of the tumor. Surgery for benign tumors (e.g., meningiomas) with mild symptoms can often be delayed until after delivery. Women with more aggressive, malignant tumors or with tumors causing seizures or severe visual impairment may require urgent surgery during pregnancy to avoid acute neurologic deterioration. Delivery also may be recommended as soon as reasonable fetal survival can be expected, sometimes by cesarean delivery immediately before neurosurgery. For women with pregnancies far from fetal viability, radiation therapy or stereotactic radiosurgery can be considered. Cranial radiation therapy is generally administered as a first therapeutic procedure to reduce the size of the mass in cases of aggressive neoplasm. However, radiation therapy, and particularly systemic chemotherapy, can pose significant hazards to the fetus, especially when administered during the first trimester.[162,170] Some women may opt for surgery after an elective abortion.

In the healthy parturient, CSF pressure may increase significantly with painful uterine contractions.[171] In patients with an intracranial mass lesion, this situation could result in an increased risk for herniation. Increased ICP from Valsalva maneuvers can further exacerbate herniation risk. The location and size of the tumor should be assessed in the individual patient so that an appropriate delivery plan can be developed with multidisciplinary input. In general, either a pain-free second stage (with instrumental vaginal delivery to avoid pushing) or cesarean delivery may be appropriate.[162,172]

Anesthetic Management

The optimal anesthetic technique for labor analgesia and cesarean delivery anesthesia in the patient with an intracranial tumor is controversial. Epidural analgesia prevents the increase in ICP that can result with pushing during the second stage of labor.[173] Several published reports have described the successful use of labor epidural analgesia in women with intracranial neoplasms[173,174]; in addition, the use of spinal anesthesia for an emergency cesarean delivery in a patient with a glioblastoma has been described.[175] However, in pregnant women with increased ICP, an unintentional dural puncture associated with an attempted epidural catheter placement can result in a fatal brain herniation.[176] As a consequence, many anesthesia providers favor general anesthesia for cesarean delivery in the patient with a brain neoplasm[177]; however, potential disadvantages of general anesthesia include (1) the loss of verbal and motor responses that facilitate neurologic assessment, and (2) the risks of increased ICP with tracheal intubation and extubation. Leffert and Schwamm proposed a decision tree for risk stratifying patients with intracranial space–occupying lesions for whom neuraxial anesthesia is being considered (Fig. 48.3).[178]

Wang and Paech[179] have reviewed specific elements in the anesthetic management of the pregnant patient undergoing neurosurgery, many of which are also relevant to the patient with an intracranial tumor undergoing cesarean delivery. The induction of general anesthesia may consist of the administration of an induction dose of propofol or thiopental and either a depolarizing or a rapid-acting nondepolarizing neuromuscular-blocking agent. Some anesthesia providers avoid succinylcholine because it may cause a transient increase in ICP, but others consider this effect to be clinically insignificant.[179] A combination of a volatile halogenated agent (sevoflurane or isoflurane), nitrous oxide, and an opioid is commonly used for maintenance of anesthesia. When appropriate, accommodations for monitoring the FHR during intracranial surgery should be made.

To preserve cerebral and uteroplacental perfusion, hemodynamic stability should be maintained through appropriate fluid administration, avoidance of aortocaval compression, the prophylactic or early use of vasopressor drugs, and intra-arterial blood pressure monitoring instituted before induction of anesthesia.[179] In general, blood pressure should be kept close to baseline measurements; in the setting of an emergency neurosurgical procedure in a patient with increased ICP, a drop in blood pressure may compromise cerebral perfusion. Fluid management for intracranial surgery should involve administration of isonatremic, isotonic, and glucose-free intravenous solutions to reduce the risk for

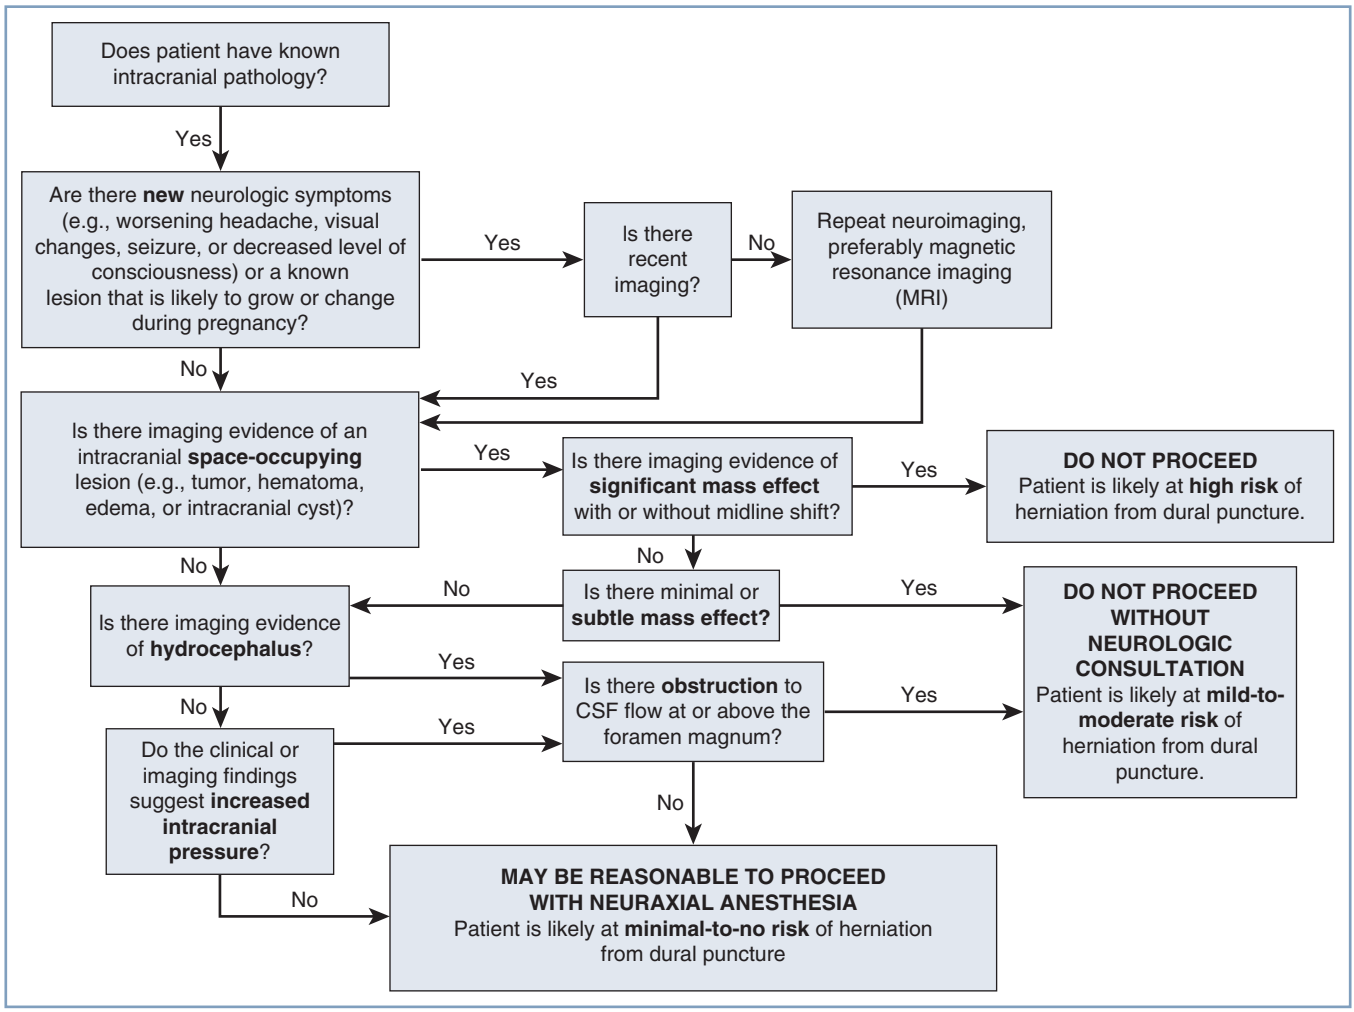

Fig. 48.3 Decision tree summarizing the critical elements for assessing the risk for neurologic deterioration from neuraxial anesthesia in patients with intracranial space–occupying lesions. *CSF,* cerebrospinal fluid. (Redrawn from Leffert LR, Schwamm LH. Neuraxial anesthesia in parturients with intracranial pathology: a comprehensive review and reassessment of risk. *Anesthesiology*. 2013;119:703–718.)

cerebral edema and hyperglycemia.[179] Mannitol administered to a pregnant woman slowly accumulates in the fetus, leading to fetal hyperosmolality and the subsequent physiologic changes of reduced fetal lung fluid production, decreased fetal urine production, and increased fetal plasma sodium concentration[179]; however, mannitol in doses of 0.25 to 0.5 mg/kg has been reported in individual cases and appears to be associated with favorable maternal and fetal outcomes.[179] Furosemide is an alternative diuretic that also should be administered cautiously.

There may be some conflict between maternal and fetal interests in the patient with increased ICP. Moderate mechanical hyperventilation may be used to reduce the increased ICP that occurs in nonpregnant patients with a brain tumor or brain injury. Minute ventilation increases during normal pregnancy, resulting in a maternal $Paco_2$ of 28 to 32 mm Hg; additional hyperventilation and hypocapnia may cause uterine artery vasoconstriction and a leftward shift in the maternal oxyhemoglobin dissociation curve (see Chapter 2). For pregnant women with an acute increase in ICP, Wang and Paech[179] have suggested a target $Paco_2$ range of 25 to 30 mm Hg; however, data are currently insufficient to support evidence-based recommendations specific to pregnant women undergoing intracranial surgery. In pregnant patients with increased ICP, we recommend maintenance of maternal $Paco_2$ in the middle or at the lower end of the normal range for pregnancy. Management should be individualized according to the clinical setting.

When the decision is made to perform a cesarean delivery and brain tumor resection sequentially during a single anesthetic, hypertension should be avoided during induction and endotracheal intubation. Some authors have used combinations of high-dose fentanyl or remifentanil, labetalol, and propofol or thiopental with succinylcholine.[179,180] Postoperatively, measures to minimize risk for respiratory depression are indicated as hypoventilation can exacerbate ICP.

Often, pregnant women with intracranial neoplasms undergo definitive tumor resection with continuation of the pregnancy. In these women, neuraxial techniques may be considered for delivery if ICP is normal.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension, previously referred to as *pseudotumor cerebri* or *benign intracranial hypertension,* is defined as an increase in ICP with a normal CSF composition in the absence of hydrocephalus or a mass lesion.[181] The disorder most often occurs in obese women of childbearing age, suggesting that hormonal factors may play a role in the pathophysiology. The majority of patients have a headache and vision symptoms, with vision loss reported in 1 in 4 affected cases. The condition may be chronic or episodic, and there is a small risk for recurrence.

Therapies include serial lumbar punctures and the administration of carbonic anhydrase inhibitors and/or corticosteroids. Lumboperitoneal shunting may be required in severe cases with visual symptoms. Weight loss appears to improve the condition.

Interaction with Pregnancy

Pregnancy in patients with idiopathic intracranial hypertension does not increase the risk for relapse or worsen the prognosis of idiopathic intracranial hypertension.[182] In the presence of severe maternal symptoms, the placement of an intracranial shunt can result in clinical improvement and normal perinatal outcomes. Overall, this disorder does not adversely affect maternal and perinatal outcomes.[182]

Anesthetic Management

Deliberate lumbar puncture represents a common form of treatment for idiopathic intracranial hypertension. Cerebellar tonsillar herniation does not occur because of the uniform, global increase in ICP. Paruchuri et al.[183] noted that there are only two published cases of cerebellar tonsillar herniation after diagnostic lumbar puncture in patients with this disorder. Both patients had severe headache, neck pain exacerbated by movement, and focal neurologic deficits. In the absence of these signs and symptoms, the anesthesia provider can provide neuraxial analgesia or anesthesia.[184]

Some anesthesia providers recommend the administration of general anesthesia for cesarean delivery in patients with *lumboperitoneal shunt*. They contend that local anesthetic agents that reach the subarachnoid space may escape into the peritoneum, making it difficult to achieve adequate anesthesia. Moreover, the performance of neuraxial anesthesia may result in trauma to the shunt catheter. However, successful use of neuraxial anesthesia in patients with lumboperitoneal shunts has been reported.[185–187] Preoperative radiographic examination may help the anesthesia provider avoid needle placement near the catheter. Both increased and decreased local anesthetic effects have been reported in patients receiving neuraxial anesthesia with shunts.[186,188] Neuraxial anesthesia with an intrathecal catheter has been performed for both vaginal and cesarean delivery in these patients. In one case, the intrathecal catheter provided a route to both administer labor analgesia and drain CSF to treat worsening symptoms caused by elevated ICP.[189] Questions regarding the functional status of an *in situ* subarachnoid shunt or the possible (very rare) use of the shunt for the administration of spinal anesthesia should be discussed with neurology or neurosurgery consultants.[187]

MATERNAL HYDROCEPHALUS WITH SHUNT

Hydrocephalus results from a variety of conditions. The most common are intracranial hemorrhage in preterm infants, fetal and neonatal infections, the Arnold-Chiari malformation, aqueductal stenosis, and the Dandy-Walker syndrome.[190] The Arnold-Chiari malformation consists of extension of a portion of cerebellar tissue into the cervical canal, with progressive hydrocephalus. The Dandy-Walker syndrome occurs with failure of development of the midline of the cerebellum, with resultant hydrocephalus of the fourth ventricle.

Ventriculoatrial or ventriculoperitoneal shunt catheters are placed for the treatment of many of these disorders. Because of advances in neonatal and neurosurgical care, women with hydrocephalus and CSF shunt catheters are reaching childbearing age in increasing numbers.

Obstetric Management

Obstetric management depends on the presence of other medical and neurologic conditions. In general, although maternal shunt dependency carries a relatively high risk for complications for some patients, proper management can lead to normal pregnancy and delivery.[191] Most pregnant women with intracranial shunt catheters can undergo labor and vaginal delivery; elective cesarean delivery is recommended only in the presence of severe neurologic symptoms or instability.[192]

Anesthetic Management

Anesthetic management of the patient with hydrocephalus depends on the location and function of the shunt. Both epidural and spinal anesthesia have been used in patients with lumboperitoneal, ventriculoatrial, and ventriculoperitoneal shunts (as discussed earlier).[185,186,188] A review of 24 studies encompassing 130 pregnancies of parturients with cerebrospinal fluid shunts found that shunt malfunctions were common in pregnancy, that epidural analgesia is safe in women with functional shunts, and that labor anesthetic management varies in response to shunt function and clinical status.[193] A basic thought process for evaluating use of neuraxial anesthesia in patients with hydrocephalus is shown in Fig. 48.3.

INTRACEREBRAL HEMORRHAGE

Cerebrovascular disease during pregnancy can result from three major mechanisms—hemorrhage, arterial infarction, and venous thrombosis. Intracerebral hemorrhage during pregnancy is most commonly associated with an arteriovenous malformation or aneurysm. Using data from the National Inpatient Sample (1995 to 2008), the prevalence of subarachnoid hemorrhage was 5.8 per 100,000 deliveries in women 15 to 44 years of age.[194] The ratio of hemorrhage from

an arteriovenous malformation to that from an aneurysm was significantly higher in pregnant than in nonpregnant patients. The mortality rate was 10.6%; subarachnoid hemorrhage was associated with 4.1% of all pregnancy-related deaths.

Data are conflicting as to whether the aneurysm bleeding rate is higher during pregnancy.[195] Some authors have reported a progressive increase in the incidence of aneurysm bleeding throughout gestation and up to 6 weeks postpartum, while others find no link between pregnancy or the puerperium and increased risk for aneurysmal hemorrhage.[178,195,196] In general, asymptomatic and unruptured aneurysms in pregnancy can be managed conservatively with close monitoring and noninvasive imaging.[195] The treatment of ruptured aneurysms during pregnancy should mimic treatment of aneurysms in nonpregnant patients. The American Heart Association (AHA) guidelines for the management of aneurysmal subarachnoid hemorrhage include monitoring and controlling blood pressure (balancing the risk for stroke, rebleeding, and maintenance of cerebral perfusion pressure) and early surgical clipping or endovascular coiling.[196] Controversy exists as to whether endovascular coiling results in better outcomes than clipping. Although the AHA has suggested that "endovascular coiling should be considered" in patients with ruptured aneurysms judged to be technically amenable to both surgical clipping and coiling, some experts argue that several factors may alter the risk-benefit ratio in pregnancy. These factors include (1) the need for exposure to ionizing radiation for coil placement, (2) the possible need for anticoagulation or use of antifibrinolytic agents, and (3) the increased rate of incomplete aneurysm occlusion associated with coiling compared with clipping.[197,198] Endovascular coiling has not been specifically studied in the pregnant population, although several cases of successful endovascular treatment of ruptured intracranial aneurysms in pregnant women have been reported.[198,199]

Bleeding from arteriovenous malformations has been reported to occur with equal or greater frequency with advancing gestational age.[197] The risk for hemorrhage from an arteriovenous malformation in pregnant women does not appear to differ from that in the general population, although the risk for bleeding appears greater during the second half of pregnancy and the first 6 weeks postpartum, corresponding to the period of high cardiac output.[197] The management of arteriovenous malformations in pregnancy does not differ from standard care of the nonpregnant patient. As with aneurysms, a multidisciplinary decision-making process allows planning based on the location of the lesion, the duration of pregnancy, and the relative risks associated with interventional and noninterventional methods of management.[178] Management of arteriovascular malformations, including those that present during pregnancy, has increasingly shifted over the past decade from a surgical to an endovascular approach.

Obstetric Management

If the lesion has been treated surgically, the patient requires no special care during labor and delivery. For an untreated aneurysm or arteriovenous malformation, the hemodynamic stress occurring during labor and delivery should be minimized. Current data do not demonstrate a definite advantage of cesarean delivery over assisted vaginal delivery.[200] The decision about the method of delivery should be based on the individual patient and her pregnancy history. For labor and vaginal delivery, neuraxial analgesia and low outlet forceps or vacuum assistance may be used to shorten the second stage of labor and attenuate fluctuations in blood pressure.

Anesthetic Management

If the parturient has undergone surgical repair of either an aneurysm or arteriovenous malformation, anesthetic management need not differ from that for other obstetric patients. Hypertension should be avoided in the parturient with an untreated lesion. If vaginal delivery is planned, epidural or CSE analgesia should be considered. For cesarean delivery, epidural, spinal, or CSE anesthesia can be used. Interdisciplinary planning is important.[197]

In some cases, the neurosurgeon may ligate or excise the vascular lesion *during* pregnancy, *before* delivery. The anesthesia provider should consider the general principles of anesthetic management for pregnant women undergoing nonobstetric surgery (see Chapter 17) as well as the special considerations for pregnant women undergoing neurosurgery (as discussed earlier).[179] The risks for hypertension and intracranial bleeding, as well as the risk for pulmonary aspiration should be considered during induction of anesthesia. It is critical to maintain stable blood pressure during induction of anesthesia, laryngoscopy, tracheal intubation, and extubation. The patient should receive adequate sedation before and after arrival in the operating room. Placement of an intra-arterial catheter is mandatory. The anesthesia provider may attenuate the hypertensive response to laryngoscopy and tracheal intubation by intravenous administration of esmolol, labetalol, lidocaine, nitroglycerin, nitroprusside, and/or an opioid (e.g., remifentanil). Succinylcholine can be used for tracheal intubation. Regardless of the choice of muscle relaxant, it is critical that laryngoscopy and tracheal intubation not be performed until the patient is anesthetized adequately.

The anesthesia provider may maintain anesthesia with nitrous oxide and modest doses of isoflurane and an opioid. Aggressive maternal hyperventilation may result in decreased uterine blood flow.[197] However, the anesthesia provider may use modest hyperventilation (e.g., $Paco_2$ of 28 to 30 mm Hg) as needed to reduce maternal ICP. The anesthesia provider should maintain left uterine displacement in patients beyond 20 weeks' gestation. Intraoperative FHR monitoring allows assessment of the fetal response to maternal general anesthesia, hemodynamic changes, and hyperventilation, but a clear plan in case of fetal compromise that is not responding to intrauterine resuscitation efforts during surgery must be discussed with the patient, anesthesia provider, neurosurgeon, and obstetrician. At many institutions, including our own, intraoperative FHR monitoring is used beginning at 24 weeks' gestation, which corresponds to the onset of extrauterine neonatal viability. Typically, an obstetric nurse monitors the FHR tracing during surgery and requests

obstetric consultation if needed. An adverse change in the FHR tracing should prompt the anesthesia provider to ensure adequate maternal oxygenation, ventilation, and perfusion. There is no consensus regarding an acceptable or safe level of hypotension in these patients, and deliberate hypotension in current neuroanesthesia practice has generally fallen out of favor. Endovascular treatment with general anesthesia avoids the need for craniotomy and deliberate hypotension.

In some cases, the obstetrician and neurosurgeon may perform a combined procedure (e.g., a cesarean delivery followed by ligation or excision of the neurovascular lesion). Principles of anesthetic management are similar to those described earlier for intracranial neurovascular surgery during pregnancy.[178,179]

CEREBRAL VEIN THROMBOSIS

Thrombosis of the cerebral veins and sinuses most often affects young adults and children; approximately 75% of the adult patients are women.[201] Thromboses commonly involve the cavernous sinus, lateral sinus, sagittal sinus, or cortical veins. Thrombosis of the cerebral veins causes venous obstruction with local effects, whereas thrombosis of the major sinuses causes intracranial hypertension. A prothrombotic risk factor or a direct cause can be identified in approximately 85% of patients. Pregnancy may be a precipitating factor for sinus thrombosis in a person with a genetically increased risk.[201]

Primary cerebral cortical vein thrombosis is the type of thrombosis most often seen in pregnancy. The estimated incidence of cerebral vein thrombosis during pregnancy is 12 cases per 100,000 deliveries in developed countries.[202] Cerebral vein thrombosis occurs more frequently during the last trimester of pregnancy and in the second and third postpartum weeks.[202] Although the etiology is unclear, pregnancy may predispose patients to this condition because of at least two factors. First, traumatic damage to the endothelial lining of vessels may occur during the second stage of labor. Second, pregnancy is a hypercoagulable state (see Chapters 2 and 38). Mechanical causes of sinus thrombosis may include head injury and lumbar puncture.[203] It has been postulated that low CSF pressure after a lumbar puncture causes the brain to shift downward, resulting in traction on the cortical veins and sinuses.

Patients with cerebral vein thrombosis may have headache, nausea and vomiting, and blurred vision. In more severe cases, lateralizing neurologic signs, lethargy, and seizures may occur. In severe cases, transtentorial herniation caused by a focal mass effect can occur. A 2017 systematic review of cerebral vein thrombosis in pregnancy linked headache alone with favorable prognosis, while coma and obtundation predicted poor outcomes.[204]

Care should be taken to differentiate cerebral vein thrombosis from post–dural puncture headache (PDPH). In general, the headache associated with cerebral vein thrombosis is more diffuse in location. Earlier teaching suggested that the headache does not vary with position, but a 2007 review concluded that the nature of the headache may change over time and often manifests "as a positional headache that overlaps the usual timing…and treatment of PDPH in the parturient."[203]

Diagnosis can be confirmed by magnetic resonance (MR) venography. The American Heart Association/American Stroke Association published a set of management guidelines in 2011; the guidelines recommend full anticoagulation with unfractionated heparin (titrated to an activated partial thromboplastin time two times normal) or weight-adjusted low-molecular-weight heparin, continued for a minimum of 6 months' duration.[202] Intra-arterial thrombolysis and thrombectomy during pregnancy and the puerperium have been described; some data suggest improved outcomes when both thrombolysis and thrombectomy are performed.[204] Lumbar puncture and drainage of a large volume of CSF may be needed to treat acute elevations in ICP that stem from reduced venous drainage; the procedure must be timed with pharmacologic anticoagulation.

Obstetric and Anesthetic Management

Cerebral vein thrombosis rarely occurs before delivery, although such an occurrence may prompt an urgent delivery if associated with maternal neurologic instability and fetal deterioration. Maternal anticoagulation contraindicates the administration of neuraxial anesthesia. The anesthesia provider should avoid systemic hypotension, which may reduce cerebral perfusion pressure and blood flow to injured areas already subjected to marginal perfusion. If the patient has an asymmetric cerebral hematoma with mass effect, dural puncture may precipitate herniation of the brainstem. Thus, it seems preferable to administer general anesthesia for cesarean delivery, with special attention to the treatment of increased ICP. Cerebral venous thrombosis is a rare, but reported, complication after spinal and epidural anesthesia, presumably caused by intracranial hypotension.[203]

MOTOR NEURON DISORDERS

Motor neuron diseases are a group of disorders characterized by progressive muscular weakness and atrophy. These disorders may affect motor function alone or in conjunction with sensory deficits. There are few data on the course of these disorders in pregnant women. This discussion focuses on three of these disorders, amyotrophic lateral sclerosis and primary spinal muscular atrophy, which are pure motor neuron disorders, and peroneal muscular atrophy, which involves both motor and sensory degeneration. Currently there is no cure for any of these degenerative disorders.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis involves progressive degeneration of anterior horn cells with progressive atrophic weakness and hyperreflexia. Patients typically succumb to respiratory failure within 6 years of diagnosis.

This disease is seen more often in patients older than 50 years of age, but there are several reports of this disorder

in pregnant women.[205,206] Physicians should assess and frequently monitor the patient's respiratory compromise throughout the peripartum period. Epidural analgesia and anesthesia have been used in these patients without evidence of worsened neurologic function postoperatively.[207,208] Patients with amyotrophic lateral sclerosis may be sensitive to the effects of nondepolarizing muscle relaxants.[209] The physiologic changes during the late stages of pregnancy may worsen marginal respiratory status in these patients, and early cesarean delivery may be warranted.[210]

Spinal Muscular Atrophy

Like amyotrophic lateral sclerosis, primary spinal muscular atrophy involves degeneration of anterior horn cells. However, affected patients tend to be younger, and this disorder progresses more slowly. Some types are hereditary. Spinal muscular atrophy mainly involves the spinal cord, without involvement of the corticospinal tract. Marked kyphoscoliosis combined with truncal and limb weakness, especially involving the proximal musculature, can occur and result in significant ventilatory limitations.

Spinal muscular atrophy may be associated with an increased incidence of preterm labor and worsened muscle weakness that persists after delivery.[211] Epidural and spinal analgesia and anesthesia have been used successfully in patients with this disorder.[212,213] In children with this rare disorder, both general and regional anesthesia have been successfully used; special attention should be paid to postoperative respiratory function.[214]

Peroneal Muscular Atrophy

Peroneal muscular atrophy, also known as *Charcot-Marie-Tooth disease,* includes several inherited peripheral motor and sensory neuropathies; it is one of the most common inherited neuromuscular diseases.[215] It involves a progressive sensory and motor degeneration of peripheral nerves and roots. The peroneal nerve is affected early. Restrictive pulmonary impairment, phrenic nerve dysfunction, diaphragmatic dysfunction, thoracic cage abnormalities, and sleep apnea have been described in association with peroneal muscular atrophy. Vocal cord dysfunction, possibly caused by laryngeal nerve involvement, can also be present. Assessment of peripartum respiratory function is essential. Approximately 30% of patients with this disorder report deterioration in overall function during pregnancy.[109]

A review of 108 deliveries found that women with this disorder have higher rates of abnormal fetal presentation, emergency operative delivery, and postpartum bleeding.[216] Both neuraxial and general anesthesia have been used for delivery.[217]

ISOLATED MONONEUROPATHIES DURING PREGNANCY

Pregnancy is associated with an increased incidence of several specific mononeuropathies: Bell's palsy, carpal tunnel syndrome, and meralgia paresthetica.

Bell's Palsy

Bell's palsy is a syndrome of acute-onset paralysis of the facial nerve; it tends to present during the third trimester and the first few weeks postpartum. The incidence during pregnancy is approximately 2.5 times higher than that in nonpregnant individuals from the same age group; the overall incidence is higher in women than in men.[218]

One study noted that pregnant patients whose symptoms progressed to complete facial paralysis within 10 days of onset were less likely to experience satisfactory recovery than a comparison group of nonpregnant patients.[219] Women with Bell's palsy are more likely than men to have symptoms of dry eyes, which can progress to secondary damage.[218] Although the prognosis for women with partial palsy is excellent, the authors of a 2017 review of Bell's palsy in pregnancy suggested that current evidence supports early treatment with glucocorticoids, particularly in cases of complete palsy.[218]

Dorsey and Camann[220] retrospectively reviewed 36 cases of Bell's palsy associated with pregnancy. Of the 36 women, 27 received spinal or epidural analgesia or anesthesia. There were no differences in incidence or progression of the Bell's palsy or maternal and fetal outcomes in relation to the type of anesthesia given; therefore, neuraxial analgesia or anesthesia does not appear to be contraindicated in patients with Bell's palsy.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is common during pregnancy; in a systematic review, the reported incidence ranged from 0.8% to 70%.[221] The disorder results from compression of the median nerve in the flexor retinaculum at the wrist. Patients typically report paresthesias and weakness in the median nerve distribution, with symptoms worse in the morning on awakening from sleep. Symptoms have been reported to persist in approximately 50% and 30% of patients after 1 year and 3 years, respectively.[221] Patients may be treated with splinting of the wrists, although in severe cases, surgery may be required. In many cases, symptoms resolve spontaneously within the first 2 months postpartum and appear to correlate with losing the weight gained during pregnancy.[222]

Meralgia Paresthetica

Meralgia paresthetica involves sensory loss and paresthesias in the lateral thigh stemming from compression of the lateral femoral cutaneous nerve. Obesity and the exaggerated lordosis of pregnancy can stretch the nerve. Symptoms of meralgia paresthetica typically resolve within 3 months of delivery. This peripheral nerve palsy and other neurologic deficits are discussed in more detail in Chapter 31.

KEY POINTS

- Symptoms of multiple sclerosis may worsen postpartum, regardless of the anesthetic technique used during delivery. However, the long-term prognosis of this disease is most likely unaffected by pregnancy.
- Multiple sclerosis does not contraindicate the use of neuraxial analgesia or anesthesia.
- Continuous neuraxial anesthesia is the method of choice for the prevention or treatment of autonomic hyperreflexia during labor and delivery in patients with spinal cord injury.
- Patients with myasthenia gravis require close surveillance during labor. Increasing muscle weakness may require an adjustment in the dosage of the anticholinesterase drug. Severe respiratory involvement may preclude the use of neuraxial anesthesia for cesarean delivery.
- The anesthesia provider should avoid succinylcholine in patients with myotonic dystrophy because fasciculations can trigger myotonia.
- Neuraxial analgesia or anesthesia does not appear to precipitate the onset of postpoliomyelitis muscular atrophy (postpolio syndrome).
- Hemodynamic stability should be maintained in the parturient with an untreated intracranial aneurysm or arteriovenous malformation. Neuraxial anesthesia should be considered during labor and delivery.
- Bell's palsy, carpal tunnel syndrome, and meralgia paresthetica occur at higher rates during pregnancy. Symptoms typically resolve postpartum.

Obesity

Ashraf S. Habib, MBBCh, MSc, MHSc, FRCA, Robert D'Angelo, MD

CHAPTER OUTLINE

Obesity is a worldwide health problem, with the prevalence in the general population growing at an alarming rate. Data from the National Health and Nutrition Examination Survey show that in 2015 to 2016, 36.5% of women of reproductive age (20 to 39 years of age) were obese,[1] compared with a prevalence of 28.3% in 1999 to 2000.[2] Although no definition of obesity specific to pregnancy exists, a pregnant woman is generally considered overweight when her body mass index (BMI) is 25.0 to 29.9 kg/m^2, and obese when her BMI is 30 kg/m^2 or greater. The World Health Organization defines three grades of obesity: class I (BMI 30.0 to 34.9 kg/m^2), class II (BMI 35.0 to 39.9 kg/m^2), and class III (BMI 40 kg/m^2 or greater). The prevalence of class III obesity among women of reproductive age has significantly increased in recent years, with a prevalence of 10% in 2013 to 2014,[3] compared with 5% in 1999 to 2000.[2] To allow for the weight gain of pregnancy, some groups have suggested adding 5 kg/m^2 to the World Health Organization classes to define pregnancy thresholds.[4,5]

Obesity is associated with an increased risk for maternal morbidity and mortality.[6,7] The care of obese parturients poses significant challenges to the anesthesia provider as a result of common comorbidities, an increased cesarean delivery rate, and technical difficulties associated with both neuraxial and general anesthesia. Understanding the pathophysiologic changes and comorbidities associated with obesity and pregnancy is crucial for the safe conduct of anesthesia in these high-risk patients.

PHYSIOLOGIC CHANGES OF OBESITY

Cardiopulmonary Changes

Obesity increases the demands on the cardiopulmonary system. The effects of obesity and pregnancy on the respiratory and cardiovascular systems are summarized in Table 49.1 and Table 49.2. As energy expenditure increases proportionate to the increase in body mass,[8] oxygen consumption and carbon dioxide (CO_2) production also increase proportionate to the increase in work performed.[9] Minute ventilation is increased owing to the elevated respiratory demand, except in the 5% to 10% of obese patients with Pickwickian syndrome, who display a reduced sensitivity to CO_2.[10] Obesity affects the body's ability to meet these demands by changing pulmonary mechanics, altering lung volumes, and impairing oxygen consumption.

Obesity increases the weight of the chest wall; thus, greater energy expenditure is required during ventilation to move this mass. Morbidly obese patients in comparison with lean controls expend a disproportionately high percentage of total oxygen consumption on respiratory work, even during quiet breathing.[11] The weight gain during pregnancy further increases the work of breathing. In obese individuals, frequent shallow respirations may represent a more efficient breathing pattern than large tidal volumes. This pattern of frequent shallow respirations contrasts to the increased tidal volumes that typically accompany pregnancy.

TABLE 49.1 Physiologic Changes in the Respiratory System Induced by Pregnancy and Obesity

	Pregnancy	Obesity	Combined Effect
Tidal volume	↑	↓	↑
Respiratory rate	↑	↔ or ↑	↑
Minute volume	↑	↓ or ↔	↑
Expiratory reserve volume	↓	↓↓	↓
Residual volume	↓	↓ or ↔	↓
Functional residual capacity	↓↓	↓↓↓	↓↓
Vital capacity	↔	↓	↓
FEV_1	↔	↓ or ↔	↔
FEV_1/VC	↔	↔	↔
Total lung capacity	↓	↓↓	↓
Compliance	↔	↓↓	↓
Work of breathing	↑	↑↑	↑
V/Q mismatch	↑	↑	↑↑
PaO_2	↓	↓↓	↓
$PaCO_2$	↓	↑	↓

↑, Increase; ↓, decrease, ↔, no change; more than one arrow represents the degree of intensity; *FEV_1*, forced expiratory volume in 1 sec; *VC,* vital capacity; *V/Q,* ventilation/perfusion.
Modified from Saravanakumar K, Rao SG, Cooper GM. Obesity and obstetric anaesthesia. *Anaesthesia.* 2006;61:36–48.

TABLE 49.2 Physiologic Changes in the Cardiovascular System Induced by Pregnancy and Obesity

	Pregnancy	Obesity	Combined Effect
Heart rate	↑	↑↑	↑↑
Stroke volume	↑↑	↑	↑
Cardiac output	↑↑	↑	↑↑↑
Blood volume	↑↑	↑	↑
Hematocrit	↓↓	↑	↓
Systemic vascular resistance	↓↓	↑	↔ or ↓
Mean arterial pressure	↓ or ↔	↑↑	↑↑
Systolic function	↔	↔ or ↓	↔ or ↓
Diastolic function	↔	↓	↓
Central venous pressure	↔	↑	↑↑
Pulmonary artery occlusion pressure	↔	↑↑	↑↑

↑, Increase; ↓, decrease, ↔, no change; more than one arrow represents the degree of intensity.
Modified from Saravanakumar K, Rao SG, Cooper GM. Obesity and obstetric anaesthesia. *Anaesthesia.* 2006;61:36–48.

Greater abdominal weight restricts diaphragm movement, especially in the supine or Trendelenburg position, thus encouraging smaller tidal volumes. Functional residual capacity (FRC) decreases at the expense of expiratory reserve volume and may be less than closing capacity. Both chest wall and lung compliance decrease, but airway resistance increases as a result of reduction in lung volumes.[12]

Pulmonary diffusion typically remains normal in most women with morbid obesity. Decreased chest wall compliance and greater abdominal weight promote airway closure in the dependent portion of the lung.[13] Ventilation preferentially occurs in the more compliant, nondependent portion of the lung. In contrast, pulmonary blood flow preferentially occurs in the dependent portion of the lung, resulting in ventilation-perfusion mismatch and hypoxemia.[13] Consistent with the positional deterioration of lung volumes, oxygenation worsens in obese individuals in the supine and Trendelenburg positions.

Blood volume and cardiac output are increased, the latter owing to increases in both stroke volume and heart rate. Both preload and left ventricular afterload are increased; these changes result in both eccentric and concentric left ventricular hypertrophy. Among morbidly obese pregnant women, left atrial size, left ventricular thickness, interventricular septal thickness, and left ventricular mass are increased compared with nonobese pregnant women.[14] The increase in heart rate limits the time for diastolic filling, thus diastolic relaxation is impaired. Pulmonary blood volume increases in proportion to increases in cardiac output and total blood volume. Pulmonary hypertension can occur and may be position dependent. A BMI of 30 kg/m^2 or more is associated with a threefold higher incidence of hypertension during pregnancy than a BMI less than 30 kg/m^2.[6] Aortocaval compression of the great vessels in the supine position may be greater in obese parturients, particularly those with a large fat panniculus.

Gastrointestinal Changes

It is unclear whether obesity in pregnancy is associated with an increase in gastric volume and a decrease in gastric pH. Roberts and Shirley[15] reported that gastric volumes aspirated from obese laboring women undergoing cesarean delivery were significantly higher than those obtained from lean controls. Studies in the general surgical population, however, reported conflicting results; some confirmed these findings[16] and others reported no difference in gastric volume and pH in obese compared with lean patients.[17]

Similarly, data regarding gastric emptying in the obese population are conflicting; studies have reported delayed, unchanged, or more rapid rates of gastric emptying in obese subjects compared with lean subjects.[18] In a nonobstetric obese population, Maltby et al.[19] reported that drinking 300 mL of clear fluid 2 hours before surgery had no effect on gastric fluid volume and pH compared with fasting after midnight. Similarly, Wong et al.[20] found that gastric emptying in obese, nonlaboring term pregnant volunteers was not delayed after ingestion of 300 mL of water compared with ingestion of 50 mL of water. The gastric volume returned to baseline 60 minutes after ingestion of water.

Both gastroesophageal reflux and hiatal hernia are more common in obese than in nonobese patients.[21] Obesity is also associated with a higher risk for difficult airway management,

which is a known risk factor for aspiration.[22] Therefore, it seems likely that morbidly obese patients are at higher risk for pulmonary aspiration of gastric contents.

Coagulation Changes

Obesity is associated with a higher risk for thromboembolic complications.[23] Venous thromboembolism is a leading cause of direct maternal mortality. In the United Kingdom, 54% of women who died from thromboembolic complications in 2009 to 2013 were overweight or obese.[24]

Obesity is associated with changes in coagulation, venous stasis, and endothelial injury that contribute to the pathogenesis of venous thromboembolism. For instance, adipose tissue secretes the following: (1) adipokines such as plasminogen activator inhibitor-1 (PAI-1), which results in impaired fibrinolysis; (2) leptin, which promotes platelet aggregation; and (3) interleukin-6, which stimulates the liver to produce coagulation factors.[25,26] C-reactive protein levels are also elevated in obese women, leading to platelet activation.[27] Venous stasis is compounded in obese women by increased intra-abdominal pressure, which leads to increased iliofemoral venous pressure.[28] Obesity was shown to be associated with endothelial dysfunction in the nonpregnant population.[29] Therefore, all risk factors that contribute to the pathogenesis of thromboembolic complications are likely to be exacerbated by obesity. The risk is further increased by reduced mobility, comorbidities such as preeclampsia, and an increased frequency of operative delivery.

Endocrine Changes

Gestational diabetes and diabetes mellitus occur more frequently in obese patients.[6] The pathologic process is attributed to the following: (1) peripheral insulin resistance as a result of augmentation of free fatty acids by visceral obesity,[30] (2) increased proinflammatory cytokine levels,[31] (3) relative gonadotropin resistance, and (4) a low sex hormone–binding globulin concentration, which leads to hyperandrogenism and decreased insulin sensitivity.[32] The concentration of adiponectin, an adipokine with insulin-sensitizing properties, is also decreased in obesity, which leads to decreased insulin sensitivity.[25]

COMORBIDITIES ASSOCIATED WITH OBESITY

Sleep Apnea

Obesity is a significant risk factor for obstructive sleep apnea (OSA), which is characterized by repeated episodes of complete or partial upper airway collapse, leading to hypoxemia and hypercarbia. Those repeated periods of hypoxemia and reoxygenation lead to significant endocrine and metabolic disturbances, which result in an increased risk for hypertension, myocardial infarction, stroke, diabetes, and metabolic syndrome.[33] It is estimated that 15% to 20% of obese pregnant women have OSA.[34]

The changes of pregnancy may both worsen and protect against OSA. For instance, weight gain[35] and estrogen-induced hyperemia and edema of nasal mucosa[36] might promote OSA, whereas sleeping in the lateral position,[37] reduced rapid eye movement (REM) sleep, and the progesterone-induced increase in minute ventilation might protect against it.

OSA may adversely affect maternal and neonatal outcomes. A large inpatient database study showed that pregnant women with OSA are at increased risk for preeclampsia, eclampsia, cardiomyopathy, and pulmonary embolism, and are five times more likely to die in the hospital during a pregnancy or delivery admission than women without OSA.[38] These differences were unchanged after controlling for obesity, but the associations with preeclampsia and severe cardiovascular complications were stronger in obese women. The association between OSA and increased risks for preeclampsia and gestational diabetes were confirmed in a large prospective study involving 3705 women.[39]

Some studies have examined the impact of maternal OSA on perinatal outcomes. A 2014 meta-analysis reported an association between sleep-disordered breathing and low birth weight, neonatal intensive care unit admission, fetal growth restriction, and a 1-minute Apgar score less than 7.

Other Comorbidities

Obesity is associated with an increased risk for a number of disease states compared with lean controls (Table 49.3).[21,23,40] These comorbidities complicate the care of obese parturients.

TABLE 49.3 Relative Risk or Odds Ratio of Comorbidities in Obese Women

Comorbidity	Relative Risk	95% CI
Type 2 diabetes[a]	12.41	9.03, 17.06
Hypertension[a]	2.42	1.95, 3.67
Coronary artery disease[a]	3.10	2.81, 3.43

IMPACT OF OBESITY ON PREGNANCY

Maternal and Fetal Complications

Obesity results in greater use of health care resources. Chu et al.[41] reported that obese pregnant women receive significantly more prenatal tests, ultrasonographic examinations, medications, and prenatal visits with a physician, and they are at greater risk for having a high-risk pregnancy, cesarean delivery, and prolonged hospitalization than pregnant women of normal weight.

Obesity is associated with a significantly increased incidence of maternal, fetal, and neonatal complications. These include a higher risk for spontaneous abortion (miscarriage), thromboembolic complications, gestational diabetes, hypertensive disorders of pregnancy, dysfunctional labor, shoulder dystocia, operative vaginal delivery, cesarean delivery, postpartum hemorrhage, wound infection, fetal macrosomia, fetal congenital anomalies, stillbirth, and neonatal death (Table 49.4).[6,42,43]

Most importantly, obesity increases the risk for death during pregnancy. The report of Confidential Enquiries into Maternal Deaths in the United Kingdom for 2012 to 2014 showed that 51% of women who died were overweight or obese, a trend that has been consistent for the last several reports.[7] The increased risk for death associated with obesity has been attributed to the associated comorbidities such as hypertensive disorders of pregnancy. The impact of obesity on maternal mortality is particularly evident in women who die of thromboembolism or cardiac disease.[44]

Obesity has also been identified as a risk factor for anesthesia-related maternal mortality. Six of the 13 direct maternal deaths attributed to anesthesia in the United Kingdom between 2003 and 2008 occurred in obese parturients.[44,45] In the United States, Mhyre et al.[46] reported that six of eight pregnant women who died of anesthesia-related deaths in Michigan between 1985 and 2003 were obese. Because of the increased risk for complications, guidelines published both in the United Kingdom[47] and by the American College of Obstetricians and Gynecologists (ACOG)[48] recommend a multidisciplinary approach to the care and treatment of obese pregnant women, including referral for antepartum consultation with an anesthesia provider.

TABLE 49.4 Obstetric Complications in Obese and Morbidly Obese Women

Outcome	Odds Ratio (95% Confidence Interval)	
	Obese versus Control	Morbidly Obese versus Control
Gestational diabetes	2.6 (2.1, 3.4)	4.0 (3.1, 5.2)
Gestational hypertension	2.5 (2.1, 3.0)	3.2 (2.6, 4.0)
Preeclampsia	1.6 (1.1, 2.3)	3.3 (2.4, 5.5)
Birth weight > 4500 g	2.0 (1.4, 3.0)	2.4 (1.5, 3.8)
Birth weight > 4000 g	1.7 (1.4, 2.0)	1.9 (1.5, 2.3)
Preterm delivery	1.1 (0.9, 1.5)	1.5 (1.1, 2.1)
Operative vaginal delivery	1.0 (0.8, 1.3)	1.7 (1.2, 2.2)
Cesarean delivery[a]	1.7 (1.4, 2.2)	3.0 (2.2, 4.0)

[a]Nulliparous women.

Data from Weiss JL, Malone FD, Emig D, et al. Obesity, obstetric complications and cesarean delivery rate—a population-based screening study. *Am J Obstet Gynecol*. 2004;190:1091–1097.

Progress of Labor and Method of Delivery

The progress of labor appears to be affected by BMI. A large multicenter study involving 118,978 patients whose labor management reflected current practice in the United States found that labor progressed more slowly with increasing BMI for both nulliparous and parous women.[49] The median time to progress from 4 to 10 cm cervical dilation increased from 5.4 hours to 7.7 hours for lean and morbidly obese *nulliparous* women, respectively, and from 4.6 hours to 5.4 hours for lean and morbidly obese *parous* women, respectively. These findings were independent of gestational age and induction of labor. Entry into the active phase of labor was also delayed in parous women as a function of BMI. Possible explanations include increased fetal size, higher labor induction rates, and/or decreased responsiveness to oxytocin.[49]

Poor uterine contractility has also been demonstrated in obese parturients. Myometrium obtained from obese women at cesarean delivery contracted with less force and frequency and had less calcium flux than that from normal-weight women.[50] This observation may be attributable to the inhibitory effect of cholesterol[50] and/or adipokines (e.g., leptin, ghrelin, apelin), which inhibit human uterine contractility *in vitro*.[51] Inadequate myometrial contractility has also been implicated in a higher rate of uterine atony and postpartum hemorrhage, after both vaginal and operative deliveries, in obese women. In a large retrospective study involving 30,298 pregnancies over an 8-year period,[52] the risk for postpartum hemorrhage was significantly higher with increasing BMI (odds ratio [OR], 2.7; 95% confidence interval [CI], 2.2 to 3.4 for obesity class III compared with nonobese).

Obesity is also associated with a higher risk for failed medical induction of labor. In a secondary analysis of data from a large labor induction trial involving 1273 patients, the duration of labor, oxytocin requirements, and cesarean delivery rates were significantly higher in women with a greater BMI.[53] In a large series from Sweden involving 233,887 deliveries, Cedergren[54] found a fourfold increase in the risk for cesarean delivery in parturients with a BMI greater than 40 kg/m^2 compared with parturients of normal weight, primarily because of failed or obstructed labor. Operative vaginal delivery, with its associated maternal and fetal morbidity, is also more likely in the obese parturient.[6]

Risk for fetal macrosomia is higher with obesity, which increases the risk for shoulder dystocia and its associated birth trauma, and predisposes to perineal lacerations, newborn infant injury, and postpartum hemorrhage.[6,55] One study examining maternal anthropometric parameters associated with shoulder dystocia reported a 2.7-fold increase in

risk for shoulder dystocia in obese compared with lean parturients, even after adjustment for potential confounders such as macrosomia and diabetes.[55]

Higher BMI, increased prepregnancy weight, and excessive maternal weight gain increase the risk for both elective and emergency cesarean delivery.[56,57] This risk is further increased by obesity-related pregnancy complications such as macrosomia, fetal growth restriction, diabetes mellitus, and hypertensive disorders of pregnancy.[42] In a meta-analysis of 33 trials,[43] the unadjusted odds ratios (95% CI) of cesarean delivery were 1.46 (1.34 to 1.60), 2.05 (1.86 to 2.27), and 2.89 (2.28 to 3.79) among overweight, obese, and morbidly obese women, respectively, compared with normal-weight pregnant women.

ANESTHETIC MANAGEMENT

The high incidence of comorbid conditions among obese pregnant women necessitates early, careful preanesthetic assessment. A number of technical matters should be considered when caring for an obese parturient.

An appropriate-sized blood pressure cuff must be used for noninvasive blood pressure measurements. Unless the length of the sphygmomanometer cuff exceeds the circumference of the arm by 20%, systolic and diastolic blood pressure measurements may overestimate true maternal blood pressure. Forearm blood pressure measurement is sometimes used if an appropriate-sized blood pressure cuff is not available or if the upper arm cuff continues to slide from its position owing to the shape of the obese patient's upper arm. There is a good correlation between upper arm and forearm noninvasive measurements, but forearm pressures exceed upper arm pressures by 10 ± 10 mm Hg (mean ± SD).[58] There is poor agreement between invasive blood pressure readings and those obtained with the currently available cylindrical blood pressure cuffs placed in various locations on the upper arm or forearm.[59] A study comparing invasive blood pressure readings with a conical blood pressure cuff specifically developed for forearm use showed good agreement with invasive blood pressure readings in obese patients.[60] In selected cases, invasive monitoring of blood pressure with an intra-arterial catheter may be desirable.[45]

Intravenous access may be difficult in obese patients. Ultrasonographic guidance may be useful; however, if peripheral intravenous access is unsuccessful, central venous cannulation may be necessary.

Appropriately sized labor beds, transportation gurneys, and operating tables, and sufficient personnel to assist with patient transport, are imperative. Although standard operating tables are generally rated for persons weighing up to 500 pounds (227 kg), this rating may be insufficient for morbidly obese patients, especially when the table is articulated. Regardless of the weight rating of the table, it is critical that the obese patient be centered over the operating table pedestal at all times. Special equipment for moving and positioning the patient, such as motorized lifts, and longer spinal/epidural needles, may be needed (see later discussion).

Labor and Vaginal Delivery

Many of the options for labor analgesia have limitations in the obese parturient. For example, obese parturients with OSA may be more susceptible to the respiratory depressant effect of systemic opioids, leading to episodes of apnea and oxyhemoglobin desaturation. Pudendal nerve block may be technically difficult in obese patients. Inhalation analgesia is useful in some patients; however, nitrous oxide has limited effectiveness and is not available in many birthing rooms. Further, inhalation analgesia may lead to a reduced level of consciousness, which can be very dangerous in an obese woman with a difficult airway.

Neuraxial analgesia represents the best option for pain relief and is particularly desirable in the obese parturient. Given the greater risks for fetal macrosomia and shoulder dystocia in obese patients, adequate analgesia is often needed to facilitate an atraumatic vaginal delivery. The use of epidural analgesia during labor allows the anesthesia provider to extend epidural analgesia to surgical anesthesia for cesarean delivery and thus avoid the need for general anesthesia with its associated risks. Given the increased likelihood for cesarean delivery and the greater risk for general anesthesia in the obese parturient, the early administration of neuraxial labor analgesia is recommended in the obese parturient.

When performing a neuraxial anesthetic technique in the obese parturient, technical difficulties may include (1) inability to palpate the spinous processes or identify the midline[5]; (2) greater depth of the epidural space,[61] which may exaggerate minor needle directional errors and increase the likelihood of identifying a lateral portion of the epidural space[62]; and (3) the presence of fat pockets as well as hormonal softening of the ligaments, which may result in a false loss of resistance and/or higher risk for unintentional dural puncture.[63] In most obese parturients, however, the epidural space can be identified with a standard-length epidural needle.[64] Therefore, it seems prudent to use a standard-length needle first, which allows the provider better control, before switching to a longer needle.

Observing the prominence of the seventh cervical vertebra and the gluteal cleft can facilitate identification of the midline. Asking the parturient about the perceived location of the needle during block placement (relative to the midline) can also facilitate identification of the midline. Marroquin et al.[65] reported that 77% of morbidly obese parturients who were questioned about the position of the needle during a difficult labor epidural needle placement provided useful feedback to the anesthesia provider. Probing the subcutaneous tissue with a needle can also help identify the spinous processes and help identify a lumbar interspace. More objectively, ultrasonographic guidance can be used to identify the midline, image the epidural space, and measure the distance from the skin to the epidural space (see Chapter 12). Sahin et al.[66] reported fewer attempts needed to establish spinal anesthesia in obese parturients undergoing cesarean delivery when preprocedure ultrasonography was performed. Ultrasound image quality, which is often compromised by excessive lumbar adiposity

in obese patients, may be improved with the paramedian sagittal oblique plane compared with the transverse plane.[67] Balki et al.[68] found a strong correlation between the skin-to-epidural space distance measured by ultrasonography and that measured by the epidural needle in obese parturients. However, soft tissue compression with the ultrasound probe resulted in underestimation of the depth of the epidural space in obese women.

Placing the patient in the sitting position facilitates identification of the midline and is preferred by many anesthesia providers when initiating a neuraxial anesthetic procedure in obese parturients. In the lateral position, gravity may cause lateral fat to sag downward and obscure the midline. Further, the distance from the skin to the epidural space is minimized when the patient is in the sitting-flexed position.[69,70]

Care is needed to avoid dislodgement of the epidural catheter after insertion. Movement of the epidural catheter relative to the skin is most striking in obese patients. Hamilton et al.[70] demonstrated that patient movement from the sitting-flexed to the lateral decubitus position causes redistribution of the soft tissue of the back. The distance from the skin to the epidural space increases, and an unsecured catheter will appear to be drawn inward by as much as 1.0 to 2.5 cm.[70] An epidural catheter secured with tape to the back of a patient in the sitting flexed position can be unintentionally dislodged from the epidural space when the patient moves from the sitting to the lateral decubitus position. Therefore, these investigators recommended that the patients assume the lateral position before the epidural catheter is secured to the skin. Alternatively, when placing the block in the sitting-flexed position, the patient should be asked to sit upright before taping the catheter to the skin.

Many authors have documented technical difficulties with neuraxial techniques in obese parturients. In 1993, Hood and Dewan[71] reported that 94% of patients who weighed more than 300 lb (136.4 kg) experienced adequate analgesia for delivery, compared with 98% of controls. More attempts were required to identify the epidural space in obese women, there was a significantly higher initial failure rate (42% versus 6%), and placement of a second or third epidural catheter was more often required. A more recent study by Tonidandel et al.[72] from the same center reported that the failure rate in morbidly obese parturients was lower than their previous study (17%), but this rate was still significantly higher than the 3% failure rate reported in the lean control group.[72] Similarly, Dresner et al.[73] reported an increased risk for failed labor epidural analgesia and need for catheter replacement with increasing BMI (2.4% for BMI less than 25 kg/m^2 versus 6.6% for BMI greater than 40 kg/m^2). Perlow and Morgan[74] reported that 74.4% of morbidly obese parturients needed more than one attempt and 14% needed more than three attempts for successful epidural catheter placement. In contrast, Bamgbade et al.[75] reported a significantly higher number of attempts to perform neuraxial anesthesia in obese parturients, but they observed no difference in the rate of failure of neuraxial anesthetic techniques for cesarean delivery in obese parturients. Kula et al.[76] reported increased rates of difficult and failed labor epidural analgesia by 2.5- and 2.1-fold, respectively, in obese compared with nonobese parturients.[76] Although some investigators have reported a higher incidence of unintentional dural puncture in morbidly obese parturients than in lean parturients,[77] others have not confirmed this finding.[78]

It is not clear if epidural local anesthetic dose requirements are altered in morbidly obese parturients. In 1980, Hodgkinson and Husain[79] administered 20 mL of 0.75% epidural bupivacaine in the L3 to L4 interspace to women undergoing elective or emergency cesarean delivery. The patients remained supine for 40 minutes after drug injection. Twenty-seven percent of the patients with a BMI less than 28 kg/m^2 needed supplementation of the block at 30 minutes, whereas none of the patients whose BMI exceeded 28 kg/m^2 required additional local anesthetic to achieve surgical anesthesia. The cephalad extent of neuroblockade was associated with patient BMI and weight but not with height. Similarly, using an up-down sequential allocation study design to estimate the median effective epidural bupivacaine dose (administered in a volume of 20 mL), Panni and Columb[80] found that obese women required significantly less epidural bupivacaine for initiation of labor analgesia than lean parturients. In contrast, Milligan et al.[81] observed that neither patient position nor obesity affected the extent of sensory blockade when 12 mL of 0.25% bupivacaine was administered for epidural labor analgesia. Duggan et al.[82] found that obesity had only a weak effect in enhancing the spread of epidural local anesthetics; this effect was only observed with the largest volume and concentration used in the study (15 mL of bupivacaine 0.75%), but not with a lower volume (10 mL) and concentration (0.5%) of bupivacaine.

The goals of epidural labor analgesia should be the provision of excellent pain relief with minimal motor block. Epidural administration of a dilute solution of local anesthetic with a lipophilic opioid provides analgesia for labor while minimizing adverse effects such as hypotension and motor blockade. The neuroblockade provided to obese parturients in labor should be bilateral and *near perfect.* Otherwise, the epidural catheter should be removed and replaced because an inadequate block with a frequent need for top-up doses may lead to failure of extending the block for cesarean delivery.[83] Regular evaluation of the parturient's neuraxial block is essential. In a study of morbidly obese parturients published in 1993, the initial administration of local anesthetic through the epidural catheter resulted in failure of analgesia/anesthesia in 42% of the women, a rate that was seven times higher than that in control parturients.[71] However, careful evaluation of the epidural block and early replacement of a malpositioned catheter resulted in a high rate of success, so that only 1 of 55 cesarean deliveries attempted with epidural anesthesia required conversion to general anesthesia because of inadequate anesthesia.

The combined spinal-epidural (CSE) technique provides a rapid onset of excellent pain relief. In the past, some providers were concerned that an epidural catheter sited as part of a CSE technique remains untested until the spinal block has regressed. Thus, recognition of a malpositioned catheter might

be delayed and result in failed epidural anesthesia should the need for emergency cesarean delivery arise. Several studies have refuted these concerns and reported a higher success rate for epidural catheters sited using a CSE technique compared with those sited using a standard epidural technique.[84,85] Presumably, the higher success rate can be attributed to observing backflow of cerebrospinal fluid (CSF) through the spinal needle, thus indirectly confirming correct epidural needle position.[84,85] Further, Booth et al.[85] found that catheter failure was more often recognized within the first 30 minutes of placement in catheters sited as part of a CSE technique compared with those sited with an epidural technique.[85]

The dural puncture epidural technique (DPE, see Chapter 12) is a modification of the CSE technique in which a spinal needle is used to puncture the dura, but no intrathecal drug is injected. Some investigators have noted improved quality of analgesia compared with an epidural technique, and fewer adverse effects compared with a CSE technique.[86] DPE analgesia may be a useful technique to consider in obese parturients with anticipated difficulty in identifying the epidural space. The backflow of CSF through the spinal needle confirms that the tip of the epidural needle is located in the posterior epidural space, decreasing the risk for block failure. However, the DPE technique has not been specifically studied in this patient population.

In cases of unintentional dural puncture, continuous spinal analgesia can be used to provide labor analgesia. In addition to providing reliable labor analgesia, continuous spinal analgesia may be converted to spinal anesthesia for emergency cesarean delivery. It is crucial, however, that the catheter be clearly labeled and all personnel are made aware of its intrathecal location. Unintentional administration of an epidural dose of local anesthetic through the spinal catheter markedly increases the risk for high spinal block and subsequent respiratory arrest.

Some have suggested that the risk for post–dural puncture headache may be lower in the obese parturient, perhaps secondary to reduced CSF leak through the dural puncture site caused by the higher intra-abdominal pressure that results from a large abdominal panniculus. However, data are conflicting. In a retrospective study of 516 women with unintentional dural puncture with a 17-gauge Tuohy needle, Peralta et al.[87] reported a significantly lower incidence of post–dural puncture headache in women with BMI greater than or equal to 31.5 kg/m^2 compared with those with BMI less than 31.5 kg/m^2 (39% versus 56%), even after controlling for pushing during the second stage of labor.[87] Conversely, two other retrospective studies found no difference in the risk for post–dural puncture headache between obese and nonobese parturients.[88,89] A third study found no reduction in the risk for post–dural puncture headache in obese parturients compared with lean parturients except in those with a BMI greater than or equal to 50 kg/m^2.[90]

Cesarean Delivery

A thorough preanesthetic evaluation is critical to the safe care of the obese parturient. Of particular importance is a thorough airway assessment. Large breasts, the greater anteroposterior diameter of the chest, airway edema, and reduced chin-to-chest distance increase the likelihood of difficult laryngoscopy and failed tracheal intubation in obstetric patients.[91] Obesity exaggerates many of the anatomic changes of pregnancy. Increased fat in the neck and shoulders increases the difficulty of positioning the patient for laryngoscopy and tracheal intubation. Excess fat deposition may also cause distorted anatomy, such as an enlarged tongue and redundant pharyngeal and palatal soft tissue. Further, the fat pads on the back of the shoulders often restrict the range of motion of the neck, exacerbating the difficulty of mask ventilation, laryngoscopy, and tracheal intubation.

All morbidly obese parturients undergoing cesarean delivery should be placed in a ramped position with left uterine displacement, regardless of the planned anesthetic technique. This position was shown to improve laryngoscopic view compared with the traditional sniffing position in morbidly obese patients undergoing elective bariatric surgery.[92] Folded blankets or a padded ramp designed for this purpose are placed under the chest and head to achieve horizontal alignment between the external auditory meatus and the sternal notch (Fig. 49.1).[93] This position aligns the oral, pharyngeal, and tracheal axes to facilitate tracheal intubation and has been shown to improve hemodynamic and respiratory parameters during laparoscopic gastric bypass surgery.[94] Modern surgical tables can also be flexed at a number of angles, and this feature can be used to optimize the patient position for laryngoscopy and tracheal intubation.

It may be difficult to position the obese patient appropriately and safely. The protuberant abdomen may shift markedly with left uterine displacement. The patient must be secured to the operating table before the table is tilted leftward; however, it is important to initiate left uterine displacement as soon as possible.

The anesthesia provider should confirm that the patient's weight does not exceed the weight limits of the operating table, consider use of lateral table extenders, and use appropriate pads to ensure that the shoulders and arms are positioned in a horizontal plane. Correct arm position will maximize patient comfort, improve stability, and avoid neurologic injury to the upper extremity.

The anesthesia care team may be asked to participate in cephalad retraction of the large panniculus by tethering retractors to an object such as the ether screen or the head of the table. Both the obstetrician and the anesthesia provider must remain cognizant of the risks for hypotension, difficulty with ventilation, and fetal compromise during cephalad retraction of the panniculus in morbidly obese patients. Hodgkinson and Husain[79] reported an intraoperative fetal death in a morbidly obese patient who had received epidural anesthesia for cesarean delivery. The death was attributed to prolonged hypotension associated with cephalad retraction of a large panniculus. A vertical and cephalad suspension of the panniculus has been suggested to avoid maternal hypotension and hypoxemia.[63] Commercially available retraction devices can also be used to retract the panniculus, but there

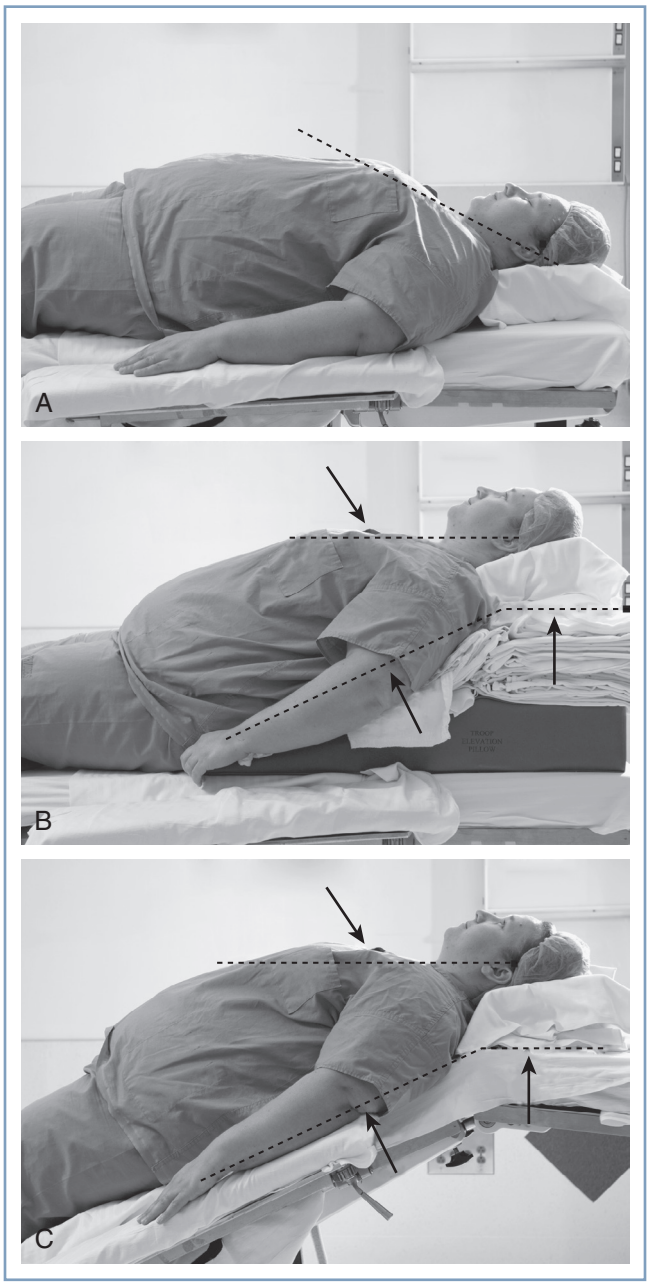

Fig. 49.1 Positioning the obese patient to facilitate intubation of the trachea. (A) Patient in the supine position using standard head support. Note that the *dashed line* (compare with *B*) is not parallel to the floor. (B) Elevating the patient's head with neck and shoulder supports so that an imaginary line drawn through the external auditory meatus and the sternal notch *(upper dashed line)* is parallel to the floor may facilitate tracheal intubation. (C) Similar positioning achieved by repositioning the operating table. Note the similarity of the upper and lower dashed lines with use of the second and third positioning techniques.

are no data to indicate whether these devices are associated with reduced risk for hypotension or ventilation compromise compared with cephalad retraction.

Pharmacologic aspiration prophylaxis is crucial in this patient population. Oral administration of 30 mL of a 0.3 M solution of sodium citrate effectively increases gastric pH within 5 minutes.[95] The anesthesia provider must be aware that the patient remains at risk for aspiration at the end of surgery; the efficacy of sodium citrate wanes 45 to 60 minutes after administration.[96] Administration of a histamine-2 (H_2)-receptor antagonist and metoclopramide provide additional protection (see Chapter 28).

Antibiotic Prophylaxis

Obesity is an independent predictor for surgical site infection.[64] The Clinical Practice Guidelines for Antibiotic Prophylaxis in Surgery recommend a dose of 3 g of cefazolin before cesarean delivery in women weighing over 120 kg[97]; however, the data supporting this recommendation are inconsistent. Pevzner et al.[98] found that a 2-g dose of cefazolin administered 30 to 60 minutes before cesarean delivery in obese and morbidly obese patients failed to achieve targeted minimum inhibitory concentrations (MICs) in 20% and 33% of patients, respectively, at the time of skin incision, and in 20% and 40% of patients, respectively, at the time of incision closure. Stitely et al.[99] randomized 20 obese patients undergoing cesarean delivery to receive 2 g or 4 g of cefazolin. The 4-g dose was associated with higher blood and tissue levels, but all collected subcutaneous and myometrial tissue samples had antibiotic concentrations above the MIC.[99] Swank et al.[100] reported that the administration of cefazolin 2 g resulted in the target MIC in all normal and overweight women, but only 20% of parturients with a BMI between 30 and 40 kg/m^2 and none of those with a BMI greater than 40 kg/m^2 reached the target MIC. Conversely, after cefazolin 3 g, the MIC target was achieved in all women with a BMI between 30 and 40 kg/m^2 and in 71% of women with a BMI greater than 40 kg/m^2.[100] Maggio et al.[101] did not find higher adipose tissue concentrations after cefazolin 3 g compared with 2 g, and there was no difference in surgical site infections between the two regimens. Similarly, two retrospective studies compared surgical site infections in morbidly obese women undergoing cesarean delivery and found no difference in surgical site infections between 2-g and 3-g regimens.[102,103]

Valent et al.[104] explored another strategy; obese women undergoing cesarean delivery were randomized to receive oral cephalexin 500 mg plus metronidazole 500 mg or placebo every 8 hours for 48 hours after delivery. All patients received a single 2-g intravenous dose of cefazolin before surgical incision. The rate of surgical site infection was significantly lower with the cephalexin/metronidazole regimen (6.4% versus 15.4%), yielding a number needed to treat of 12 (95% CI, 6.7 to 33.8).[104]

Neuraxial Techniques

Neuraxial anesthesia is the anesthetic technique of choice in the obese parturient. Single-shot spinal anesthesia provides reliable, fast onset and dense neuroblockade, and it is a common anesthetic technique in nonobese parturients undergoing planned cesarean delivery. However, concerns about the use of single-shot spinal anesthesia in obese patients include technical difficulties, appropriate dosing, and insufficient duration of anesthesia.

Spinal anesthesia is technically feasible in morbidly obese pregnant women, although a longer spinal needle may be required. The distribution of adipose tissue varies among obese patients. Spinal needle placement can be uneventful in women who do not have excessive adipose tissue over the midline of the back. However, in others with excessive adipose tissue at the needle placement site, identification of the intrathecal space with a small-gauge spinal needle can be very challenging. Identification of the epidural space with a large-gauge epidural needle is often technically easier, and a needle-through-needle CSE technique may be easier to perform than a single-shot spinal technique in the morbidly obese parturient. Ross et al.[105] reported fewer attempts to establish the neuraxial block with a CSE technique compared with a single-shot spinal technique in morbidly obese parturients undergoing elective cesarean delivery.[105]

The duration of surgery is often prolonged in the obese parturient[4]; therefore, single-shot spinal anesthesia may not have sufficient duration. Because intraoperative induction of general anesthesia is undesirable and potentially hazardous in morbidly obese pregnant women, a continuous neuraxial technique such as a CSE or epidural technique that allows the maintenance of neuraxial anesthesia with the epidural catheter is preferable to a single-shot spinal technique. Epidural anesthesia is preferred if the patient has a well-functioning epidural catheter *in situ.* Otherwise, a CSE technique may be preferable because it combines the reliability of the spinal block and the flexibility of epidural anesthesia. It also gives the option of initiating the block with a low dose of intrathecal local anesthetic, with the ability to increase the cephalad neuroblockade by administering additional local anesthetic via the epidural catheter if needed (i.e., sequential CSE anesthesia). Continuous spinal anesthesia with a spinal catheter is also an option. Some anesthesia providers have suggested that this technique should be considered in the setting of emergency cesarean delivery for obese parturients because it may be technically easier to rapidly identify the spinal space with a large-gauge epidural needle than with a spinal needle.[64] The use of a double-catheter technique has been described if a high vertical supraumbilical abdominal incision is planned; a lumbar spinal catheter or CSE technique is used for intraoperative anesthesia and a thoracic epidural catheter is used for postoperative analgesia and to achieve adequate anesthesia for the upper end of the incision if needed.[106,107]

Local anesthetic dosing for neuraxial techniques. The choice of local anesthetic dose in morbidly obese parturients in controversial. It has been a long-held belief that neuraxial local anesthetic doses should be reduced in obese patients because of fear of an unpredictable and exaggerated spread of local anesthetic, resulting in a high block. Magnetic resonance imaging (MRI) has confirmed that obese patients have a reduced lumbar CSF volume.[108] Engorgement of the epidural veins secondary to compression of the inferior vena cava by the gravid uterus and abdominal panniculus, as well as inward movement of soft tissue through the intervertebral foramina as a result of increased abdominal pressure, may be responsible for the reduced CSF volume in these patients. A separate study using magnetic resonance imaging (MRI) demonstrated an inverse correlation between the cephalad extent of neuroblockade and lumbar CSF volume[109]; this finding suggests that reduced CSF volume in obese patients increases the risk for a high spinal block.

Multiple studies, however, do not support the concern of exaggerated cephalad spread of spinal anesthesia in morbidly obese women undergoing cesarean delivery. In an up-down sequential allocation dose-finding study, Lee et al.[110] reported that the estimated ED_{95} (effective dose in 95% of patients) for hyperbaric bupivacaine was similar in obese and nonobese patients; no patient had an excessively high cephalad block with bupivacaine doses up to 12 mg. In another study, Carvalho et al.[111] estimated the ED_{50} (median effective dose) and ED_{95} for hyperbaric spinal bupivacaine for cesarean delivery in 42 morbidly obese parturients who were randomized to receive doses that ranged from 5 to 11 mg as part of a CSE technique. They reported that the ED_{50} and ED_{95} in these morbidly obese parturients were similar to those in nonobese parturients enrolled in a previous study performed by the same authors using similar methodology. Although it was common to obtain a satisfactory initial sensory level, even with the lowest doses, few of the low-dose blocks were adequate for surgery, and many required supplementation via the epidural catheter. Thus, the findings of these studies suggest that reducing the dose of intrathecal bupivacaine is not justified in morbidly obese patients and might increase the risk for inadequate anesthesia.

Superobese parturients with a BMI greater than 50 kg/m^2 are rarely included in these studies. Ngaka et al.[112] reported a higher block level by a median of 2 dermatomes but no significant differences in vasopressor requirements, hand grip strength, and peak expiratory flow rate in 25 morbidly obese parturients with a mean BMI of 51 kg/m^2 compared with nonobese parturients after receiving hyperbaric bupivacaine 10 mg. Another retrospective study compared the incidence of high spinal anesthesia (defined as need to convert to general anesthesia within 20 minutes of initiation of spinal anesthesia because of high neuroblockade or a cephalad extent of anesthesia higher than T2) in nonobese, obesity class I, II, III, and superobese (BMI greater than 50 kg/m^2) women.[113] Anesthesia was induced with hyperbaric bupivacaine (predominant dose 12 mg). The incidence of high spinal anesthesia was increased in superobese women (2.5%) compared with all other groups (0.71% or less). Vasopressor requirements were also higher in this group; unscheduled cesarean delivery was a risk factor for high spinal anesthesia.[113] In summary, these studies suggest that intrathecal dose reduction may be warranted in parturients with a BMI greater than 50 kg/m^2, ideally as part of a CSE technique, but not in obese women with a BMI less than 50 kg/m^2. In our practice, we use a dose of hyperbaric bupivacaine 9 mg to 10.5 mg as part of a needle-though-needle CSE technique in superobese parturients.

Results of studies of epidural local anesthetic dosing in morbidly obese parturients are also inconsistent (see earlier discussion). Unlike single-shot spinal anesthesia in which titration of the dose is not possible, careful titration of

epidural anesthesia is recommended to achieve the desired dermatomal level of neuroblockade.

General Anesthesia

Difficult mask ventilation and tracheal intubation are associated with more rapid oxyhemoglobin desaturation during apnea in obese patients than in lean individuals. The association between obesity and a short neck can make tracheal intubation difficult in this population.[114] In a series of patients who received general anesthesia for cesarean delivery, the incidence of difficult tracheal intubation was 33% among women who weighed more than 300 lb (136.4 kg).[71] This study was performed at a time when video laryngoscopes were not available in routine practice. Quinn et al.[115] conducted a 2-year survey of failed tracheal intubation in obstetric patients in the United Kingdom and reported that BMI was an independent predictor of failed intubation; the odds increase by 7% for each 1-kg/m^2 increase in BMI.

Airway management. The potential for failed tracheal intubation and difficult mask ventilation in the obese patient underscores the need for an experienced assistant during induction of general anesthesia. The primary anesthesia provider may fatigue rapidly with attempted mask ventilation of an obese patient. Further, the jaw-thrust maneuver may require the use of both hands, and additional personnel will be required to provide positive-pressure ventilation and cricoid pressure. A short-handled laryngoscope, assorted laryngoscope blades, various sizes of endotracheal tubes, endotracheal tube guides, supraglottic airway devices, a video laryngoscope, a fiberoptic intubation device, and equipment suitable for emergency surgical airway (e.g., cricothyrotomy) should be readily available.[116] A failed tracheal intubation algorithm should be initiated and help should be called immediately in the event of failed tracheal intubation (see Chapter 29). Supraglottic airway devices may be lifesaving in these situations. Some experts have suggested that a video laryngoscope should be the first-line device used in obstetric patients[117]; this recommendation may be particularly relevant in the obese parturient.

Awake tracheal intubation using video laryngoscopy or direct fiberoptic laryngoscopy is an alternative method of securing the anticipated difficult airway. However, women requiring urgent cesarean delivery may not be ideal candidates for awake tracheal intubation because of the lack of adequate time to optimally prepare the airway.

When preanesthetic assessment suggests that tracheal intubation will not be difficult, a rapid-sequence induction is indicated. The administration of general anesthesia begins with effective denitrogenation (so-called preoxygenation). During apnea, pregnant women become hypoxemic more rapidly than nonpregnant women, and obese patients become hypoxemic more rapidly than nonobese patients.[118] Therefore, adequate denitrogenation is essential before the induction of general anesthesia in obese pregnant women. A nasal cannula insufflating oxygen 5 L/min during the period of apnea and tracheal intubation increases the time to desaturation and should be strongly considered in the obese parturient.[118]

The technique of denitrogenation is important. One study demonstrated that four maximal inspirations of 100% oxygen within 30 seconds (4-deep breaths [DB]) provide benefit similar to that provided by 3 minutes of tidal-volume breathing of 100% oxygen before rapid-sequence induction of general anesthesia for cesarean delivery.[119] However, another study reported a more rapid onset of hypoxemia in patients who used 4-DB than patients who used 3 minutes of tidal-volume breathing of 100% oxygen.[120] Goldberg et al.[121] evaluated the use of both techniques in morbidly obese nonpregnant patients undergoing gastric bypass surgery. The techniques provided similar increases in Pao_2, but patients who used the 3-minute technique showed evidence of slight retention of CO_2. The investigators speculated that a blunted ventilatory response to CO_2 contributed to the increase in $Paco_2$. Later data from a study in 20 pregnant volunteers (at 36 to 38 weeks' gestation) compared 3 minutes of tidal-volume breathing with 4-DB or eight deep breaths in 1 minute (8-DB) of 100% oxygen by measuring end-tidal fractional oxygen concentration ($FETO_2$) after preoxygenation.[122] An $FETO_2$ value of 90% or greater was achieved in 76% of women after either the 3-minute or the 8-DB method, compared with only 18% of women after the 4-DB method of preoxygenation.[122] The investigators concluded that for emergency cesarean delivery using general anesthesia, the 8-DB method was as effective as the 3-minute tidal volume method of preoxygenation and was more quickly performed.

It is wise to apply a tight-fitting face mask and administer 100% oxygen as soon as the patient enters the operating room; this maneuver helps achieve denitrogenation while the patient is moved to the operating table and other preparations are being made. It then seems reasonable to let circumstances dictate the selected method of denitrogenation. When the 3-minute tidal volume breathing technique is selected, the anesthesia provider should encourage the patient to take several deep breaths. In urgent situations, such as emergency cesarean delivery for maternal hemorrhage, the patient should be instructed to take eight deep breaths (the 8-DB method) to extend the safe interval before oxyhemoglobin desaturation occurs. When time allows, the 8-DB method is preferred over the 4-DB method.

Induction and maintenance of anesthesia. The dose of intravenous induction agents should be based on lean body weight rather than total body weight.[123] This practice will avoid excessive doses of drug with subsequent adverse effects. Propofol 2 to 2.8 mg/kg, thiopental 4 to 5 mg/kg, or other induction agents can be used according to availability, clinical circumstances, and anesthesia provider preference. All these agents will cross the placenta and can affect the neonate.

Succinylcholine in doses of 1.0 to 1.5 mg/kg is commonly used for rapid-sequence induction and tracheal intubation in obese parturients. Lemmens and Brodsky[124] compared the efficacy of succinylcholine in dosing regimens of 1 mg/kg based on ideal body weight, lean body weight, and total body weight in morbidly obese nonpregnant patients. The third regimen (1 mg/kg total body weight) was superior for providing complete neuromuscular paralysis and predictable

laryngoscopic conditions in almost every patient, whereas intubating conditions were poor in one-third of the patients dosed according to ideal body weight. The investigators also noted that "none of these dosing regimens will provide…a safe (short) duration of apnea."

Rocuronium at a dose of 1 to 1.2 mg/kg provides equivalent intubating conditions to succinylcholine 1 mg/kg. However, this dose range is associated with a significantly prolonged duration of neuromuscular blockade.[125] In obese patients, the dose of rocuronium should be based on ideal body weight.[126] Sugammadex will effectively reverse high-dose rocuronium (1.2 mg/kg) in 2 minutes.[127] Sugammadex has been used successfully in obstetric patients with no major adverse maternal or neonatal effects.[128] The optimal dosing regimen in obese patients is not clear; two studies in nonpregnant obese patients suggested that sugammadex dosing can be based on ideal body weight plus 40%[129] or on corrected body weight: ideal body weight + 0.4(total body weight − ideal body weight).[130] However, its use has not been specifically studied in obese parturients, and its safety in this patient population remains to be confirmed. Inadequate reversal of neuromuscular blockade in an obese parturient[131] and recurarization in another obese patient undergoing bariatric surgery[132] have been reported following administration of sugammadex for reversal of rocuronium-induced neuromuscular blockade, highlighting the importance of appropriate dosing and vigilance in ensuring adequate recovery in this patient population.

Maintenance of anesthesia is usually achieved with a volatile halogenated agent with or without nitrous oxide. No evidence suggests that obesity alters the minimum alveolar concentration (MAC) of volatile halogenated anesthetic agents in pregnant women. In theory, the body fat reservoir could increase the threat of biotransformation of volatile halogenated agents, which would increase the risk for organ toxicity. Isoflurane is an appropriate choice for morbidly obese parturients owing to its limited biotransformation.[133] Desflurane and sevoflurane are associated with a shorter time to extubation than isoflurane in obese patients, although the difference may not be clinically relevant.[134,135]

Morbidly obese patients may require administration of a higher inspired oxygen concentration and may not tolerate usual concentrations of nitrous oxide. Moreover, general anesthesia reduces FRC. The supine and Trendelenburg positions further decrease FRC, thus increasing the risk for intraoperative hypoxemia. The following strategies have been recommended to reduce the risk for small airway closure, atelectasis, and hypoxemia in obese patients: (1) use of inspired oxygen concentration of less than 0.8, (2) ventilation with tidal volumes ranging from 6 to 10 mL/kg ideal body weight, (3) increasing the respiratory rate to maintain physiologic $Paco_2$, (4) use of manual or automated periodic lung inflation (i.e., a recruitment maneuver), and (5) application of positive end-expiratory pressure (approximately 10 cm H_2O).[136]

Emergence from general anesthesia is a critical period. Indeed, maternal deaths from hypoventilation and airway obstruction have been reported during emergence and recovery from general anesthesia.[46] It is imperative that the patient is fully awake with complete reversal of neuromuscular blockade before tracheal extubation, which preferably should be performed in the semi-upright position to minimize diaphragmatic compression by abdominal viscera. Trained personnel should provide postoperative care before the discharge of the patient to the ward.

POSTOPERATIVE COMPLICATIONS

Obesity increases the risk for postoperative complications such as endometritis, urinary tract infection, wound infection, wound dehiscence, peripheral nerve injury, hemorrhage, deep vein thrombosis, pulmonary thromboembolism, atelectasis, pneumonia, respiratory depression, hypoxemia, tracheal reintubation, myocardial infarction, cardiac arrest, and maternal death.[64,137]

The combination of obesity, OSA, general anesthesia, and opioid administration may increase the risk for opioid-induced respiratory depression. In a report on maternal mortality in Michigan, Mhyre et al.[46] found that all anesthesia-related maternal deaths from airway obstruction or hypoventilation occurred during emergence and recovery, with obesity identified as a significant risk factor for these complications. The American Society of Anesthesiologists has issued Practice Guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea, which include recommendations for the preoperative, intraoperative, and postoperative management of these patients (Box 49.1).[138] These recommendations are not intended specifically for pregnant women, but they do provide some guidance for the care of the obese parturient with OSA undergoing cesarean delivery.

POSTOPERATIVE CARE

Postoperative Analgesia

Adequate postoperative analgesia is crucial to facilitate early mobilization, thereby reducing the risk for thromboembolic and pulmonary complications. However, the ideal analgesic regimen in the obese parturient remains unclear. Neuraxial morphine has been shown to provide superior analgesia to that provided by parenteral and oral opioids after cesarean delivery, at the expense of increased opioid-related side effects such as pruritus and nausea.[139,140] There is a concern, however, that obese patients might be at greater risk for respiratory depression after neuraxial opioid administration, although there are few data. In a series of 856 patients who received intrathecal morphine 0.2 mg combined with hyperbaric bupivacaine for cesarean delivery, respiratory depression (defined as an Sao_2 of 85% or less and/or a respiratory rate of 10 breaths per minute or less) occurred in 8 patients, all of whom were obese.[141] Conversely, a large retrospective study including 5036 parturients who received neuraxial morphine, 63% of whom were obese, did not identify any instances of respiratory depression, defined as need for naloxone or rapid response team calls for respiratory complications.[142] The risk for sedation and respiratory depression might be greater

BOX 49.1 American Society of Anesthesiologists Practice Guidelines for Perioperative Management of Patients with Obstructive Sleep Apnea

Preoperative

- Preoperative initiation of continuous positive airway pressure (CPAP) should be considered, particularly if obstructive sleep apnea (OSA) is severe.
- Patients with known or suspected OSA may have a difficult airway and therefore should be managed according to the ASA Practice Guidelines for Management of the Difficult Airway[a] or other similar airway management guidelines.

Intraoperative

- The potential for postoperative respiratory compromise should be considered.
- Neuraxial anesthesia (spinal/epidural/combined spinal-epidural) should be considered.
- Patients at increased perioperative risk from OSA should be extubated while awake.
- Full reversal of neuromuscular blockade should be verified before tracheal extubation.
- When possible, extubation and recovery should be carried out in the lateral, semi-upright position, or other nonsupine position.

Postoperative

- Postoperative analgesia: regional analgesic techniques should be considered to reduce or eliminate the requirement for systemic opioids in patients at increased perioperative risk from OSA.
- If neuraxial analgesia is planned, the anesthesia provider should weigh the benefits (improved analgesia, decreased need for systemic opioids) and risks (respiratory depression from rostral spread) of using an opioid or opioid–local anesthetic mixture compared with a local anesthetic alone.
- If a patient-controlled systemic opioid analgesic technique is used, a continuous background infusion should be used with extreme caution or avoided entirely.
- Nonsteroidal antiinflammatory agents and other modalities should be considered if appropriate to reduce opioid requirements.
- Concurrent administration of sedative agents increases the risk for respiratory depression and airway obstruction.
- Supplemental oxygen should be administered continuously to all patients who are at increased perioperative risk from OSA until they are able to maintain their baseline oxygen saturation while breathing room air.
- Hospitalized patients at increased risk for respiratory compromise from OSA should be monitored with continuous pulse oximetry after discharge from the post–anesthesia care unit.

with systemic opioids compared with neuraxial opioids, although there are no data comparing the risk for respiratory depression between the two routes of opioid administration in this patient population. In patients who have not received neuraxial opioid analgesia, systemic opioids are best administered using an intravenous patient-controlled analgesia (PCA) system. With all routes of opioid administration, vigilance and appropriate postoperative monitoring are essential in the obese patient who may have undiagnosed OSA and be at a greater risk for opioid-induced respiratory depression. The use of sedative agents or magnesium sulfate in the postoperative period may also increase the risk for respiratory depression.

A multimodal analgesic regimen including regular administration of a nonsteroidal antiinflammatory drug and acetaminophen may contribute to opioid sparing and improve postoperative analgesia (see Chapter 27). A systematic review of randomized controlled trials found that local anesthetic wound infiltration was associated with a reduction in opioid consumption and pain scores in women undergoing cesarean delivery, but did not reduce the incidence of opioid-related side effects.[143] There are limited data on the use of this technique in women receiving neuraxial morphine, but the review suggested that opioid sparing was only achieved in women who did not receive neuraxial morphine. Analgesia was better with catheter placement below compared with above the fascia.

Similarly, transversus abdominis plane (TAP) block was found to produce opioid sparing and reduce pain scores and opioid-related adverse effects in women who did not receive neuraxial morphine as part of their neuraxial anesthetic technique.[144] However, performance of TAP block may be technically challenging in the obese parturient with a large abdominal panniculus. Recently, quadratus lumborum block was reported to be effective for postcesarean analgesia; one study found greater opioid sparing with this technique compared with TAP blocks.[145] Some approaches to the quadratus lumborum block may be technically easier than the TAP block in obese parturients. Patient-controlled epidural analgesia (PCEA) may be another option. Investigators found that PCEA with ropivacaine provides analgesia comparable to that provided by epidural morphine, but with more motor block, thus delaying patient mobilization.[146] PCEA techniques have not been specifically studied in obese parturients.

Thromboprophylaxis

The American College of Chest Physicians (ACCP) published guidelines for antithrombotic therapy in the parturient.[147] They used major and minor risk factors to identify women at increased risk for venous thromboembolism after cesarean delivery; obesity (BMI greater than 30 kg/m^2) was classified as a minor risk factor. Thromboprophylaxis was recommended in the presence of one major risk factor (risk for thromboembolism greater than 3%) or two minor risk factors (combined risk greater than 3%) (see Box 38.1). In the setting of emergency cesarean delivery (a minor risk factor), an additional minor risk factor (e.g., obesity) results in a risk greater than

3%, and, therefore, mechanical or pharmacologic thromboprophylaxis is recommended.

The ACOG thromboembolism guidelines do not specifically address the obese parturient.[148] Instead, they recommend perioperative mechanical thromboprophylaxis for all women, with the addition of low-molecular-weight heparin (LMWH) in selected high-risk parturients, without specifying obese women. In the United Kingdom, the Royal College of Obstetricians and Gynaecologists' (RCOG) guidelines recommend thromboprophylaxis for at least 10 days with LMWH for all obese parturients undergoing emergency or elective cesarean delivery.[149] Further, the RCOG guidelines recommend thromboprophylaxis with LMWH for at least 10 days after vaginal delivery in all morbidly obese women. The National Partnership for Maternal Safety published a consensus bundle on venous thromboembolism in 2016.[150] Mechanical thromboprophylaxis is recommended for all women undergoing cesarean delivery, with the addition of pharmacologic prophylaxis for those with risk factors, including obesity. For women with vaginal delivery, the Partnership recommends following the ACCP guidelines for hospitalized nonsurgical patients.[147]

KEY POINTS

- The presence of coexisting disease(s) complicates obstetric and anesthetic management of the morbidly obese pregnant woman.
- The obese pregnant woman is at increased risk for obstetric, anesthetic, neonatal, surgical, and postoperative complications.
- The obese pregnant woman should be referred to an anesthesia provider for preanesthesia consultation.
- Airway complications, which can occur during the postoperative period as well as during the induction and emergence from general anesthesia, constitute the most common cause of anesthesia-related maternal death.
- The anesthesia provider should perform a careful, thorough assessment of the airway in every obese pregnant woman and should consider securing the airway before induction of general anesthesia when a difficult airway is anticipated.
- Early administration of neuraxial labor analgesia is advised in obese parturients; anesthesia providers should critically evaluate the quality of the epidural block and replace any neuraxial catheter that does not provide excellent analgesia.
- Continuous spinal anesthesia should be considered in emergency settings involving potentially difficult tracheal intubation and in cases of unintentional dural puncture in morbidly obese patients.
- Morbidly obese parturients may be at significant risk for obstructive sleep apnea; therefore, they should be carefully monitored with continuous pulse oximetry for postoperative hypoxemia resulting from airway obstruction and/or respiratory depression after discharge from the postanesthesia care unit.

Psychiatric Disorders

Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM (Anaesthesiology), Vijay J. Roach, MBBS, MRCOG, FRANZCOG, MHKCOG

CHAPTER OUTLINE

Psychiatric disorders occur commonly during pregnancy and can have significant effects on the mother, child, and family, and important economic costs to society. Suicide is a major cause of maternal mortality. Women have higher rates than men of many psychiatric disorders, such as anxiety, feeding and eating disorders, and depression; the reproductive years coincide with the greatest period of risk.[1] Management can be difficult and may be complicated by variable presentation of symptoms, social stigmas, confusion with normal symptoms of pregnancy, and inconsistent published treatment recommendations. Further, pregnant women with psychiatric disorders may resist drug treatment because of their desire to avoid fetal harm. Psychiatric disorders during pregnancy may be associated with other aspects of poor maternal health and deficient prenatal care, which may affect anesthesia care.[2] Women with a history of previous psychiatric hospitalization or an identified mental illness are at increased risk for cesarean delivery.[3]

CLASSIFICATION

Internationally, psychiatric disorders are most commonly classified according to the *International Statistical Classification of Diseases and Related Health Problems (ICD-10)*[a] produced by the World Health Organization. In the United States, a clinical modification of *ICD* is used *(ICD-10-CM)*.[b] Although in the United States *ICD* is the official diagnostic system for mental disorders, the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)*, published by the American Psychiatric Association (APA), is widely used.[4] These classification systems provide standardized language and criteria for diagnosis and classification of mental disorders; however, definitions may not have precise boundaries and there may be considerable overlap between "mental" and "physical" disorders.[4]

EPIDEMIOLOGY

It has been estimated that more than 500,000 pregnancies each year in the United States involve women who have a psychiatric illness that either predates or emerges during pregnancy.[1] Psychiatric illness occurs in approximately 15% of pregnant women, and 10% to 13% of fetuses are exposed

[a] http://apps.who.int/classifications/icd10/browse/2010/en
[b] https://www.cdc.gov/nchs/icd/icd10cm.htm

to psychotropic drugs.[5] The World Health Organization has reclassified maternal suicide as a direct cause of maternal death, and the *Confidential Enquiries into Maternal Deaths in the United Kingdom*[6] has identified suicide as an important cause of maternal mortality and the leading cause of direct maternal deaths occurring within 1 year after the end of pregnancy.

Pregnancy is widely considered a time of increased vulnerability to psychiatric disorders. However, studies suggest that the prevalence is similar between pregnant and nonpregnant women.[7] A conspicuous exception is the risk for major depressive disorder, which is increased during the postpartum period. Identified risk factors for developing psychiatric disorders during pregnancy include younger age, unmarried status, exposure to traumatic or stressful life events, pregnancy complications, and poor overall health. Treatment rates among pregnant women with psychiatric disorders are often low.

MOOD DISORDERS

Mood disorders include depressive disorders and bipolar disorders ("manic-depressive disorders").[4]

Major Depressive Disorder

The *DSM-5* has defined criteria for major depressive disorder that are based on the presence, within the same 2-week period, of specific symptoms that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning; these symptoms should not be the result of the physiologic effects of a substance.[4] Although depression is recognized as being relatively common during pregnancy, many of its symptoms (e.g., weight gain, appetite changes, sleep disturbances, fatigue) must be differentiated from symptoms that may occur during normal pregnancy. Risk factors for depression during pregnancy include a history of depression or bipolar disorder, childhood mistreatment, being a single mother or having more than three children, marital problems, unwanted pregnancy, smoking, low income, age younger than 20 years, poor social support, and domestic violence.[8,9] The risk for major depressive illness is increased in women who have a miscarriage (i.e., early pregnancy loss); this most frequently occurs in the first month after miscarriage and is more likely to occur in women who are childless or who have a prior history of major depressive disorder.[10] Depression during pregnancy is associated with an increased risk for poor obstetric outcomes such as miscarriage, preterm birth, and low birth weight.[11]

Bipolar (Manic-Depressive) Disorder

Patients with bipolar disorder (BPD) have episodes of major depression with other distinct periods of mania or hypomania. A strong familial association exists. *DSM-5* diagnostic criteria for mania specify a distinct period when there is abnormally and persistently elevated, expansive, or irritable mood and persistently increased goal-directed activity or energy, which lasts at least 1 week and is present most of nearly every day or requires hospitalization.[4] Specific symptoms are listed, which should be severe enough to cause marked impairment in occupational functioning, social activities, and interpersonal relationships and necessitate hospitalization or have psychotic features; symptoms should not meet criteria for a mixed episode and should not be caused by substance abuse or general medical conditions (e.g., hyperthyroidism).[4] BPD in pregnancy is particularly important because there is a strong link between discontinuation of medication and relapse of BPD and a relatively high suicide rate among patients. Treatment of BPD typically consists of mood stabilizer and antipsychotic medication, with psychotherapy as an adjunct.[12] Electroconvulsive therapy (ECT) is very effective for patients with BPD and severe depression.

Postpartum Depression

Postpartum depression describes a major depressive episode that occurs in the first 4 to 6 weeks after birth. Symptoms do not differ from those of depression occurring at other times. There may be accompanying psychotic features, which are thought to be more common in nulliparous women,[4,13] and there is a high risk for recurrence in subsequent pregnancies. It is important to differentiate postpartum depression from the "baby blues," which affects up to 70% of women in the first 10 days after delivery and is transient without functional impairment. It is also important to differentiate postpartum depression from delirium that arises from physical causes.[4] In a systematic review, Robertson et al.[14] showed that the strongest predictors of postpartum depression were (1) depression, anxiety, or stressful life events occurring during pregnancy or the early puerperium; (2) low levels of social support; and (3) previous history of depression. Biologic effects such as hormonal changes and psychological and social role changes that occur with childbirth may increase the risk for postpartum depression.[15] In a retrospective study, Ding et al.[16] showed an association between use of labor epidural analgesia and a decreased risk for postpartum depression; further research is required to confirm these findings.

Postpartum Psychosis

Postpartum psychosis occurs within 2 weeks of approximately 1 to 2 per 1000 live births; a relatively high risk continues for the first 3 months postpartum.[17] The risk is higher in patients with a history of BPD or a history of previous postpartum psychosis,[18] as well as in women with major depression and schizophrenia. Typical features include prominence of cognitive symptoms such as disorganization, confusion, impaired sensorium, disorientation, and distractibility.[17] Infanticide is rare and may be associated with command hallucinations to kill the infant or delusions that the infant is possessed.[13]

ANXIETY DISORDERS

Anxiety disorders affect women twice as often as men and are the most common psychiatric disorders during pregnancy and the postpartum period.[19] There is a wide range of anxiety

disorders, including **panic disorder, separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder, agoraphobia, generalized anxiety disorder, substance/medication-induced anxiety disorder, anxiety disorder due to another medical condition, other specified anxiety disorder,** and **unspecified anxiety disorder.** Closely related to anxiety disorders are **trauma- and stressor-related disorders,** which includes **posttraumatic stress disorder** and **obsessive-compulsive disorder.**[4] Clinical features of anxiety disorders in pregnant women are similar to those in nonpregnant women, but concern about the pregnancy and the fetus may be the predominant feature.[20]

Panic Disorder

Panic disorder is characterized by the occurrence of recurrent, unexpected panic attacks. Affected women experience discrete episodes of intense fear or discomfort in the absence of a true danger; these episodes are accompanied by somatic or cognitive symptoms such as palpitations, sweating, shaking, dyspnea, choking, chest pain, nausea, paresthesias, chills, and/or flushes. Typically there is a rapid onset and peak of symptoms that may be accompanied by an urge to escape.[4] It is important to be aware of the possibility that panic attacks may occur during preparation of a patient for cesarean delivery. Panic attacks with hyperventilation may mimic local anesthetic systemic toxicity.[21] Patients with panic disorder often have comorbid major depression.[19]

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) occurs after the experience of a traumatic event that evokes intense fear or helplessness and has been estimated to occur in 4% to 6% of women in pregnancy or postpartum.[22] PTSD may arise during the perinatal period, or preexisting PTSD can be exacerbated during pregnancy. Symptoms of PTSD are more common after emergency cesarean delivery than after other modes of delivery,[23] and PTSD has resulted from (1) awareness during general anesthesia,[24] (2) inadequate neuraxial anesthesia for cesarean delivery,[25] and (3) inadequate pain control during vaginal delivery.[25] The risk for PTSD may be increased if the pregnancy has resulted from rape or if memories of sexual trauma are triggered. It has been suggested that the childbirth experience itself can precipitate PTSD with a resulting fear of pregnancy termed *tocophobia.*[1] Fear of vaginal delivery may be a factor that contributes to maternal request for cesarean delivery.[23]

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by the presence of obsessions (intrusive thoughts or images) and compulsions (repetitive or ritualistic behaviors or thought patterns).[19] OCD is more common in pregnant and postpartum women than in the general population.[26] Obsessions most frequently center around contamination or aggression toward the child and may lead to compulsive cleaning, checking, or avoidance of the child. Care should be taken to identify infanticidal ideation.[19]

FEEDING AND EATING DISORDERS

There are conflicting data on the effect of pregnancy in patients with feeding and eating disorders, which include **anorexia nervosa** and **bulimia nervosa** as well as **pica, rumination disorder, avoidant/restrictive food intake disorder, binge-eating disorder, other specified feeding or eating disorder,** and **unspecified feeding or eating disorder.**[4] Improvement in symptoms during pregnancy has been described, but conversely, pregnancy may result in body image preoccupations and unfavorable eating habits that may develop into a frank eating disorder.[17] Although fertility is reduced in patients with anorexia nervosa, patients may still conceive. Patients with eating disorders have a higher risk for psychiatric comorbidity, including anxiety and postpartum depression,[1] and are at greater risk for fetal growth restriction and cesarean delivery.[17]

SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDERS

These disorders include schizophrenia, other psychotic disorders, and schizotypal (personality) disorder. Defining features include abnormalities in one or more of the following areas: hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms.[4] In **schizophrenia,** the disorder lasts for at least 6 months, with at least one month of active symptoms.[4]

Limited data are available on the course of psychotic disorders in pregnancy; both deterioration and improvement have been reported. The postpartum period is thought to be a high-risk period for relapse.[17] Compared with women without psychotic disorders, pregnant women who have psychotic disorders often receive less prenatal care; have poorer nutrition; exhibit greater use of tobacco, alcohol, and illicit drugs; and have higher rates of obstetric interventions and obstetric complications.[1,17] Fear of loss of child custody may result in underreporting of symptoms.[17]

OTHER DISORDERS

Personality Disorders

Personality disorders have high prevalence rates of approximately 10% in the general population and up to 40% among psychiatric patients.[27] The *DSM-5* lists 10 specific personality disorders that are grouped into three clusters based on descriptive similarities. Patients in cluster A (**paranoid, schizoid, schizotypal**) appear odd or eccentric; patients in cluster B (**antisocial, borderline, histrionic, narcissistic**) appear dramatic, emotional, or erratic; and patients in cluster C (**avoidant, dependent, obsessive-compulsive**) appear anxious and fearful.[4] There is also one further category, **personality disorder not otherwise specified.** The *DSM-5* also provides an alternative dimensional model for personality disorders based on both personality functioning and pathologic personality traits that takes the perspective that personality disorders represent maladaptive variants of personality

traits that merge into normality and into one another.[4] This accounts for the observation that patients who meet criteria for a specific personality disorder frequently also meet criteria for other personality disorders.[4]

Pseudocyesis

Pseudocyesis is a clinical syndrome in which a woman firmly believes that she is pregnant in the absence of a true gestation. Patients may develop convincing signs and symptoms suggestive of pregnancy, including abdominal enlargement and menstrual disturbance.[28] Diagnosis can be made using a pregnancy test and ultrasonography. Physical diagnoses should be excluded. For example, tumors such as bronchogenic carcinoma may produce hormones (e.g., human chorionic gonadotrophin [hCG]) that can cause secondary amenorrhea, which may be confused with pregnancy.[29]

Denial of Pregnancy

In contrast to pseudocyesis, denial of pregnancy is more common, with an estimated incidence of 1 in 400 to 516 pregnancies.[30] It may be associated with adverse outcomes, including psychological stress, unassisted delivery, and infanticide. Patients who are identified should be referred for psychiatric assessment.[30]

Substance Abuse

Substance abuse during pregnancy is discussed in Chapter 53.

MANAGEMENT OF PSYCHIATRIC DISORDERS IN PREGNANCY

General Considerations

Guidelines for the management of pregnant women with psychiatric disorders have been published by the American College of Obstetricians and Gynecologists (ACOG) and the APA,[13,15] and guidelines are also available from the United Kingdom[31] and Australia.[32]

Screening for anxiety and depression in pregnancy and in the postpartum period is effective for diagnosing perinatal mental health problems. This can be achieved through face-to-face screening and online. Pregnant women should also be screened for substance abuse and domestic violence.[32]

Treatment options for different psychiatric disorders overlap and include nonpharmacologic and pharmacologic therapies. Data are limited on pregnancy-specific efficacy of treatments, but in general, response in pregnant patients is thought to be similar to that in nonpregnant patients.[1] A family-centered approach is recommended, and cultural and social context should be taken into account. Nonpharmacologic therapies are especially important because of maternal preferences and concerns about potential effects of drugs on the fetus and infant.[7] Although there is often concern about potential harmful effects of psychotropic drugs given during pregnancy and lactation, it appears that most psychotropic drugs are relatively safe, and there is a significant risk for exacerbation of illness and serious harm associated with cessation or withholding of psychotrophic drugs.[5]

Because diabetes, obesity, smoking, and substance abuse are more common in people with psychiatric disorders, it can be difficult to separate the effects of psychiatric drugs on the fetus from the effects of these other factors. Further, some of the risks associated with psychiatric drugs may be attributable to the fact that women who take medication for psychiatric disorders are likely to have more severe disease than women not on medication (i.e., confounding by indication).[8]

General recommendations for the management of women with psychiatric disorders include the following[33]: (1) a psychiatric history should be identified prenatally and, even if affected patients are well, they should be frequently monitored and supported during pregnancy and the first few weeks postpartum; (2) psychiatric services should have priority-care pathways for pregnant and postpartum women; and (3) care by multiple psychiatric teams should be avoided. Conversely, care should be taken to avoid misattribution of physical symptoms to psychological causes in patients with no psychiatric history and other concurrent disease. All patients with psychiatric disorders, particularly those with acute or postpartum psychosis, should be carefully screened for thoughts of harm to themselves and/or their infants.

A multidisciplinary approach is essential in the management of pregnant patients with psychiatric disorders, especially because many anesthesia providers may not be familiar with management of these patients. Patients who are noncooperative or violent may be challenging and require patience, compassion, and emotional support. Flexibility in management is important. For example, general anesthesia may sometimes be required if neuraxial anesthesia is considered impractical or unsafe.

Psychological and Psychosocial Therapies

Psychological and psychosocial interventions include cognitive behavioral therapy, interpersonal therapy, nondirective counseling, and peer support; these strategies are particularly effective for management of anxiety disorders and depression. Promising interventions for postpartum depression include professionally-based postpartum home visits, lay- or peer-based postpartum telephone support, and interpersonal psychotherapy.[34]

Psychotropic Drugs

There is often concern about potential harmful fetal/neonatal effects of psychotropic drugs given during pregnancy and lactation. However, because of the difficulties of performing experimental studies in this area, much of the available evidence is based on observational studies that are unable to differentiate association and causation. The decision to initiate or continue a pregnant woman on psychotropic medication requires the physician and patient to weigh carefully the possible risks associated with medications versus the serious potential consequences of inadequately treated disease. Psychiatric medications should generally be continued in pregnant women presenting for anesthesia and surgery.

Box 50.1 outlines principles for the use of psychiatric medications during pregnancy. The use of nonanesthetic

BOX 50.1 General Principles Related to the Use of Psychiatric Drugs in Pregnancy

- Use nonpharmacologic therapy when possible, but do not assume that it is always better to avoid psychotropic drugs.
- Be aware that discontinuing medication exchanges the fetal and neonatal risks of drug exposure for the risks of untreated maternal illness.
- Be aware that all psychotropic drugs cross the placenta and pass into breast milk, and that the major risk for teratogenesis occurs during embryogenesis (i.e., 3 to 8 weeks' gestation).
- Use drugs with largest up-to-date evidence of safety for the mother and fetus.
- Prescribe the smallest number of drugs possible, preferring monotherapy to multiple medications.
- Use the lowest effective doses, and minimize changing drug regimens.
- Prefer medications with fewer metabolites, higher protein binding, and fewer drug interactions.
- Monitor mental state and adjust doses as pregnancy progresses because of alteration in pharmacokinetics.
- Involve the mother and partner/family in decisions, and document decisions.

drugs during pregnancy and lactation is discussed in Chapter 14.

Antidepressants are the most common psychotropic drugs prescribed in pregnancy. Previously, **tricyclic antidepressants** were commonly used and have generally been considered safe to use in pregnancy. These drugs may have anticholinergic side effects, including dilated pupils, agitation, seizures, delirium, hyperthermia, and arrhythmias, and they have a greater fatality risk after overdose compared with newer agents. Tricyclic antidepressants have been largely replaced by **serotonin reuptake inhibitors (SRIs),** which are a mainstay therapy for depression and anxiety. These drugs include **selective serotonin reuptake inhibitors (SSRIs)** such as **sertraline** (Zoloft), **paroxetine** (Paxil), **fluoxetine** (Prozac), and **citalopram** (Celexa), and **serotonin-norepinephrine reuptake inhibitors (SNRIs)** such as **desvenlafaxine** (Pristi/Khedezla), **duloxetine** (Cymbalta), **levomilnacipran** (Fetzima) and **venlafaxine** (Effexor XR). Much research has investigated the possible association between the use of SRIs in pregnancy and an increased risk for congenital abnormalities including cardiovascular defects, persistent pulmonary hypertension, and postnatal adaptation syndrome; although the overall risk is considered to be small, the subject remains controversial.[35] Reassuring results from a recent large retrospective study from Sweden showed that, after accounting for confounding variables, first-trimester exposure to SRIs was associated with a small increased risk for preterm birth but no increased risk for a small for gestational age infant at delivery, autism spectrum disorder, or attention-deficit/hyperactivity disorder.[36] Serotonin syndrome (i.e., agitation, restlessness, hallucinations, increased body temperature, vomiting) may occur with an overdose or a combination of serotonergic drugs.[37]

Routine prescription of **benzodiazepines** for pregnant women is typically avoided, except for short-term treatment of extreme anxiety and agitation, because of concern for risks including oral clefts, floppy baby syndrome, and neonatal withdrawal syndrome.[13]

Lithium is a foundation therapy for management of BPD. Early studies reported that use of lithium in early pregnancy was associated with an increased risk for congenital malformations, with particular concern for cardiac abnormalities, especially Ebstein's anomaly. Although the risk now appears to be less than initially thought, it has been recommended that women who are exposed to lithium in the first trimester undergo fetal echocardiography. Exposure in later gestation has been associated with fetal and neonatal diabetes insipidus, polyhydramnios (thought to occur from fetal diabetes insipidus), thyroid dysfunction, cardiac arrhythmias, hypoglycemia, preterm delivery, and floppy baby syndrome.[13] Renal clearance of lithium is increased in pregnancy; therefore, serum levels should be closely monitored in pregnant women who are taking lithium. Discontinuation of lithium is associated with a high risk for recurrent illness, particularly in the postpartum period.

Anticonvulsant drugs are often used as mood stabilizers in patients with BPD. **Valproate** use in pregnancy is associated with a dose-related risk for many congenital anomalies (e.g., craniofacial, limb, cardiovascular abnormalities) and a variable risk for cognitive impairment.[1] **Fetal valproate syndrome,** which includes fetal growth restriction, facial dysmorphology, and limb and heart defects, has been described.[13] **Carbamazepine** has also been associated with congenital abnormalities, although with less frequency or severity compared with valproate.[1] **Fetal carbamazepine syndrome,** which includes facial dysmorphism and fingernail hypoplasia, has been described.[13] **Lamotrigine** appears to be associated with less fetal risk than occurs with valproate and carbamazepine.[10,13] Folate supplementation should be offered to patients taking anticonvulsants to reduce the risk for neural tube defects.

Typical antipsychotic drugs (e.g., **haloperidol, thioridazine, fluphenazine, perphenazine, chlorpromazine, trifluoperazine**) have a long history of use in pregnant patients and generally have minimal teratogenic effects.[13] The phenothiazines are also used for their antiemetic effects. Fetal and neonatal toxicity after maternal exposure can include dyskinesia, extrapyramidal side effects, neonatal jaundice, and postnatal intestinal obstruction. The **neuroleptic malignant syndrome** is of particular interest to anesthesia providers because of its similarity to malignant hyperthermia. Features

include hyperthermia, rigidity, mental status alteration, creatine kinase elevation, sympathetic nervous system lability, tachycardia, and tachypnea.[38] Treatment is largely supportive and includes discontinuation of triggering agents, antipyretics, cooling, rehydration, and management of autonomic instability. Use of dantrolene, bromocriptine, and amantadine has been described.[37]

Atypical antipsychotic drugs (e.g., **clozapine, olanzapine, quetiapine, risperidone, ziprasidone, aripiprazole**) are now commonly used for schizophrenia and also for BPD, OCD, and resistant depression. Although these drugs are well tolerated, fewer data about reproductive safety are available, when compared with older drugs.

Drug Interactions

A number of drug interactions involving psychiatric drugs are relevant to anesthesia providers. The most important of these involve monoamine oxidase inhibitors (MAOIs), which include older irreversible drugs (e.g., phenelzine, tranylcypromine) and newer reversible drugs (e.g., selegiline, moclobemide). Potential interactions include (1) hypertension after administration of an indirect-acting vasopressor (e.g., ephedrine, metaraminol), which results from increased norepinephrine concentration in sympathetic nerve endings; and (2) excitatory interactions associated with serotonin toxicity. The latter are characterized by clonus, hyperreflexia, hyperthermia, and agitation, and may be precipitated by coadministration of an MAOI and an SRI. Of note, phenylpiperidine opioids, especially meperidine (pethidine), but also tramadol, methadone, and dextromethorphan, are weak serotonin reuptake inhibitors and have been implicated in toxic reactions associated with MAOIs, including hyperpyrexic coma. Irreversible MAOIs should be stopped 2 weeks before administration of anesthesia to allow regeneration of MAO and restoration of normal monoamine metabolism, and reversible MAOIs should be stopped for 24 hours before administration of anesthesia.[39]

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is considered an important treatment option in the pregnant patient with psychiatric disease, especially when balancing the risk for morbidity from psychiatric illness and the potential adverse effects of psychiatric drugs. Indications include major unipolar or bipolar depressive episodes, mania, and certain acute schizophrenia exacerbations. Acute suicide risk, poor response to medications, and patient preference may also affect the decision to use ECT.[40] Contraindications include anticipated intolerance of associated physiologic changes that result from autonomic activation during ECT (e.g., increased intracranial pressure). Relative contraindications include hypertensive disease and impaired uteroplacental perfusion.

There is a paucity of controlled data evaluating the use of ECT in pregnancy, with most information coming from case series. The APA has endorsed the use of ECT in all three trimesters of pregnancy.[41] The use of ECT in pregnancy has been considered effective with low risk to the mother and fetus.[42] However, a recent systematic review reported that adverse events such as decreased fetal heart rate, uterine contractions, and preterm labor occurred in 29% of cases.[43]

ECT for pregnant patients should be administered in a facility that can handle fetal emergencies. Anesthetic agents that have been used include thiopental, methohexital, propofol, succinylcholine, and anticholinergics.[43] Suggested guidelines for ECT during pregnancy are summarized in Box 50.2. Denitrogenation (preoxygenation), left uterine displacement, and fetal heart rate and uterine contraction monitoring should be used. Pharmacologic aspiration prophylaxis and tracheal intubation should be considered in patients with symptoms of gastroesophageal reflux. Some anesthesia providers contend that tracheal intubation should be performed after 20 weeks' gestation, when the enlarging uterus has arisen out of the pelvis.

BOX 50.2 Suggested Guidelines for Electroconvulsive Therapy during Pregnancy

- Obtain preoperative obstetric consultation.
- Monitor fetal heart rate and check for uterine contractions before and after the procedure.
- Ensure adequate hydration and denitrogenation (preoxygenation).
- Maintain left uterine displacement after 18 to 20 weeks' gestation.
- Consider pharmacologic aspiration prophylaxis and tracheal intubation in patients with symptoms of gastroesophageal reflux.
- Observe for vaginal bleeding after the procedure.

Modified from Miller LJ. Use of electroconvulsive therapy during pregnancy. *Hosp Community Psychiatry*. 1994;45:444–450.

KEY POINTS

- Psychiatric disorders occur commonly during pregnancy, but their prevalence is often underestimated and underappreciated.
- Anxiety disorders are the most common psychiatric disorders in pregnant women.
- The risk for major depressive disorder is increased during the postpartum period.
- Suicide is an important cause of maternal mortality.
- Psychological and psychosocial interventions are effective for many psychiatric diseases in pregnancy.
- When managing pregnant patients with psychiatric disorders, the risks of withholding psychiatric drugs because of concerns for harmful fetal effects must be balanced against the potential consequences of untreated disease.

- Patients with a previous psychiatric history should be identified prenatally and frequently monitored and supported during pregnancy and the first few weeks postpartum. Psychiatric services should have priority-care pathways for pregnant and postpartum women, and care by multiple psychiatric teams should be avoided.
- A multidisciplinary approach is essential in the management of pregnant patients with psychiatric disorders, and the partner and family should be involved with decisions.
- Awareness during general anesthesia for cesarean delivery, inadequate neuraxial anesthesia for cesarean delivery, and poor pain control during vaginal delivery may result in posttraumatic stress disorder in susceptible patients.
- Anesthesia providers should be aware of potential drug interactions with psychotropic drugs.

Renal Disease

Daniel Katz, MD, Yaakov Beilin, MD

CHAPTER OUTLINE

"Children of women with renal disease used to be born dangerously or not at all—not at all if their doctors had their way."[1] This statement describes early experiences with maternal renal disease and pregnancy outcome. It remains true that renal disease, either preexisting or occurring during gestation, may impair maternal and fetal health. Experience and investigations during the past three decades have significantly improved both maternal and neonatal outcomes in pregnant women with renal disease.[2]

PHYSIOLOGIC CHANGES IN PREGNANCY

A review of the renal physiologic changes that occur during normal pregnancy is helpful to understand and evaluate coexisting renal disorders (see Chapter 2). Early in gestation, increased intravascular volume leads to renal enlargement. Hormonal changes result in dilation of the renal pelvis and ureters; dilation often is accompanied by decreased ureteral peristalsis. Dilated uterine and ovarian veins, and the gravid uterus, may obstruct ureter drainage at the pelvic brim. Together, these changes predispose pregnant women to vesicoureteric reflux and ascending infection. Alterations in glomerular hemodynamics and tubular function also occur. Increased cardiac output and decreased intrarenal vascular resistance cause an 80% increase in renal blood flow and a 50% increase in glomerular filtration rate (GFR) during pregnancy. These changes are somewhat less pronounced near term. Because of the increased GFR, a serum creatinine concentration greater than 0.6 to 0.8 mg/dL and a blood urea nitrogen (BUN) concentration greater than 8 to 9 mg/dL (upper limit of normal for the pregnant patient) suggest renal insufficiency in the pregnant woman. Tubular sodium reabsorption and osmoregulation are reset, allowing a "physiologic hypervolemia" during gestation. Modest proteinuria, up to 300 mg in 24 hours, also occurs during pregnancy.[3]

Urinary tract infections (see Chapter 36) and renal dysfunction associated with hypertensive disorders of pregnancy (see Chapter 35) are discussed elsewhere in this text.

RENAL PARENCHYMAL DISEASE

Definition and Pathophysiology

Renal parenchymal disease consists of two general groups of disorders, **glomerulopathies** and **tubulointerstitial disease.** Glomerulopathies are further subdivided into disorders that involve inflammatory or necrotizing lesions—the **nephritic syndromes**—and disorders that involve abnormal

permeability to protein and other macromolecules—the **nephrotic syndromes.** More than 20 specific glomerulopathies exist. The nomenclature for these glomerulopathies is complex, and specific diseases are not discussed in detail here.

Tubulointerstitial diseases are disorders characterized by abnormal tubular function. They result in abnormal urine composition and concentration but are not characterized by decreased GFR until late in the disease course. The disorders in this category include interstitial nephritis, acute tubular necrosis, multiple myeloma of the kidney, and functional tubular defects such as renal tubular acidosis.

Patients with renal parenchymal disorders may remain asymptomatic for years, and they may exhibit only proteinuria and microscopic hematuria, with little if any evidence of reduced renal function. Spontaneous recovery or improvement with treatment occurs with many glomerulopathies. However, other patients exhibit progressive nephropathy, hypertension, and renal insufficiency. The incidence of kidney disease in pregnancy is approximately 0.12%.[4] In two-thirds of these patients, the disorder results from glomerulopathy, and in one-third, from tubulointerstitial disease.[5]

Diagnosis

Women with preexisting disease may choose to become pregnant without the counsel of their nephrologist. When such patients become pregnant, the obstetrician and nephrologist seek to define the extent of renal involvement. Serial blood pressure measurements are obtained to define the severity of hypertension and the efficacy of current antihypertensive therapy. Creatinine clearance and the level of proteinuria should be determined. Urinalysis yields information about the presence of renal casts and bacteriuria. The determination of serum creatinine and BUN concentrations defines the extent of renal insufficiency. A serum creatinine concentration greater than 0.8 mg/dL, which may be normal in the nonpregnant woman, may represent significant renal insufficiency during pregnancy. Alternatively, the obstetrician may first detect renal dysfunction through routine prenatal screening tests since patients may otherwise be asymptomatic, as symptoms rarely develop until GFR decreases by 25%.[6] If proteinuria, hematuria, or azotemia is detected, a complete biochemical evaluation should be performed.

Both preeclampsia and renal disease may manifest as hypertension, proteinuria, and edema. The distinction between the two disorders is often unclear, especially after 20 weeks' gestation. Fisher et al.[7] evaluated 176 renal biopsy specimens obtained from hypertensive women immediately postpartum, most of whom had a clinical diagnosis of preeclampsia. The clinicopathologic correlation was poor. Histologic evidence of preeclampsia (e.g., glomerular endotheliosis without hypercellularity) was present in only 65% of these hypertensive women. Primary renal disease was present in 20%, and hypertensive nephrosclerosis occurred in 11%. Nulliparous women (84%) were more likely to have a correct diagnosis of preeclampsia than parous women (38%), further demonstrating the difficulty in making the diagnosis in different patient populations.

Renal tissue biopsy is often used to establish a diagnosis in nonpregnant patients. The decision to perform a kidney biopsy in the parturient is complex, as the value of the clinical information obtained that may guide therapy must be balanced against the risks associated with the procedure. Studies reporting the safety of biopsies are small and heterogeneous. A recent meta-analysis by Piccoli et al.[8] compared complication rates from 243 renal biopsies performed during pregnancy with 1236 performed in the postpartum period. Significant complications occurred in 7% of biopsies performed before delivery compared with 1% in the postpartum period. Most complications were minor and included groin pain as well as hematuria. The authors did report, however, that more serious complications (e.g., bleeding and loin pain) occurred the further along in pregnancy the biopsy was performed and seemed to peak around 25 weeks' gestation. It should be noted that in 23 of the studies in the meta-analysis, kidney biopsies were performed as a means to characterize morphologies in preeclampsia, a practice that is no longer recommended and may have influenced the subject pool substantially. Given the apparent increase in risk associated with biopsy during pregnancy, it should only be performed in patients with a high likelihood of severe glomerular disease and when definitive diagnosis is critical to guide appropriate and immediate treatment.[8,9]

Emerging research in the area of biomarkers may further guide treatment and management in this population as well as preclude the need for biopsy. When diagnosis is obtained through antineutrophil cytoplasmic antibodies or through double-stranded DNA antibodies, empiric treatment may begin with steroids, azathioprine, or calcineurin inhibitors in lieu of a kidney biopsy in a variety of the disorders, including lupus nephritis and glomerulonephritis.[9] Novel biomarkers such as soluble urokinase plasminogen activator receptor (suPAR) for focal segmental glomerulosclerosis, M-type phospholipase A2 receptor (PLA2R) in membranous nephropathy, and others have been described in case reports and once further developed may change diagnosis and management.[10,11]

Effect of Pregnancy on Preexisting Kidney Disease

The extent to which pregnancy affects preexisting renal disease depends on the level of renal insufficiency before pregnancy. Among women with mild antenatal renal insufficiency, pregnancy does not substantially alter the natural course of renal disease.[12,13] Jungers et al.[12] evaluated the effect of pregnancy on renal function among 360 women with primary glomerulonephritis. During the study period, 171 (48%) women became pregnant. All study subjects had normal renal function at the time of entry into the study, and all patients who became pregnant had normal renal function at conception. In the case-control analysis of the study, pregnancy was not identified as a risk factor for progression to end-stage renal failure. Limardo et al.[13] evaluated 223 women with biopsy-documented IgA nephropathy who had a serum creatinine level greater than 1.2 mg/dL, 136 of whom became

pregnant. Women were observed for a minimum of 5 years (median, 10 years), and pregnancy did not seem to affect long-term outcome of kidney disease or the onset of proteinuria or hypertension.

In contrast, Jones and Hayslett[14] analyzed the outcome of 82 pregnancies in 67 women with preexisting moderate or severe renal insufficiency (i.e., serum creatinine level greater than 1.4 mg/dL before pregnancy or at the first antepartum visit). The mean ± standard deviation serum creatinine concentration increased from 1.9 ± 0.8 mg/dL in early pregnancy to 2.5 ± 1.3 mg/dL in the third trimester. The prevalence of hypertension rose from 28% at baseline to 48% during late pregnancy. Pregnancy-related deterioration of maternal renal function occurred in 43% of cases. Purdy et al.[15] also found that greater than 40% of women with moderate to severe kidney disease had deterioration in renal function caused by pregnancy. Women with a serum creatinine concentration greater than 2.0 mg/dL who became pregnant had a one in three chance of developing dialysis-dependent end-stage renal disease during or shortly after pregnancy.[16] In summary, the preponderance of evidence seems to demonstrate that while pregnancy exacerbates renal disease, it appears to have a greater effect on those who present with moderate to severe levels of renal dysfunction before pregnancy.

The pathophysiology by which pregnancy exacerbates renal disease is unknown. One hypothesis is that increased glomerular perfusion, which normally accompanies pregnancy, paradoxically causes further injury to the kidneys in patients with preexisting impairment of function. However, this hypothesis is unsupported by published data, which demonstrate no evidence of hyperfiltration (i.e., an initial decline in serum creatinine concentration) during early pregnancy in patients with renal disease.[17] An alternative hypothesis is that preexisting renal disease may induce a cascade of platelet aggregation, microvascular fibrin thrombus formation, and endothelial dysfunction that leads to microvascular injury in the already tenuous kidneys.[16] In addition to general changes to renal mechanics discussed earlier, exacerbation or improvement of the initial disease process during pregnancy could also alter the long-term course of renal dysfunction.

Effect on the Mother and Fetus

Pregnant women with chronic kidney disease (CKD) are at an increased risk for maternal and fetal complications. Nevis et al.[18] systematically reviewed all published observational studies of women with CKD that included a control group for comparison, excluding retrospective studies. They identified 13 studies between 1966 and 2010 that included at least five women. Maternal complications included gestational hypertension, preeclampsia/eclampsia, and maternal mortality. Adverse fetal outcomes included preterm births, fetal growth restriction (also known as intrauterine growth restriction), small-for-gestational-age infants, neonatal mortality, stillbirths, and low birth weight. Adverse maternal outcomes were found in 12 studies, and when examined in aggregate, their incidence was five times greater than in women without kidney disease. Adverse fetal outcomes were identified in nine studies, and when examined in aggregate, the incidence was two times greater than in the otherwise healthy women. There was no analysis of the variance of magnitude of the effect by specific outcome.

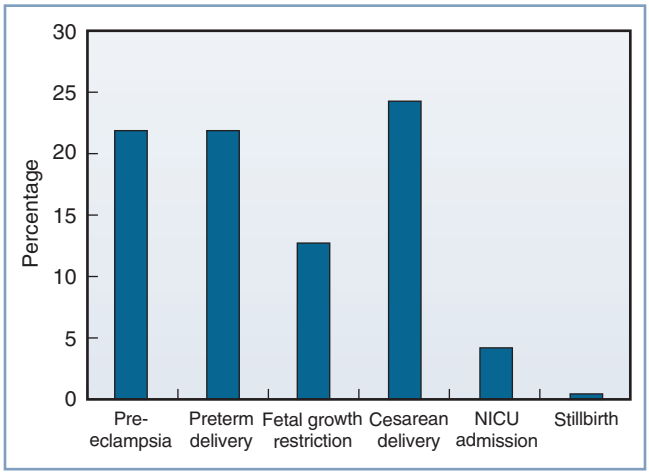

Fig. 51.1 Rate of short-term pregnancy outcome in women with primary renal disease. *NICU,* neonatal intensive care unit. (From Bar J, Orvieto R, Shalev Y, et al. Pregnancy outcome in women with primary renal disease. *Isr Med Assoc J.* 2000;2:178–181.)

The incidence of obstetric complications is proportional to the extent of preexisting maternal renal disease and preexisting hypertension.[19] Bar et al.[20] evaluated maternal and neonatal outcomes in 38 women (46 pregnancies) with primary renal disease. They did not have a control group of women without renal disease. They observed that most women (98%) had a successful pregnancy, but many had complications including superimposed preeclampsia (22%), preterm delivery (22%), fetal growth restriction (13%), and cesarean delivery (24%) (Fig. 51.1). In a logistic regression model, only preexisting hypertension and an elevated preconception serum uric acid level were independent predictors of poor outcome. Other factors (e.g., degree of preexisting renal impairment) were not found to be significant predictors, but because 90% of the cohort had mild disease the study may have been underpowered to detect an association. In a study of women with moderate to severe renal disease, Jones and Hayslett found the complication rate was much higher.[14] The incidence of preterm birth was 59%, the incidence of fetal growth restriction was 37%, and the cesarean delivery rate was 59%. The largest literature review on the topic by Lindheimer and Davison[21] supports the results of prior studies, demonstrating good outcomes for patients with mild renal disease (serum creatinine less than or equal to 1.4 mg/dL) in which over 95% of patients had live births (75% were size appropriate for gestational age). Outcomes worsened substantially as renal dysfunction increased, with patients suffering from severe dysfunction (serum creatinine greater than or equal to 2.0 mg/dL) having a successful obstetric outcome only 78% of the time and with 40% of patients developing end-stage renal failure within 1 year postpartum.

Medical and Obstetric Management

During pregnancy, the nephrologist and the obstetrician monitor maternal renal function, blood pressure, and fetal development at frequent intervals. Monthly determination of serum creatinine concentration, creatinine clearance, and proteinuria allows the recognition of renal deterioration and establishes a baseline for the patient, which may be useful in diagnosing superimposed preeclampsia if it occurs. An antepartum consultation with the anesthesia provider should also be considered to address issues such as peripartum medication and fluid management, and to perform an overall risk assessment to discuss and develop potential plans for anesthetic technique and monitoring.

Some glomerulopathies respond to corticosteroids, and corticosteroid therapy should be continued during pregnancy. Rapid deterioration of renal function that occurs before 28 weeks' gestation may require renal biopsy to exclude rapidly progressive glomerulopathies that require treatment, as discussed earlier. Antihypertensive therapy should be instituted as needed (see Chapter 35). As in patients with iron deficiency anemia or patients who refuse blood products, recombinant human erythropoietin has been used successfully to improve maternal anemia in patients with CKD.[22] Because of its large molecular weight, recombinant erythropoietin does not appear to cross the placenta or have an adverse impact on the fetus.[23] In the non-CKD population, doses of 4000 units subcutaneously 3 times per week for 4 weeks in the third trimester for the treatment of iron deficiency anemia caused a gain of 1.9 ± 1.0 g/dL of hemoglobin at delivery, although the optimal dose range and timing in pregnancy are unknown.[24] Data in the CKD population are limited to case reports and small case series. In patients who are treated with erythropoietin, a decreased response to the current dose may actually be the first sign that the patient is pregnant.[25] As in the non-CKD population, no optimal regimen is known; however, it should be noted that doses may need to be changed during varying stages of the pregnancy to keep the hemoglobin target within the range of 11 to 12 g/dL, as recommended by the National Kidney Foundation for the pregnant patient. Efficacy has been shown in pregnant patients with CKD and end-stage renal disease on hemodialysis, as well as renal transplant recipients; however, the efficacy and doses are highly variable, and the number of cases reported is very small.[22,23,26] Protein restriction places the fetus at risk for growth restriction and is not used. Deterioration of maternal renal function, the onset of preeclampsia, or evidence of fetal compromise may necessitate urgent delivery.

Hemodialysis and Long-Term Ambulatory Peritoneal Dialysis

When renal disease has progressed to end-stage renal failure (i.e., GFR less than 5 mL/min), fertility is suppressed and conception and pregnancy are rare. Less than 10% of premenopausal patients undergoing dialysis have regular menses. Luteinizing hormone and follicle-stimulating hormone concentrations assume an anovulatory pattern, which causes 40% of affected women to be amenorrheic. One-half of all female patients undergoing dialysis exhibit hyperprolactinemia because of reduced clearance and hypothalamic disturbances.[27] Toma et al.[28] surveyed 2504 dialysis units in Japan and reported only 172 pregnancies among 38,889 women who were undergoing dialysis.

When pregnancy does occur, there are several important management considerations necessary to maximize the probability of a successful outcome. There are two modalities of dialysis: extracorporeal hemodialysis and intracorporeal peritoneal dialysis. **Hemodialysis** necessitates vascular access and the need for anticoagulation of the extracorporeal circuit and may be complicated by cardiovascular instability, large fluid and electrolyte shifts, and the risk for hepatitis. Hypotension may compromise uteroplacental perfusion and cause fetal compromise. Even when hypotension and major fluid shifts are avoided, Doppler ultrasonographic examination of uterine and umbilical artery flow during hemodialysis suggests the occurrence of a redistribution of arterial flow away from the uteroplacental vascular bed.[29] Fetal heart rate monitoring is recommended during dialysis.[30] Rapid removal of maternal solutes and reduced oncotic pressure with attendant free-water diffusion into the amniotic cavity may lead to polyhydramnios. Hemodynamic consequences are minimized by more frequent but shorter dialysis runs. Long-term ambulatory **peritoneal dialysis** allows less hemodynamic trespass, a more stable fetal environment, and the freedom to undergo dialysis at home. However, peritoneal dialysis may not be associated with greater fetal survival. Complications of this modality include peritonitis and catheter difficulties.[31]

Rates of successful pregnancy in women undergoing dialysis vary by study but range between 50% and 70%.[28,32] A meta-analysis and systematic review by Piccoli et al.[33] reviewed almost 550 pregnancies in patients undergoing both hemodialysis and peritoneal dialysis and reported a low maternal/perinatal mortality rate (0.4%), with a malformation rate of approximately 2%, which is in line with the risk in the general population. Fetal complications are most often seen in the form of respiratory distress, sepsis, and retinopathy and are likely a result of the higher incidence of preterm birth rather than related specifically to dialysis. The optimal dialysis schedule is an area of active research, with a trend toward more favorable outcomes with longer and more frequent dialysis sessions. BUN levels should be kept below 50 mg/dL before dialysis and below 30 mg/dL after dialysis.[31] At birth, azotemia in the newborn is similar to that in the mother, but this quickly corrects because the newborn has normal kidney function. The long-term effects of intrauterine azotemia on newborn cognitive development are unknown; however, it appears that if the neonate survives the complications from preterm delivery, further development may be normal.[34]

Patients undergoing hemodialysis have a high rate of viral hepatitis, a greater frequency of active tuberculosis, and a higher rate of infection with vancomycin-resistant enterococci, human immunodeficiency virus (HIV), and methicillin-resistant *Staphylococcus aureus*. The risk for hepatitis C virus (HCV) infection is particularly of concern, with

reported rates as high as 36%. However, with improvement in aseptic technique and more attention to handwashing, the decline in the reuse of dialysis equipment, and the use of dedicated isolated dialysis machines for HCV-seropositive patients, the rates of infection and seroconversion can be markedly reduced.[35,36]

Anesthetic Management

Anesthetic management is influenced by the extent of renal dysfunction and hypertension. The parturient with stable renal disease, mild to moderate renal insufficiency, well-controlled hypertension, and euvolemia requires minimal special consideration. In contrast, the dialysis patient with end-stage renal failure presents many anesthetic challenges because renal disease may affect almost every organ system (Box 51.1). Poorly controlled hypertension leads to left ventricular hypertrophy and dysfunction. Symptoms of cardiovascular compromise should prompt a cardiac workup including echocardiography to evaluate ventricular function. An intra-arterial catheter also may aid the management of the parturient with poorly controlled hypertension, especially when multiple agents are required to control blood pressure or when the continuous infusion of antihypertensive agents is required. Uremic pericarditis, cardiomyopathy, and accelerated atherosclerosis are rarely seen until advanced uremia has been present for several years.

Normochromic, normocytic anemia secondary to impaired erythropoietin production, chronic gastrointestinal bleeding, and vitamin deficiency are common findings. Typically, the anemia is well tolerated and does not require transfusion unless excessive surgical bleeding occurs. Uremic toxins may cause functional platelet defects; these abnormalities are reversed by dialysis. Thrombocytopenia may also occur as a result of increased peripheral destruction of platelets. Generalized coagulopathy may result from the anticoagulation used during the dialysis process.[37] A full coagulation profile and careful bleeding history should be performed, especially before the initiation of neuraxial anesthesia. Hemodialysis fistulas should be padded carefully to prevent thrombosis. Blood pressure cuffs should not be placed on these extremities.

Neuraxial Anesthesia

Neuraxial anesthesia is the preferred technique for both labor analgesia and cesarean delivery, but there are some unique considerations in the parturient with renal disease. Uremic patients may be hypervolemic or hypovolemic, depending on the time elapsed since their last dialysis session. Hypovolemia and autonomic neuropathy may lead to profound hypotension during the initiation of sympathetic blockade. Intravascular volume should be assessed before induction of anesthesia. Assessment of clinical signs (e.g., current body weight relative to dry body weight, skin turgor, mucous membranes, tachycardia) is generally sufficient. Transthoracic echocardiography may be useful when the volume status remains unclear. Although there are no studies in the CKD patient, a role for intravenous prehydration to prevent hypotension is unlikely because this modality is not efficacious in the healthy parturient.[38] There is insufficient evidence to recommend spinal versus epidural techniques for the patient with renal disease. Frequent monitoring of blood pressure and immediate treatment of hypotension is suggested.[39] Preexisting peripheral neuropathy should be documented before the administration of neuraxial anesthesia.

Local anesthetic systemic toxicity (LAST) after bupivacaine brachial plexus blockade has been reported in patients with chronic renal failure.[40] Whether LAST is related to toxic

BOX 51.1 Chronic Renal Failure: Abnormalities That May Affect Anesthetic Management

Cardiovascular
- Hypertension
- Fluid overload
- Ventricular hypertrophy
- Accelerated atherosclerosis
- Uremic pericarditis
- Uremic cardiomyopathy

Pulmonary
- Increased risk for difficult airway
- Recurrent pulmonary infections
- Pleural effusion

Metabolic and Endocrine
- Hyperkalemia
- Metabolic acidosis
- Hyponatremia
- Hypocalcemia
- Hypermagnesemia
- Decreased protein binding of drugs
- Hypoglycemia

Hematologic
- Anemia
- Platelet dysfunction
- Decreased coagulation factors
- Leukocyte dysfunction

Neurologic
- Autonomic neuropathy
- Mental status changes
- Peripheral neuropathy
- Restless legs syndrome
- Seizure disorder

Gastrointestinal
- Delayed gastric emptying
- Increased gastric acidity
- Hepatic venous congestion
- Hepatitis (viral or drug-induced)
- Malnutrition

Neurologic
- Autonomic neuropathy
- Peripheral neuropathy
- Cerebrovascular insufficiency

levels of local anesthetic unique to the renal failure patient is unclear. Rice et al.[41] found no significant difference in the pharmacokinetic profile of bupivacaine after brachial plexus blockade in a group of uremic patients and in patients with normal renal function. There are no published data on the pharmacokinetics of epidurally administered local anesthetic agents in patients with chronic renal failure.

Orko et al.[42] administered spinal anesthesia with plain bupivacaine 22.5 mg to 20 nonpregnant patients with chronic renal failure and 20 control patients. Maximal segmental anesthesia occurred more rapidly in the patients with renal disease (21 minutes versus 35 minutes), but the duration was reduced. Further, the extent of sensory blockade was two segments higher in the patients with renal disease. There were no untoward effects in any of the patients. Potential mechanisms proposed for these findings included a difference in blood pH and potassium concentration, as well as the existence of underlying neuropathy increasing susceptibility to blockade. An alternative hypothesis suggested that the hyperdynamic state of uremia causes further distension of epidural veins, hastening onset and decreasing duration through a washout phenomenon.

General Anesthesia

Patients with chronic uremia exhibit delayed gastric emptying and hyperacidity, which may increase the risk for aspiration pneumonitis. In addition to sodium citrate, when time allows, the anesthesia provider also should consider administering a histamine-2 (H_2)-receptor antagonist and metoclopramide. Recommended single doses for patients with renal failure are ranitidine 50 mg and metoclopramide 10 mg given intravenously, which do not differ from patients without renal failure.

All the standard induction agents are safe in patients with renal failure. Etomidate may have an advantage if the volume status is unknown or if there is left ventricular dysfunction. Propofol exhibits normal volume of distribution and elimination in patients with renal failure and is also commonly used. Protein binding of propofol is unaffected by renal failure.[43] Uremia increases blood-brain barrier permeability to many drugs.[44] These changes may warrant a small reduction in the dose of propofol or thiopental for induction. The serum potassium concentration should be determined before induction of anesthesia. If the potassium concentration is greater than 5.5 mEq/L, dialysis should be performed before an elective procedure. Succinylcholine will cause a 0.5 to 0.7 mEq/L increase in potassium concentration, which is similar to the increment that occurs in patients without renal disease.[45] If the patient is already hyperkalemic, this mild elevation may be sufficient to precipitate cardiac dysrhythmias. Plasma cholinesterase concentrations are normal, even after dialysis, and the duration of action of succinylcholine is not prolonged.[46]

Neuromuscular blockade should be maintained with an agent that does not rely on renal elimination. Cisatracurium undergoes Hofmann degradation, and therefore the duration of action is not prolonged in patients with renal failure. Hypermagnesemia, commonly found in patients with kidney disease, may potentiate neuromuscular blockade.[47] Although anticholinesterase agents undergo renal elimination and have a prolonged duration in patients with renal insufficiency, the volume of distribution remains the same, and standard doses are used for the reversal of neuromuscular blockade.

Postoperative Analgesia

The principles of postoperative analgesia for the woman with renal disease are the same as for healthy women, with some important considerations because drug clearance can be altered for opioids and their metabolites (see Chapter 27). Morphine is generally safe as a single dose, but with longer-term use its metabolite, morphine-6-glucuronide, may accumulate. Meperidine is of particular concern because its active metabolite, normeperidine, is neurotoxic and is renally excreted. Hydromorphone and oxycodone, and their metabolites hydromorphone-3-glucuronide and α- and β-oxycodol, respectively, are also renally excreted and may accumulate with prolonged use. Fentanyl and sufentanil are only minimally excreted in the urine, and they may be particularly useful because they are short-acting drugs. Remifentanil is metabolized by blood and tissue esterases and is not dependent on the kidney for excretion, making it safe for use in patients with renal failure.[48] The safest approach may be to use neuraxial opioids because small doses are administered. Alternative techniques that avoid opioids such as transversus abdominis plane (TAP) block may also be considered, especially when neuraxial opioids are not administered (see Chapter 27).[49] Nonsteroidal antiinflammatory drugs (NSAIDs), although effective, are best avoided as they may worsen renal function and can interact with several renal medications including loop diuretics.[50]

ACUTE KIDNEY INJURY

Definition and Epidemiology

Acute kidney injury (AKI) is a serious potential complication that can develop in pregnancy. The inciting disorders vary throughout the world. In developing countries, septic abortion is the leading cause of pregnancy-related AKI (PR-AKI).[51,52] In developed countries, severe preeclampsia/eclampsia, acute pyelonephritis of pregnancy, and bilateral renal cortical necrosis are the most common underlying disorders.[53,54] Rapid deterioration of renal function leads to an accumulation of fluid and nitrogenous waste products with impaired electrolyte regulation. Definitions for renal dysfunction in the general population vary and have changed over time. What used to be called acute renal failure (ARF) is now included among a greater spectrum of disorders including varying levels of kidney dysfunction, and is now termed AKI.[55] Recent guidelines and recommendations (including definitions) have been maintained by the Kidney Disease: Improving Global Outcomes (KDIGO) consortium of the International Society of Nephrologists (Table 51.1).[56] These definitions and recommendations are based on the RIFLE (risk, injury, failure, loss, and end-stage renal failure) and

TABLE 51.1 KDIGO Staging of Acute Kidney Injury

Stage	Serum Creatinine	Urine Output
1	1.5–1.9 times baseline or increase in serum creatinine to ≥ 0.3 mg/dL (≥ 26.5 μmol/L)	< 0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	< 0.5 mL/kg/h for ≥ 12 h
3	3 times baseline or increase in serum creatinine to ≥ 4.0 mg/dL (≥ 353.6 μmol/L) or initiation of renal replacement therapy, or in patients < 18 years, decrease in eGFR to < 35 mL/min/1.73 m^2	< 0.3 mL/kg/h for ≥ 24 h or anuria ≥ 12 h

KDIGO, Kidney Disease: Improving Global Outcomes; *eGFR,* estimated glomerular filtration rate.

Acute Kidney Injury Network criteria, which have been applied to the pregnant population because no similar guidance exists for pregnant patients.[57–59] Fortunately, during the past five decades, the incidence of PR-AKI has decreased worldwide from 1 in 3,000 to 1 in 15,000.[60] This progress has resulted from improved obstetric care and fewer septic abortions.[61] Although the overall incidence of PR-AKI is declining worldwide, it has been increasing in incidence in the United States and Canada. Mehrabadi et al.[62] reported that the incidence of PR-AKI rose from 2.4 per 10,000 deliveries between 1991 to 2001 to 6.6 per 10,000 deliveries between 2010 to 2011. It should be noted that the overall severity of AKI decreased, which is likely because of an increase in vigilance and a change in diagnostic thresholds. However, AKI associated with the need for dialysis and AKI associated with maternal death increased from 0.27 to 0.36 and 0.13 to 0.23 per 10,000 deliveries, respectively. The increase in the need for dialysis was abolished by controlling for chronic hypertension and chronic kidney disease, demonstrating an increase in the incidence of these conditions between the two cohorts.

Pathophysiology and Diagnosis

AKI is defined by one of the following criteria: increase in serum creatinine by greater than or equal to 0.3 mg/dL within 48 hours, increase in serum creatinine to greater than or equal to 1.5 times baseline within the last 7 days, or urine volume less than or equal to 0.5 mL/kg/h for 6 hours.[55,63] Once the diagnosis is made, it is recommended to stage the level of severity of AKI. This is an important component of management because the risk for death and renal replacement therapy increases significantly with each stage (see Table 51.1).[64] AKI is subdivided according to underlying cause (i.e., prerenal, intrarenal, and postrenal) (Box 51.2).

Prerenal Causes

The most common prerenal causes of PR-AKI—hyperemesis gravidarum and obstetric hemorrhage—lead to hypovolemia and inadequate renal perfusion.[65,66] Urinary indices show urinary osmolality greater than 500 mOsm/kg, urine sodium less than 20 mEq/L, fractional sodium excretion less than 1%, and a urinary-to-plasma creatinine ratio greater than 40.[67] Concealed hemorrhage from placental abruption may remain unrecognized until hypotension and renal failure ensue.[68] Women with preeclampsia may be more likely to develop AKI after hemorrhage because of preexisting intravascular contraction and widespread maternal endothelial dysfunction.[69] Women who developed preeclampsia during pregnancy, with or without renal failure, are more likely to develop renal failure later in life.[70]

BOX 51.2 Causes of Acute Kidney Injury during Pregnancy

Prerenal
- Hyperemesis gravidarum
- Uterine hemorrhage
- Heart failure

Intrarenal
- Acute tubular necrosis
- Septic abortion
- Amniotic fluid embolism
- Drug-induced acute interstitial nephritis
- Acute glomerulonephritis
- Bilateral renal cortical necrosis
- Acute pyelonephritis
- Preeclampsia/eclampsia
- Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
- Acute fatty liver of pregnancy
- Idiopathic postpartum renal failure

Postrenal
- Urolithiasis
- Ureteral obstruction by the gravid uterus

Intrarenal Causes

An intrarenal cause is diagnosed once prerenal and postrenal causes of AKI have been excluded. In general, oliguric intrarenal AKI is not easily reversed and must run its course. Causes include acute tubular necrosis, interstitial nephritis, and acute glomerulonephritis as well as a few causes unique to pregnancy. The latter include renal cortical necrosis, acute pyelonephritis, severe preeclampsia/eclampsia, acute fatty liver of pregnancy, and idiopathic postpartum renal failure. A thorough history, review of medications, and urinalysis typically help determine the specific initiating factor.[71]

Acute tubular necrosis may result from nephrotoxic drugs, amniotic fluid embolism, rhabdomyolysis, intrauterine fetal death, and prolonged renal ischemia secondary to hemorrhage or septic shock. Urinalysis demonstrates dirty brown epithelial cell casts and coarse granular casts. Urinary indices show urine osmolality less than 350 mOsm/kg, urine sodium concentration greater than 40 mEq/L, fractional sodium excretion greater than 1%, and a urinary-to-plasma creatinine ratio less than 20.[71]

Acute interstitial nephritis is caused by NSAIDs and various antibiotics. Patients typically exhibit fever, rash, eosinophilia, and urine eosinophils.

Acute glomerulonephritis is rare during pregnancy. It is suggested by hematuria, red cell casts, and proteinuria. Urinary indices of acute glomerulonephritis are similar to those of prerenal AKI.

Bilateral renal cortical necrosis, which is rarely observed in the nonobstetric patient, is responsible for 10% to 38% of cases of PR-AKI.[51,72–74] It may occur during early or late pregnancy. Hemorrhage is the most common precipitating event. The pathogenesis of this disorder is unclear but may involve renal hypoperfusion or endothelial damage by endotoxins imposed on the normal hypercoagulable state of pregnancy.[75] A single dose of endotoxin may precipitate bilateral renal cortical necrosis in pregnant animals and has led some investigators to view this disorder as a clinical analogue of the experimental Sanarelli-Shwartzman reaction.[69] Extensive microthrombi are found within the glomeruli and renal arterioles. Diagnosis is made by selective renal arteriography, which reveals absence or patchiness of blood flow in the cortex. Renal biopsy may also be performed in the absence of active coagulopathy.[76]

Acute pyelonephritis is one of the most common infectious complications of pregnancy (see Chapter 36). Although acute pyelonephritis rarely leads to AKI in the nongravid patient, it accounts for 5% of cases of PR-AKI.[69] The reason for this greater susceptibility is unclear. Whalley et al.[77] noted that acute pyelonephritis causes a marked reduction of GFR in pregnant women. In contrast, pyelonephritis causes little reduction in GFR in nonpregnant patients. The kidney may be more sensitive to bacterial endotoxins during pregnancy.

Severe preeclampsia/eclampsia may be responsible for, or contributes to, 40% to 60% of cases of PR-AKI.[78,79] Renal failure is generally associated with severe preeclampsia or HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, where the incidence ranges from 3% to 15%.[79,80] However, many cases of renal dysfunction and failure may only mimic preeclampsia and may actually result from other factors.[7] Other causes of AKI should be considered before preeclampsia is determined to be the basis of renal failure.

Gul et al.[80] analyzed the maternal and fetal outcomes of 132 patients with HELLP syndrome. Despite the high rate of major complications in these patients, even when examining those with the most severe levels of renal failure (creatinine greater than 2.0 mg/dL), of whom 50% required dialysis, no patient was discharged with renal impairment, and there was no maternal mortality. Perinatal mortality, however, was high, at 26.1% when serum creatinine was greater than 1.2 mg/dL and increased to 37.5% when greater than 2.0 mg/dL.

Renal histology in a woman with HELLP syndrome and renal failure demonstrated thrombotic microangiopathy and acute tubular necrosis, suggesting a possible pathogenesis of acute renal failure associated with HELLP syndrome.[81] Of interest, Flynn et al.[82] reported the successful use of cadaveric kidneys procured from a parturient who died after HELLP syndrome and AKI. Both recipients had acceptable graft function 2 years after transplantation.

Acute fatty liver of pregnancy, a rare but life-threatening disorder of pregnancy, is associated with a 60% to 100% incidence of AKI. Specific clinical features of acute fatty liver of pregnancy are discussed in Chapter 45.

The syndrome of **idiopathic postpartum renal failure** was initially described in 1968 by Robson et al.[83] Subsequently, approximately 200 cases have been reported. This syndrome is characterized by AKI, microangiopathic hemolytic anemia, and thrombocytopenia occurring 2 days to 10 weeks after an uncomplicated delivery. It appears closely related to the hemolytic-uremic syndrome. Idiopathic postpartum renal failure is typically preceded by a viral upper respiratory tract or gastrointestinal syndrome that rapidly progresses to AKI. The use of ethinyl estradiol as a contraceptive may also be causally related to this syndrome.[84] Spontaneous bleeding, congestive heart failure, hypertension, and seizures have been reported.[85] Some investigators believe that this syndrome represents a clinical analogue to the generalized Shwartzman reaction, a condition induced in laboratory animals by two successive injections of endotoxin, which results in factor XII activation, thrombin generation, and fibrin deposition.[69] Others consider the platelet deposition to be the primary event that leads to microvascular thrombi.[85]

Management involves plasma exchange transfusion, dialysis, and antiplatelet therapy. The role of heparin therapy in idiopathic postpartum renal failure is controversial. The morbidity and mortality among affected patients vary by study. Reports from 1979 and 1988 suggested a mortality rate of approximately 50%.[86,87] Although survival has improved with prompt diagnosis and aggressive treatment, morbidity is still high. Shrivastava et al.[88] reported three patients who had postpartum hemolytic-uremic syndrome and had initial recovery with immediate exchange transfusion; long-term follow-up was not reported. Dashe et al.[89] reported 10 patients with peripartum or postpartum hemolytic-uremic syndrome and followed their course for a mean of 9 years. Although all 10 initially survived, one subsequently died and all had major morbidity, including recurrence of renal failure, hypertension, and seizures.

Postrenal Causes

The postrenal causes of PR-AKI include nephrolithiasis and ureteral obstruction by the gravid uterus.[90] The latter complication is more likely in pregnant women with polyhydramnios or multiple gestation.[91] Preexisting ureteral dilation and impaired peristalsis increase the risk for obstructive uropathy during pregnancy. Flank pain and decreased urine output during late gestation should alert the clinician to this possibility. Courban et al.[92] reported an unusual case of multiple uterine leiomyomas that caused obstructive uropathy that resulted in PR-AKI.

Effect on the Mother and Fetus

Although maternal prognosis has improved significantly in developed countries, mortality ranges between 20% and 30%

in developing countries, likely because of the lack of availability of renal replacement therapy.[52,93] Although mortality in developed countries is very low, up to one-third of mothers do not have complete recovery and suffer long-term sequelae from their AKI episode. The prognosis for the fetus is poorer than that for the mother, with fetal mortality as high as 65% depending on onset and severity of disease.[94]

Medical and Obstetric Management

Management is directed toward rapid recognition of the underlying abnormality. Reversible disorders such as hypovolemia, concealed uterine hemorrhage, urinary tract infection, ureteral obstruction, and drug-induced AKI must be excluded. Urine osmolality (greater than 500 mOsm/kg) is a useful laboratory test to identify reversible prerenal causes. Intravascular volume should be optimized. Electrolyte and acid-base status should be monitored carefully. Hypertension and preeclampsia must be managed aggressively. Many obstetric causes of AKI also may cause disseminated intravascular coagulation; therefore, coagulation abnormalities should be excluded in pregnant women with AKI.[53]

Because urea and other metabolic products cross the placenta, hemodialysis or peritoneal dialysis should be directed toward maintaining the postdialysis BUN concentration at or below 30 mg/dL. Fluid shifts during hemodialysis should be minimized by short but frequent periods of dialysis. If the fetus is mature, delivery should be accomplished when the maternal condition is stabilized. The pediatrician must be alerted to the presence of high fetal BUN levels, which may lead to an osmotic diuresis and neonatal dehydration. Ertürk et al.[95] reported the first known delivery of a healthy infant during a hemodialysis session. All nephrotoxic drugs should be discontinued and avoided if possible. Renal dosing of medications (e.g., muscle relaxants, antibiotics, magnesium) should be considered in these patients.

Anesthetic Management

A multidisciplinary approach involving anesthesia providers, obstetricians, and nephrologists should be employed to optimize the maternal condition before delivery in a woman with AKI. The level of azotemia, electrolyte balance, and hematologic status should be assessed. If the BUN level is greater than 80 mg/dL or if the serum potassium concentration is greater than 5.5 mEq/L, dialysis should be performed before vaginal or cesarean delivery. Neuraxial anesthesia may be administered in the absence of coagulopathy, thrombocytopenia, and severe hypovolemia. Volume status may be difficult to assess. In the past, it was common to place a central line or pulmonary artery catheter to assess volume status, but this is now rarely done given the advent of transthoracic echocardiography.

Both spinal and epidural analgesia/anesthesia are safe and preferred to general anesthesia. As the sympathetic blockade dissipates, the mother should be monitored for evidence of volume overload and pulmonary edema. General anesthesia may be required for urgent cesarean delivery or in patients with coagulopathy or hemorrhage.

RENAL TRANSPLANTATION

Although pregnancy is uncommon in women undergoing long-term dialysis,[28] fertility is improved within months of transplantation. In a review of female renal transplant patients in the United States, a pregnancy rate of 20 per 1000 was estimated in transplanted patients in the year 2000 compared with 100 per 1000 in the general population.[96]

Although a successful obstetric outcome can be anticipated in more than 95% of kidney transplant recipients, they are at greater risk for both maternal and fetal complications than healthy women. In a systematic review of articles published between 2000 and 2010, Deshpande et al.[97] reported pregnancy-related outcome data in kidney transplant recipients. Fifty studies representing 4706 pregnancies in 3570 recipients met inclusion criteria. The incidences of preeclampsia (27%), gestational diabetes (8%), cesarean delivery (56.9%), and preterm delivery (45.6%) were greater than in the general population. Smaller more recent cohort studies have found similar increases in complication rates, including one study from Norway that demonstrated an increased incidence rate ratio for developing preeclampsia of 6.06 (95% CI, 3.118 to 11.55).[98] In a separate cohort study examining renal transplant patients in the United Kingdom, potential predictive factors for poorer outcomes were described, including: greater than one prior kidney transplant, first-trimester serum creatinine greater than 125 μmol/L, and a diastolic blood pressure greater than 90 mm Hg in both the second and third trimesters.[99]

Effect of Pregnancy on the Renal Allograft

When a kidney is removed from a donor and transplanted into an anephric recipient, it undergoes a process of hyperfiltration. This is a maladaptive response that, in the short term, attempts to bring the GFR toward the rate of a binephric system. In the long term, this hyperfiltration may lead to glomerular sclerosis and loss of renal function if it is associated with increased glomerular or capillary pressure.[100] In normal pregnancy, the GFR increases by 30% to 50% during the first and second trimesters and subsequently decreases somewhat during the third trimester. Theoretically, this additional hyperfiltration of pregnancy predisposes the patient to a loss of renal function.

Baylis and Reckelhoff[101] allayed many of these concerns by demonstrating that gestational hyperfiltration is not associated with increased glomerular pressure because of matching afferent and efferent arteriolar vasodilation. They produced hyperfiltration in rodent kidneys by performing uninephrectomy, maintaining the animals on a high-protein diet, and subjecting them to five consecutive pregnancies. The investigators observed no functional impairment or renal histologic changes in this animal model. In addition, they demonstrated that glomerular pressure is lower in female rats than in male rats 10 months after uninephrectomy.[102] Similar sex advantage has been seen in humans after uninephrectomy.[103]

There have been a number of studies assessing graft function after pregnancy. Most studies suggest that there is no adverse

TABLE 51.2 Effect of Pregnancy on Long-Term Function of Renal Allografts[a]

Parameter	Pregnant Group ($n = 18$)	Nonpregnant Control Group ($n = 18$)
Plasma creatinine (mg/dL)	1.26 ± 0.83 (19% increase)	1.44 ± 0.59 (8% increase)
Glomerular filtration rate (mL/min)	58 ± 29 (18% decrease)	56 ± 32 (7% decrease)
Mean arterial pressure (mm Hg)	96 ± 12 (1% decrease)	101 ± 9 (5% increase)
Graft loss or chronic rejection	2 (11%)	2 (11%)

[a]Percentage increase or decrease represents change from initial assessment to end of follow-up. No statistically significant differences were noted. Continuous variables are shown as mean ± standard deviation. From Sturgiss SN, Davison JM. Effect of pregnancy on long-term function of renal allografts. *Am J Kidney Dis.* 1992;19:167–172.

effect provided renal function is normal before conception and there is no evidence of hypertension.[104–107] Levidiotis et al.[104] analyzed 40 years of outcome data from the Australian and New Zealand Dialysis and Transplant Registry and did not find any impact of pregnancy on 20-year graft or patient survival.

Rahamimov et al.[105] compared long-term graft survival, kidney function, and patient survival between women who became pregnant after renal transplantation ($n = 39$; 55 births) and those who did not ($n = 117$). Each pregnant woman was matched with three nonpregnant women for 12 factors that may affect graft survival. Graft survival (61.6%) and patient survival (84.8%) in the pregnant women did not differ from the matched nonpregnant group (68.7% graft and 78.8% patient survival) during the 15-year follow-up study.

Sturgiss and Davison[106] performed a case-control study of 36 renal transplant recipients, of whom 18 became pregnant and 18 did not. Groups were matched according to age, early rejection episodes, primary renal function, interval since transplantation, and extent of histocompatibility. The investigators noted no significant difference between the two groups in plasma creatinine concentration, GFR, mean arterial blood pressure, or the number who suffered graft loss or chronic rejection over a mean follow-up period of 12 years (Table 51.2).

Kashanizadeh et al.[107] also compared graft survival, allograft function, and patient survival between transplant recipients who conceived ($n = 86$) and those who did not ($n = 125$). They, too, did not find a difference in 5-year graft or patient survival between groups. Interestingly, they noted a smaller increase in creatinine levels in women who had conceived, suggesting that pregnancy might exert a protective effect, but this finding has not been confirmed by others.[108]

Effect on the Fetus

Although pregnancy seems to have minimal effect on maternal health or allograft survival in renal transplant recipients, fetal outcome is less favorable. In the Norwegian cohort study mentioned earlier, the adjusted incidence rate ratio of patients with preterm delivery was 4.45 (95% CI, 2.13 to 9.30).[98] Likewise, the incidence of delivering an infant below the 10th percentile in birth weight was double that of the control cohort, and the risk for stillbirth or perinatal death within the first 24 hours was tenfold greater. Despite the increases in relative risk, absolute outcomes are reassuring. For example, in a large systematic review, Deshpande et al.[97] found a 73.5% live birth rate in renal transplant patients.

Most posttransplantation protocols consist of a primary immunosuppressant (cyclosporine or tacrolimus) and one or two adjunctive agents (azathioprine, mycophenolate mofetil, sirolimus, and/or corticosteroids).[109] Despite transplacental exposure to immunosuppressant drugs, congenital anomalies and other adverse effects are not greater than in the general population, but none of the studies included patients who were receiving mycophenolate mofetil.[110,111] There have been reports of congenital defects with mycophenolate mofetil, including cleft lip and palate, microtia, absence of auditory canals, brachydactyly of the fifth finger, and hypoplastic toenails; therefore, its use has to be weighed against the risk for allograft rejection.[112]

Intrauterine exposure to cyclosporine impairs development and function of T, B, and NK lymphocytes in neonates. This effect, as well as depressed levels of serum immunoglobulin, persists during the first year of life.[113] These factors place the infant at risk for a suboptimal immunologic response after administration of classic vaccines and for adverse effects after administration of live, attenuated vaccines.

Transplant recipients may become infected with cytomegalovirus (CMV) at the time of transplantation, or they may experience reactivation secondary to immunosuppression. Active CMV infection during pregnancy is associated with congenital anomalies (e.g., cerebral cysts, microcephaly, mental retardation). In addition, active neonatal CMV infection may lead to serious illness or death.

After renal transplantation, residual impairment of renal function may lead to false-positive results of biochemical screening for trisomy 21. Karidas et al.[114] demonstrated a significant correlation between free β-subunit human chorionic gonadotropin and BUN and creatinine concentrations. Similar alterations in alpha-fetoprotein levels were not observed. In this setting, the double-marker biochemical test may be interpreted inaccurately. In patients with altered BUN and creatinine concentrations, first-trimester nuchal translucency measurement—in combination with second-trimester ultrasonography—may be a more useful screening regimen (see Chapter 6).

Medical and Obstetric Management

Discontinuation of immunosuppressant therapy, even years after transplantation, may lead to acute rejection. Thus, the renal transplant recipient's immunosuppressant regimen must be continued during pregnancy unless toxicity results, although some practitioners discontinue mycophenolate mofetil. Cyclosporine requirements increase during pregnancy, most likely because of enhanced metabolism.[115] The

pregnant patient must be intensively monitored for any evidence of acute or chronic allograft rejection, infection, ureteral and renal artery obstruction, impaired renal function, hypertension, fluid volume disturbances, anemia, or any combination of these symptoms. As noted earlier, recombinant human erythropoietin (darbepoetin) has been successfully used to treat anemia during pregnancy. There are reports in the posttransplant patient as well, although the degree of success and dosage regimens are highly variable.[26,116]

Initial laboratory studies in pregnant renal transplant patients include (1) complete blood cell count, (2) renal function tests, (3) serum electrolyte and glucose concentrations, and (4) viral serologic testing for CMV, hepatitis B virus, HCV, and HIV. Serial ultrasonographic assessments allow the recognition of fetal anomalies and the evaluation of fetal growth.

Cultures of the lower genital tract should be obtained in women with lesions suggestive of herpes simplex virus infection. A patient who presents in labor and with evidence of active genital herpes simplex virus infection should undergo cesarean delivery (see Chapter 36).

Vaginal examinations are minimized and always performed in a strict aseptic manner. The renal allograft is typically implanted in the extraperitoneal iliac fossa and does not impair vaginal delivery. Prophylactic antibiotics and stress-dose corticosteroids are indicated in patients who undergo cesarean delivery.

Anesthetic Management

In the absence of renal dysfunction and hypertension, anesthetic management of the parturient with a renal transplant is similar to that of the healthy parturient. Strict aseptic technique is maintained during the placement of intravascular catheters and the performance of neuraxial anesthetic techniques. Sowter et al.[117] reported an epidural abscess that occurred 23 days after epidural anesthesia in a nonpregnant patient receiving corticosteroid therapy for rheumatoid arthritis. Fortunately, this complication is exceedingly rare. In the absence of systemic infection, immunosuppression itself should not be considered a contraindication to administration of epidural or spinal anesthesia.

UROLITHIASIS

Definition and Epidemiology

Urolithiasis is characterized by the abnormal formation of calculi within the renal calyces or pelvis. Calculi may lodge within the ureters or bladder. The disorder affects 1% to 5% of the general U.S. population, but it is more common in the southeastern "stone belt" and mountainous regions. Symptomatic urolithiasis occurs during 1 in 188 to 1 in 4600 pregnancies and is more common among whites than African Americans, and more common in multiparous women in the second and third trimesters.[118,119] This incidence approximates that observed among nonpregnant young women, suggesting that pregnancy does not affect the rate of urolithiasis.

Pathophysiology

The presence of urolithiasis presumes an underlying physiologic abnormality that leads to persistent supersaturation of the particular minerals involved. During pregnancy, an elevated plasma 1,25-dihydroxyvitamin D level causes greater intestinal absorption of calcium, net mobilization of calcium from bone, and a state of absorptive hypercalciuria.[120] Ultimately, these changes provide calcium for the fetal skeleton. Because pregnant women do not develop urolithiasis at a rate greater than that in the general population, it would appear that the occurrence of other physiologic changes during pregnancy offsets these factors that might promote the formation of stones. Calcium stone inhibitors such as citrate, magnesium, and glycoprotein are excreted in the urine to a greater extent during pregnancy.[121] As expected, calcium stones account for the majority of stones in both the general population (80%) as well as in pregnancy (74%). However, whereas calcium oxalate stones are more prominent in the general population, calcium phosphate stones are more common in pregnancy.[122,123] This difference is thought to be caused by both the renal physiologic changes of pregnancy as well as a higher pH of urine in the parturient.

Diagnosis

As mentioned earlier, urolithiasis most commonly manifests during the second or third trimester. Only 20% of affected pregnant women recount a prior history of renal calculi. More than 80% of cases of gestational urolithiasis are diagnosed in parous women, possibly reflecting the higher incidence of this disease with advanced age.[124] Similar to that seen in nonpregnant women, stones occur with equal frequency on the right and left sides.[125] The signs and symptoms of urolithiasis during pregnancy are often nonspecific and may include flank pain, hematuria, nausea, vomiting, and fever; these must be differentiated from those occurring from ectopic pregnancy, preterm labor, appendicitis, pyelonephritis, and benign hematuria of pregnancy. A history of previous urolithiasis, recurrent urinary tract infections, or urologic surgery is suggestive. Examination may reveal costovertebral tenderness, abdominal tenderness, pyuria, and hematuria. Urolithiasis must be considered in patients with pyelonephritis who remain febrile or have continued bacteriuria despite 48 hours of parenteral antibiotics.

The initial imaging modality for the evaluation of urolithiasis during pregnancy is transabdominal ultrasonography. Transabdominal ultrasonography is diagnostic in about 60% of cases and does not expose the mother or fetus to radiation.[126] Color Doppler ultrasonography allows the identification of ureteral jets; the asymmetry or absence of these jets indicates the presence of urinary calculi. Transvaginal ultrasonography may augment suboptimal transabdominal ultrasonographic images.[127] Combining ultrasound evaluation with assessment of the intrarenal artery resistive index increases the accuracy of ultrasonography to greater than 70%.[128]

If urinary calculi are not successfully visualized with ultrasonography and clinical suspicion for urolithiasis remains

high, magnetic resonance (MR) urography should be considered because it does not use ionizing radiation or iodinated contrast media (see Chapter 17).[129] If the diagnosis is still unclear and the patient has persistent flank pain after both these tests, some experts recommend low-dose computed tomography,[130] whereas others recommend intravenous pyelography.[124]

Effect of Pregnancy on Urolithiasis

In an effort to determine any effect of pregnancy on the natural history of urolithiasis, Coe et al.[131] reviewed the records of 58 pregnancies in women with the preexisting diagnosis of urolithiasis. The stone recurrence rate in this group was 0.49 stone per patient-year, which was not significantly different from the rate of 0.44 stone per patient-year in the general population. The authors concluded that pregnancy does not alter the activity or severity of stone disease.

Effect on the Mother and Fetus

In a retrospective cohort study, Swartz et al.[132] compared pregnant women with nephrolithiasis ($n = 2339$) with randomly selected women without nephrolithiasis ($n = 6729$). The investigators found that women with nephrolithiasis had an almost twofold higher rate of preterm delivery. However, these women were not at increased risk for other adverse pregnancy outcomes, including premature rupture of the membranes, low birth weight, and infant death. The etiology of preterm labor and perhaps delivery is unclear but may be related to urinary tract infections that occur with a greater frequency in those with urolithiasis.[133] Honoré[134] suggested that there is a higher incidence of renal stones among women who have a spontaneous abortion. He hypothesized that abnormalities of calcium hemostasis may lead to myometrial hyperirritability or abnormal hormonal secretion by the corpus luteum, the placenta, or both. Rare cases of ureteral rupture[135] and obstructed labor caused by a bladder calculus[136] have been reported.

Urologic and Obstetric Management

Women with a history of urolithiasis should increase their intake of fluids. Calcium supplementation through prenatal vitamins should be avoided in women with recurrent urolithiasis. During pregnancy, 70% of calculi pass spontaneously with conservative management (e.g., hydration, antibiotics if the patient is febrile, bed rest, analgesia). More aggressive therapy will be required if conservative management is not successful. The decision to move beyond conservative therapy should be taken on a case-by-case basis. Infected hydronephrosis, especially with impaired renal function or urosepsis, is an indication for more aggressive therapy.[118]

Medical management, commonly used for treatment of urolithiasis,[118,119] is limited during pregnancy by fetal concerns. Medical expulsive therapy with alpha-adrenergic receptor blocking agents has been used successfully to increase the rate of stone passage and decrease pain associated with expulsion by relaxing ureteral smooth muscle.[137] There are no randomized studies examining safety or efficacy in the pregnant population; however, a survey study reported that 44.3% of respondent urologists endorsed its use in the pregnant population.[138] Other medical treatments that are used to treat urolithiasis, including thiazide diuretics, xanthine oxidase inhibitors, and D-penicillamine, are contraindicated during pregnancy owing to possible effects on the fetus.[139,140]

Urologic intervention is indicated in the patient with persistent pyelonephritis, deterioration of renal function, massive hydronephrosis, persistent pain, or sepsis. Ureteral stent placement with ureteroscopy and ultrasonographic guidance, or percutaneous nephrostomy, should be considered because either one can be performed without the need for anesthesia or radiation exposure.[141] Holmium:yttrium-aluminum-garnet (YAG) laser lithotripsy, using state-of-the-art ureteroscopes, is an emerging technique for stone management in pregnancy.[142] Extracorporeal lithotripsy should be avoided during pregnancy because the shockwaves may be harmful to the fetus.[143]

The following conditions may raise suspicion of the presence of **primary hyperparathyroidism** in a pregnant woman: (1) urolithiasis with or without pancreatitis, (2) hyperemesis beyond the first trimester, (3) a history of recurrent spontaneous abortion or intrauterine fetal death, (4) neonatal hypocalcemia or tetany, and (5) a total serum calcium concentration greater than 10.1 mg/dL during the second trimester or greater than 8.8 mg/dL during the third trimester.[144]

Anesthetic Management

Anesthesia providers are occasionally asked to provide analgesia for patients with renal or ureteral stones. The ureters receive sensory innervation through the renal, ovarian, and hypogastric plexuses (T11 to L1 spinal segments). During conservative management of urolithiasis, epidural analgesia provides the patient with significant pain relief and facilitates the passage of the calculus, possibly through decreased ureteral spasm.[145,146] Ready and Johnson[145] reported the use of epidural analgesia in a patient with severe renal colic at 23 weeks' gestation. Analgesia that was maintained for 16 hours allowed the passage of the stone. Neuraxial analgesia avoids the use of systemic opioids, which impair normal peristalsis in ureteric smooth muscle. Improved maternal pain control may also decrease endogenous catecholamine release and improve uteroplacental blood flow.

KEY POINTS

- Pregnant women with moderate or severe renal insufficiency are at increased risk for deterioration of renal function, exacerbation of hypertension, and other obstetric complications, including fetal growth restriction and preterm delivery.

- Patients requiring renal dialysis have decreased fertility, and pregnancy is rare.
- Pregnancy does not affect the long-term survival of a renal allograft.
- Both preeclampsia and renal disease may manifest as hypertension, proteinuria, and edema; the distinction between the two disorders is often unclear, especially after 20 weeks' gestation.
- Renal disease affects almost every organ system, so a thorough history before initiation of anesthesia, with emphasis on the cardiac and respiratory system, is critical.
- Anesthetic management is influenced by the extent of renal dysfunction and hypertension.
- Neuraxial anesthetic techniques are safe and are the preferred methods for labor analgesia and cesarean delivery anesthesia.
- Renal transplantation improves fertility rates within a few months of transplantation. Immunosuppressive therapy must be continued during pregnancy in renal transplant patients. The anesthesia provider should maintain strict aseptic technique during the placement of intravascular catheters and the performance of neuraxial anesthetic techniques.
- Epidural analgesia may facilitate the spontaneous passage of renal calculi.

Respiratory Disease

Karen S. Lindeman, MD

CHAPTER OUTLINE

ASTHMA

Definition

Asthma is defined by the presence of the following three characteristic findings: (1) reversible airway obstruction, (2) airway inflammation, and (3) airway hyperresponsiveness. **Airway obstruction** produces the clinical manifestations of wheezing, cough, and dyspnea. **Airway inflammation** modulates the course of asthma by independently producing airway obstruction and enhancing airway hyperresponsiveness. **Airway hyperresponsiveness** is marked by exaggerated responses to a wide variety of bronchoconstrictor stimuli, including histamine, methacholine, prostaglandin $F_{2\alpha}$, hypoosmotic solutions, and cold air.

Epidemiology

Asthma is an increasingly common problem among young, otherwise healthy women of childbearing age. From 2001 to 2010, the prevalence of asthma in the United States increased from 7.3% to 8.4%.[1,2]

The prevalence of asthma in women of childbearing age also continues to rise. The rate was approximately 3% in the 1990s and has increased to approximately 8.8% in the early 2000s.[3]

Pathophysiology

Asthma is believed to occur under a variety of environmental influences in the presence of genetic susceptibility.[4] The underlying defect that produces the clinical syndrome of asthma is unknown. The most important potential mechanisms are (1) an enhancement of contractility or an impairment of relaxation of airway smooth muscle, (2) a neural imbalance, (3) airway inflammation, and (4) changes in the function of the airway epithelium.

Airway Smooth Muscle

Contraction of airway smooth muscle is believed to be the most important factor in producing acute airway obstruction. For many years, an enhancement of airway smooth muscle responsiveness to contractile agonists was assumed to be a major mechanism of asthma. To test this hypothesis, investigators attempted to correlate airway responsiveness *in vivo* and *in vitro* in humans[5–9] and in the basenji-greyhound dog model of asthma.[10] These studies did not demonstrate a significant correlation between the airway response to histamine or cholinergic agonists *in vivo* and airway smooth muscle contraction *in vitro.* Some studies actually demonstrated a negative correlation between the *in vivo* and *in vitro* responses,

suggesting that diminished responsiveness may represent a chronic adaptive response of airway smooth muscle.

Instead of an enhancement in responsiveness to contractile stimuli, a reduction in responsiveness to relaxant stimuli may contribute to airway obstruction. One study demonstrated impaired relaxant responses to isoproterenol in airway smooth muscle from human asthmatic subjects in comparison with the responsiveness of airway smooth muscle from controls.[11] Other evidence substantiates the presence of impaired airway relaxation in asthmatic subjects *in vivo*.[12] Although the mechanism for this effect is poorly understood, a reduction in airway sensitivity to beta-adrenergic agonists could contribute to airway hyperresponsiveness by altering the balance between constricting and dilating influences.

Neural Components

A balance between constricting and dilating influences also exists with respect to the autonomic nervous system. A shift in this balance, with an increase in constricting influences, may be a mechanism of asthma.

The parasympathetic nervous system provides the dominant constrictor input to the airways (Fig. 52.1). Efferent cholinergic fibers travel in the vagus nerve to synapse in ganglia within the airway wall.[13] Postganglionic fibers release acetylcholine to activate muscarinic receptors and stimulate airway smooth muscle contraction. A negative feedback system limits release of acetylcholine from nerve terminals. Muscarinic autoreceptors, or receptors on the nerve ending,[14] also are activated by acetylcholine and inhibit further release of acetylcholine from the nerve terminal.

The importance of exaggerated cholinergic efferent activity in the pathogenesis of airway hyperreactivity has been debated extensively. The relatively limited efficacy of anticholinergic agents in relieving clinical bronchospasm, as well as growing evidence supporting other mechanisms, suggests that this pathway has a limited role in the pathophysiology of asthma. However, this mechanism appears to be very important in the perioperative management of asthmatic subjects. Reflex stimulation of airway smooth muscle by placement of a tracheal tube represents one of the most important causes of bronchospasm in the perioperative period.

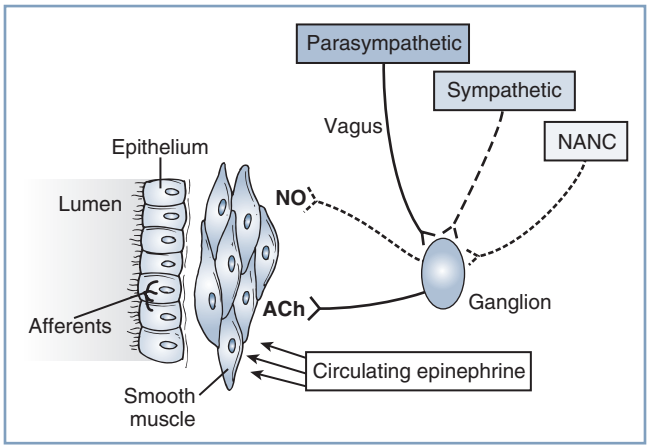

Fig. 52.1 Neural control of the airway. Parasympathetic, sympathetic, and nonadrenergic noncholinergic *(NANC)* efferents innervate ganglia within the airway wall. Postganglionic cholinergic efferents release acetylcholine *(ACh)* to constrict airway smooth muscle. Postganglionic NANC efferents release nitric oxide *(NO)* to relax airway smooth muscle. Circulating epinephrine relaxes the airway. Afferents from the airway originate in the epithelium and are activated by airway irritation, as occurs with tracheal intubation.

An alternative mechanism by which the parasympathetic nervous system may contribute to airway hyperresponsiveness is through dysfunction of the muscarinic autoreceptors. Dysfunction of these receptors allows increased postganglionic release of acetylcholine after reflex stimulation.[15] This mechanism is well established in a guinea pig model of viral infection[16] and may explain the airway hyperresponsiveness that occurs for several weeks after an upper respiratory tract infection, although additional autoreceptor-independent mechanisms may also be present.[17] The role of this mechanism in the pathophysiology of clinical asthma is unclear.

The sympathetic nervous system primarily acts to decrease airway tone. In contrast to the parasympathetic nervous system, sympathetic innervation of airway smooth muscle in human subjects is either sparse or absent.[18] Circulating catecholamines activate beta-adrenergic receptors in airway smooth muscle and provide the primary sympathetic efferent input to human airways. Because airways of normal human subjects do not become hyperresponsive after beta-adrenergic blockade,[19] it is unlikely that impaired catecholamine secretion contributes significantly to the pathogenesis of asthma.

The alpha-adrenergic system is thought to play a relatively minor role in determining the state of airway responsiveness. Although alpha-adrenergic receptors are present in human airways,[20] the protective effects of alpha-adrenergic antagonists have been disappointing and can be attributed to other properties, such as antihistamine activity.

In addition to cholinergic and adrenergic input, a third neural system, the nonadrenergic noncholinergic (NANC) system, provides efferent nerves to the airways. Both constricting and dilating pathways have been identified.[21] Nitric oxide serves as the inhibitory NANC neurotransmitter in human airways.[22] Potentially, a relative increase in constricting influences or a decrease in dilating influences in the NANC system could contribute to asthma. However, asthmatic subjects demonstrated no deficit in NANC inhibitory pathways,[23] and inhibition of NANC excitatory neurotransmission did not improve airway hyperresponsiveness.[24] Thus, current evidence does not support imbalance of the NANC system as a major mechanism of asthma.

Airway Inflammation

Airway inflammation appears to serve primarily as a modulating influence in asthma. Inflammation is certainly present in some but not all asthmatic subjects.[25] The process of inflammation involves the occurrence of airway wall edema and infiltration of the mucosa by a variety of inflammatory cells, including neutrophils, mast cells, helper T lymphocytes, macrophages, and eosinophils. These cells produce and release mediators of inflammation, such as histamine, leukotrienes, platelet-activating factor, prostaglandins, thromboxanes,

cytokines, serotonin, and nitric oxide.[26] Mediators can modulate airway responsiveness by stimulating airway smooth muscle contraction,[27] directing migration of inflammatory cells,[28] modifying neural control of the airways,[29] increasing mucosal permeability,[30] or disrupting airway epithelium.[31] In addition, airway inflammation can reduce airway diameter. Airway hyperresponsiveness is correlated with increased baseline airway tone.[32] The overall importance of inflammation in asthma has been debated. Although inflammation appears to modulate the course of asthma, other factors certainly contribute to the pathogenesis.

Airway Epithelium

The epithelium provides a barrier to protect the subepithelial layers against stimuli that could provoke bronchospasm. Airways of asthmatic subjects demonstrate areas of epithelial destruction,[33] and the clinical significance of this finding has been demonstrated.[34]

The epithelium not only serves as a barrier but also plays an active role in the maintenance of airway tone. The epithelium produces constricting and dilating factors.[35,36] An alteration in the balance between these factors could alter airway responsiveness. The relative importance of alterations in epithelial function in the pathogenesis of asthma is unknown.

Diagnosis

Medical History

The classic symptoms of asthma include wheezing, cough, dyspnea, and chest tightness. A patient's medical history also should include information about the pattern and severity of the symptoms, precipitating and aggravating factors, and the duration and course of these symptoms.

Physical Examination

Physical examination is directed to the respiratory tract. Auscultation of the chest may reveal wheezing and a prolonged phase of expiration.

Laboratory Studies

Laboratory studies that aid in the diagnosis of asthma depend on findings from the medical history and physical examination. In general, pulmonary function tests are useful to document the severity and establish the reversibility of obstruction (Box 52.1). In the absence of additional findings, other tests are not as useful in establishing the diagnosis of asthma. Bronchoprovocation tests (with agents such as methacholine or histamine) are used when the history and physical examination strongly suggest the presence of asthma but spirometry does not show airway obstruction.

Interaction with Pregnancy

Effects of Pregnancy on Asthma

The overall course of asthma has been reported to improve, worsen, or remain the same during pregnancy.[37] Although earlier evidence suggested that patients with more severe asthma are more likely to experience deterioration during pregnancy, other studies indicate that asthma severity during pregnancy is similar to severity during the year before pregnancy, provided that patients continue to use their prescribed medication during pregnancy. Even mild asthma can become significantly more severe if women discontinue their prescribed medication during pregnancy.[38] A likely reason for the variation in the results of published studies is the difference in methods of assessing the severity of asthma. Most studies have used either clinical symptoms or requirements for pharmacologic therapy as indicators of the course of the disease. These measures do not correlate with objective measures of airway obstruction.[39] Juniper et al.[40] measured methacholine sensitivity before, during, and after pregnancy. Measurements of sensitivity to methacholine made during the second and third trimesters were lower than preconception or postpartum measurements (Fig. 52.2). Although these findings suggest a reduction in airway hyperresponsiveness during pregnancy, the limited study population (16 subjects) makes extrapolation of the data to the general population unclear. Conversely, a small ($n = 20$) prospective study showed temporary declines in pulmonary function between 21 and 28 weeks' gestation that returned to baseline later in the pregnancy.[41] Exacerbations of asthma during labor and delivery occur in as many as 20% of subjects.[38]

A number of mechanisms may be responsible for the changes in the clinical course of asthma during pregnancy (Box 52.2). An increase in the progesterone level is thought to be one mechanism that improves asthma during pregnancy. Progesterone relaxes uterine and gastrointestinal smooth muscle and may or may not have similar effects on airway smooth muscle. However, Juniper et al.[40] did not demonstrate a strong association between methacholine responsiveness and progesterone levels during pregnancy, suggesting that progesterone does not play a central role in attenuating airway hyperresponsiveness. In contrast, progesterone may actually worsen asthma by enhancing inflammation.[42] Thus, effects of pregnancy on asthma appear to involve a number of factors other than direct effects of hormones on airway smooth muscle.

Effects of Asthma on the Parturient and Fetus

Many investigators have questioned whether maternal asthma adversely affects perinatal outcome. Differences in study design (e.g., retrospective, prospective) and differences in severity and treatment of asthma may account for different

BOX 52.2 Factors That May Improve or Worsen Asthma during Pregnancy

Factors That May Improve Asthma

- Progesterone-induced relaxation of airway smooth muscle
- Increased production of bronchodilating prostaglandins
- Higher circulating cortisol level

Factors That May Worsen Asthma

- Decreased sensitivity to beta-adrenergic agonists
- Increased production of bronchoconstricting prostaglandins
- Reduced sensitivity to circulating cortisol because of binding of steroid hormones (e.g., progesterone) to cortisol receptors

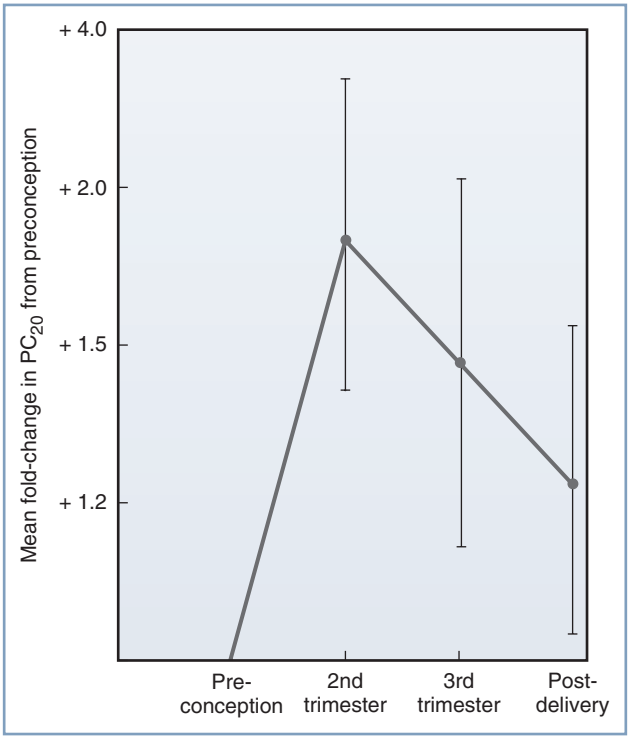

Fig. 52.2 Airway responsiveness before, during, and after pregnancy expressed as fold change in PC_{20}—dose of methacholine needed to reduce FEV_1 (forced expiratory volume in 1 second) by 20%—compared with values before conception ($n = 16$; $P = .033$ for the effect of pregnancy on airway responsiveness). (From Juniper EF, Daniel EE, Roberts RS, et al. Improvement in airway responsiveness and asthma severity during pregnancy. *Am Rev Respir Dis.* 1989;140: 924–931.)

study results. Some studies have reported an increased incidence of preeclampsia,[43,44] cesarean delivery,[45–47] low-birthweight (LBW) infants,[48] preterm labor,[49] antepartum and postpartum hemorrhage,[50] and perinatal mortality.[51] Diabetes mellitus appears to be more common among asthmatic patients treated with corticosteroids.[52] Severe or poorly controlled asthma is a predictor of adverse outcome. Although asthma in pregnancy is associated with an increased risk for adverse perinatal outcomes, a meta-analysis of cohort studies suggested that active asthma management, which is intended to reduce the exacerbation rate, may reduce the risk for perinatal complications, particularly preterm delivery.[53] No

- Direct airway smooth muscle relaxation
- Enhanced mucociliary transport
- Decreased airway edema
- Inhibition of cholinergic neurotransmission

controlled studies have documented better perinatal outcome with aggressive asthma treatment. Potential mechanisms of increased perinatal morbidity and mortality in patients with uncontrolled asthma include hypoxemia and hypocapnia, inflammation, and altered placental function from asthma-associated mediator release.[54] Siddiqui et al.[55] have documented an association between preeclampsia and airway hyperresponsiveness and have proposed that the mechanism involves an interaction between mast cells and smooth muscle. A large prospective study is needed to confirm this association.

Medical Management

Pharmacologic therapy for asthma during pregnancy is directed toward avoiding acute exacerbations and episodes of status asthmaticus. Ideally, management should begin before conception. Although general principles typically dictate that unnecessary medication should be avoided during pregnancy, studies investigating the effects of asthma on perinatal outcome suggest that the risks for uncontrolled asthma are significantly higher than medication-associated risks.[56] Medications that are currently used to treat asthma fall into two general categories: bronchodilators and antiinflammatory agents. These agents generally are safe for the fetus. The prophylactic use of antibiotics is unnecessary.

Bronchodilators

Beta-adrenergic agonists exert beneficial effects in asthmatic patients by activation of β_2-adrenergic receptors, which mediate a number of processes (Box 52.3). Short-acting beta-adrenergic agonists represent the most effective therapy for acute exacerbations of asthma.[57] Daily use of long-acting beta-adrenergic agonists is controversial. Long-acting beta-adrenergic agonist therapy is associated with a significant increase in the risk for death,[58] but controlled studies have not confirmed a cause-and-effect relationship. Certain genetic polymorphisms affect responses to short-acting but not long-acting beta-adrenergic agonists,[59] leading to hopes that a personalized approach to therapy would improve clinical efficacy. Although regular use of beta-adrenergic agonists in asthma may be beneficial in conjunction with other forms of therapy, these agents do not appear to provide optimal control when used alone. Conversely, no compelling evidence requires that beta-adrenergic agonists be discontinued after conception or that their use be reserved for treatment of an acute exacerbation.

These agents may be administered as aerosols, orally, or parenterally. The aerosol route is generally preferred during

pregnancy because high concentrations of the medication can be delivered directly to the site of activity in the airways, with relatively less drug delivered to the uteroplacental circulation.

The limited number of human studies investigating the fetal safety of long-term administration of a beta-adrenergic agonist have not shown significant adverse neonatal outcomes.[60,61] In addition, the long history of use of these agents without reports of teratogenicity suggests that their use should not be restricted because of fetal concerns. Optimal control of maternal symptoms of asthma appears to be more important for the fetus than potential detrimental effects of beta-adrenergic agonists.

On the basis of the potential risks associated with long-term single-agent therapy with a beta-adrenergic agonist, a paradoxical approach to the treatment of asthma may involve long-term administration of a beta-adrenergic antagonist.[62] This approach is analogous to the paradigm based in the cardiovascular system, in which long-term administration of a beta-adrenergic antagonist is beneficial in patients with congestive heart failure. Studies in asthmatic patients are ongoing.

Methylxanthines (e.g., **theophylline, aminophylline**) were used for many years in the long-term treatment of asthma. Although their mechanism of action is controversial, relaxation of airway smooth muscle is the most prominent effect. The ability of the agents to inhibit intracellular phosphodiesterase and increase concentrations of cyclic adenosine monophosphate (cAMP) is not the mechanism of bronchodilation, because these effects do not occur at clinically relevant concentrations *in vivo*.[63] Furthermore, in the patient taking antiinflammatory agents and beta-adrenergic agonists, methylxanthines add little to optimal asthmatic control.[64] Although their use is now limited to patients whose asthma responds poorly to other forms of therapy, methylxanthines do not appear to cause significant adverse fetal outcomes.[60] Serum concentrations of theophylline should be monitored carefully, especially in the third trimester, when theophylline clearance decreases.[65]

Bronchodilation with **anticholinergic agents** occurs through the blockade of muscarinic receptors on airway smooth muscle. Overall, anticholinergic agents alone are not as effective as beta-adrenergic agonists, but some patients show better response to anticholinergic agents.[66] The effects of adding anticholinergic agents to beta-adrenergic agonists for acute and chronic asthma were evaluated in meta-analyses of randomized trials. Anticholinergic agents improved lung function in acute asthma[67] but had little benefit in chronic asthma.[68] The **quaternary anticholinergic agent ipratropium bromide** can be delivered as an aerosol, allowing higher concentrations in the lung with reduced systemic absorption and potential effects on the fetus. Human data on the safety of anticholinergic agents and on potential teratogenicity are lacking, but ipratropium bromide is not associated with teratogenicity in animal studies.[69]

Magnesium sulfate relaxes airway smooth muscle, most likely via its antagonism of calcium entry into airway smooth muscle cells.[70] Its use is limited primarily to acute bronchospasm.[71]

Antiinflammatory Agents

Proposed mechanisms of action for corticosteroids are (1) decreases in cellular infiltration and mediator release, (2) reduction in airway permeability, and (3) upregulation of the beta-adrenergic system.[72] Unlike bronchodilators, corticosteroids not only reduce airway sensitivity to a constrictor stimulus[73] but also decrease the maximal extent of airway narrowing, a feature that may predict severity of an acute asthmatic episode.[74]

The use of **inhaled corticosteroids** has gained popularity. This route of administration is effective and may limit fetal side effects. Studies have assessed the effects of systemic and inhaled corticosteroids on the fetus. Neither systemic nor inhaled corticosteroids have been proven to increase the risk for congenital malformations in humans. Inhaled corticosteroids do not affect glucocorticoid-regulated pathways in the fetus and therefore are unlikely to cause adverse effects on fetal growth and development.[75] Although oral corticosteroid use is associated with an increased incidence of LBW infants,[76] inhaled corticosteroids do not appear to increase perinatal risk.[77] Of interest, use of inhaled corticosteroids guided by measurements of exhaled nitric oxide reduce exacerbations, but improvements in perinatal outcomes have not been proven.[78]

Corticosteroids may increase perinatal morbidity by exacerbating maternal glucose intolerance, especially in women who also receive treatment with a beta-adrenergic agonist. Thus, careful monitoring of maternal glucose concentration is indicated in asthmatic women who require treatment with a corticosteroid during pregnancy. However, because of the efficacy of corticosteroids in controlling severe asthma during pregnancy, these agents should not be withheld from the medical regimen.

Some authorities have recommended that corticosteroid-dependent asthmatic women receive large doses of parenteral corticosteroids during labor to prevent complications related to adrenal suppression.[79,80] The scientific basis for this recommendation is questionable. Although physiologic glucocorticoid replacement reduced hemodynamic instability and mortality in adrenalectomized primates that underwent surgery, supraphysiologic doses provided no additional benefit.[81] Furthermore, inhaled corticosteroids in moderate doses do not produce adrenocortical suppression.[82] There is little information about the benefit of corticosteroid replacement therapy during labor. The potential for adrenal insufficiency in infants of asthmatic mothers taking inhaled or oral corticosteroids appears to be very low, most likely owing to the widespread use of either prednisone or prednisolone. In the mother, prednisone is converted rapidly to prednisolone, which crosses the placental barrier to a very limited extent.

Cromolyn sodium and **nedocromil sodium** belong to a class of drugs that are thought to reduce inflammation and mediator release primarily by stabilizing mast cells and perhaps other inflammatory cells. Nedocromil also inhibits

cellular chloride ion flux, a feature that may explain its ability to affect a range of airway cells, including nerve cells.[83]

Cromolyn and nedocromil are administered as aerosols. Limited studies suggest that cromolyn is safe during pregnancy,[84] and clinical experience is greater with cromolyn than with nedocromil. Thus, use of cromolyn is preferred.

On the basis of the observation that leukotrienes are released into the airways by immune cells and contribute to the inflammatory process, other forms of antiinflammatory therapy are **leukotriene receptor antagonists** and **leukotriene synthesis inhibitors.** Safety data for the use of these agents in pregnancy are scarce. Bracken et al.[48] did not observe adverse neonatal outcomes in nine women exposed to these agents. A later prospective study of 96 women showed that use of leukotriene receptor antagonists was not associated with a specific pattern of congenital abnormalities, but the investigators cautioned that extrapolation of the data to a large population would require additional studies because of the limited sample size of the study.

A recombinant monoclonal anti-IgE antibody, **omalizumab,** is used specifically in patients with allergic asthma that is refractory to inhaled corticosteroids. Experience in pregnancy is limited.[85]

Obstetric Management

The following aspects of obstetric management of the asthmatic parturient may differ from that of the nonasthmatic patient: (1) induction of labor, (2) management of postpartum hemorrhage, and (3) treatment of hypertension.

For induction of labor, prostaglandins should be administered cautiously in women with asthma. Prostaglandin $F_{2\alpha}$ constricts airways *in vivo*[86] and *in vitro.*[87] Airways of asthmatic subjects demonstrate greater sensitivity to prostaglandin $F_{2\alpha}$, and its use to induce labor is associated with bronchospasm.[88] Prostaglandin E_2 can have either dilating or constricting effects on the airways, perhaps because of its ability to activate a variety of different types of prostaglandin receptors.[89] Because of the known risk for bronchospasm after exposure to prostaglandin $F_{2\alpha}$ and the possible risk after exposure to prostaglandin E_2, alternative methods of induction of labor are preferred in asthmatic women.

Likewise, asthma represents a relative contraindication to the administration of 15-methyl prostaglandin $F_{2\alpha}$ (carboprost, Hemabate) for the treatment of postpartum hemorrhage. The use of ergot alkaloids to treat postpartum hemorrhage in asthmatic women has also been questioned. Although controlled studies have not been performed, ergot alkaloids have been associated with episodes of acute bronchospasm,[90,91] on the basis of either their tryptaminergic actions or their ability to activate $alpha_1$-adrenergic receptors on airway smooth muscle cells. Oxytocin, which does not significantly affect airway tone, is the preferred ecbolic agent in asthmatic patients.

Beta-adrenergic receptor antagonists are used to treat hypertension in some pregnant women. In asthmatic women, these agents may provoke bronchospasm when used acutely.[92] Other antihypertensive agents, such as hydralazine, nifedipine, or nitroglycerin, do not seem to enhance airway responsiveness.

Anesthetic Management

Preoperative Assessment

During the preoperative evaluation, the anesthesia provider should assess the severity of the disease and whether an acute asthmatic episode is present. The medical history should include information about symptoms of wheezing, dyspnea, and cough. Further information should be sought about the frequency and severity of symptoms, the course of these symptoms during pregnancy, and the date of the most recent exacerbation. Patients who have frequent, severe attacks are at increased risk for morbidity in the peripartum period.

Physical examination should focus on the pulmonary system. Chest auscultation may demonstrate wheezing with or without a prolonged expiratory phase. However, wheezing may not be audible if air movement is markedly reduced. Additional signs of an acute exacerbation of asthma include tachypnea, an exaggerated (greater than 20 mm Hg) pulsus paradoxus, and the use of accessory respiratory muscles.

In a pregnant woman with stable asthma, laboratory tests add little to anesthetic management. However, if an acute exacerbation is suspected, chest radiographic examination, arterial blood gas measurements, and pulmonary function tests may assist with diagnosis and therapy. **Chest radiographic examination** helps diagnose precipitating or complicating conditions such as pneumonia, pneumothorax, and heart failure. During an episode of acute asthma, **arterial blood gas measurements** often show hypoxemia and respiratory alkalosis. After a prolonged, severe episode, arterial carbon dioxide tension increases as a result of fatigue. **Spirometry** measures the volume of gas exhaled over time (see Box 52.1). The most convenient indirect measurement for assessing airway obstruction during labor is the **peak expiratory flow rate,** which can be measured at the bedside with a Wright peak flowmeter.[93]

Management during Labor and Vaginal Delivery

The goals of analgesia for labor and delivery in asthmatic women include (1) provision of pain relief, (2) reduction in the stimulus to hyperpnea, and (3) prevention or relief of maternal stress. The goal of adequate pain relief does not differ for asthmatic women. It is important to prevent hyperpnea and stress in women who describe asthmatic episodes triggered by exercise or stress. These goals should be accomplished with minimal sedation, minimal paralysis of the muscles of respiration, and minimal depression of the fetus. Possible analgesic regimens include systemic opioids, paracervical block, pudendal nerve block, lumbar sympathetic block, and epidural or spinal analgesia using local anesthetic agents, opioids, or both.

Systemic opioids may provide reasonable pain relief and reduce the stimulus to hyperpnea, especially during the early part of the first stage of labor. In theory, opioids reduce the risk for bronchospasm in asthmatic subjects. Opiate receptors are believed to be present in the respiratory tract[94] and to

inhibit release of excitatory neuropeptides. The clinical relevance of these findings is unknown, because moderate doses of inhaled morphine do not significantly alter airway tone. Conversely, high doses of some opioids (e.g., morphine) may increase the risk for bronchospasm by releasing histamine. The risk associated with using moderate doses of morphine does not seem excessive, because airway tone does not change in subjects with moderate to severe asthma after inhalation of morphine.[95] An opioid that does not release histamine (e.g., fentanyl, remifentanil) may be a better choice for the asthmatic parturient. High doses of opioids are not desirable in subjects with active wheezing because of the risks for maternal and neonatal respiratory depression (see Chapter 22).

Paracervical block and **pudendal nerve block** performed by an obstetrician are acceptable choices for analgesia during the first and second stages of labor, respectively. These techniques provide analgesia without sedation or paralysis of the respiratory muscles. The problems with these techniques in asthmatic women are similar to those in nonasthmatic parturients (see Chapter 24).

Lumbar sympathetic block also provides pain relief without sedation or motor block during the first stage of labor. This technique has the same limitations as for women without asthma (see Chapter 24).

Intrathecal and **epidural opioid** techniques are useful during the first stage of labor and do not produce motor block (see Chapter 23). The advantage of the absence of motor block should be weighed against the risk for respiratory depression in asthmatic subjects.

Advantages of the use of local anesthetic agents for **lumbar epidural analgesia** in asthmatic patients include continuous pain relief and a reduction in the stimulus to hyperventilation. These goals typically are achieved without maternal sedation or neonatal depression. Unlike other analgesic techniques, continuous lumbar epidural analgesia adds a margin of safety by providing the opportunity to extend the sensory block for cesarean delivery. The possibility of extension allows the anesthesia provider to avoid some of the risks associated with general anesthesia. The most significant disadvantage of epidural local anesthetics in an asthmatic subject is the risk for a high thoracic motor block and respiratory insufficiency. Use of an appropriate epidural catheter test dose and maintenance of a sensory level at the 10th thoracic dermatome minimize this risk. In addition, the use of a dilute concentration of local anesthetic combined with a modest dose of an opioid produces satisfactory analgesia with less motor block than local anesthetic alone.[96]

Management during Cesarean Delivery

The choice between neuraxial anesthesia and general anesthesia for cesarean delivery depends on obstetric considerations and the respiratory status of the parturient. In general, avoidance of airway instrumentation is desirable, because tracheal intubation markedly increases airway tone in asthmatic subjects.[97]

The most significant advantage of neuraxial anesthesia in the asthmatic patient is that this technique obviates the necessity for tracheal intubation. Neuraxial anesthesia is associated with a lower incidence of bronchospasm than general anesthesia in asthmatic subjects.[98] Stable asthmatic patients can undergo either spinal or epidural anesthesia. In unstable asthmatic patients who require the use of accessory muscles of respiration, neuraxial anesthesia may be hazardous because of impaired ventilatory capacity in the presence of a high thoracic motor block. Intrathecal administration of either ropivacaine or levobupivacaine, which may produce less motor block than bupivacaine, does not confer any advantage with respect to pulmonary function in women receiving spinal anesthesia for cesarean delivery.[99]

The adrenal medulla receives innervation from preganglionic sympathetic fibers arising from the sixth thoracic to the second lumbar spinal segment.[100] Some authors have postulated that neuraxial anesthesia and the ensuing sympathectomy could precipitate or potentiate bronchospasm during cesarean delivery in asthmatic subjects by reducing adrenal output of epinephrine. This possibility seems remote. First, although epinephrine infusion can reduce airway reactivity in asthmatic subjects,[101] epinephrine concentrations do not decrease during nonobstetric surgery performed with neuraxial anesthesia that achieves high thoracic sensory levels.[102,103] Second, the idea that neuraxial anesthesia may prevent increases in circulating epinephrine that are required to compensate for stress-induced bronchospasm does not appear to be valid. Bronchoconstriction does not stimulate epinephrine secretion in human asthmatic subjects.[104] Thus, neuraxial anesthesia is appropriate for cesarean delivery in stable asthmatic subjects.

General anesthesia for asthmatic women undergoing cesarean delivery requires a balance between the competing considerations of pulmonary aspiration and intraoperative bronchospasm. Although airway instrumentation provides a great stimulus for bronchospasm, the high risk for aspiration mandates tracheal intubation during administration of general anesthesia in parturients.

Most commonly, options for tracheal intubation include awake intubation and rapid-sequence induction, although mask induction of general anesthesia with sevoflurane has been described in a parturient with status asthmaticus.[105] Indications for awake intubation in asthmatic subjects are similar to those for nonasthmatic patients, and pretreatment with a local anesthetic and a beta-adrenergic agonist can attenuate reflex-induced bronchoconstriction after awake intubation. The benefits of topical local anesthetics and airway nerve blocks for awake intubation should be weighed against a possible increase in the risk for aspiration from the loss of protective airway reflexes. Rapid-sequence induction for cesarean delivery in asthmatic patients is most often accomplished using either **propofol** or **ketamine.** A sympathomimetic agent, ketamine has long been considered the intravenous induction agent of choice for asthmatic subjects. Ketamine relaxes airway smooth muscle and inhibits neural reflexes.[106] Propofol provides better protection than thiopental against bronchospasm associated with tracheal intubation in asthmatic patients,[107] but it has not been compared directly

with ketamine in humans. Beneficial airway effects of propofol, like those of ketamine, also appear to occur via inhibition of airway reflexes. Intravenous **lidocaine,** which also inhibits airway reflexes, attenuates irritant-induced bronchoconstriction,[108] including tracheal intubation, and produces an additional protective effect above that of beta-adrenergic agonist pretreatment alone.[109]

In patients *without* asthma, maintenance of general anesthesia typically includes administration of a low concentration of a volatile halogenated anesthetic agent, with or without nitrous oxide, before delivery of the infant. After delivery, maintenance of anesthesia typically consists of nitrous oxide and an intravenous opioid, with or without a low concentration of a volatile halogenated agent. In *asthmatic* parturients, the **volatile halogenated anesthetic agents** are considered the agents of choice for the maintenance of anesthesia. These agents attenuate airway responsiveness through direct effects on airway smooth muscle,[110–112] inhibition of airway reflexes,[113] and effects on the epithelium.[114]

A high concentration of a volatile halogenated anesthetic agent has salutary effects on the airways but also increases the risk for hemorrhage during cesarean delivery by causing dose-dependent uterine relaxation.[115] Alternatively, nitrous oxide, an intravenous opioid, and a low concentration of a volatile halogenated agent may be given. Although halothane and isoflurane are approximately equipotent bronchodilators at high concentrations, halothane produces greater bronchodilation at lower concentrations[116] and therefore may be preferable for anesthesia for cesarean delivery. Sevoflurane acts as a bronchodilator in large and small airways[117] and reverses airway constriction associated with tracheal intubation.[118] Effects of desflurane are controversial. Desflurane protects against a direct stimulus to the airways[119] but may be less effective against reflex stimuli, such as tracheal intubation.[120]

A bronchodilator can be added if bronchospasm occurs. The potential disadvantage of this technique is that the most effective bronchodilators (i.e., the beta-adrenergic agonists) also relax uterine smooth muscle. The administration of a beta-adrenergic agonist by aerosol delivers a relatively greater dose of drug to the airways and minimizes uterine relaxation.

Emergence from general anesthesia, as with induction, requires a balance between reducing the risk for aspiration and lowering the risk for bronchospasm. Extubation of the trachea when the patient is awake minimizes the risk for aspiration, but the tracheal tube may stimulate reflexes and precipitate bronchospasm as the depth of anesthesia is reduced. If bronchospasm occurs during emergence, bronchodilators can be administered. For refractory bronchospasm, continued mechanical ventilation in an intensive care unit may be required.

CIGARETTE SMOKING

Epidemiology

Cigarette smoking is a significant, preventable cause of maternal morbidity and perinatal morbidity and mortality.[121] The prevalence of smoking among pregnant women in the United States declined from 18.1% in 1991 to 8.4% in 2014, and approximately 72% of women who smoke quit smoking during pregnancy.[122]

Pathophysiology

Cigarette smoke contains a large number of separate components that have a variety of biologic effects. Nonrespiratory effects of cigarette smoking are described in Chapter 53.

The primary respiratory effects of cigarette smoking include alterations in small airway function, increased mucus secretion, and impairment of ciliary transport.[123] The precise mechanisms for these effects are unknown. Smoking also is associated with an increase in nonspecific airway reactivity, possibly through epithelial damage, altered airway geometry caused by increased mucus secretion, or upregulation of endothelin receptors.[124] These changes lead to a marked increase in the incidence of postoperative pulmonary complications.

Interaction with Pregnancy

Few studies have documented the respiratory effects of cigarette smoking during pregnancy. In one study, reductions in forced expiratory flow rates suggested that pregnant women who smoke cigarettes have greater small airway resistance than those who do not smoke.[125] These and other abnormalities were similar to the changes in airway function observed in nonpregnant smokers. Although further studies are warranted, other respiratory effects of cigarette smoking in pregnant women are likely to be similar to those effects in nonpregnant women.

Cigarette smoking adversely affects pregnancy in a number of ways. The association between smoking and LBW has a genetic influence, such that the specific variation of the nicotinic acetylcholine receptor gene cluster is associated with lower newborn birth weight in smokers but not in nonsmokers.[126] One potential mechanism for these detrimental effects may be chronic, intermittent reductions in uterine perfusion. In a rodent model, reductions in uterine blood flow following inhaled nicotine were mediated by sympathetic nicotinic acetylcholine receptors.[127] In addition, even low levels of cigarette smoke alter fetal metabolic pathways.[128] Further details regarding adverse maternal and fetal effects of smoking are described in Chapter 53.

Medical Management

Cessation of smoking is the preferred form of medical management. Smoking cessation programs are effective in pregnant women.[129] Nonpharmacologic methods are preferred to pharmacologic methods (e.g., nicotine patches) because of insufficient safety information for the latter. Das et al.[130] demonstrated that smoking cessation before or early in pregnancy results in prompt improvement in maternal airway function. Smoking cessation reduces perioperative complications in the nonpregnant patient undergoing surgery,[131] but no controlled studies have evaluated effects of smoking cessation on peripartum outcome.

Anesthetic Management

Tracheal intubation is associated with bronchospasm in smokers.[132] For vaginal delivery, any of the analgesic techniques described earlier for asthmatic parturients are acceptable. For cesarean delivery, neuraxial anesthesia achieves the goal of avoiding airway instrumentation and is therefore preferable to general anesthesia, although no controlled studies have documented differences in peripartum morbidity. If general anesthesia is required, the methods for reducing the risk for intraoperative bronchospasm described previously may be considered. During induction of general anesthesia in smokers, the formulation of propofol containing sulfite results in greater respiratory resistance after tracheal intubation than the formulation containing ethylenediaminetetraacetic acid (EDTA).[133] The clinical significance of this finding is unknown. One study noted that respiratory resistance did not decrease after tracheal intubation in smokers anesthetized with desflurane,[120] suggesting that other volatile halogenated anesthetic agents might be preferable.

CYSTIC FIBROSIS

Epidemiology

Cystic fibrosis, a lethal genetic disorder that is transmitted as an autosomal recessive trait, affects approximately 1 in 3500 births in the United States.[134] Because of improvements in diagnosis and therapy, a growing number of women with cystic fibrosis survive to reproductive age. From 2005 to 2014, the pregnancy rate in cystic fibrosis patients in the United States decreased approximately 2% per year, but whether this is limited to cystic fibrosis patients or simply reflects the U.S. trend has not been determined.[135]

Pathophysiology

Clinical features of cystic fibrosis result from abnormalities of epithelial tissues, especially in the respiratory, digestive, and reproductive tracts. The underlying mechanism is a defect in cAMP-mediated activation of chloride (Cl^-) conductance in the epithelium.[136,137] Normal epithelial cells secrete Cl^- in response to an increase in intracellular cAMP. In cystic fibrosis, a genetic mutation makes epithelial cells unable to alter Cl^- permeability in response to changes in cAMP. The gene responsible for cystic fibrosis is located on chromosome 7 and encodes a protein known as the *cystic fibrosis transmembrane regulator* (CFTR),[138,139] which may be absent or dysfunctional as a result of multiple mutations. The CFTR acts as a Cl^- channel but also has a number of other actions. Cystic fibrosis is characterized by impaired water flow from the interior to the exterior of epithelial cells, leading to obstruction of exocrine glands with mucus.

In the lungs, abnormalities of electrolyte transport alter the composition of airway secretions. Inflammation, with infiltration of polymorphonuclear leukocytes, also contributes to changes in airway secretions.[140] Large numbers of disintegrating neutrophils release DNA in quantities sufficient to overwhelm the ability of deoxyribonuclease I (DNAse I), an endogenously released enzyme, to digest extracellular DNA. Undigested DNA increases the viscosity of airway secretions, which causes obstruction of small airways and reduced lung volumes. The ensuing ventilation-perfusion inequalities produce arterial hypoxemia. Some patients have hyperreactive airways. Spontaneous pneumothorax often occurs. Chronic airway obstruction and impaired mucus clearance increase the frequency of pulmonary infection. Most patients become colonized or infected with *Pseudomonas aeruginosa.* Eventually, tissue damage leads to bronchiectasis and pulmonary insufficiency. Chronic hypoxemia and lung destruction may produce pulmonary hypertension and cor pulmonale. Nonrespiratory manifestations of cystic fibrosis include pancreatic exocrine insufficiency, intestinal obstruction, and infertility.

Diagnosis

Clinical criteria for the diagnosis of cystic fibrosis include (1) the presence of chronic obstructive lung disease and colonization with *P. aeruginosa* before 20 years of age, (2) exocrine pancreatic insufficiency, and (3) a family history of cystic fibrosis. Laboratory findings include (1) sweat Cl^- concentrations greater than 60 mEq/L, (2) CFTR genotype with two known cystic fibrosis mutations, and (3) detection of CFTR dysfunction by the nasal potential difference test.[141] Chest radiographic examination often demonstrates hyperinflation, and arterial blood gas measurements may show hypoxemia. Pulmonary function tests, which can reveal obstructive or restrictive lung patterns, are useful to assess the severity of the disease. With serial measurements, clinicians should look for evidence of an increased residual volume and a reduced FEV_1 (forced expiratory volume in 1 second).[142]

Interaction with Pregnancy

Effect of Pregnancy on Cystic Fibrosis

The following factors may contribute to the deterioration of pulmonary function during pregnancy: (1) increased airway responsiveness and obstruction (as can occur in patients with asthma), (2) increased work of breathing, and (3) cardiovascular changes such as congestive heart failure and pulmonary hypertension associated with the increased blood volume of pregnancy.

In spite of potential negative effects of pregnancy on the course of cystic fibrosis, long-term maternal outcome does not appear to be affected.[143] However, temporary reductions in FEV_1 in the immediate postpartum period may occur,[144] and prepregnancy FEV_1 is a useful predictor of ability to tolerate pregnancy.[145]

Effect of Cystic Fibrosis on Pregnancy

Cystic fibrosis has been associated with an increased risk for LBW infants and preterm delivery, but recent evidence suggests that improved care of these patients can mitigate these problems.[146] Potential mechanisms for these complications include chronic hypoxemia and poor maternal nutrition.

Medical Management

Respiratory management of cystic fibrosis is primarily symptomatic. Patients with large volumes of mucus production undergo mechanical airway clearance. Some patients inhale recombinant human DNAse I to reduce viscosity of lung secretions caused by accumulating DNA. Hypertonic saline inhalation aids clearance of airway mucus.[147] Bronchodilators may help those patients who manifest a reversible component of airway obstruction. Continuous oxygen therapy may benefit patients with hypoxemia and cor pulmonale.

Long-term antibiotic therapy with inhaled tobramycin reduces both the incidence of recurrent pulmonary infection and the frequency of exacerbations in patients with cystic fibrosis.[148] Long-term administration of oral azithromycin also decreases exacerbations from cystic fibrosis[149] through either its antibiotic or its antiinflammatory properties. Effects of long-term antibiotic therapy on the fetus are unknown.

Other forms of therapy include gene therapy and lung transplantation. The goal of gene therapy is to improve function of the defective CFTR protein. Ivacaftor and lumacaftor/ivacaftor combination therapy are used for patients with certain specific mutations. With only anecdotal experience in pregnancy, the safety of these CFTR modulators for the fetus has not yet been established. Significant pulmonary deterioration sometimes leads to double-lung transplantation, although it is unclear whether transplantation alters survival.[150]

Obstetric Management

Because of the influence of pregravid maternal health on pregnancy outcome, the primary obstetric issue centers on the advisability of pregnancy in patients with cystic fibrosis. Criteria for the termination of pregnancy are not clearly defined. Genetic counseling regarding the risk for cystic fibrosis in the offspring is another important component of obstetric management.

Anesthetic Management

Considerations for anesthetic management focus primarily on the pulmonary system. Because of the high incidence of hypoxemia in patients with cystic fibrosis, continuous monitoring of oxygen saturation and appropriate oxygen therapy are advisable.

The goals of pain relief during labor are to provide adequate analgesia and to prevent maternal hyperventilation while avoiding high thoracic motor block and respiratory depression. High thoracic motor block may impair the parturient's ability to cough and eliminate thick secretions. Hyperventilation increases the work of breathing and may cause decompensation in patients with severe pulmonary dysfunction. For pain relief during labor, parenteral opioid analgesia may worsen pulmonary function by depressing respiratory drive and inhibiting cough. Intrathecal opioids have been used successfully,[151] but patients should be monitored carefully for respiratory depression. Continuous lumbar epidural analgesia, with a sensory nerve block maintained at the level of the 10th thoracic dermatome, can provide excellent pain relief and reduce the stimulus for hyperventilation, with minimal motor block of the thorax. A dilute solution of bupivacaine, with or without an opioid, provides sensory analgesia with minimal motor block and is therefore nearly ideal in this setting.[152] In healthy parturients, this technique actually improves respiratory function slightly.[153]

Cesarean delivery necessitates the choice between general anesthesia and neuraxial anesthesia. Among patients with cystic fibrosis, no studies have documented differences in outcome between general anesthesia and neuraxial anesthesia. Neuraxial anesthesia offers the advantage of avoiding tracheal intubation, which may be associated with bronchospasm or obstruction of the tracheal tube with secretions. Neuraxial anesthesia also avoids positive-pressure ventilation, which may enlarge a preexisting pneumothorax. The primary consideration for neuraxial anesthesia during cesarean delivery is to avoid a high thoracic motor block, which may impair ventilation and the ability to cough. Effective spinal anesthesia for cesarean delivery slightly decreases vital capacity.[154] Methods for reducing the risk for excessively high motor block include the use of a continuous catheter technique, which allows titration of the local anesthetic agent to achieve the desired sensory level, and the use of the lowest concentration of local anesthetic (with or without an opioid) that provides surgical anesthesia. Both epidural anesthesia[155] and combined spinal-epidural anesthesia[156,157] have been used in parturients with cystic fibrosis.

For general anesthesia, techniques to reduce the risk for bronchospasm, as described for patients with asthma (see earlier discussion), may be warranted. Additional considerations include (1) humidification of gases to prevent inspissation of mucus, (2) frequent suctioning to remove excess secretions, and (3) use of ventilator settings that allow an appropriately long expiratory phase to prevent air trapping and pneumothorax. It may also be prudent to avoid nitrous oxide in the parturient with cystic fibrosis, because of the risk for pneumothorax. Patients with cystic fibrosis should be allowed to awaken fully before extubation of the trachea. Chest physiotherapy may be required in the immediate postoperative period.

RESPIRATORY FAILURE

Epidemiology

The prevalence of respiratory failure during pregnancy is thought to be as many as 1 in 500.[158] While the most common obstetric causes are hypertensive disease and hemorrhage,[159] a significant number of patients suffer from **acute respiratory distress syndrome (ARDS).** A large database analysis of more than 55 million pregnancies from 2006 to 2012 revealed that the number of pregnant patients requiring mechanical ventilation as a result of ARDS increased from 36.5 cases per 100,000 live births in 2006 to 59.6 cases per 100,000 live births in 2012, and the in-hospital mortality rate was 9%.[160]

Pathophysiology

The pathophysiology of respiratory failure depends on the underlying disorder. ARDS results from a group of

predisposing conditions, but a common final pathway leads to similar manifestations.[161] Damage to the alveolar and capillary membranes initiates a cascade of events leading to fluid transudation that often is accompanied by pulmonary venoconstriction. Direct injury to the alveolar and capillary membranes can result from pulmonary aspiration of gastric contents and perhaps oxygen toxicity. Indirect toxicity can result from humoral and cellular mechanisms caused by triggers such as sepsis and amniotic fluid embolism. Transudation of fluid leads to atelectasis, airway obstruction, reduced lung compliance, and altered ventilation-perfusion relationships. Both physiologic dead space and shunt fractions are increased.

Diagnosis

A variety of disorders can cause acute respiratory failure during pregnancy (Box 52.4). Specific diagnostic criteria depend on the disorder.

The diagnosis of ARDS requires the exclusion of other disorders. Prominent characteristics of ARDS include arterial hypoxemia, radiographic evidence of pulmonary infiltrates, and reduced lung compliance in the setting of a recognized predisposing condition.[162]

Interaction with Pregnancy

Pregnancy is not known to alter the overall course of respiratory failure. However, differences in outcome between pregnant and nonpregnant patients have been observed in subsets of patients with respiratory failure. In a series of patients with **severe acute respiratory syndrome (SARS),** pregnant patients had greater morbidity.[163] Mortality rates are similar in pregnant and nonpregnant subjects. Although delivery of the infant has been suggested as a means to improve maternal respiratory status, evidence indicates that improvement cannot be expected in every patient.[164]

The most significant effect of respiratory failure on pregnancy is a reduction in oxygen delivery to the fetus. This reduction results most commonly from maternal arterial hypoxemia or maternal hypotension, which often accompanies respiratory failure. Hypotension may result from associated underlying conditions or from elevated mean airway pressures during mechanical ventilation. High rates of prenatal complications with or without preterm delivery have been reported.[165,166]

BOX 52.4 Etiology of Respiratory Failure during Pregnancy

Adult Respiratory Distress Syndrome (ARDS)
- Infection
  - Bacterial or viral pneumonia
  - Endometritis
  - Pyelonephritis
  - Sepsis
- Preeclampsia
- Hemorrhage
  - Multiple transfusions
  - Disseminated intravascular coagulation
- Aspiration of gastric contents
- Embolism
- Drugs
  - Salicylates
  - Opioids

Pulmonary Embolism
- Thromboembolism
- Amniotic fluid embolism
- Venous air embolism

Cystic Fibrosis

Pulmonary Edema
- Beta-adrenergic receptor agonists (e.g., ritodrine, terbutaline)
- Cardiogenic

Medical Management

Therapeutic strategies for managing respiratory failure during pregnancy do not differ qualitatively from those in nonpregnant patients. The primary goals of medical management are to (1) eliminate predisposing conditions, (2) limit fluid transudation, and (3) maintain maternal oxygen delivery. Fluid restriction and diuretics help limit fluid transudation, although this therapy must be used cautiously when the underlying cause of respiratory failure is associated with intravascular fluid depletion. The goals for maintenance of oxygen delivery may differ quantitatively during pregnancy. Oxygen delivery to the fetus worsens significantly when Pao_2 decreases below 70 mm Hg or oxygen saturation (Sao_2) falls below 95%.[167] Standard methods of maintaining oxygen delivery include (1) administration of a higher inspired concentration of oxygen, (2) administration of bronchodilators in the presence of reversible airway obstruction, (3) administration of pharmacologic agents to support the circulation as needed, and (4) mechanical ventilation. A higher inspired oxygen concentration, delivered by face mask, is safe during pregnancy and may obviate the necessity of tracheal intubation and its risks for aspiration and difficult airway management. Bronchodilator therapy can also be used for respiratory failure, as described earlier for asthma. Pharmacologic agents for circulatory support include agents with both alpha- and beta-adrenergic receptor activity.

Indications for tracheal intubation and mechanical ventilation are similar for pregnant and nonpregnant patients with respiratory failure.[163,168] Maternal and fetal effects of current approaches to mechanical ventilation, including use of low tidal volumes and permissive hypercapnia, have not been studied in pregnant patients. Positive end-expiratory pressure may be used if cardiac output is maintained to allow sufficient blood flow to the uterus.

Some pregnant patients with respiratory failure do not show adequate response to conventional methods of treatment. For these patients, treatment options include extracorporeal membrane oxygenation (ECMO),[169] high-frequency

oscillatory ventilation,[170] and inhaled **nitric oxide.**[171] Nitric oxide relaxes vascular smooth muscle. Rapid inactivation of nitric oxide by binding to hemoglobin in the circulation allows inhaled nitric oxide to produce pulmonary vasodilation without systemic vascular effect. Selective pulmonary vasodilation in well-ventilated areas of the lung presumably would improve oxygen delivery. The safety of these alternative forms of treatment in pregnancy is unknown because reports of their use are anecdotal.

Obstetric Management

Because the beneficial effects of delivery on the course of respiratory failure have not been proven, indications for induction of labor or cesarean delivery in this setting are not well defined. Small observational studies have not clearly shown an association between delivery and improved respiratory status in pregnant women with respiratory failure.[161,172,173] Further, data to support decisions regarding mode of delivery are limited. Vaginal delivery is possible during mechanical ventilation[174,175] and may avoid complications of major intra-abdominal surgery in a critically ill woman.

Anesthetic Management

The anesthetic management of patients with respiratory failure requires appropriate medical management. During labor, analgesia for mechanically ventilated patients can be achieved with intravenous opioids, which are often used for sedation during mechanical ventilation. Lumbar epidural analgesia provides pain relief without the neonatal respiratory depression associated with high doses of opioids. Labor epidural analgesia also reduces oxygen consumption,[176] which may be beneficial in hypoxemic patients. The use of labor epidural analgesia in patients with respiratory failure depends on underlying conditions and ongoing therapy. Close attention should be paid to intravascular volume, adequacy of coagulation, and presence or absence of infection.

In mechanically ventilated patients, general endotracheal anesthesia is often the most convenient choice for cesarean delivery. Aside from the issues of medical management (as discussed earlier), the techniques and pharmacologic agents do not differ substantially from those used in patients without respiratory failure.

KEY POINTS

- Patients with asthma, infection, respiratory failure, or cystic fibrosis and patients who smoke cigarettes may have reversible airway obstruction.
- In patients with airway hyperresponsiveness, tracheal intubation provides one of the most significant stimuli for bronchospasm during the perioperative period.
- Inhaled $beta_2$-adrenergic agonists are the most effective therapy for perioperative bronchospasm.
- Most bronchodilators also produce uterine relaxation. However, their administration by aerosol should minimize their effects on uterine tone.
- Neuraxial anesthesia is often the anesthetic technique of choice in patients with respiratory disease because it does not require tracheal intubation.
- Techniques of neuraxial anesthesia should be modified to reduce the likelihood of a high thoracic motor block in patients with significant respiratory disease.

Substance Use Disorders

Lisa R. Leffert, MD

CHAPTER OUTLINE

Use of licit and illicit substances by pregnant women can pose a significant risk to maternal and fetal health. To improve diagnosis and reduce the moral tenor, the *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition *(DSM-5)* replaced the term *substance abuse* with a continuum of mild, moderate, or severe *substance use disorder.*[1] Estimates of the prevalence of maternal substance use vary depending on the particular licit or illicit substance, the maternal age group, the extent of use, and the data source. Overall, the rate of past-month illicit drug use in pregnant women as reported in the National Survey on Drug Use and Health in 2015 was 4.7% compared with 12.5% of nonpregnant women 15 to 44 years of age.[2]

Anesthesia providers play a fundamental role in caring for these patients during labor and delivery and postpartum. Depending on the particular substance, pregnant women may experience little to no acute and chronic adverse effects, or alternatively, may manifest one or more of the following: (1) cardiovascular, pulmonary, and neurologic complications or (2) obstetric complications (e.g., fetal growth restriction, preterm labor, placental abruption, fetal death).[3–8] Patients with substance use disorder may also have heightened sensitivity to pain and/or tolerance to opioid analgesics,[9–12] which may impact acute postoperative pain management.

DRUG DETECTION

Optimal care requires developing a therapeutic bond with these patients and identifying what substances have been taken.[13] Providers should ask questions in a respectful and nonjudgmental manner. It is vital to respect patient confidentiality, which may mean speaking to the patient without family or friends present. Self-reporting typically underrepresents the true prevalence of drug use.[14–16] Therefore, health care providers should be familiar with the characteristic signs and symptoms associated with acute and chronic intoxication. Although analysis of urine, meconium, and hair are the most common methods to test pregnant patients and their infants for the presence of illicit drugs, analysis of saliva, umbilical cord tissue, amniotic fluid, and neonatal gastric aspirate can also be done (Tables 53.1 and 53.2).[14–19] It is vital to understand which compounds a particular drug test identifies before interpreting the results. Caregivers should be aware that the immunoassays most commonly used in drug testing can have false-positive or false-negative results in the presence of structurally related drugs or additives. Gas chromatography with mass spectrometry ideally should be used to provide confirmation of positive results.[16]

LICIT SUBSTANCES

Alcohol

Epidemiology

Since 1981, official advisories have warned against the use of alcohol by pregnant women or women considering pregnancy.[20] Yet, the 2015 National Survey on Drug Use and Health noted that 9.3% of pregnant women 15 to 44 years of age reported past-month alcohol use, 4.6% reported binge drinking, and 0.8% reported heavy drinking.[2] Not all of these women have alcohol use disorder or are drinking alcohol recklessly. Some may not be aware that they are pregnant, or

TABLE 53.1 Drug Detection: Overview

Specimen	Advantages	Limitations
Urine	Detection of diverse group of illicit substances (except volatile alcohols) Specimen and test readily available Short turnaround time (30 min at point of care; 2 h for laboratory specimens) More sensitive test (compared with meconium and hair) for cannabis	Underrepresents most illicit drug use Significant false-positive rate for phencyclidine (PCP) Narrow detection window compared with that for meconium and hair Specimen can more easily be adulterated
Blood	Most commonly used for volatile alcohols (can detect other illicit substances) Specimen and test readily available	Invasive Narrow detection window compared with that for urine, meconium, and hair
Meconium	Highly sensitive (compared with urine testing) for cocaine and opioids Wide detection window No false-positive results for cocaine Noninvasive	Report may be delayed (days) Low sensitivity and specificity for detecting cannabinoids, heroin, and amphetamines via immunoassay
Hair	Highly sensitive test for detecting cocaine (three times that of urine) and opioids Wide detection window (reflects chronic cumulative use) Samples can be stored at room temperature Samples can be analyzed remote from collection	Multiple hairs required; harvested close to scalp Environmental contamination may cause false-positive result Low sensitivity for detecting tetrahydrocannabinol and alcohol
Umbilical cord blood	Comparable to meconium with more rapid results May reflect a wide window of detection Ability to detect codeine, morphine, 6-MAM (heroin metabolite), and meconin Noninvasive	Specimen not available before delivery Lower sensitivity to methadone, cocaine, and opiates compared with meconium
Oral fluid	Highly sensitive for methamphetamine and other basic drugs Easy, noninvasive Primarily detects parent compound	If mouth is dry, salivary stimulation may be associated with a decreased drug concentration in oral fluid

6-MAM, 6-monoacetylmorphine.
Data from references 14,15,17,130,209–213

TABLE 53.2 Drug Detection Window in Urine[a]

Drug[b]	Analyte	Detection Window
Tobacco	Cotinine	19 h (urine $T_{1/2}$)
	Nicotine	2 h (urine $T_{1/2}$)
Cocaine	Cocaine	3–6 h
	Benzoylecgonine	IV use: 1–2 days Intranasal use: 2–3 days
Amphetamines	Amphetamine	1–3 days
	Methamphetamine	Smoked: 60 h
Methylenedioxymethamphetamine (MDMA, ecstasy)	MDMA	1–3 days
Marijuana (cannabis)	Tetrahydrocannabinol (THC)	Smoked: 10 h
	THCCOOH	Up to 25 days
Lysergic acid diethylamide (LSD)	LSD	24 h
	2-Oxo-3-OH-LSD	96 h
Heroin	6-monoacetyl morphine	IV use: 2–4.5 h
	Morphine	19–54 h
Prescription opioids	Oxycodone	2–4 days
	Fentanyl	24–72 h
	Hydrocodone	2–4 days
Benzodiazepines	Flunitrazepam: 7-aminoflunitrazepam	< 72 h Chronic use: 4–6 wk
γ-Hydroxybutyric acid (GHB)	Rapidly metabolized to CO_2 and H_2O	< 12 h

IV, Intravenously; $T_{1/2}$, half-life.
[a]Average values based on recent use; precise values may vary according to method of ingestion, assay employed, and duration of use.
[b]Detection of methadone, buprenorphine, oxycodone, and oxymorphone typically requires an additional screening test. Data from references 4,19,75,100,214

may not be knowledgeable of the ill effects on their pregnancy.

Pharmacology

Alcohol is absorbed through the gastrointestinal tract, primarily within the small intestine, and is then metabolized by alcohol and acetaldehyde dehydrogenases.[21–23] This process leads to the production of acetaldehyde and the reduction of nicotinamide adenine dinucleotide (NAD^+) to NADH. The intracellular accumulation of NADH relative to NAD^+ results in metabolic derangements, including the inhibition of fatty acid oxidation, resulting in a fatty liver and the inhibition of gluconeogenesis, leading to hypoglycemia or lactic acidosis. A small residual amount (2% to 8%) of alcohol is excreted via the lungs, urine, and sweat.

Systemic Effects

Legally defined "intoxication" implies a blood alcohol level of at least 80 to 100 mg/dL, although behavioral, cognitive, and psychomotor changes can occur at levels of 20 to 30 mg/dL (e.g., after one to two drinks)[21–23] (Table 53.3).

Alcohol has complex effects on the central nervous system (CNS); it acts as both a depressant and a stimulant through a variety of neurotransmitter pathways.[23] Consuming alcohol in conjunction with barbiturates or benzodiazepines compounds these effects. Endogenous opioids interact with alcohol to "reinforce" further alcohol use; this effect is blunted by opioid antagonists such as naltrexone, which can be used in the treatment of alcohol use disorder.

Alcohol and its metabolites (e.g., acetaldehyde) can be directly toxic to brain tissue.[21,22] Chronic alcoholism is associated with brain atrophy that results in impairment of memory, abstract problem-solving, verbal learning, and visual-spatial processing. Additional adverse neurologic effects result from vitamin (e.g., thiamine, vitamin B_{12}) deficiencies.

Heavy alcohol consumption can result in hepatic cirrhosis, which, in turn, can lead to encephalopathy, coagulopathy, and esophageal varices (Table 53.4). Gastrointestinal mucosa injury, pancreatitis, and cardiomyopathy may also occur.[7,8,22,24] In a retrospective cohort study of the Nationwide Inpatient Sample database, women with a diagnosis of alcohol use disorder undergoing cesarean delivery were twice as likely as women without alcohol use disorders to develop a hospital-acquired infection, including urinary tract infection or sepsis.[25] The underlying pathophysiology was not reported but could involve an immunocompromised state in chronic alcohol users.

Symptoms of acute alcohol withdrawal (e.g., nausea, vomiting, tachycardia, hypertension, arrhythmias, tremor, hallucinations, agitation, seizures) usually occur within 6 to 48 hours after cessation of chronic consumption (Table 53.5).[7,8] Pharmacologic therapy to minimize the signs and symptoms of alcohol withdrawal includes the use of benzodiazepines and alpha$_2$-adrenergic receptor agonists (e.g., clonidine).[7] Dexmedetomidine, a potent alpha$_2$-adrenergic receptor agonist, has also been investigated as an adjunct therapy.[26] The most severe form of withdrawal symptoms, **delirium tremens,** manifests as agitation, disorientation, hallucinations, and fever combined with autonomic instability. Delirium tremens, though rare in pregnant women, can lead to maternal and fetal death if untreated.[7]

Effects on Pregnancy and the Fetus

Intrauterine alcohol exposure is the leading cause of preventable birth defects in the United States.[27,28] No safe level of alcohol consumption by pregnant women has been identified as studies investigating minimal to moderate prenatal alcohol exposure during pregnancy have been limited by confounding variables.[29,30] According to the National Organization on Fetal Alcohol Syndrome, *fetal alcohol spectrum disorders (FASD)* is the "umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy. These effects include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications."[31] Fetal alcohol syndrome (FAS) refers to a clinical diagnosis and is based on the presence of particular neonatal facial features (e.g., small palpebral fissures, flat mid-face with a short upturned nose, thin upper lip) and significant impairment in neurodevelopment and physical growth.[27,32] A recent meta-analysis identified a range of complications that occur with a high prevalence in children affected by FAS including disorders of conduct and language disorder, chronic serous otitis media, and peripheral nerve abnormalities.[33] Education and screening for prenatal alcohol exposure can facilitate treatment and improve pregnancy outcomes by encouraging cessation of alcohol consumption as soon as pregnancy is recognized.

Anesthetic Management

Alcohol-intoxicated parturients are at increased risk for behavioral problems, electrolyte abnormalities, greater gastric acid secretion, and co-intoxication with other substances.[7,8] Determining whether the patient can protect her airway is of paramount importance because acute intoxication increases the risk for pulmonary aspiration of gastric contents. In addition, these patients may have intravascular volume depletion secondary to vomiting, inadequate oral intake, diuresis, and hypoalbuminemia. Significant alcohol ingestion in the setting of poor oral intake may also manifest as severe hypoglycemia.[22,24,34]

Neuraxial analgesia or anesthesia can be safely administered for labor or cesarean delivery in patients with alcohol use disorders provided that (1) the patient is cooperative, (2) there is no evidence of coagulopathy (as a result of liver disease), (3) the patient is volume replete, and (4) baseline neurologic deficits (e.g., peripheral neuropathy, cognitive deficits) are assessed and documented.[7]

If emergency delivery is required and the patient is either uncooperative or too sedated to protect her airway, general anesthesia will be necessary. The patient should receive pharmacologic aspiration prophylaxis (e.g., nonparticulate antacid, histamine-2 (H_2)-receptor antagonist, metoclopramide) and should undergo a rapid-sequence induction of general anesthesia.[35]

TABLE 53.3 Acute Intoxication and Organ Dysfunction

Substance	Neurologic	Cardiovascular	Pulmonary	Gastrointestinal	Hematologic	Other

Evidence from published reports is inconclusive about predictable differences in anesthetic requirements in patients with acute and chronic alcohol use.[36] Acute alcohol intoxication is believed to decrease anesthetic requirement, in part because of the additive effect of alcohol and other CNS depressants. The notion that chronic alcoholics require more anesthesia than their non–alcohol-using counterparts is based primarily on data from an abstract published by Han in 1969,[37] who demonstrated that the mean minimum alveolar concentration (MAC) for halothane in six chronic, nonpregnant, heavy alcohol users was significantly greater than that for six healthy adults. Subsequently, Swerdlow et al.[38] assessed the response to thiopental in 11 nonpregnant, chronic alcohol users. After eliminating potential confounders such as acute intoxication, withdrawal, polysubstance use, and end-organ dysfunction, they found that chronic alcohol intake did not

TABLE 53.5 Symptoms of and Treatment for Substance Use Withdrawal

Substance	Symptoms	Therapy
Alcohol (ethanol)	Nausea Vomiting Tachycardia Hypertension Tremor Hallucinations Agitation	Benzodiazepines and alpha$_2$-adrenergic agonist (e.g., clonidine)
	Delirium tremens: Autonomic instability/arrhythmias Seizures Severe tremors Disorientation Fever	Benzodiazepines and alpha$_2$-adrenergic receptor agonists (e.g., clonidine) Antiarrhythmics Anticonvulsants (e.g., phenytoin)
Tobacco	Cravings Irritability Headache Cough Insomnia	Nicotine replacement therapies, including patch, gum, and inhalers
Caffeine	Headache Anxiety Depressed mood Fatigue	Supportive care Caffeine ingestion
Cannabis	Mild abstinence syndrome Headache Restlessness Tremor Anxiety Autonomic effects	Supportive care
Cocaine	Prolonged sleep phase Hunger Anxiety Weakness Headache Tremors and seizures	Supportive care Reintroduction of drug, if necessary, with slow taper
Amphetamines	Fatigue Depression Hunger Intense cravings	Tricyclic antidepressants, dopaminergic agents (e.g., bromocriptine), and amino acid therapy (no therapy has proved to be successful)
Hallucinogens (e.g., phencyclidine [PCP], lysergic acid diethylamide [LSD])	No clearly associated withdrawal symptoms, although psychological dependence can occur	Not applicable
Opioids (e.g., heroin)	Flu-like symptoms, such as fatigue, weakness, restlessness, rhinorrhea, perspiration, fever, diarrhea	Supportive therapy Alpha$_2$-adrenergic agonists (e.g., clonidine) Doxepin Reintroduction of drug, if necessary, with slow taper
Volatile substances (e.g., ethylene glycol, toluene, glue)	Not applicable	Not applicable

alter thiopental dose requirements, pharmacokinetics, or pharmacodynamics. No large population studies have assessed dose requirements for volatile anesthetic agents or hypnotic agents in patients who chronically use alcohol.

Short-term consumption of alcohol inhibits the metabolism of drugs by the liver (through competition for cytochrome P450), which results in higher plasma concentrations of hepatically metabolized drugs. *Long-term* consumption of alcohol increases the activity of cytochrome P450, resulting in decreased levels of medications such as diazepam and labetalol, and increased levels of toxic metabolites that occur from hepatic degradation of illicit drugs such as cocaine.[22] Both pregnancy and liver disease can lead to decreased plasma concentrations of pseudocholinesterase; however, this does not seem to have a clinically significant effect on the degradation of succinylcholine or ester local anesthetics.[36]

Pregnant women who regularly consume large amounts of alcohol and undergo general anesthesia for cesarean delivery

may be at high risk for awareness under anesthesia.[39] The high doses of volatile anesthetics often recommended in nonpregnant, chronic alcohol-using patients can lead to significant uterine atony and potential increased blood loss. Therefore, a balanced anesthetic technique that combines induction with generous doses of a hypnotic agent with succinylcholine, followed by maintenance with a volatile anesthetic agent (limited to 0.5 to 0.8 MAC after delivery to prevent uterine atony), nitrous oxide, and an opioid and a benzodiazepine (for analgesia and amnesia), should be considered. Withholding additional muscle relaxation after induction and adding a brain function monitor if time and circumstance permit may help identify patients who could benefit from additional anesthesia.[40]

Caffeine

Epidemiology

On a daily basis, 80% to 98% of women drink caffeine-containing beverages.[7,41] The prevalence of consumption of caffeine-containing beverages during pregnancy is unknown.

Pharmacology

Caffeine (1,3,7-trimethylxanthine) is a naturally occurring alkaloid found in coffee, tea, cocoa, and some soft drinks and medicines.[41,42] The primary sources of caffeine in the adult diet are coffee (56 to 100 mg/100 mL if brewed) and tea (20 to 73 mg/100 mL). Caffeine is readily absorbed through the gastrointestinal tract with maximum blood concentrations 1 to 1.5 hours after ingestion. Caffeine undergoes hepatic metabolism and is then excreted in the urine.[41,42] In pregnancy, the half-life increases from 4 hours in the first trimester to 11.5 to 18 hours by the third trimester.[43] Caffeine crosses the placenta and can also be found in breast milk. The half-life in the neonate is prolonged compared with that in children and in nonpregnant women. Habitual use of caffeine at levels greater than 500 to 600 mg/day is defined in some studies as abuse.[44,45]

Systemic Effects

Caffeine acts as an antagonist at the adenosine receptor. In the absence of the inhibitory effects of adenosine, the neurotransmitters norepinephrine, dopamine, and serotonin are released in increased concentrations.[41,46] Systemic effects of caffeine include CNS stimulation, changes in blood pressure and metabolic rate, and diuresis (see Table 53.3).[42] The side effects attributed to caffeine vary among individuals, in part related to the doses ingested and the chronicity of use. Studies of the effects of caffeine on alertness, vigilance, mood, and memory have produced inconsistent results.[41]

Moderate caffeine intake (less than or equal to 400 mg/day or less than or equal to 4 cups of coffee/day) does not seem to negatively affect cardiovascular health in most people. Although some people who ingest caffeine report tachycardia and palpitations, doses lower than 450 mg/day do not appear to increase significant cardiac arrhythmias in healthy patients or those with ischemia or ventricular ectopy. Caffeine doses as low as 250 mg have been reported to have a hypertensive effect after acute ingestion (an increase in systolic blood pressure of 5 to 15 mm Hg and an increase in diastolic blood pressure of 5 to 10 mm Hg), particularly in caffeine-naïve individuals; however, epidemiologic studies have produced inconsistent results. Caffeine appears to affect bladder function in women. Moderate caffeine intake may exacerbate preexisting bladder symptoms, and excessive intake (greater than 400 mg/day) increases the risk for bladder dysfunction.[41]

Evidence suggests that caffeine is not a human carcinogen.[42] The lethal dose of caffeine in humans has been estimated to be 10 g; however, only a few such cases have been reported.[41]

Caffeine withdrawal is associated with headache, anxiety, depressed mood, and fatigue (see Table 53.5). Typically, symptoms begin 12 to 24 hours after cessation of use, peak at 20 to 48 hours, and last up to 7 days. The severity and likelihood of symptoms are not predictable.[41]

Effects on Pregnancy and the Fetus

Caffeine readily crosses the placenta. Whereas animal studies have shown a teratogenic effect with very high doses, moderate doses do not appear to result in teratogenesis in humans.[41,44,47] There is some evidence that caffeine at doses greater than 300 mg/day may result in fetal growth restriction and decreased birth weight, particularly in women who also smoke or drink significant amounts of alcohol,[41] although previous studies have not shown an association between low or moderate caffeine intake (less than 300 mg/day) and greater risk for spontaneous abortion or preterm delivery.[44] Weng et al.[48] found that caffeine consumption greater than 200 mg/day was associated with an increased risk for miscarriage, particularly among pregnant women who did not have a previous history of miscarriage.

Moderate first-trimester caffeine intake was found to have either no significant effect or to have a protective effect on the development of maternal gestational diabetes mellitus, depending on the population studied.[45] Moderate intake of caffeine in lactating women does not adversely affect postnatal development.[41,42]

Anesthetic Management

Caffeine may enhance the side effects of beta-adrenergic receptor agonists such as epinephrine and albuterol. Caffeine may also increase the risk for a hypertensive crisis in patients taking monoamine oxidase inhibitors (MAOIs). Chronic caffeine use causes an increase in CYP1A2 activity, which can have potential effects on medications degraded by this enzyme. The elimination of theophylline and acetaminophen can be slowed by habitual caffeine consumption, resulting in higher serum drug concentrations. In contrast, serum concentrations of lithium may be decreased secondary to caffeine-enhanced elimination.[42]

Perhaps of greatest significance to the anesthesia provider is the potential for **caffeine withdrawal headache** when caffeine intake is abruptly stopped during labor and delivery. Caffeine withdrawal should be considered in a postpartum

patient with a nonspecific, nonpositional headache without associated lateralizing neurologic findings (see Chapter 30). Evidence for the efficacy of caffeine in the treatment of post–dural puncture headache is scant (see Chapter 30).[49]

Tobacco

Epidemiology

As public awareness has grown regarding the hazards of smoking during pregnancy, the prevalence of cigarette smoking during pregnancy has declined; an estimated 18% of pregnant women reported smoking (in the past month) in 2003,[50] compared with 13.6% in 2015.[2] The percentage of young pregnant and nonpregnant female smokers 18 to 25 years of age was equivalent (23%), but fewer older pregnant women (26 to 44 years of age) reported smoking than nonpregnant women of the same age range (8.1% versus 23.3%).[2] Among the approximately 40% of patients who stop smoking when they discover that they are pregnant, 60% to 80% return to smoking by 6 months postpartum.[51]

Pharmacology

More than 4000 chemicals are found in tobacco, including nicotine, carbon monoxide, and cyanides.[23] Tobacco is most often smoked, but it can also be chewed or sniffed. Nicotine, the principal component of tobacco, acts at peripheral and central nicotinic (acetylcholine) receptors throughout the body to affect the release of catecholamines. Nicotine's effects begin immediately on exposure, and the half-life is typically a few hours; it is then rapidly metabolized in the liver and the lungs and excreted by the kidneys. Nicotine's acute effects are of shorter duration in heavy smokers than in light smokers.

Carbon monoxide, another key component, interferes with oxygen delivery to the cells by competitively binding to hemoglobin, decreasing the latter's oxygen-binding capacity and shifting the oxyhemoglobin dissociation curve to the left.[52] Depending on the extent of smoke inhalation, carbon monoxide may occupy 3% to 15% (or more) of the oxygen-carrying capacity of the blood.[53]

Systemic Effects

Smoking alters maternal physiology through tobacco's acute pharmacologic action and its contribution to comorbid disease. Peripherally, nicotine increases sympathetic tone, thereby increasing maternal heart rate, blood pressure, and cardiac work (see Table 53.3).[54] Nicotine affects neurotransmitter release in different areas of the brain, producing feelings of alertness, euphoria, and, ultimately, dependence.[23,54]

Increased production of carboxyhemoglobin is thought to be a major factor in the impaired wound healing observed in smokers.[52] Smoking also promotes atherosclerosis. The pulmonary effects of tobacco smoking include changes in the increased volume of mucus, impaired mucociliary clearance, and an increased incidence of bronchitis and chronic obstructive pulmonary disease (see Table 53.4).[54]

Tobacco is addictive, and cessation of its use produces withdrawal symptoms of cravings, irritability, headache, cough, and insomnia (see Table 53.5). Smoking cessation interventions include counseling and therapy, hypnosis, acupuncture, and pharmacologic therapy. There is insufficient evidence to recommend nicotine replacement therapy (e.g., nicotine patch) in pregnancy[55]; the American College of Obstetricians and Gynecologists (ACOG) recommends that it be used only when nonpharmacologic interventions have failed.[50]

Effects on Pregnancy and the Fetus

Nicotine has a low molecular weight and readily crosses the placenta, eventually yielding higher fetal than maternal nicotine concentrations.[3] Smoking may result in decreased fetal oxygenation as a result of increased concentrations of carboxyhemoglobin and reduced uteroplacental perfusion. This compromised state can lead to decreased uptake of nourishing amino acids by the placenta.[56] Smoking also adversely affects fetal growth.[56–58] Salihu et al.[58] documented that infant mortality was 40% higher in the offspring of women who smoked than in the offspring of nonsmoking women; this risk increased in a dose-dependent fashion for infants that were small for gestational age (SGA). In a more recent study, smoking cessation in early pregnancy was associated with a greater reduction in risk for fetal growth restriction compared with cessation later in pregnancy.[59]

Smoking is also associated with higher incidences of spontaneous fetal loss, preterm labor, placental abruption, and sudden infant death syndrome (SIDS).[50,55,60,61] Paradoxically, smoking has been associated with a reduced risk for preeclampsia, although this may be related to the higher rates of early pregnancy loss among pregnant smokers (see Chapter 35).[62,63]

Although the negative impact of fetal tobacco exposure on growth appears to resolve by 2 years of age,[64] there may be other long-term effects. A growing number of studies indicate that prenatal smoking exposure may be associated with an increased risk for attention deficit/hyperactivity disorder, although it is not clear whether the relationship is causal. Holz et al.[65] examined offspring exposed to prenatal smoking using functional magnetic resonance imaging in a prospective 25-year study. After controlling for confounders, including adversity and sex, prenatal smoking exposure appeared to have long-term effects on neural activity and development. A recent study by Quinn et al.[66] suggested this association may be caused by confounding effects of other lifestyle and genetic issues; when cousins and siblings discordant on prenatal smoking and severe mental illness were compared, there was no increased risk for severe mental illness in the smoking-exposed newborns.

Anesthetic Management

Smoking is a risk factor for several perioperative complications, including respiratory sequelae and impaired wound healing.[52,54] Smoking results in increased airway secretions, decreased ciliary motility, and impaired gas exchange.[54] Smoking is also associated with an increase in nonspecific airway reactivity, and tracheal intubation may provoke

bronchospasm. Smokers may be more likely to cough following emergence from general anesthesia, but the data are mixed and may be related to the specific volatile agent used.[67,68]

The physiologic benefits of smoking cessation are progressive. Even brief smoke-free intervals can result in a reduction in the carboxyhemoglobin concentration, some improved ciliary function, and decreased small airway obstruction.[69] However, 6 months of abstinence may be required before the function of alveolar macrophages and pulmonary cytokines during and after general anesthesia in former smokers is similar to that of nonsmokers.[69] Neuraxial anesthesia avoids airway manipulation and is typically preferred in parturients who smoke.

ILLICIT SUBSTANCES AND MISUSE OF MEDICATIONS

Amphetamines and "Club" Drugs

Amphetamines have historically been prescribed as components of nasal decongestants, bronchodilators, weight-loss drugs, and therapies for narcolepsy and attention deficit/hyperactivity disorder.[70] However, because of their high potential for misuse, amphetamines have been categorized by the U.S. Drug Enforcement Agency (DEA) as Schedule II stimulants since 1971.[71] MDMA (3,4-methylenedioxymethamphetamine) ("ecstasy") and methamphetamine are thought to be the most widely misused amphetamines.[71]

Epidemiology

Though the prevalence of MDMA in pregnant women is unknown, 5.7% of women 12 years of age and older reported past-year use of MDMA in 2015.[2] Polydrug use in women who use methamphetamine and MDMA appears to be common.[71,72]

Pharmacology

Amphetamines (and related compounds) are amines that exist as either salts of various acids or free bases. Used illicitly, they can be ingested orally, inhaled, or, less commonly, injected, resulting in significant CNS penetration.[23] The plasma half-life ranges from 5 to 30 hours. Metabolism is variable; up to 30% of the parent compound can be found in the urine. Detection of these compounds and their metabolites in the urine is possible up to several days after ingestion.[4]

Methamphetamine ("speed" or "crystal meth") is a congener of amphetamine that contains a methyl radical.[71] This white, odorless, bitter-tasting powder can be smoked, snorted, ingested orally, or administered rectally.[72] The availability of this compound is facilitated by its production in low-cost home laboratories. Methamphetamine is more potent than amphetamine and has a longer half-life; 50% of the drug is cleared in 12 hours. When it is smoked or injected intravenously, the "flash" from this drug is intense and of short duration. Snorting produces euphoria within 5 minutes, and oral ingestion does so within 20 minutes.[70]

MDMA has grown in popularity, particularly among young women.[73] MDMA has a methylenedioxy group attached to the aromatic ring of the amphetamine molecule that confers some of its hallucinogenic effects (see later).[74] The effects of MDMA typically begin approximately 20 minutes after ingestion and last approximately 6 hours; large doses have effects for up to 2 days. MDMA is metabolized by the liver and excreted by the kidneys.[4]

The "club" drug, γ-hydroxybutyric acid (GHB), also known as liquid ecstasy or liquid X, is derived from gamma-aminobutyric acid (GABA), which readily enters the brain when ingested, producing hallucinogenic, anxiolytic, euphoric, and sedative effects.[75] Severe cardiorespiratory depression, coma, and seizures can occur at high doses. Overdose is common, owing in part to the variable individual responses to the drug.[75,76] Chronic use may be associated with a downregulation of GABA receptors, and withdrawal manifests as insomnia, tachycardia, hypertension, and nausea/vomiting.[75]

The newest designer drug of the phenethylamine class is 3,4-methylenedioxypyrovalerone (MDPV), also known as "bath salts." Typically sold in crystal or powder form that can be snorted, smoked, or injected, this substance acts as a norepinephrine and dopamine reuptake inhibitor.[77] It is not detected by common drug screening tests. Adverse effects resemble those of amphetamines (e.g., agitation, hypertension, and tachycardia), and dependence and withdrawal can occur.[78] In rare instances, it can cause severe hyperthermia or hyponatremia. Until recently, bath salts could be purchased legally online, at some convenience stores, or in "head shops," but its active ingredients were banned by the Drug Enforcement Administration (DEA) after several deaths were reported.[79]

Systemic Effects

Acute amphetamine ingestion leads to indirect sympathetic activation through the release of norepinephrine, dopamine, and serotonin from adrenergic nerve terminals (see Table 53.3).[4,80] The physiologic effects of amphetamines are similar to those of cocaine and other stimulants, with two important differences: (1) amphetamines and their derivatives lack local anesthetic properties, and (2) amphetamine can inhibit monoamine oxidase activity, leading to decreased degradation of catecholamines.[4] Amphetamine-induced seizures can masquerade as eclampsia.[81]

Long-term use of high doses of amphetamines can have a number of adverse maternal effects, including damage to the cardiovascular and neurologic systems, and behavioral changes such as hostility, violence, hallucinations, and paranoid psychosis (see Table 53.4).[72] Methamphetamine has a much longer duration of action than cocaine, because a smaller fraction of the former drug is metabolized.[70]

The **cardiovascular** effects of amphetamines and their derivatives are similar to those of cocaine[4]: vasoconstriction, tachycardia, and labile blood pressure.[24] Patients are typically hypertensive, although catecholamine depletion can result in hypotension. Arrhythmias, myocardial ischemia, endothelial

damage, and acceleration of atherosclerosis can also occur. Recommendations for the management of cardiovascular complications associated with amphetamines and cocaine are similar, including resuscitation using intravenous fluids or judicious use of phenylephrine for hypotension. If pharmacotherapy is needed to treat hypertension, then labetalol, an alpha- and beta-adrenergic receptor antagonist, may be preferred over a pure beta-adrenergic receptor antagonist. Direct vasodilators (e.g., nitrates or hydralazine) can be used but may exacerbate tachycardia.[4] Acute amphetamine or cocaine intoxication can mimic the signs and symptoms of severe preeclampsia or eclampsia with its associated hypertension, severe headache, and even seizures. Factors such as labile blood pressure and a positive toxicology screen should raise the index of suspicion for ingestion of amphetamines or cocaine.

The pleasurable effects of methamphetamine and the deleterious **neurologic** sequelae are believed to be the result of high levels of dopamine in the brain. In addition to positive feelings, patients who have taken methamphetamine may experience anxiety, mood disturbances, paranoia, and hallucinations. Severe intracranial hypertension[5] and hemorrhagic stroke[82] have been reported in the setting of acute use. Chronic use has been associated with impairment of motor function and verbal learning as well as with significant changes in the areas of the brain associated with memory and emotion (see Table 53.4).[70] Volkow et al.[83] observed that prolonged abstinence (12 to 17 months) resulted in significant recovery of brain dopamine transporters, although performance on neuropsychological tests did not improve to the same extent. In addition, psychotic features of long-time amphetamine use may be precipitated by stress in former users after months or even years of abstinence.[70]

MDMA use has been associated with numerous adverse effects, including hyperthermia, hyponatremia, and seizures.[10] Healthy volunteers given MDMA in experimental settings have demonstrated central nervous system effects that include enhanced mood, heightened awareness, and also a dose-dependent moderate increase in blood pressure.[84,85] Recreational MDMA use has also been associated with neurohormonal changes, including increased cortisol and oxytocin.[86]

Psychostimulant withdrawal causes fatigue, depression, hunger, and intense cravings (see Table 53.5). Pharmacologic therapy for stimulant withdrawal (e.g., tricyclic antidepressants, dopaminergic agents [e.g., bromocriptine], amino acid replacement therapy) has not been particularly successful.[87] In the setting of methamphetamine overdose, the ensuing seizures, severe hypertension, and hyperthermia can be fatal. Treatment goals include provision of a calm environment (with or without a benzodiazepine) and airway protection. Active cooling, antihypertensive agents, and anticonvulsants should be used as needed.[74,87]

Effects on Pregnancy and the Fetus

Ingestion of amphetamines results in high levels of circulating catecholamines, which may lead to vasoconstriction and decreased uteroplacental blood flow. Animal studies have suggested that intrauterine exposure to methamphetamine is associated with an increased incidence of retinal defects, cleft palate, and rib malformations and a decreased overall rate of growth and motor development.[72,88] Results from a retrospective cohort study indicate that methamphetamine use in pregnant women was associated with an increased risk for gestational hypertension, preeclampsia, fetal death, abruption, preterm birth, neonatal death, and infant death.[89] The Infant Development, Environment and Lifestyle (IDEAL) prospective study revealed that children prenatally exposed to methamphetamine were at a higher risk for impaired executive function, attention deficit/hyperactivity disorder, and increased aggressive behavior, although early adversity is a likely confounding variable.[90–92]

Anesthetic Management

Amphetamines cause (indirect) sympathetic activation. Intoxicated patients are at risk for dangerous cardiovascular events, including hemodynamic instability and cardiac arrest. Recommendations for anesthetic management for patients with amphetamine and cocaine toxicity are similar.[4]

A cooperative patient may be a candidate for neuraxial analgesia or anesthesia, although refractory hypotension has been reported in a case of a long-time amphetamine user undergoing neuraxial anesthesia with intravenous propofol sedation.[93] The authors attributed the response to downregulation of beta-adrenergic receptors and catecholamine depletion. As with cocaine, phenylephrine may be a better choice for the treatment of hypotension than ephedrine; as an indirect-acting agent, ephedrine may either cause an exaggerated hemodynamic response if circulating catecholamines are high, or be ineffective if the amphetamine-intoxicated patient is catecholamine-depleted.

Parturients who are amphetamine users may be at increased risk for urgent cesarean delivery requiring general anesthesia. Evidence from animal studies suggests that acute ingestion of amphetamines increases the MAC for volatile halogenated anesthetic agents, whereas chronic ingestion of amphetamines decreases the MAC of volatile agents.[94,95] There is a well-recognized association between methamphetamine use and severe tooth decay (i.e., "meth mouth") which can present a significant hazard during laryngoscopy. The airway assessment should include attention to fragile or loose teeth that might be dislodged during laryngoscopy as well as to the possibility of burns throughout the airway. High doses of MDMA can cause rhabdomyolysis.[74]

Cocaine

Although the use of cocaine dates back to 600 AD,[96] cocaine was formally introduced into clinical practice as a local anesthetic in the 1880s. During this period, Sigmund Freud also experimented with cocaine's ability to combat hunger, fatigue, and opiate addiction.[96,97] Cocaine has both vasoconstrictive and local anesthetic properties as a result of its ability to block sodium channels during depolarization.

Epidemiology

The prevalence of cocaine use during pregnancy is difficult to estimate as 60% to 90% of pregnant cocaine users engage in polysubstance use, including tobacco.[98,99] Survey data in 2015 reported the prevalence of past-month cocaine use in pregnant women 15 to 44 years of age as 1 in 1000.[2]

Pharmacology

Cocaine (benzoylmethylecgonine) is an ester of benzoic acid and the base ecgonine, which is the parent compound of atropine and scopolamine.[97,100] When dissolved in hydrochloric acid to form a water-soluble powder (cocaine hydrochloride), cocaine can be chewed, administered intravenously ("mainlined"), or taken intranasally ("snorted"). Intrarectal and intravaginal use has also been reported.[101] When cocaine is processed with either sodium bicarbonate ("crack") or ammonia and ether ("free base"), the resulting cocaine alkaloid can be smoked.[97,100,102] The amount (dose) and duration of exposure are more important determinants of the cocaine effects than is the chemical formulation. Smoked cocaine ("crack" or free base) is rapidly absorbed through the lungs and reaches the brain in 6 to 8 seconds; intravenous cocaine reaches the brain in 12 to 16 seconds; and snorted cocaine reaches the brain in 3 to 5 minutes.[103] The typical half-life of cocaine is 30 to 90 minutes, although its effects can last as long as 6 hours.[97]

Cocaine is metabolized to ecgonine esters and benzoylecgonine (biologically inactive) by plasma and hepatic cholinesterases and to norcocaine (biologically active) by nonenzymatic hydrolysis. Only small amounts of cocaine are excreted unchanged in the urine. In the presence of alcohol, cocaine is transesterified to cocaethylene, which has a longer half-life and greater physiologic effects than cocaine.[102,103]

Systemic Effects

Cocaine has complex actions on the central and peripheral nervous systems and on nerve conduction. The powerful sympathomimetic effects of cocaine are caused by the drug's inhibition of the reuptake of norepinephrine, dopamine, and serotonin, which allows these neurotransmitters to accumulate at the synaptic clefts and produce sustained stimulation.[96,102,103] This process can result in as much as a fivefold increase in circulating concentrations of catecholamines,[4] which, in turn, may lead to feelings of euphoria, increased energy, and decreased fear.[96,103] Repetitive use of cocaine eventually leads to depletion of neurotransmitter stores, upregulation of receptors, and a higher dose requirement to achieve the desired euphoric effects.[97]

The peripheral nervous system effects of cocaine and its derivatives result from binding to tissue receptors involved in monoamine reuptake, which results in hypertension and/or labile blood pressure and tachycardia. Cocaine produces widespread small and large vessel occlusion through vasospasm, thrombosis, and endothelial injury, which may result in significant end-organ damage.[97]

Cocaine has profound effects on the **cardiovascular** system, and pregnancy appears to enhance them. Acute administration of cocaine increases peripheral vascular resistance, cardiac contractility, and myocardial oxygen demand (see Table 53.3).[97,104] Coronary vasoconstriction also occurs; a greater effect occurs in diseased vessel segments than in nondiseased segments.[102] Studies *in vitro* have indicated that cocaine can have a procoagulant effect in small and large vessels.[4] This may lead to thrombus formation and coronary plaque rupture in the setting of cocaine-induced hypertension.[97,105]

Cocaine-induced chest pain is a common complaint among young people presenting to the emergency department.[106] Mittleman et al.[105] found that cocaine use was associated with a significant, abrupt, and transient increase in the risk for acute myocardial infarction in patients who were otherwise at low risk.[107] The occurrence of cocaine-induced electrocardiographic changes is fairly common and is not necessarily associated with true ischemia.[102,108] If ischemia is suspected, treatment with supplemental oxygen, aspirin, vasodilators, with or without reperfusion therapy,[106] as well as measurement of troponin levels,[107] is indicated. Although cocaine users who suffer a myocardial infarction have fewer postinfarction sequelae than the general population, the incidence of major cardiovascular complications is not trivial; 5% to 7% have congestive heart failure, 4% to 17% have ventricular arrhythmias, and up to 2% die.[102]

Prompt recognition of acute cocaine-induced cardiovascular toxicity facilitates management. Not all cocaine-induced hypertension in pregnant women requires immediate intervention, but if pharmacotherapy is used, it is important to understand the potential undesired consequences. **Beta-adrenergic receptor blockade may result in unopposed alpha-adrenergic receptor–mediated vasoconstriction** that can lead to coronary artery vasoconstriction and myocardial failure. Labetalol, an alpha- and a beta-adrenergic receptor antagonist, may be preferred, although it does not ameliorate cocaine-induced coronary artery vasoconstriction. Direct vasodilators (e.g., nitrates, hydralazine) can be used but may cause further tachycardia.[4,102] Hydralazine treated the hypertension in cocaine-intoxicated pregnant ewes but did not restore uterine blood flow.[109] Calcium entry–blocking agents, such as nifedipine and nimodipine, have been found to potentiate the toxic effects of cocaine in animal models, although the mechanism has not been determined.[4,110,111] Sedatives (e.g., benzodiazepines) or magnesium sulfate may ameliorate cocaine's cardiovascular effects.[4,102]

Other acute cardiovascular effects of cocaine include QT prolongation, bradycardia, and arrhythmias, including supraventricular or ventricular tachycardia and ventricular fibrillation.[97] Severe bradycardia can be treated with atropine or electrical pacing. Stable supraventricular tachycardia (SVT) can be treated with vagal maneuvers or the use of adenosine. In the unstable patient with SVT, direct current (DC) cardioversion may be required.[112,113]

In a retrospective multicenter study, Shih et al.[114] found that the use of lidocaine in nonpregnant patients with cocaine-induced myocardial infarction was not associated with significant cardiovascular or CNS toxicity. Although

amiodarone therapy for maternal and fetal arrhythmias has been described as having only minor adverse effects in some patients, there are also reports of associated fetal hypothyroidism and fetal growth restriction.[112,115,116] Thus, amiodarone in pregnant women is reserved for malignant arrhythmias that are refractory to other therapies.

Long-time cocaine use can cause left ventricular hypertrophy or dilated cardiomyopathy with accompanying systolic dysfunction (see Table 53.4).[97,102] Aortic dissection has also been reported.[102] Intravenous use of cocaine and other injectable drugs increases the risk for development of infective endocarditis. Noncardiogenic pulmonary edema, pulmonary hypertension, and right-sided heart failure can also occur in the setting of cocaine use.[4,97]

The **neurologic** complications of cocaine may be transient or permanent. Morbidity and mortality may result from subarachnoid hemorrhage, intracerebral hemorrhage, cerebral vasculitis, and/or transient ischemic attacks.[6,82,117] Many cocaine-using patients in whom cerebral infarct(s) and hemorrhage developed had additional risk factors for stroke, including hypertension, alcohol use, or smoking. Cocaine-induced seizures, if self-limited, are typically treated with supportive care and benzodiazepines.[117]

Respiratory complications occur in 25% of cocaine users. Smoking cocaine can have profound respiratory effects, which include bronchospasm, chronic cough, and diffusion capacity abnormalities.[101,103] Cocaine-using parturients are at increased risk for peripartum wheezing.[6] Inhaled cocaine vapor can produce thermal airway burns. "Snorting" cocaine can lead to epistaxis, oral ulcers, and nasal septal injury. The intense pulmonary and bronchial arterial vasoconstriction produced by cocaine can cause interstitial and alveolar hemorrhage. Pneumothorax, pneumomediastinum, and pneumopericardium have also been reported.[97]

Cocaine ingestion can result in serious **gastrointestinal** complications, such as ischemia, ulceration, and perforation.[103] In addition, cocaine's anticholinergic effects include delayed gastric emptying and an increased risk for aspiration.[97] Although some cocaine users have abnormal liver enzyme levels, cocaine is not clearly hepatotoxic.[103]

Hematologic consequences of cocaine exposure during pregnancy may, on rare instances, include thrombocytopenia.[10,118,119] Cocaine-induced thrombocytopenia has a clinical course similar to that of idiopathic thrombocytopenic purpura, and is responsive to therapy with corticosteroids and, in one published case, splenectomy.[119] Whereas Kain et al.[118] found the rate of thrombocytopenia to be higher in the cocaine group than in the drug-free group (6.7% versus 1.5%, respectively), Gershon et al.[120] found that in pregnant women who tested positive for cocaine, only 2.5% had a platelet count lower than 140,000/mm^3, compared with 4.7% in the cocaine-negative group.

Renal failure can result from cocaine use secondary to rhabdomyolysis, renal infarction, or impaired immunologic function.[97] Cocaine-using patients have a higher prevalence of syphilis, human immunodeficiency virus (HIV) infection, and other **infectious diseases** compared with non–cocaine-using patients, even after controlling for intravenous drug use.[103,121] Studies of the **endocrine system** in gravid ewes have shown that cocaine exposure results in increases in maternal adrenocorticotropic hormone and cortisol as well as maternal and fetal plasma glucose and lactate.[122,123]

Cocaine also impairs cutaneous vasodilation and sweating. The lethal effects of cocaine are related, in part, to the drug's tendency to produce **hyperthermia,** particularly in hot weather.[124]

Cocaine use has been associated with **sudden death** from several of the factors discussed earlier, including cardiac arrhythmias, respiratory arrest, status epilepticus, and impaired thermoregulation.

Cocaine withdrawal can be difficult to recognize because of its nonspecific signs and symptoms: extreme fatigue followed by hunger, anxiety, weakness, headache, tremors, and seizures (see Table 53.5). Recommended therapy involves supportive care and reintroduction of the drug, if necessary, followed by a slow taper over days to weeks.[24]

Effects on Pregnancy and the Fetus

Pregnant women metabolize cocaine to norcocaine to a greater extent than their nonpregnant counterparts, exposing both mother and fetus to this more potent metabolite.[96,100] With its low molecular weight and high lipophilicity, it is mostly un-ionized at physiologic pH and readily crosses the placenta.[6,96]

Woods et al.[125] demonstrated that cocaine increases both heart rate and myocardial oxygen consumption and decreases cardiac output to a greater extent in gravid ewes than in nonpregnant ewes. Cocaine also increases maternal blood pressure and decreases uterine blood flow in gravid ewes.[126]

In a 2011 meta-analysis, Gouin et al.[127] found that cocaine use during pregnancy was associated with significantly higher risk for preterm birth. Obstetric complications associated with maternal cocaine use include a higher incidence of placental abruption and preterm labor; the latter occurs in 17% to 29% of women who use cocaine.[128] Acute cocaine toxicity can mimic preeclampsia or eclampsia when pregnant women present with hypertension, headache, blurred vision, and/or seizures but can be differentiated through a positive urine test result for cocaine, the presence of normal laboratory measurements, and rapid resolution of symptoms without delivery.[129] There is also an association between cocaine use and an increased risk for sexually transmitted diseases and failure to obtain prenatal care.[130]

The impact of maternal use of cocaine (particularly "crack") on the fetus has been the subject of intense legal, political, and scientific debate since the 1980s.[131] Initial animal data and retrospective human studies suggested an increased risk for major congenital anomalies (e.g., genitourinary and abdominal wall defects) in fetuses exposed to cocaine. However, these reports are confounded by concurrent use of other drugs and low statistical power.[132] Subsequent studies found no significant difference in type or number of congenital anomalies between infants with exposure to cocaine *in*

utero and infants without exposure, after accounting for confounding variables.[133,134]

Frank et al.[135] reviewed studies published between 1984 and 2000 to assess the possible relationships between maternal cocaine use during pregnancy and childhood outcome. After controlling for possible confounding factors, they found no consistent negative association with physical growth, developmental test scores, or the expressive or receptive language skills. They observed less optimal motor performance up to 7 months of age, after which the differences between cocaine-exposed and nonexposed infants disappeared.

Studies investigating trajectories of motor, mental, or behavioral development in infants with prenatal cocaine exposure have had conflicting results, in part related to confounding risk factors such as exposure to adverse postnatal environments.[136–138] In a 15-year follow-up study of adolescents prenatally exposed to cocaine, Richardson at al.[139] noted that exposure to violence partially mediated the impact on (self-reported) delinquent behaviors by the adolescents. In addition, the first-trimester exposed adolescents had poorer performance on tests related to problem solving and abstract thinking.

In terms of physical health measures, Bauer et al.[133] found that infectious complications, such as hepatitis, syphilis, and, to a lesser extent, HIV infection, were more common in infants of cocaine-abusing mothers.

Anesthetic Management

Cocaine-using patients are at risk for acute and chronic multiorgan system dysfunction[121] and the need for urgent cesarean delivery. During labor, early administration of neuraxial anesthesia should be encouraged if the patient is cooperative and has a platelet count above the threshold of concern for the anesthesia provider.[140] Neuraxial anesthesia can reduce levels of circulating catecholamines and mitigate some of the systemic effects of cocaine.[6] Also, an epidural catheter placed for labor analgesia can usually be utilized for a cesarean delivery anesthetic. Treatment of hypotension should include volume resuscitation, and, if needed, careful titration of a direct-acting vasopressor, such as phenylephrine.[10,141]

When an ester local anesthetic (or succinylcholine) is administered to a patient who has ingested cocaine, these medications may compete with cocaine for available plasma cholinesterase[6,100]; however, the clinical significance of these effects is not reported. Despite the theoretical risk for altered metabolism of succinylcholine, a standard intubating dose should be administered.[99] Changes in μ- and κ-opioid receptors and altered baseline endorphin levels may result in an increased perception of pain in cocaine-using patients despite the presence of an apparently satisfactory level of neuraxial anesthesia.[10] Ross et al.[142] observed a reduction in duration of intrathecal sufentanil analgesia during labor in cocaine-abusing women, although the quality of analgesia was not diminished.

Cocaine-using patients who receive general anesthesia are at greater risk for hypertension and tachycardia during and after laryngoscopy and tracheal intubation.[6,7] If general anesthesia is required, premedication with a benzodiazepine or an opioid may help attenuate the acute physiologic effects of cocaine. As the anticholinergic effects of cocaine can delay gastric emptying and may also increase the risk for aspiration, pharmacologic prophylaxis and a rapid-sequence induction of general anesthesia are indicated. Propofol may be well tolerated, whereas ketamine may potentiate the CNS vasoconstrictive effects of cocaine, potentially increasing the risk for cerebrovascular morbidity.[10] Both etomidate and cocaine can result in disinhibition of the CNS control of extrapyramidal activity, and their effects may be additive.[143] Dexmedetomidine, an alpha$_2$-adrenergic receptor agonist, has been shown in animal studies to delay the onset of cocaine-induced seizures and may be useful in selected patients.[144] Early studies in dogs demonstrated that acute cocaine ingestion can cause hyperthermia in both laboratory animals and humans[97,124]; therefore, core temperature should be monitored in cocaine-abusing patients. However, given the propensity for nasal septal defects in these patients, temperature probes (and other tubes and monitors) should *not* be inserted intranasally. Active warming should be used only if the patient is hypothermic.

Marijuana (Cannabis)

Marijuana is the most common illicit drug used in pregnancy, with 4.7% of pregnant women between 15 and 44 years of age reporting past-month marijuana use in 2015.[2] Although marijuana use is lower in the pregnant than in nonpregnant population (12.5%), the use in pregnancy is increasing. Contributing factors are thought to include the legalization of medical marijuana, the decriminalization of recreational marijuana, and the drug's antiemetic properties.

Pharmacology

Marijuana contains more than 400 compounds, including 60 cannabinoids. Most of the psychotropic effects are caused by 9-tetrahydrocannabinol (THC).[10,145] The THC content in marijuana has tripled since 1995.[146] Noncannabinoid constituents of marijuana are similar to those in tobacco without the nicotine. Inhaled THC is absorbed through the lungs and reaches the brain within minutes. Oral ingestion of marijuana results in blood THC concentrations that are 25% to 30% of those obtained by smoking, but with a delayed onset of up to 2 hours. The lipid-soluble cannabinoids are sequestered in fatty tissues and gradually released into other tissues. Thus, a single ingestion can have an elimination half-life of up to 7 days; complete elimination of the inactive metabolite 11-nor-9-carboxy-delta-9-tetrahydrocannabinol (THCCOOH) takes as long as 25 to 30 days. Metabolism occurs in the liver, with excretion in the urine. Measured concentrations of metabolites in the blood and urine correlate poorly with the degree of intoxication.[145] Synthetic cannabinoids feature the primary psychoactive component of cannabis and are not detected on routine urine assays for THC.[147]

Systemic Effects

Cannabis interacts with specific cannabinoid receptors in the brain and peripheral nerves. Psychoactive effects include

anxiolysis, analgesia, appetite stimulation, euphoria, and, sometimes, dysphoria (see Table 53.3).[145] Marijuana intoxication impairs cognitive and psychomotor function. Impairment of memory, attention, and the ability to process complex information can occur with long-time heavy use (see Table 53.4). It is unclear whether these effects are reversible.

Acute intoxication with marijuana appears to have a biphasic effect on the autonomic nervous system; low doses cause tachycardia and higher cardiac output caused by increased sympathetic and decreased parasympathetic tone. In contrast, high doses produce sympathetic inhibition and parasympathetic stimulation, resulting in bradycardia and hypotension.[4,10] Although ventricular ectopy can occur, life-threatening arrhythmias in patients without preexisting cardiac disease are rare, and autonomic disturbances are generally well tolerated. Reversible ST-segment and T-wave abnormalities may occur, perhaps as a result of the higher heart rate associated with marijuana use.[4] Synthetic cannabinoids produce more exaggerated physiologic effects. Although large studies are lacking, case reports indicate the dangers of its use. For example, two separate cases are reported of otherwise healthy women who developed ischemic stroke after first-time use.[148]

As with tobacco, the respiratory consequences of smoking marijuana include mucociliary dysfunction, increased susceptibility to bronchitis, and chronic obstructive pulmonary disease (see Table 53.4). Acute intoxication may cause conjunctival vasodilation and visible reddening of the eyes. Although high doses of marijuana can cause hallucinations and psychosis, fatal overdose has not been documented.[5,145]

Withdrawal from long-time marijuana use may produce a mild abstinence syndrome that includes headache, restlessness, tremor, anxiety, and autonomic effects, similar to those of withdrawal from benzodiazepines and hypnotic drugs (see Table 53.5).[4,149]

Effects on Pregnancy and the Fetus

It is difficult to ascertain specific effects of marijuana on pregnancy, because women who use marijuana often engage in polysubstance use. Although marijuana use is not associated with congenital abnormalities,[150] some studies have shown use in pregnancy to be associated with an increased risk for stillbirth, preterm birth, and neurobehavioral abnormalities.[151–153] However, a recent retrospective cohort study of 8138 pregnant women did not find marijuana use to be associated with poor neonatal outcomes, such as low birth weight or low Apgar scores, after adjusting for confounders.[154] Long-term associated effects in children include inattention and impulsivity, deficits in problem solving, academic underachievement, and a predisposition to smoking marijuana and tobacco.[155–157] There is no safe amount of marijuana recommended during pregnancy or lactation, and the ACOG discourages the use of marijuana during pregnancy and lactation.[158]

Anesthetic Management

Neuraxial analgesia is typically preferred during labor and delivery and can be safely performed in patients who use marijuana, in the absence of other contraindications. Drug-related changes in heart rate and blood pressure are usually well tolerated in otherwise healthy, acutely intoxicated patients. However, the administration of atropine, pancuronium, and ketamine can exacerbate existing tachycardia.[10]

Long-time marijuana smokers are at risk for similar respiratory complications during and after general anesthesia as tobacco smokers, specifically, increased airway secretions, impaired mucociliary clearance, and potentially increased airway reactivity.[54,145] Persistent postextubation laryngospasm in a patient with a history of heavy marijuana smoking has been reported.[159]

As acute intoxication with marijuana can have additive effects with those of sedative agents and volatile anesthetic agents, including myocardial depression,[10,24] careful titration to clinical effect is recommended. The effect of marijuana on pain perception has been explored in an experimental model of human pain. Wallace et al.[160] found that smoked marijuana had a differential effect on pain scores; a low dose had no effect, a medium dose reduced pain, and a high dose significantly increased pain. The clinical implications of these findings are unclear.

Hallucinogens

LSD (lysergic acid diethylamide), PCP (phencyclidine), psilocybin, ayahuasca, and mescaline are each hallucinogens.[87] As discussed earlier in the amphetamine section, 3,4-methylenedioxymethamphetamine (MDMA) also has hallucinogenic effects.

Epidemiology

Hallucinogen use in pregnancy is thought to be uncommon.[7,161] Survey data from 2015 reported a 0.1% prevalence of past month hallucinogen use in pregnant women compared with 0.5% in nonpregnant women ages 15-44.[2]

Pharmacology

The hallucinogens are a diverse group of drugs notable for their complex mechanism of actions that include agonist, partial agonist, and antagonist effects at serotonergic, dopaminergic, and adrenergic receptors. Overall, the adrenergic effects of these drugs are mild compared with those of cocaine and amphetamines.[4]

Both **psilocybin,** the hallucinogen in some wild mushrooms, and the synthetic compound **LSD,** are indole derivatives that chemically resemble serotonin.[4,87] When ingested orally, intranasally, intravenously, or rectally, or smoked, they evoke auditory, visual, and tactile hallucinations. Clinical effects usually develop over 15 to 60 minutes and last for 6 to 12 hours.[7,87] LSD is 100 times more potent than psilocybin and can be detected in urine or plasma for up to 3 days. LSD is metabolized by the liver and has a plasma half-life of 100 minutes.[4] The potency of individual samples of psilocybin varies with physiologic effects typically occurring at doses of 20 to 60 mg. Most of the drug is excreted in the first 8 hours, although small amounts are excreted for up to 1 week.[87] **Ayahuasca (DMT)** is a psychoactive brew used in ritual healing ceremonies and is composed primarily of two Amazonian

plants; the key ingredients are β-carboline and tryptamine derivatives.[162,163] Its potency and effects are greatly dependent on the relative concentrations of its constituents. **Phencyclidine,** initially developed as a general anesthetic agent, was removed from the legal market in 1978. **Ketamine,** a related compound, is an anesthetic agent that is also a drug of abuse. Both bind to the *N*-methyl-D-aspartate (NMDA) receptor. The psychological effects of PCP typically last 12 to 48 hours. Ketamine has a shorter duration of action than PCP.[87]

Unlike the phenylethylamines MDMA and GHB, which also have properties of amphetamines, mescaline is exclusively hallucinogenic. Found as the active ingredient in peyote cactus buttons, mescaline is typically eaten or drunk as a tea. The effects of mescaline, which last approximately 12 hours, include visual hallucinations, nausea, and vomiting.[87]

Systemic Effects

Ingestion of hallucinogens causes activation of the sympathetic nervous system, which results in hypertension, tachycardia, dilated pupils, and increased core body temperature (see Table 53.3).[7] The **cardiovascular effects** of these drugs are rarely serious, although some instances of supraventricular tachycardia and acute myocardial infarction have been reported. Myocardial infarction may result from vasospasm and increased platelet aggregation.[4]

Carotid artery occlusion has been reported after the use of LSD. PCP use has been associated with seizures, delayed hypertensive crisis, and intracerebral hemorrhage.[5] Overdose with PCP can be associated with confusion and combativeness, which may progress to seizures and catatonia.

Some users of LSD experience a "bad trip," which is likely to be a manifestation of an acute anxiety reaction. Other users report "flashbacks" or systemic effects of these drugs that occur months or even years after ingestion. Some of these episodes are likely a result of delayed release of small amounts of drug from fatty tissues. The use of LSD may unmask an underlying psychiatric disorder in vulnerable patients.[87]

The psychological effects of psilocybin include giddiness, visual hallucinations, and gastrointestinal dysfunction. Morbidity is associated primarily with inadvertent ingestion of toxic species of mushrooms.[87] Although psychological dependence on these drugs has been observed, no clearly associated withdrawal symptoms occur with abstinence (see Table 53.5).[7]

A direct causal relationship between use of these drugs and death has not been documented; however, hallucinogens can cause feelings of paranoia and panic that can lead to accidents or fatalities.[5,7]

Effects on Pregnancy and the Fetus

There is conflicting evidence as to whether intrauterine PCP exposure has deleterious fetal effects. Mvula et al.[164] found that PCP-positive women had smaller and more preterm infants compared with non–PCP-positive women. The PCP-positive women were also more likely to have syphilis and diabetes and to use tobacco, alcohol, and marijuana. Early reports of chromosomal damage secondary to LSD were not confirmed by later studies.[5] The effect of prenatal exposure of ayahuasca has led to active discussion in the literature without a definitive conclusion.[162,163]

Anesthetic Management

Management of a hallucinogen-intoxicated patient is primarily supportive and noninterventional.[4] Stressful situations can provoke panic attacks, which in turn can intensify the physiologic effects of these drugs. Specific recommendations include provision of a quiet, supportive environment and administration of a benzodiazepine if needed. Neuroleptic medications are relatively contraindicated as they can intensify toxic reactions.[4,7]

Hemodynamic perturbations are usually relatively mild and well tolerated.[10] Occasionally, patients experience supraventricular tachycardia, hypertension, and myocardial ischemia.[4] The acutely intoxicated patient may have an exaggerated response to ephedrine[7]; phenylephrine is preferable and should be titrated to effect. LSD may have some intrinsic anticholinesterase activity, but the clinical significance is unclear. Hallucinogens may also prolong opioid-induced analgesia and respiratory depression.[10]

Either neuraxial or general anesthesia can be administered for vaginal or cesarean delivery in the usual fashion, as the clinical situation warrants.

Opioids

Opioids refer to the class of naturally occurring and synthetic drugs that are structurally and functionally related to morphine. The term *opiate* specifically describes any of the narcotic alkaloids found in the juice of poppy plants, including morphine and codeine.[23]

Epidemiology

As in the general population, the frequency of opioid use disorders in pregnant women has increased dramatically; a large population-based study revealed a 127% increase in prevalence (from 0.17% in 1998 to 0.39% in 2011 in the 20 to 34 years age group) and an increased risk for in-hospital mortality (Fig. 53.1).[165] Historically, opioids were thought to be safe for pregnant women and were liberally prescribed for treatment of back and abdominal pain and headache.[166,167]

Pharmacology

The naturally occurring opioids are metabolized to morphine, which has a plasma half-life of 2 to 3 hours. Morphine then undergoes rapid metabolism in the liver and is excreted in the urine, where both active and inactive metabolites can be detected for up to 2 days in occasional users, and longer in chronic users.[4,23]

Heroin (**diacetylmorphine or diamorphine**) is a commonly used and highly addictive semisynthetic analogue of morphine that has no legal use in the United States. It can be smoked, snorted, or injected intravenously or intramuscularly. The speed of onset varies from less than 1 minute to 15 minutes, depending on the delivery method. The elimination half-life is typically 1 to 2 hours. Heroin is more lipid soluble

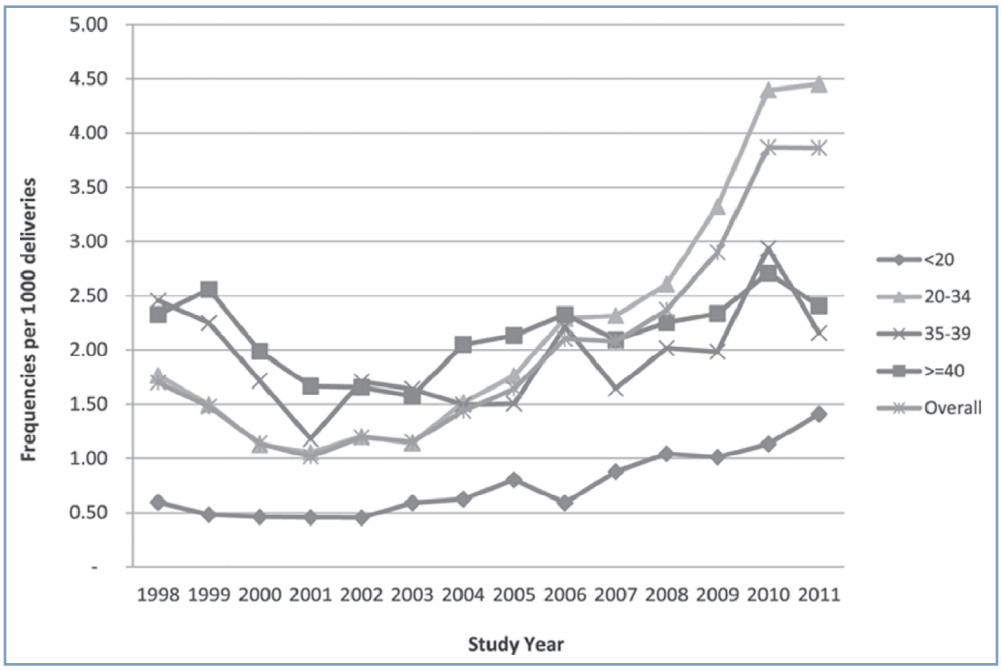

Fig. 53.1 Opioid abuse or dependence per 1000 deliveries, overall and by age: United States 1998 to 2011. (From Maeda A, Bateman BT, Clancy CR, et al. Opioid abuse and dependence during pregnancy: temporal trends and obstetrical outcomes. *Anesthesiology*. 2014;121:1158–1165.)

than other opioids and rapidly crosses the blood-brain barrier, resulting in significant and toxic CNS effects.[168] Heroin is metabolized by cytochrome P450 in the liver and excreted in the urine.[4,23,24,168] The concomitant use of drugs such as omeprazole or amitriptyline can inhibit clearance, while anticonvulsants may increase clearance.[169]

The formulation of street heroin has become increasingly pure. In 1990, a typical 100-mg bag of powder had up to 8% pure heroin mixed with inert, often toxic additives. The current heroin content is as high as 45% to 90%. Heroin is now often mixed with the semisynthetic opioids, fentanyl or carfentanil, which greatly increase its lethal overdose potential.

Rapidly acting semisynthetic opioids such as **oxycodone** and **hydrocodone** are prescribed legitimately and used illicitly. The oral bioavailability of oxycodone is higher than that of morphine, and its potency with oral ingestion is greater.[23]

Methadone is a synthetic compound that is structurally unrelated to the other opioids but has similar effects.[23] It is formulated as a racemic mixture of two enantiomers: R-methadone, which is a potent μ- and δ-opioid receptor agonist, and S-methadone, which is a noncompetitive NMDA antagonist that prevents the reuptake of 5-hydroxytryptamine and norepinephrine.[170] Available in powder form, methadone can be reconstituted for oral, rectal, or intravenous use.[171] Oral bioavailability of methadone is roughly three times that of morphine.[170,171] There is significant interindividual variability in its clinical effect and duration of action, with the peak effect occurring approximately 3 hours after oral ingestion, and its half-life varying from 15 to 40 hours.[23,24,170–172] Life-threatening complications can result from the cumulative effects of successive doses[170] or from prolongation of the cardiac QTc interval prompting the lethal arrhythmia, *torsades de pointes.*

Unlike morphine, methadone undergoes biotransformation (rather than conjugation) in the liver and is excreted primarily by the fecal route. Methadone has been used since the 1960s for medication-assisted therapy for patients suffering from opioid-use disorders and since the 1970s for this indication in pregnant patients. Methadone must be dispensed daily from a certified clinic, when used for medication-assisted therapy. Methadone is also used as an analgesic in patients with chronic pain.[170,172] Pregnancy is associated with greater methadone metabolism and reduced bioavailability because of greater maternal blood volume and changes in hepatic enzymatic activity and glomerular filtration rate.[23,172,173]

Buprenorphine (Subutex) is a semisynthetic opioid that acts as a partial μ-opioid receptor agonist (with low intrinsic opioid activity) and κ-opioid receptor antagonist that can also be used for medication-assisted therapy for patients suffering from opioid-use disorders.[174–176] **Suboxone,** one of the two sublingual formulations of this drug, contains naloxone, which is biochemically active only if the user attempts to snort, inject, or cook the drug.[175] Buprenorphine binding to the μ-opioid receptor is up to 1000 times greater than that of morphine, with a slow dissociation half-life of approximately 166 minutes.[175] Primary metabolism of buprenorphine occurs in the liver with excretion in the bile.[177] Like methadone, buprenorphine can prolong the QTc interval. Buprenorphine has a ceiling effect at 24 to 32 mg, which decreases the risk for respiratory depression.[175,178] Burprenorphine is prescribed by physicians who have taken an 8-hour training course to become a certified provider. These courses

are available from the American Academy of Addiction Psychiatry, the American Society of Addiction Medicine, and the American Osteopathic Academy of Addiction Medicine.

Fentanyl is a highly potent synthetic opioid that can be delivered by intravenous, transmucosal, intranasal, buccal, epidural, intrathecal, or inhalational routes.[179] Though fentanyl has a rapid speed of onset, its duration of action is limited by redistribution (half-life ranging from 3.1 to 7.9 hours). Highly lipid soluble, this opioid is primarily metabolized by the liver, although 10% of fentanyl is excreted by the kidneys.[180] Fentanyl has increasingly become a drug of misuse, as its components are easy and inexpensive to obtain, and its effects are powerful. Work is currently underway on a fentanyl vaccine to protect against its lethal effects.[181] Carfentanil, an elephant tranquilizer that is 100 times more potent than fentanyl, has also appeared as an opioid of misuse.[182]

Systemic Effects

Opioids mimic the activity of endogenous peptides and exert their effects through binding to μ-, δ-, and κ-opioid receptors. Morphine and heroin exert their euphoric, analgesic, and reinforcing effects primarily through stimulation of the μ-opioid receptor. Long-time opioid misuse causes neuroadaptations in the brain that may explain the manifestations of withdrawal.[23,168]

Opioids act in the CNS to reduce sympathetic activity and increase parasympathetic activity; they also promote histamine release from mast cells. The resulting cardiovascular effects include bradycardia, hypotension, and, in some cases, potentially lethal tachyarrhythmias and bradyarrhythmias (see Table 53.3). Noncardiogenic pulmonary edema has been observed in some cases of overdose and is believed to be caused by hypoxia, intense pulmonary vasoconstriction, and, in some cases, the use of reversal agents (e.g., naloxone).[4]

Opioid-induced respiratory depression occurs through a direct effect on the brainstem that reduces the ventilatory response to hypercarbia.[168] Opioid overdose can progress from miosis and respiratory depression to obtundation and death.[5,8] As opioid overdose deaths in the general population have increased by almost threefold (2002 to 2015), one aspect of the public health response has been a proliferation of more easily accessible, opioid antagonist (i.e. naloxone) therapy.[183] Treatment of overdose also includes maintenance of a patent airway and provision of hemodynamic support as needed.[4]

Women who use opioids or other drugs intravenously are at risk for infective endocarditis (usually affecting right-sided valves), HIV infection, viral hepatitis, septic emboli, and pulmonary abscess formation.[4,24] In addition, hilar adenopathy may develop as a result of ingestion of additives such as quinine and starch. Opioid-dependent patients may have additional end-organ damage and may exhibit opioid tolerance, physical dependence, and withdrawal.[184]

Studies have found an association between opioid administration and abnormal pain sensitivity, including opioid-induced hyperalgesia (OIH) and allodynia (see Table 53.4).[9,185] Opioid tolerance develops with chronic use and is related to amount and duration of drug exposure; tolerance results from changes in drug distribution and metabolism (pharmacokinetics) and in receptor density and activity (pharmacodynamics).[184] However, tolerance to side effects such as sedation does not develop to the same degree.[185] Both opioid-induced hyperalgesia and tolerance can lead to challenges in pain management in the peripartum period, specifically after cesarean delivery or other surgery.

Acute opioid withdrawal results from sympathetic hyperactivity, resulting in flulike signs and symptoms such as fatigue, weakness, restlessness, rhinorrhea, perspiration, fever, and diarrhea (see Table 53.5).[5,24] These manifestations can persist for several days if not treated. The onset and duration of withdrawal symptoms vary with the opioid taken; morphine or heroin withdrawal symptoms typically begin within 6 to 18 hours after the last dose, reach their peak intensity by 3 days, and last for 7 to 10 days. Methadone withdrawal symptoms are delayed, with onset within 24 to 48 hours, peak intensity within 3 to 21 days, and duration up to 6 to 7 weeks.[184] Clonidine, an alpha$_2$-adrenergic receptor agonist, can modulate these effects, although postural hypotension may result.[24] Acute withdrawal can also be treated by administration of a short-acting opioid and initiation of a gradual dose taper.[7]

Whereas medically supervised opioid detoxification during pregnancy is reported, it is generally not recommended primarily because of the high rate of relapse.[186] Instead, the ACOG recommends medication-assisted therapy in combination with behavior modification therapy. Several studies have shown that methadone-assisted therapy promotes better medical and prenatal care,[187] fewer unplanned pregnancies,[12] decreased neonatal opioid withdrawal syndrome (NOWS) symptoms, and less maternal illicit drug use at delivery.[171,173] Medication-assisted therapy with buprenorphine has also shown favorable results with particular advantages regarding neonatal outcomes.[11]

Effects on Pregnancy and the Fetus

In 2010, Jones et al.[176] performed a landmark, multicenter, randomized controlled trial comparing the neonatal effects of methadone and buprenorphine therapy on NOWS when used as part of an opioid dependence program during pregnancy. Although the percentage of neonates requiring treatment for NOWS did not differ between groups, the infants of buprenorphine-treated mothers spent 58% less time in the hospital and received 89% less morphine therapy for NOWS compared with those of methadone-treated mothers.

When obstetric complications were compared in methadone- and buprenorphine-treated pregnant women, maternal weight gain, cesarean delivery rates, birth weights, and Apgar scores were similar.[178] However, more favorable neonatal growth outcomes and fewer medical complications and overdoses were present in women treated with buprenorphine.[178,188] Based on these data, the ACOG suggests that buprenorphine be considered "a potential first-line medication for pregnant opioid-dependent women who are new to treatment."[186]

Neonatal opioid withdrawal syndrome (NOWS), which occurs in neonates repeatedly exposed to opioids *in utero,* is characterized by irritability, poor feeding, abnormal sleep patterns, diarrhea, fever, and seizures. Affected neonates may also have autonomic symptoms such as yawning and mottling. If prolonged and untreated, NOWS can result in death.[3,189]

In general, published reports have not shown an increased risk for birth defects after prenatal exposure to oxycodone, meperidine, or propoxyphene, but they have shown an association between congenital heart defects and early use of codeine.[186] Two retrospective population-based studies showed an association between maternal therapeutic use of opioid medications early in pregnancy and spina bifida, cardiac defects, and gastroschisis,[190,191] but data were obtained retrospectively via maternal interviews and did not control for dose, therapeutic indication, duration, or frequency of opioid exposure. A separate large population-based study showed an increased risk for several adverse pregnancy outcomes in women with opioid misuse or dependence, including preterm labor, fetal growth restriction, transfusion, and in-hospital mortality.[165]

Heroin use during pregnancy is associated with first-trimester spontaneous abortion, preterm delivery, and fetal growth restriction, in part as a result of poor maternal nutrition.[3,171,187,189] Maternal and neonatal infection and NOWS have also been described. Children born to women using heroin were found to have normal development at the time of entry into school.[3] *In utero* heroin exposure may be associated with a high rate of attention deficit/hyperactivity disorder.[192]

Anesthetic Management

Preanesthesia assessment and communication. Establishing trust and effective communication is critical in the care of opioid-tolerant or methadone- or buprenorphine-maintained patients and may improve the ability to elicit a more complete drug history. Ideally, the anesthesia provider would meet the patient before she presents for delivery and develop a mutually agreeable strategy for pain management with appropriate goals for pain intensity scores. Providers, family, and patients may express concern that exposure to opioids or other sedatives will prompt cravings or a frank relapse. Although withholding appropriate analgesic and anxiolytic medications from such a patient is not justified, patient monitoring (e.g., drug screens, pill counts) may be necessary.[184]

Opioid maintenance requirements. Chronic opioid requirements or pharmacologic maintenance therapy should be continued throughout the hospitalization and postpartum,[135,170,171,184] with additional therapies for acute pain management. The precise dose of methadone must be confirmed with the dispenser, because improper dosing can result in inadequate analgesia, withdrawal phenomena, or life-threatening overdose.[170] Any methadone or buprenorphine dose adjustments during pregnancy or postpartum must be done in close consultation with the prescribing physicians.[186] Some providers may advocate for the substitution of an equivalent dose of a pure opioid agonist for buprenorphine in advance of delivery to maximize the effect of peripartum opioid analgesics. As in the nonobstetric population, this approach requires the careful coordination of the involved providers, an explicit protocol that outlines when the buprenorphine should be stopped and resumed, and which opioid and at what dose should be substituted in the interim. Proponents of maintaining buprenorphine therapy throughout the delivery period note that most admissions for delivery are unplanned, which can complicate efforts to enact this plan. It can also be challenging to safely manage this predelivery transition from buprenorphine to opioid-agonist therapy in the outpatient setting without increasing the risk for maternal or fetal withdrawal or relapse. Similarly, reintroduction of buprenorphine therapy in the early postpartum period may promote acute withdrawal or relapse at a vulnerable time.[193] An alternative approach is to continue the buprenorphine therapy through delivery and the postpartum period. Buprenorphine or methadone doses can then be divided (e.g., buprenorphine three times daily) to maximize the analgesic properties of the medication.[175,186] However, this strategy should only be attempted if administration of the correct total dose can be ensured. In all cases, the use of multimodal pain management techniques, described later, is crucial.

Anesthetic technique and dose requirements. The peripartum anesthetic goals for chronic opioid-using parturients or those receiving methadone or buprenorphine maintenance therapy include, as for all patients, provision of a safe environment that maximizes maternal comfort and bonding with her neonate. Neuraxial analgesia or anesthesia is the technique of choice for those undergoing vaginal or cesarean delivery, assuming that the patient is cooperative and has no evidence of coagulopathy or other contraindication.[186] In a review of relevant publications, Cassidy and Cyna[194] catalogued the needs of opioid-dependent patients across a broad range of anesthetic techniques and modes of delivery. The proportion of these women that required general anesthesia for cesarean delivery, or the number who requested epidural labor analgesia, did not differ compared with the proportions in non–opioid-dependent women. However, a significant incidence of pain management challenges was observed, particularly after cesarean delivery; 26% of the patients required consultation for inpatient pain management in addition to usual labor analgesia, and 74% of the patients had difficulties with postcesarean analgesia. These women also had significant vascular access problems and generated more emergency calls for fainting and collapse.

Labor analgesia. Meyer et al.[11,12] noted that pregnant women on methadone or buprenorphine maintenance therapy had similar pain scores and analgesia requirements during labor and vaginal delivery compared with matched controls. It is therefore reasonable to expect that patient reports of inadequate labor epidural analgesia should be treated as they would be in patients without opioid use disorder. Epidural catheter replacement should be promptly offered as needed. In contrast, mixed opioid agonist/antagonist drugs (e.g., nalbuphine) that

are commonly employed for labor analgesia or in some cases treatment of neuraxial opioid-induced pruritus should be avoided in patients with a history of opioid use disorder because they can precipitate withdrawal. If neuraxial techniques are contraindicated for labor, inhaled nitrous oxide or intravenous patient-controlled analgesia with opioid agonists can be used, acknowledging that the opioid requirement is likely to be considerably higher. Multimodal therapy, including a fixed schedule of nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen (paracetamol), should be used after vaginal delivery.[184]

Cesarean delivery anesthesia. Whenever feasible, neuraxial anesthesia (spinal, epidural, or combined spinal-epidural anesthesia) should be utilized for cesarean delivery anesthesia. If general anesthesia is needed, there is the potential for decreased MAC in a patient with acute opioid intoxication as well as the potential for cross-tolerance with CNS depressants in a patient with a history of long-time opioid use.[7] However, given that obstetric patients are, in general, a group at high risk for awareness under general anesthesia, it is prudent to prioritize an adequate depth of anesthesia.[195]

Postoperative analgesia. Postoperative pain management can be particularly challenging in patients with a history of chronic opioid use. Both methadone- and buprenorphine-maintained women had higher pain scores and received 70% and 47% more opioids, respectively, after cesarean delivery.[11,12] For cesarean delivery, multimodal analgesia with a fixed schedule of NSAID and acetaminophen therapy is highly recommended. Although perioperative use of gabapentin, an NMDA receptor antagonist, has not produced significant additional benefits with neuraxial opioids in the general obstetric population,[196] it is possible that these high-risk patients would benefit from gabapentin administration. (However, cumulative increased risk for respiratory depression with high-dose neuraxial morphine, gabapentin, and any additional opioids has been reported in the nonpregnant population.[197,198]) Similarly, these patients may benefit from the higher neuraxial opioid dosing strategy described by Booth et al.[199] for patients predicted to have severe pain after cesarean delivery (i.e., 300 μg spinal morphine and 1 g acetaminophen every 6 hours for 24 hours). Low-dose ketamine, another NMDA antagonist, has also been used as a single intraoperative dose[200] or as a low-dose postoperative infusion to augment analgesia.[201] Other strategies include using patient-controlled epidural analgesia (consider placing a low thoracic epidural catheter for this purpose), transversus abdominis plane (TAP) blocks (single shot or via a continuous catheter), or IV patient-controlled opioid analgesia, similar to that in women who are not chronic opioid users (see Chapter 27).

Volatile Substances

Volatile substances are chemically diverse and readily available and can be sniffed, aerosolized, or ingested to produce feelings of euphoria, excitement, and invulnerability.[202–204] The five classes of these substances include aromatic hydrocarbons (e.g., toluene), halocarbons (e.g., trichloroethlyene-TCY), aliphatic hydrocarbons (e.g., propane), inhaled anesthetics (e.g., halogenated ethers and nitrous oxide), and akyl nitrites (e.g., amyl nitrite).[204]

Epidemiology

The 2015 National Survey on Drug Use and Health reported that 0.7% of the general population 12 years of age and older used inhalants in the past year[2]; the prevalence of use in pregnant women is unknown.

Pharmacology

Volatile substances act by diverse mechanisms, although they commonly have low vapor pressure and high volatility at room air, which facilitates rapid absorption. Excretion is primarily through the lungs.[204] Exposure is typically to very high concentrations, for short durations (e.g., 15 minutes). Detection, although difficult, can be enhanced by the presence of the "glue sniffer's" facial rash[24] or the odor of the inhalant.[203] Laboratory assays can detect many solvents in the blood within 10 hours of exposure. Urine assays are available only for certain volatile substances (e.g., toluene, chlorinated solvents) but may provide a longer window of detection.[4]

Toluene, a primary component of household paint and cleaning agents, is sniffed or ingested orally for its transient euphoric effects.[10] Whereas animal studies suggest that only a small fraction of the original vapor reaches the brain, the effects on GABA, glutamate, and other neurotransmitter systems are profound.[204] **Ethylene glycol,** a bittersweet-tasting component of antifreeze, brake fluids, and industrial solvents, is sometimes used as an inexpensive substitute for alcohol. Readily absorbed via the gastrointestinal tract, this solvent reaches maximal blood concentrations within 1 to 4 hours. It is metabolized by the hepatic enzyme alcohol dehydrogenase to four toxic organic acids. Primary screening for ethylene glycol intoxication includes serum anion-gap metabolic acidosis, high urine osmolality with an osmol gap, and the presence of calcium oxalate crystals in the urine.[205,206]

Systemic Effects

Typically, the user of volatile substances feels an initial sense of euphoria followed by a brief period of disinhibition and impulsivity. Intoxication can be prolonged through repeated inhalation of the solvent. As the dose increases, dizziness, diplopia, and disorientation manifest, followed by headache, nausea, vomiting, drowsiness, and sleep.[203]

Mucous membrane irritation can result in rhinorrhea, epistaxis, excessive salivation, and conjunctival redness. Nausea, vomiting, and diarrhea can also occur.[203] Ingestion of volatile substances can lead to potentially lethal tachyarrhythmias, likely secondary to sympathetic stimulation, or bradyarrhythmias from decreased sinoatrial node automaticity or direct vagal stimulation and myocardial depression (see Table 53.3).[4] Hypoxemia may occur as a result of formation of carboxyhemoglobinemia, methemoglobinemia, or suffocation.[4,203,207]

Chronic inhalant use can cause multiorgan system disease, with **cardiac** (e.g., cardiomyopathy, arrhythmias, myocardial

infarction), **pulmonary** (e.g., wheezing, acute respiratory distress syndrome, pulmonary hypertension), **central and peripheral nervous system** (e.g., cognitive impairment, ataxia, muscle weakness, peripheral neuropathy), and **autonomic dysfunction** (see Table 53.4).[4,5] Renal toxicity, aplastic anemia, and hepatocellular carcinoma have also been reported.[87,203] Imaging studies have demonstrated loss of brain mass, white matter degeneration, and subcortical abnormalities in long-term users. Significant methemoglobinemia with attendant cyanosis can also occur from exposure to some compounds.[4,203,207]

Cessation of chronic use can lead to reversal of many of the pathophysiologic changes, although the CNS effects may persist. Death from inhalant use typically occurs from suffocation, aspiration, or accidental injury. **Sudden sniffing death syndrome,** likely secondary to a fatal arrhythmia in the setting of a sensitized myocardium, electrolyte abnormalities, and hypoxemia, has been reported in both new and long-term users.[203]

With ingestion of ethylene glycol, inebriation and accumulation of the toxic metabolite glycolic acid occurs, resulting in CNS depression and seizure activity. Cardiopulmonary manifestations occurring 12 to 24 hours after ingestion may be fatal. **Renal failure** is likely to occur 24 to 72 hours after ingestion in survivors. The estimated lethal dose of undiluted ethylene glycol is 1.4 mL/kg. Treatment of ethylene glycol ingestion may require the induction of emesis with ipecac or the use of gastric lavage. The conversion of ethylene glycol to its toxic metabolites can be prevented with the use of the antidote **fomepizole** or **ethanol.** Hemodialysis may be warranted.[206]

Ingestion of toluene can similarly cause cardiac arrhythmias, acute respiratory distress syndrome, hepatic failure, cerebral edema, and death.[10]

Effects on Pregnancy and the Fetus

In animal studies, acute and chronic toluene exposure during pregnancy results in the presence of toluene in the fetal brain.[208] Volatile substance use has been associated with human fetal growth restriction, preterm delivery, and perinatal mortality.[7]

Ethylene glycol intoxication was misdiagnosed as eclampsia in a patient who presented at 26 weeks' gestation with hypertension and seizures followed by coma.[205] Her course, complicated by hemodynamic instability, severe metabolic acidosis, and acute renal failure, eventually prompted suspicion of intoxication. Toxicology investigation confirmed ethylene glycol poisoning. The patient was successfully treated with hemodialysis and intravenous ethanol, and the neonate was treated with diuresis and replacement transfusion.

Anesthetic Management

Identification of volatile substance use in the parturient is critical to safe anesthetic care.[207] Decontamination of skin and clothing is required.[203] A careful physical examination, including the oropharynx and documentation of preexisting neurologic deficits, should be undertaken, and electrolyte abnormalities should be corrected.[7]

If the patient is cooperative and able to protect her airway, neuraxial labor analgesia can be administered. Initial treatment of hypotension should include intravenous fluids first, and then phenylephrine, given the propensity toward arrhythmias. Atropine should be readily available but used with caution. In a stable patient with sustained tachyarrhythmias, selective beta-adrenergic receptor antagonists should be the first-line therapy.[4]

In intoxicated or otherwise uncooperative patients, rapid-sequence induction of general anesthesia for cesarean delivery may be indicated.[7] Propofol or etomidate may be preferred induction agents to ketamine as the latter may exacerbate tachyarrhythmias. Oxygenation and ventilation can be complicated by preexisting pulmonary complications.

KEY POINTS

- Licit and illicit substance use by pregnant women may result in significant maternal and fetal risks.
- Anesthesia providers often care for women with substance use disorders during labor or cesarean delivery.
- Maternal self-reporting underestimates the true incidence of substance use. Drug testing (e.g., urine, blood, oral fluid, hair, meconium) should be employed if substance use disorder is suspected.
- Optimal care of these patients requires developing a therapeutic bond and an explicit pain management plan. Anesthesia providers should ask patients questions about substance use disorder in a respectful and nonjudgmental manner.
- Neuraxial anesthetic techniques are the preferred methods for labor analgesia and cesarean delivery anesthesia for most patients with a history of substance use disorder, provided that the patient is cooperative, is able to protect her airway, and does not have a coagulopathy or a platelet count below the threshold of concern for the anesthesia provider.
- Although patients with alcohol or other substance use disorder may have abnormal pain sensitivity, providers should not assume that the etiology of inadequate neuraxial labor analgesia is solely a result of the patient's disorder. Opioid-tolerant patients can have inadequate (failed) neuraxial analgesia and anesthesia just like their opioid-naïve counterparts.
- Smoking during pregnancy negatively affects fetal growth. Pregnant women who smoke are more likely to suffer respiratory complications and impaired wound healing.

- Moderate maternal caffeine intake (less than 300 mg/day) does not appear to have adverse maternal or fetal effects.
- Marijuana is thought to be the most common illicit substance used by pregnant women. Smoking marijuana increases maternal respiratory comorbidities. There may be long-term effects on exposed offspring including inattention and impulsivity, deficits in problem solving, and academic underachievement.
- Cocaine use has been associated with sudden death from a variety of factors, including cardiac arrhythmias, respiratory arrest, status epilepticus, and impaired thermoregulation. Maternal cocaine use increases the likelihood of placental abruption and urgent cesarean delivery.
- Acute cocaine intoxication can mimic preeclampsia, eclampsia, or malignant hyperthermia.
- Evidence is conflicting as to whether intrauterine hallucinogen exposure has deleterious effects on the fetus.
- Volatile substance use can lead to severe maternal hypoxemia and potentially lethal arrhythmias.
- Ingestion of amphetamines results in high levels of circulating catecholamines, leading to hemodynamic instability and, in some cases, cardiac arrest.
- Care of the opioid-dependent patient should involve maintenance of long-term opioid requirements, multimodal management of acute pain, and avoidance of opioid antagonists and mixed agonist/antagonist agents (unless the patient shows signs of overdose).
- Buprenorphine is increasingly becoming the opioid medication-assisted therapy of choice in patients who use heroin or have other opioid use disorders. Goals of care in these and methadone-maintained patients include continuing their methadone or buprenorphine treatment, adding multimodal acute pain therapy, and avoiding opioid antagonists and mixed agonists/agonist-antagonist agents.

Trauma and Critical Care

Luis D. Pacheco, MD, Edward R. Sherwood, MD, PhD

CHAPTER OUTLINE

The management of critically ill obstetric patients most commonly involves treatment of disease processes that occur as a direct consequence of pregnancy. Although sometimes life-threatening, these conditions are usually reversible. Delivery of the infant often attenuates or ablates the disease process, and the mother typically recovers with supportive and resuscitative measures. Primary obstetric disorders account for 50% to 80% of intensive care unit (ICU) admissions for pregnant patients; approximately 80% of these admissions result from preeclampsia, sepsis, and/or hemorrhage (Box 54.1).[1,2] The estimated ICU admission rate for obstetric patients is 0.5% to 1% in the United States; the mortality rate among this population is 12% to 20%.[2]

Trauma accounts for 45% to 50% of all maternal deaths in the United States, and it is the most common nonobstetric cause of maternal death.[2,3] Other common nonobstetric causes of ICU admission are respiratory failure, endocrine disorders, preexisting autoimmune disease, and thromboembolic disorders.[2,3] Ethnic minorities and women with low socioeconomic status have the highest rates of morbidity and mortality. Modern medicine has allowed women with complex medical problems such as congenital heart disease and cystic fibrosis to survive into childbearing age, and these patients are at increased risk for complications during pregnancy and have a higher incidence of ICU admission. Among critically ill obstetric patients admitted to an ICU, the most common cause of death is acute respiratory distress syndrome (ARDS), which can complicate both obstetric and nonobstetric disease processes.[4]

Critical maternal illness places the fetus at significant risk for morbidity and mortality. Important fetal risk factors include maternal shock, transfusion of blood products, and early gestational age at the time of critical maternal illness.[2-4]

TRAUMA DURING PREGNANCY

Epidemiology

Trauma affects 5% to 7% of pregnancies in the United States and is the leading nonobstetric cause of maternal death; as many as 20% of affected women require emergency surgery.[5,6] It is likely that the reported incidence of maternal trauma is underestimated due to underreporting, especially in cases of domestic violence.[7] Motor vehicle accidents are the most common cause of injury-related maternal death (49% to 70%), followed by domestic violence (11% to 25%) and falls (9% to 23%).[8–11] Not using a seat belt is a major risk factor for maternal and fetal injury in motor vehicle trauma.[12] Penetrating trauma and burns are less common than blunt mechanisms of injury.[11] The rate of maternal trauma admission to an ICU increases with each trimester: 8% occur in the first trimester, 40% in the second trimester, and 52% in the third trimester.[13] Most women are able to continue their pregnancy at home, but up to 38% are hospitalized until delivery.

Risk factors for maternal trauma include age younger than 25 years, low socioeconomic status, minority race, use of illicit drugs or alcohol, and domestic violence.[13,14] It is important to remember that any female patient of reproductive age who is a victim of trauma could be pregnant at the time of injury.

Complications and Outcomes

As in the general population, hemorrhagic shock and brain injury are the most common mechanisms of death in pregnant

BOX 54.1 Causes of Critical Illness in Pregnancy

Obstetric Causes
- Acute fatty liver of pregnancy
- Amniotic fluid embolism
- Cardiomyopathy
- Chorioamnionitis
- HELLP syndrome
- Hemorrhage
- Pelvic septic thrombophlebitis
- Placental abruption
- Preeclampsia/eclampsia
- Puerperal sepsis

Nonobstetric Causes
- Acute renal failure
- Autoimmune disorders
- Chronic respiratory disease
- Diabetic ketoacidosis
- Drug abuse
- Pneumonia
- Pulmonary thromboembolism
- Trauma
- Urinary tract infection

HELLP, Hemolysis, elevated liver enzymes, low platelet count.

BOX 54.2 Factors Associated with Fetal Demise after Trauma
- Ejection from vehicle
- Maternal pelvic fracture
- High maternal Injury Severity Score (> 15)
- Maternal death
- Maternal hypotension
- Uterine rupture
- Uterine tenderness
- Placental abruption
- Vaginal bleeding
- Abnormal fetal heart rate pattern
- Amniotic fluid on pelvic examination
- Maternal history of alcohol use
- Maternal history of smoking

trauma victims.[15] Pelvic and acetabular fractures also pose a significant risk. Injuries and complications that are unique to pregnant trauma victims include uterine rupture, placental abruption, preterm labor, and direct fetal injury. Although rare (0.6% of injuries), uterine rupture is a major threat to the life of both the mother (10% mortality) and the fetus (near 100% mortality).[16] Placental abruption complicates 1% to 5% of minor injuries and 20% to 60% of major trauma and usually occurs from 16 weeks' gestation onward.[17] Placental abruption can cause major overt and occult hemorrhage and coagulopathy and should be considered as a possible source of bleeding in the unstable pregnant trauma patient. Preterm labor is a common (25%) complication of trauma and can be precipitated even in cases of apparently minor injury.[18] Premature rupture of membranes (PROM) increases the risk for both preterm labor and infection. Amniotic fluid embolism is a rare complication of maternal trauma, but it should be considered as part of the differential diagnosis in patients who are refractory to resuscitation.

Fetal-maternal (transplacental) hemorrhage can occur after trauma and result in maternal isoimmunization with the D antigen of the fetal red blood cell Rhesus protein complex (Rh_0[D]) in the Rh-negative mother (see Chapter 6). The **Kleihauer-Betke test** is used to identify fetal blood in the maternal circulation after maternal injury. Acid applied to a peripheral maternal blood smear eliminates adult hemoglobin, while fetal hemoglobin is resistant. Subsequent staining lights up the intact fetal cells against a background of pale maternal cells, and the ratio of fetal to maternal cells can be used to calculate the total volume of fetal red blood cells in the maternal circulation. When fetal-maternal hemorrhage is present, treatment with Rh_0(D) immune globulin (RhoGAM) is generally indicated. In a study performed at the R. Adams Cowley Shock Trauma Center of the University of Maryland, more than 50% of evaluated pregnant trauma victims were positive for fetal-maternal hemorrhage as determined by a positive Kleihauer-Betke test.[19] Essentially all patients with a positive test had uterine contractions, whereas patients with a negative Kleihauer-Betke test did not have contractions. The investigators concluded that the Kleihauer-Betke test was a sensitive and specific predictor of preterm labor in pregnant trauma patients and should be performed in all victims regardless of blood Rh phenotype.

Fetal Trauma and Outcome

The fetal mortality rate after maternal blunt trauma has been reported to range from 3.4% to 38.0%; placental abruption, uterine rupture, maternal shock, and maternal death are the most frequent factors associated with fetal demise (Box 54.2).[14,20] The risk for direct fetal trauma increases with gestational age because the bony pelvis protects the uterus and fetus before 13 weeks' gestation. Pregnant women who sustain blunt trauma have a lower risk for bowel injury than nonpregnant patients because the uterus acts as a shield and pushes the abdominal contents into the upper abdomen.[21] Maternal pelvic fractures are associated with uteroplacental injury and fetal skull fractures. Skull fracture is the most common direct fetal injury and has a reported fetal mortality rate of 42%.[22]

The relationship between the Injury Severity Score (ISS) (see later discussion) and fetal outcome is controversial. Some studies have shown a direct relationship between the ISS and the incidence of fetal demise, whereas others have not.[23,24] Analysis of outcomes from 1075 pregnant trauma victims showed that an ISS of greater than 15 was associated with increased risk for fetal demise.[23] In contrast, a study using data from the state of Washington found no correlation between ISS and pregnancy outcomes.[24] Fetal demise occurred even in women with low ISS. Evidence suggests that decreased serum bicarbonate, an indicator of systemic hypoperfusion, is associated with fetal demise after maternal trauma. Altered

maternal mental status and the presence of head trauma have also been linked to adverse fetal outcomes.

It is crucial to preserve maternal cardiac output, blood pressure, and oxygen delivery to optimize maternal recovery and protect fetal well-being. However, fetal loss can occur even if the mother has not incurred serious injuries. Thus, all pregnant women should be evaluated in a medical setting after trauma, regardless of the apparent severity of injury. The fetus remains at risk for delayed complications after maternal discharge from the hospital. Delayed complications include a twofold increase in the risk for preterm delivery and a ninefold increase in the risk for fetal death.[24] Late complications of trauma, such as cerebral palsy, have also been reported in children born to mothers who experienced trauma during pregnancy.[25]

Initial Assessment and Resuscitation

The initial assessment and resuscitation should focus on the mother; it is axiomatic that maternal resuscitation typically facilitates fetal resuscitation. A systematic approach to initial resuscitation and stabilization should be used (Fig. 54.1).[26] Immediate interventions are initiated to identify and

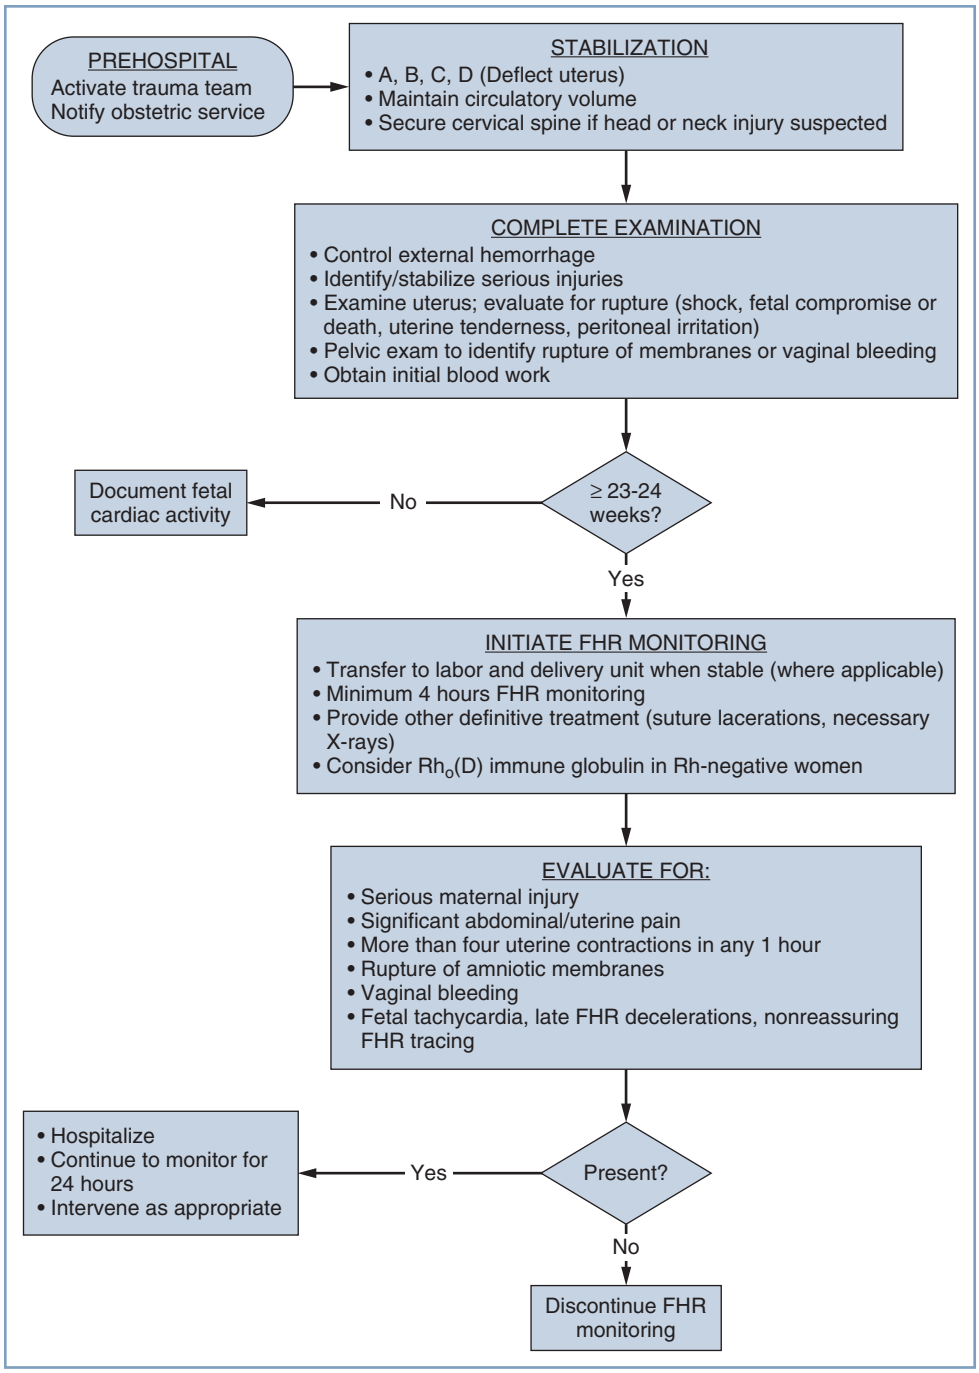

Fig. 54.1 Algorithm for management of the pregnant woman after trauma. *A, B, C,* Airway, breathing, circulation; *FHR,* fetal heart rate. (Modified from Chames MC, Pearlman MD. Trauma during pregnancy: outcomes and clinical management. *Clin Obstet Gynecol.* 2008;51:398–408.)

treat life-threatening conditions based on the principles of Advanced Trauma Life Support (ATLS).[27] Initial focus should be placed on ensuring adequate airway protection, ventilation (breathing), and circulation (the "ABCs" of resuscitation). Pregnant women experience significant changes in cardiopulmonary and metabolic function that must be considered during resuscitation (Table 54.1).

Airway

Airway patency, stabilization, and protection should be ensured as quickly as possible in all critically injured patients, including those who are pregnant. The status of the patient's airway can be quickly assessed by eliciting a verbal response. The inability to speak is an indication of severely impaired mental status or the inability to move adequate air to mediate phonation, either of which should prompt interventions to secure and protect the airway. Additional means of assessing airway patency include auscultation of the chest, assessment of chest movement, and assessment of air movement at the mouth and nose. Immediate interventions to establish airway patency include head-tilt and jaw-thrust maneuvers, as well as placement of an oral or nasopharyngeal airway to facilitate bag-and-mask ventilation and oxygenation.

TABLE 54.1 Physiologic Changes of Pregnancy That May Affect Trauma Management

Parameter	Effect of Pregnancy	Implications
Airway		
Functional residual capacity	Decreased by 20%	More rapid oxyhemoglobin desaturation during periods of apnea
Oxygen consumption	Increased by 15%–20%	
Airway edema	May be present	Tracheal intubation more difficult
Lower esophageal sphincter tone	Decreased	Increased risk for aspiration
Gastric emptying	Decreased during labor	
Breathing		
Diaphragm	Displaced cephalad	Place chest tubes at higher intercostal space
Respiratory rate	No change	
Tidal volume	Increased 35%–45%	
pH	7.42–7.46, partially compensated respiratory alkalosis	
$PaCO_2$	28–32 mm Hg	Reflects normal hyperventilation
HCO_3^-	19–22 mEq/L	Reduced buffering capacity
Base deficit	2–3 mEq/L	
PaO_2	100–107 mm Hg	
Circulation		
Blood volume	Increased by 40%–50%	Significant blood loss may occur before onset of symptoms and hypotension
Cardiac output	Increased by 40%–50%	
Heart rate	Increased by 15%–25%	Early diagnosis of hypovolemia more difficult
Systolic blood pressure	Decreased by 5–15 mm Hg (more pronounced during mid-pregnancy)	
Diastolic blood pressure	Decreased by 5–15 mm Hg (more pronounced during mid- pregnancy)	
Hemoglobin	10–12 g/dL	Physiologic anemia
Gravid uterus	Aortocaval compression	Decreased cardiac output in the supine position; left uterine displacement required
Other		
Coagulation factors	Increased	Hypercoagulable state
BUN, creatinine	Decreased	Abnormal measurements often overlooked[a]
Symphysis pubis/sacroiliac joints	Widened	May alter radiographic interpretations

BUN, Blood urea nitrogen.
[a]The reported measurements may fall within the normal range for the hospital laboratory, but the measurements may actually be abnormally high for a pregnant patient.

It is essential to consider the possibility of cervical spine injury, facial fractures, and skull base injuries. Excessive head-tilt maneuvers can worsen injury if a cervical spine fracture is present. Patients who have sustained severe trauma should be suspected of having a cervical spine injury until proven otherwise. Cervical spine injury must be ruled out by radiographic and physical examination criteria.[27] The cervical spine should be stabilized with a hard collar and in-line stabilization until the severity of injury has been established. In cases of documented cervical spine injury, great care must be taken not to worsen spinal cord injury. A nasopharyngeal airway should not be placed in patients with suspected facial or skull base fractures to avoid further trauma and worsening of preexisting conditions.

Most patients who require interventions to open or support the airway, as just described, will ultimately require tracheal intubation. Indications for tracheal intubation include impaired mental status, airway obstruction, inability to clear secretions or blood from the airway, inadequate spontaneous ventilation, and hypoxemia that is refractory to supplemental oxygen administration.[28] Tracheal intubation of pregnant patients is complicated by changes in respiratory system structure and function (see Table 54.1) (see Chapter 29).[17] Among the most prominent alterations are airway (including vocal cord) edema, decreased functional residual capacity, and increased oxygen consumption. Airway edema impairs vocal cord visualization, thus complicating laryngoscopy and tracheal intubation. Decreased functional residual capacity and increased oxygen consumption result in more rapid oxyhemoglobin desaturation during periods of apnea. These factors increase the risk for failed tracheal intubation and hypoxemia.

Gastric emptying is normal in pregnant women before the onset of labor. However, lower esophageal sphincter tone is commonly decreased in pregnant women (see Table 54.1). Thus, pregnant women are at increased risk for regurgitation and pulmonary aspiration of gastric contents, and similar to all trauma victims, are considered to have a full stomach on arrival in the emergency department or operating room. Therefore, in most cases, rapid-sequence induction of general anesthesia is performed to facilitate tracheal intubation. However, the specific tracheal intubation technique will depend on the practitioner's skills and resources, as well as on the location of the patient's injuries. Alternative approaches to rapid-sequence induction include awake tracheal intubation and tracheostomy.

Several factors can complicate tracheal intubation in the trauma patient. The patient may be combative, which complicates awake tracheal intubation strategies. Blood in the airway can also limit the use of a fiberoptic bronchoscope and impair visualization of the glottis when using a standard or video laryngoscope. The presence of facial fractures, direct airway injuries, trauma-induced airway edema, and tracheal deviation can limit access to the airway.

Finally, airway management, including tracheal intubation, is more challenging in the presence of cervical spine injury. If cervical spine injury is present or suspected, it is crucial to avoid flexion, extension, or lateral movement of the neck. The spine is protected using in-line stabilization and/or a hard cervical collar. Airway management devices such as a gum elastic bougie, a video laryngoscope, a lighted intubating stylette, and/or an intubating supraglottic airway (SGA), among others, should be available for use if standard laryngoscopy is difficult or impossible. An SGA such as a laryngeal mask airway can be used to temporarily provide ventilation in cases in which mask ventilation and tracheal intubation have failed, but an SGA will not provide protection from aspiration and should be replaced by a secure airway device as soon as possible. In some cases, cricothyroidotomy or tracheostomy may be necessary to provide a secure airway.

Breathing

Adequate ventilation and oxygenation should be ensured for the benefit of both the mother and the fetus. Supplemental oxygen should be administered immediately, even if the patient is breathing spontaneously. Mechanical ventilation is often necessary after tracheal intubation in patients with respiratory failure and/or hypoxemia. Ventilation can be compromised by trauma-associated factors such as pneumothorax, hemothorax, lung contusion, mediastinal compression, and chest wall injuries. These problems must be identified during the primary survey and treated to optimize ventilation and oxygenation. In women with advanced pregnancy, it may be necessary to place chest tubes more cephalad than normal owing to the cephalad displacement of the diaphragm and intraabdominal structures by the gravid uterus. Pregnant trauma patients should be ventilated to maintain $Paco_2$ at a level that is normal for pregnancy (28 to 32 mm Hg) (see Table 54.1). Positive end-expiratory pressure (PEEP) may be added to improve oxygenation, if indicated; however, PEEP should be titrated carefully in the hypovolemic patient because it may impair venous return and worsen cardiac output and organ perfusion.

Circulation

Once respiratory stabilization has been achieved, it is essential to assess cardiovascular function and to determine whether the patient is in shock. Two large-bore peripheral intravenous catheters should be placed in the upper extremities to facilitate resuscitation. Central venous access facilitates rapid resuscitation but may be difficult to obtain. Intraosseous cannulation should be considered if it is difficult or impossible to obtain peripheral or central venous access.

Fluid resuscitation should be initiated using crystalloid solution, but blood transfusion should be considered if significant blood loss is apparent or suspected. Left uterine displacement should be initiated immediately to prevent or minimize aortocaval compression by the gravid uterus. The adverse effects of aortocaval compression may be exacerbated during periods of trauma-associated hypovolemia. The use of the pneumatic antishock garment to stabilize fractures or control hemorrhage is relatively contraindicated in pregnant women owing to its adverse effects on venous return.

BOX 54.3 Clinical Signs of Shock in the Trauma Patient

- Agitation
- Confusion
- Poor capillary refill
- Mottled appearance
- Cool extremities
- Diaphoresis
- Tachypnea
- Tachycardia
- Weak distal pulses
- Hypotension
- Decreased pulse pressure
- Decreased urine output
- Lactic acidosis

The hallmark clinical signs of shock are listed in Box 54.3. The presence of these signs indicates a need for timely and appropriate fluid resuscitation. A rapid assessment of sources of blood loss should be performed. In trauma victims, the most common locations of exsanguinating blood loss are the chest, abdomen, retroperitoneum, long bones, and external sites. In the pregnant trauma patient, placental abruption and uterine rupture are also potential sources of hemorrhage. A brief physical examination will identify fractures of the long bones and external sites of bleeding. Thoracic blood loss and pelvic fractures can be identified by chest and pelvic radiographs, respectively. Focused abdominal sonography in trauma (FAST) or diagnostic peritoneal lavage can be used to identify intra-abdominal bleeding. However, diagnostic peritoneal lavage may be difficult to perform safely in advanced pregnancy. FAST can be rapidly performed to assess the hepatorenal, splenorenal, and pelvic spaces, which are the most common sites of major hemorrhage in trauma patients. FAST can also be used to assess uteroplacental integrity and the presence of intrauterine bleeding. Finally, ultrasonography facilitates assessment of cardiac filling and recognition of cardiac tamponade in patients with thoracic trauma.

It is important to recognize that pregnant trauma patients may lose a significant amount of blood before the development of hypotension. Pregnant patients have a 40% to 50% increase in blood volume by the third trimester. Classic signs of hypovolemia such as tachycardia, hypotension, and poor capillary refill may not be evident until blood loss approaches 1.5 to 2 liters. Therefore, it is likely that a pregnant trauma victim will have lost significantly more blood volume and oxygen-carrying capacity than a comparable nonpregnant patient when signs of cardiovascular deterioration become evident. Resuscitation should be guided by apparent blood loss to maintain adequate maternal cardiac output and uteroplacental perfusion. Because of the physiologic anemia of pregnancy, oxygen-carrying capacity may be significantly impaired at the time that hypovolemia becomes evident. In addition, maternal perfusion of vital organs is often sustained at the expense of uteroplacental perfusion. Uterine blood flow may decrease by as much as 30% before the mother shows signs of hypovolemia. Therefore, a nonreassuring fetal heart rate (FHR) pattern may be the first sign of significant intravascular volume loss. Fluids should be warmed to minimize the risk for hypothermia, which can contribute to coagulopathy, arrhythmias, and altered drug responses.

Fluid resuscitation. Current practice supports the use of **crystalloid solutions** to resuscitate the hypovolemic trauma victim during the early phases of resuscitation. However, the crystalloid versus colloid debate remains to be fully resolved. The Saline versus Albumin Fluid Evaluation (SAFE)[29] did not show any difference in survival in nonpregnant trauma patients randomized to receive resuscitation with colloid or crystalloid, with the exception of patients with head trauma, who had poorer outcomes when resuscitated with albumin. The CRISTAL trial also did not demonstrate differences in 28-day mortality when comparing crystalloid to colloid, but 90-day mortality was lower in patients who received colloid.[30] However, the authors considered the results exploratory and cautioned against conclusions about the efficacy of colloid solutions until further investigations are completed. Colloid solutions are anecdotally preferred in some trauma centers.

Balanced salt solutions (lactated Ringer's solution, PlasmaLyte) are typically preferred over normal saline in patients without closed head injury. Balanced salt solutions have significant buffering properties and are less likely than normal saline solution to cause hyperchloremic metabolic acidosis during high-volume resuscitation. A 2018 trial showed that use of balanced crystalloids for resuscitation of critically ill patients was associated with a lower incidence of the composite outcome (death, need for renal-replacement therapy, or renal dysfunction) compared with normal saline.[31] Other buffered salt solutions such as Ringer's ethyl pyruvate and Ringer's hydroxybutyrate also may have value. Currently, no evidence supports the use of one buffered isotonic crystalloid solution over another.

The use of **hypertonic crystalloid solutions** such as 3% sodium chloride is controversial; currently no evidence supports their use in pregnant trauma victims. Hypernatremia is a risk in patients resuscitated with hypertonic saline, and some studies have shown increased mortality in patients resuscitated with hypertonic crystalloid solutions.[32] In a 2017 systematic review, Wu et al.[33] did not identify significant survival or complication risk associated with hypertonic saline resuscitation compared with isotonic saline in patients with hemorrhagic shock.[33] Nevertheless, a recent paper by Asehnoune et al.[34] reported improved adjusted 90-day survival in trauma patients with intracranial hypertension treated with continuous hyperosmolar therapy.[34] In general, hypertonic resuscitation does not appear to be beneficial to trauma patients without traumatic brain injury but may benefit patients with traumatic brain injury and elevated intracranial pressure (ICP).

Some practitioners have advocated **hypovolemic resuscitation** in patients with major hemorrhage after trauma.[35] This technique employs **permissive hypotension** (systolic blood pressure of 80 to 90 mm Hg) until hemorrhage can be controlled in the operative setting. The underlying premise of

hypovolemic (hypotensive) resuscitation is that overresuscitation worsens ongoing blood loss as a result of higher perfusion pressure and dilution of clotting factors. Small boluses of fluids are administered to maintain perfusion in patients without evidence of closed head injury. The use of hypotensive resuscitation is likely detrimental in patients with closed head injury because it is crucial to maintain adequate cerebral perfusion pressure (CPP) in patients with elevated ICP.[36] (CPP is the difference between mean arterial pressure [MAP] and ICP.) No definitive published data support the use of hypotensive resuscitation in pregnant trauma patients. Current guidelines do not support this approach because it may compromise uteroplacental perfusion.

The resuscitative endovascular balloon occlusion of the aorta (REBOA) catheter is a large-vessel occlusion device that is typically deployed into the aorta during periods of severe intraabdominal and pelvic hemorrhage, and is becoming increasingly utilized in cases of major trauma.[37] A proximal pressure transducer is used to titrate balloon inflation to maintain central pressures and limit downstream bleeding as reparative procedures are executed. The device is a less invasive alternative to emergency department thoracotomy and aortic cross-clamping to temporize noncompressible torso hemorrhage. In patients without penetrating thoracic injury, Brenner et al.[38] reported a survival benefit for REBOA compared with patients who received resuscitative thoracotomy.[38] The efficacy of the approach remains to be fully determined in all subsets of trauma patients with hemorrhage; a prospective study of the device is underway. The effectiveness and safety of the REBOA catheter remains to be established in critically injured pregnant patients.

Damage control principles and resuscitation. The traditional approach to treatment of traumatic life-threatening injuries has been definitive operative repair. However, some patients experience progressive physiologic decline during long surgical procedures and develop severe derangements such as hypothermia, metabolic acidosis, and coagulopathy, a combination that has become known as the *deadly triad*.[39] These pathologic alterations require rapid and effective treatment to prevent severe morbidity and death. More recently, practitioners have advocated the use of a more targeted surgical approach, termed **damage control surgery,** which is initiated to control hemorrhage without providing early definitive repair of injuries.[40] Major surgical bleeding is controlled, and the thoracic and abdominal cavities are packed to provide hemostasis. Gastrointestinal diversion is performed, and body cavities are temporarily closed, often using vacuum-type closure systems. Active volume resuscitation is performed using blood products rather than crystalloids, an approach known as **damage control resuscitation,** to achieve metabolic homeostasis. Once stable hemodynamic and acid-base status, coagulation function, and temperature are achieved, the patient is returned to the operating room for definitive repair of injuries.

Blood products. All trauma centers should have rapid access to **type O, Rh-negative blood** for emergency use before type-specific or cross-matched blood is available. Recently, trauma specialists have advocated damage-control resuscitation using packed red blood cells (PRBCs), platelets, and fresh frozen plasma mixed in equal proportions (1:1:1) (see Chapter 37). Several investigators have reported the value of this approach in military practice, and they have specifically observed that this approach results in more effective resuscitation, less coagulopathy, and improved survival than more traditional approaches.[41] Based on experience over the last few years, damage-control resuscitation is also considered to be the optimal strategy for managing civilian patients with exsanguinating trauma.[42] The Pragmatic, Randomized, Optimal Platelet and Plasma Ratios (PROPPR) trial showed that damage-control surgery and balanced blood product resuscitation (1:1:1 ratio) is associated with improved hemostasis at 3 hours after intervention and a decreased incidence of death by exsanguination at 24 hours after injury, although overall mortality at 24 hours and 30 days after injury was not improved compared with patients receiving damage-control surgery with blood products in a 1:1:2 ratio.[43] Based on current evidence, the Eastern Association for the Surgery of Trauma recommends the use of balanced blood product resuscitation in exsanguinating trauma patients.[44]

Despite implementation of damage-control resuscitation, coagulopathy remains a significant problem for trauma patients requiring large-volume resuscitation. Damage-control resuscitation provides clotting factors via transfused plasma and direct administration of platelets. However, tissue injury and release of endogenous anticoagulants often results in sustained alterations in coagulation. Consequently, some practitioners advocate adopting a goal-directed approach to treat trauma-induced coagulopathy based on viscoelastic monitoring, either with thromboelastography (TEG) or rotational thromboelastometry (ROTEM) (see Chapter 44).[45] Gonzalez et al.[46] reported that goal-directed treatment of trauma-associated coagulopathy, compared with standard assessment of coagulation status, was associated with lower mortality and decreased use of plasma and platelets during the acute phase of resuscitation.[46] However, there were limitations associated with the study, and further work is needed to define the benefits of goal-directed treatment of coagulopathy in the trauma patient suffering large-volume hemorrhage.

Secondary Survey

As in all trauma cases, it is crucial to evaluate the mother for significant abdominal, thoracic, orthopedic, and neurologic injuries. A head-to-toe examination should be performed to determine the presence of injuries and the need for intervention. A more detailed evaluation of neurologic function, as well as examination of the head and neck, should be performed. This survey includes examination of posterior structures that may be obscured by the supine position and the presence of a cervical collar. The torso should be examined to identify thoracic and abdominal injuries. The thoracic examination should include chest auscultation, inspection, and palpation. Palpation of the abdomen should be performed to evaluate abdominal tenderness, and a rectal examination should be performed to identify evidence of intraluminal bleeding.

The extremities must be examined to identify deformities, and each joint should be manipulated. Distal perfusion of the extremities must be continuously monitored, especially in limbs that show signs of significant injury. This is accomplished by evaluation of distal pulses and capillary refill. In cases of penetrating injury, the sites of entry and exit should be identified. It is especially important to examine carefully the areas that are difficult to access such as the oral cavity, perineum, axilla, scalp, and back. Once the secondary survey has been performed, more targeted assessments of suspected injuries can be performed using radiologic imaging.

Fetal survey. After initial stabilization of the mother, information about the pregnancy should be gathered through a focused history and physical examination. The history should include the date of the last menstrual period, expected date of delivery, and status of the pregnancy. In cases in which there is uncertainty regarding fetal age, an approximate determination can be made by measuring fundal height. The fetal age is estimated to be 1 week for each centimeter of fundal height above the symphysis pubis. In addition to the assessment of fundal height, the abdominal examination should include an assessment of uterine tenderness and consistency, the presence or absence of uterine contractions, and fetal position and movement.

A pelvic examination should be performed to evaluate cervical dilation and effacement, fetal station, and the presence of amniotic fluid and blood. The FHR is assessed by Doppler auscultation or ultrasonography. If maternal stability permits, ultrasonography facilitates estimation of fetal age and assessment of uteroplacental injury.

If no fetal cardiac activity is identified, fetal resuscitation should not be attempted (see Fig. 54.1). In a series of 441 pregnant trauma patients, the absence of a detectable FHR was associated with fetal death in all cases.[6] When an FHR is detected, an assessment of fetal viability should be performed. An estimated gestational age of 23 to 24 weeks and an estimated fetal weight of 500 g are common thresholds for extrauterine fetal viability. The FHR should be monitored in cases in which the fetus is determined to be viable. In cases in which a nonviable fetus is present, the importance of FHR monitoring is unclear. However, alterations in FHR and FHR variability may signal maternal deterioration and serve as a good monitor of the effectiveness of maternal resuscitation.

FHR monitoring is generally performed with external Doppler auscultation, and a tocodynamometer is used to assess uterine contractions. Adverse fetal outcomes are unlikely in cases with a reassuring FHR tracing and no early warning signs of uteroplacental injury (bleeding, abdominal pain).[47] In contrast, an abnormal FHR tracing or evidence of uteroplacental injury (vaginal bleeding, uterine contractions, uterine tenderness, presence of amniotic fluid on vaginal examination) predicts poor fetal outcome in approximately 50% of cases.[48]

Fetal Monitoring

Continuous electronic FHR monitoring is the current standard of care for pregnant trauma victims with a viable fetus.[6,13] FHR monitoring should be initiated as soon as maternal stabilization allows, because placental abruption can occur early during the course of resuscitation. Continuous electronic FHR monitoring is more sensitive for placental abruption than ultrasonography, physical examination, or Kleihauer-Betke testing. Occasional uterine contractions are common after trauma and are usually not associated with poor fetal outcome.[9,48,49] Random uterine contractions usually resolve within a few hours of the accident. However, regular and prolonged uterine contractions (eight contractions per hour for more than 4 hours) are associated with placental abruption, which has a high fetal mortality rate.[50] The diagnosis of placental abruption should trigger immediate cesarean delivery for both fetal and maternal indications; a large percentage of viable fetuses can be rescued if expedited delivery is performed, and placental abruption will exacerbate maternal hemorrhage and coagulopathy. The presence of fetal bradycardia and/or frequent late FHR decelerations should also prompt delivery if the mother is stable and adequately resuscitated.

The ideal duration of FHR monitoring has not been determined. However, a common practice, based on a prospective study of 60 pregnant trauma patients at more than 20 weeks' gestation, is to monitor the FHR for 4 hours.[51] If maternal-fetal abnormalities are not detected within 4 hours, it is generally considered safe to discontinue FHR monitoring because a normal FHR tracing has a negative predictive value of 100% when combined with a normal maternal physical examination. However, the presence of abnormalities such as vaginal bleeding, spontaneous rupture of membranes, category II and III FHR patterns, persistent uterine contractions, uterine tenderness, abdominal pain, and/or need for maternal analgesia should prompt further FHR monitoring. The sensitivity of ultrasonography for placental abruption ranges from 50% to 80%, but ultrasonography is a safe and effective means of assessing fetal viability, FHR, placental location, gestational age, and amniotic fluid volume. It is particularly valuable in the presence of maternal tachycardia, when it can be difficult to differentiate maternal and fetal heart rates using Doppler auscultation.

Laboratory Studies

Laboratory evaluation in pregnant trauma patients does not differ from the evaluation for nonpregnant patients, with a few exceptions. As for all trauma patients, the laboratory evaluation will be driven by the type and severity of injury. For most patients with significant injury, standard analysis includes a complete blood cell count, coagulation studies, serum electrolyte measurements, blood glucose and lactate levels, liver function tests, arterial blood gas analysis, urinalysis, and toxicology screening, as well as sending a blood sample for typing and cross-matching for compatible blood products (Box 54.4).

The presence of disseminated intravascular coagulation (DIC) and low blood bicarbonate levels is associated with poor fetal outcome.[8,52] Both abnormalities reflect severe maternal injury and should prompt aggressive maternal

BOX 54.4 Initial Laboratory Analysis for the Pregnant Trauma Patient

- Blood type and cross-match
- Complete blood cell count
- Prothrombin (INR) and partial thromboplastin times
- Fibrinogen
- Serum electrolytes, BUN, creatinine, glucose
- Liver function tests
- Serum amylase level
- Blood lactate
- Arterial blood gas measurement
- Toxicology screen
- Kleihauer-Betke assay
- Urinalysis

BUN, Blood urea nitrogen; *INR,* international normalized ratio.

resuscitation. Of special consideration in pregnant trauma patients is maternal-fetal hemorrhage. The Kleihauer-Betke test is used to detect the entry of fetal blood into the maternal circulation.[19] Although typically performed in Rh_0(D) antigen–negative mothers to detect transplacental hemorrhage and the potential for developing Rh_0(D) sensitization, this test may help predict adverse fetal outcomes in all pregnant trauma patients (see earlier discussion).

Imaging

The pregnant trauma patient often requires imaging to evaluate orthopedic, head, thoracic, and abdominal injuries. Although many patients and physicians are concerned about the fetal effects of ionizing radiation, the risks for teratogenesis, malignancy, and gene mutation are small with a radiation exposure less than 5 to 10 rads (see Chapter 17).[53,54] Less than 1% of trauma patients receive more than 3 rads of radiation exposure. When possible, the fetus should be shielded with lead. Intravenous pyelography subjects the fetus to as much as 1.4 rads of exposure, but the test can be invaluable in diagnosing injuries to the kidneys, ureters, and bladder. Computed tomography (CT) is associated with greater radiation exposure than plain radiography, but exposure levels are generally below that considered to be dangerous to the fetus. Modern multidetector (multislice) CT results in higher fetal radiation exposure, but it has significant advantages in speed and image resolution. Overall, the small risk for fetal radiation exposure is outweighed by the benefits to the injured mother and, by extension, the fetus.

Injury Scoring

Several injury scoring scales have been developed over the past 40 years. The scoring systems provide a framework for standardizing clinical management, benchmarking outcomes, and planning research. Presently, no reliable scoring tool exists for predicting maternal or fetal outcome after trauma. Currently used scoring systems include (1) anatomic injury scales that rely on physical examination and diagnostic procedures, (2) physiologic injury scales that rely on assessment of physiologic responses and function, and (3) combination injury scales.

One of the first anatomy-based injury scales was the **Abbreviated Injury Scale (AIS)** developed by the Association for the Advancement of Automotive Medicine.[55] Each of nine body regions is given an injury severity score that ranges from 1 (minor) to 6 (maximal [currently untreatable]). Although the AIS effectively describes the severity of injuries at specific locations, it provides a limited assessment of the overall pathophysiologic impact of all injuries. The **Injury Severity Score (ISS),** which was developed to address this issue, is obtained by summing the square of the three highest severity scores from the AIS. The ISS ranges from 1 to 75. Minor injuries are classified as an ISS of less than 9; moderate, from 9 to 15; serious, from 16 to 25; and severe, greater than 25. The ISS correlates with the risk for preterm delivery after trauma, but its value in predicting fetal death, placental abruption, and other adverse outcomes is controversial.[14] The American Association for the Surgery of Trauma developed the **Organ Injury Scale (OIS)**[56]; this is an organ-based severity scale designed to facilitate clinical investigation and outcomes research.

The value of injury scoring scales in predicting adverse maternal and fetal outcomes remains to be established. Distelhorst et al.[57] reported improved birth outcomes in pregnant patients treated at dedicated trauma centers. However, after controlling for the ISS, the level of trauma designation was not associated with any differences in most birth outcomes, with the exception of *higher* risk for preterm labor and meconium-stained amniotic fluid at level 1 and 2 centers compared with level 3 and 4 centers.[58] It is not known whether trauma level designation correlates with level of maternal care designation, or whether level of maternal care designation predicts trauma outcomes during pregnancy.[59]

Anatomic scoring systems have value in describing the extent and severity of injuries to specific organ systems. However, physiologic scoring systems may add prognostic value. The **Glasgow Coma Scale (GCS),** which is among the most widely used physiologic scoring systems, evaluates the neurologic status of the trauma patient. The GCS evaluates eye opening, verbal response, and motor activity; scores range from 3 to 15, with 3 indicating the absence of neurologic activity and 15 representing intact neurologic function. A GCS score of less than 9 reflects severe impairment, whereas as a score of 9 to 12 reflects moderate disability. However, concerns have been raised about interrater reliability and lack of prognostic utility for the GCS. Some researchers have proposed that a simplified motor score would be more reliable. Evidence suggests that the GCS score has a poor correlation with fetal outcome.[14]

Traumatic Brain Injury

Brain injury is the most common severe injury in patients who suffer from motor vehicle accidents, and it is a major cause of mortality among pregnant trauma victims.[60] It is important to perform a thorough neurologic examination

with particular attention to level of consciousness. Altered mental status may be an indicator of evolving intracranial pathology, intoxication, hypoperfusion, and/or metabolic disturbances. Mental status should be reevaluated frequently because intracranial pathologic processes may not be apparent on initial evaluation and may evolve during the course of resuscitation.

Elevated ICP is a common finding in patients with traumatic brain injury and may be a significant threat to life. Head CT is the imaging study of choice for identifying the site and severity of intracranial pathologic processes in trauma patients, and it should be performed within 1 hour of arrival in the emergency department.

Crystalloid fluid resuscitation should be used for resuscitation in patients with traumatic brain injury; resuscitation with albumin is deleterious in patients with traumatic brain injury (see earlier discussion).[29] The use of hypertonic crystalloids to resuscitate patients with traumatic brain injury is controversial.[33,34] Hypotensive resuscitation is contraindicated in patients with traumatic brain injury and elevated ICP. It is crucial to maintain mean arterial pressure and CPP to minimize the risk for brain ischemia and permanent brain injury. The extent of brain injury will worsen if CPP is not maintained. It is also important to maintain cerebral oxygen delivery by optimizing maternal cardiac output and blood oxygen-carrying capacity.

It may be necessary to intubate the trachea of patients with deteriorating mental status for airway protection and provision of ventilatory support. Hypoventilation should be avoided because it increases ICP. Hyperventilation to a $Paco_2$ between 25 and 30 mm Hg will provide a transient decrease in ICP and may be useful until definitive treatment can be initiated. However, hyperventilation can be disadvantageous for the fetus because it can decrease uteroplacental blood flow by decreasing maternal cardiac output and blood pressure, and perhaps by causing uteroplacental vasoconstriction. Therefore, it is prudent to maintain $Paco_2$ at levels that are normal in pregnant women (28 to 32 mm Hg). Additional maneuvers to decrease ICP include treatment with a diuretic such as mannitol or furosemide and elevation of the head 30 to 45 degrees. Treatment with hypertonic saline can also decrease intracranial volume and ICP, and may improve outcomes in patients with traumatic brain injury.[34]

Corticosteroids are no longer recommended for patients with traumatic brain injury because their administration in this setting is associated with increased mortality. Barbiturates decrease cerebral oxygen use and blood flow and may provide cerebral protection in patients with severe impairment. Both mannitol and furosemide cross the placenta and could cause alterations in fetal plasma osmolality and decrease fetal intravascular volume. However, concern regarding adverse fetal effects should be overridden by the needs of the mother in cases of traumatic brain injury.

Cardiopulmonary Resuscitation

The incidence of cardiac arrest in pregnancy is reported to be 1:20,000 to 1:40,000 patients in industrialized countries.[61,62] Cardiac arrest during hospitalization for delivery is more common, because it includes postpartum cardiac arrest.[62,63] The most frequent causes are trauma, peripartum hemorrhage, embolic phenomena, stroke, preeclampsia/eclampsia, sepsis, status asthmaticus, and anesthesia-related complications.[63,64]

BOX 54.5 Modification of Cardiopulmonary Resuscitation during Pregnancy

- Perform manual left uterine displacement.
- Anticipate difficult airway management.
- Obtain intravenous access above the diaphragm.
- If patient is receiving magnesium sulfate, discontinue magnesium infusion and administer calcium chloride or calcium gluconate.
- Remove all fetal monitors before delivery; internal fetal monitors may be cut externally. Fetal monitor removal should not delay defibrillation.
- If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate resuscitative hysterotomy or cesarean delivery should be performed if gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest.
- Continue all resuscitation efforts during and after cesarean delivery.

Summarized from Jeejeebhoy FM, Zelop CM, Lipman S, et al. Cardiac arrest in pregnancy: a scientific statement from the American Heart Association. *Circulation.* 2015;132:1747–1773.

Cardiopulmonary resuscitation should be initiated immediately (see Chapter 41). The 2015 American Heart Association (AHA) guidelines highlight the importance of initiating high-quality chest compressions to facilitate circulation. Recent guidelines have simplified the list of modifications to cardiopulmonary resuscitation during pregnancy (Box 54.5)[65]; for the most part, pregnant women benefit from standard high-quality cardiopulmonary resuscitation similar to that performed in nonpregnant patients. Hands should be placed in the usual location on the center of the victim's chest; there is no scientific evidence to support changing the hand position from that used to resuscitate nonpregnant patients.[65] Chest compressions should be performed at a rate of 100 per minute at a depth of at least 5 cm. Interruptions should be minimized. Cardiac arrest in the pregnant patient is complicated by the physiologic changes of pregnancy, particularly the effect of the gravid uterus on aortocaval blood flow. Well-performed chest compressions in the nonpregnant patient typically result in cardiac output that is approximately 30% of normal. In pregnant patients, aortocaval compression reduces the cardiac output that results from chest compressions. Therefore, the AHA guidelines advocate manual left uterine displacement with the patient in the supine position (Fig. 54.2).[65]

In the hospital setting, the airway should be secured and the mother ventilated with 100% oxygen. Chest impedance is unchanged during pregnancy; therefore, the usual voltage levels for defibrillation should be used in pregnant patients.[65] Electric cardioversion during pregnancy appears to be safe for

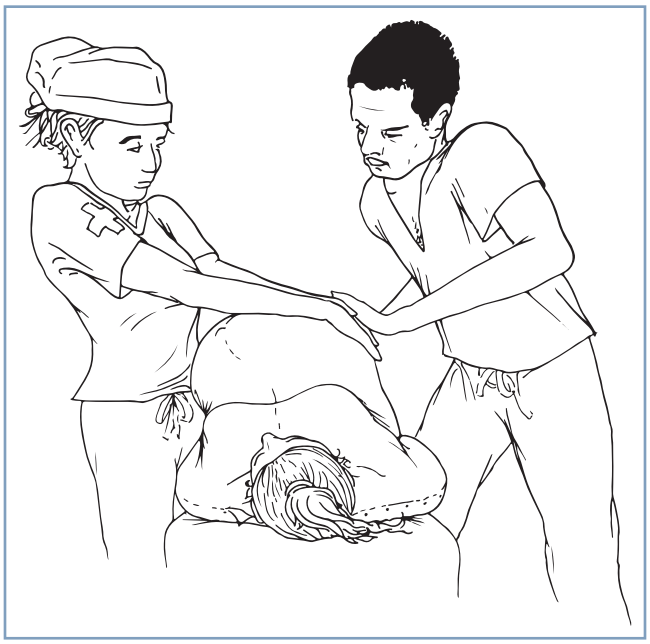

Fig. 54.2 Manual left uterine displacement (LUD) should be performed for any woman in cardiac arrest in whom the uterus can be palpated at or above the umbilicus. LUD can be performed from the right or left side. From the left side, the uterus is cupped and lifted off the major vessels to the left. From the right side, the uterus is pushed upward and to the left. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

the fetus (see Chapter 41); removal of fetal scalp electrodes should not delay maternal defibrillation. Intravenous or intraosseous access should be secured to facilitate resuscitation. Advanced Cardiac Life Support (ACLS) guidelines should be followed to identify and treat causes of cardiopulmonary arrest.

If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate cesarean delivery (resuscitative hysterotomy) should be performed if gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest. Timely delivery facilitates successful resuscitation of both the mother and the infant.[65] Furthermore, early uterine evacuation optimizes maternal resuscitation, even if the fetus has already died. A systematic review of case reports identified 54% survival to hospital discharge among 94 women suffering cardiac arrest during pregnancy; survival was associated with the time to cesarean delivery.[66] In a prospective descriptive study performed in the United Kingdom, Beckett et al.[62] reported a 42% mortality rate for women suffering cardiac arrest during pregnancy. Survival was lowest among women who arrested at home, for whom timely cesarean delivery was not available. After 24 weeks' gestational age, delivery improves perinatal survival. In the UK cohort, 79% (46/58) of infants delivered during maternal cardiac arrest survived, 14 to women who did not survive.[62]

Management of the Brain-Dead Patient

Brain death in the pregnant patient is a rare occurrence. Esmaeilzadeh et al.[67] summarized 30 cases published between 1982 and 2010. Nontraumatic brain injury, primarily intracranial hemorrhage, was the cause of death in 26 of 30 cases. The mean gestational ages at times of injury and delivery were 22 and 29.5 weeks, respectively. Twelve viable infants survived beyond the neonatal period.

In cases of maternal brain death, care providers should focus on saving the life of the fetus; maternal organ preservation for harvest and donation is a secondary consideration. Maintenance of vital functions in mothers with catastrophic brain injury is justified to meet these two goals, but in many cases ethical and legal concerns must be addressed. Consideration must be given to gestational age and the chance for fetal survival. Before 23 weeks' gestation, the chance for extrauterine fetal survival is small. In general, management should follow current guidelines for organ preservation therapy.

The question of whether to preserve maternal circulation and organ function to facilitate fetal development is an ethical dilemma. A fundamental issue relates to the support of the brain-dead mother as an incubator for the unborn fetus. Some professionals argue such an approach is unethical, whereas others view prolonged somatic support as a case of organ donation with the fetus as the recipient. In many cases, the mother's wishes are not known. If the mother indicated a wish to donate organs, prolonged somatic maternal support may be appropriate. Currently, there is no generally accepted lower limit of gestational age for maintenance of maternal support. Each case must be addressed on an individual basis, with close communication among the family, a cohort of care providers, and the hospital ethics committee.

CRITICAL CARE DURING PREGNANCY

Stroke

Ischemic Stroke

Pregnant women are at increased risk for ischemic stroke compared with their nonpregnant counterparts.[68] Pregnancy is a hypercoagulable state characterized by decreased fibrinolysis, increased levels of clotting factors, and decreased levels of certain natural anticoagulants (e.g., protein S). Clinical manifestations of ischemic stroke are similar to those seen in the nonpregnant population and include focal neurologic symptoms, seizures, decreased level of consciousness, and abnormal cranial nerve function. Once the diagnosis is suspected, and initial evaluation and therapy—including airway protection—have been addressed, non–contrast-enhanced CT should follow immediately.[69] The fetal radiation exposure from this test is less than 1 rad.[54] If CT shows no evidence of hemorrhagic stroke, the patient is assumed to have an ischemic stroke. Magnetic resonance imaging is more sensitive in detecting early ischemic events; however, the test is more time-consuming and not widely available. Consideration of thrombolytic therapy should follow, including evaluation of contraindications for thrombolytic therapy (Box 54.6). Thrombolytic therapy with recombinant tissue plasminogen activator (r-tPA) has been reported during pregnancy and appears to be safe for the fetus; transplacental passage of r-tPA is minimal. However, retroplacental bleeding with pregnancy

BOX 54.6 Major Contraindications for Thrombolysis in Ischemic Stroke Patients

- History of a previous intracranial hemorrhage
- Genitourinary or gastrointestinal bleeding in the previous 3 weeks
- Closed head trauma in the previous 3 months
- Major surgery in the previous 2 weeks
- Blood pressure above 185/110 mm Hg despite antihypertensive therapy
- Acute active bleeding
- Evidence that symptoms are clearing spontaneously
- Hemorrhagic transformation on initial imaging
- Massive ischemic stroke (hypodensity affecting more than one-third of the cerebral hemisphere)
- Platelet count < 100,000/mm^3
- Concurrent heparin or warfarin therapy with a prolonged PT or aPTT
- Blood glucose < 50 mg/dL (symptoms may be caused by hypoglycemia)
- Evidence of a seizure with postictal residual neurologic impairment

PT, Prothrombin time; *aPTT,* activated partial thromboplastin time. Summarized from Powers WJ, Rabinstein AA, Ackerson T, et al. 2018 Guidelines for the early management of patients with acute ischemic stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke.* 2018;49:e46–e110.

loss has been reported.[70–72] Consultation with an experienced neurologist is recommended.

The r-tPA is administered intravenously at a dose of 0.9 mg/kg (maximum, 90 mg) over 1 hour (10% of the dose is commonly administered as an initial bolus over the first minute).[69] The therapeutic window (i.e., time from onset of symptoms to administration of the agent) is 4.5 hours. Patients who are candidates for this therapy should be watched closely in an ICU environment that includes fetal surveillance by a maternal-fetal medicine specialist. Blood pressure should be maintained below 180/105 mm Hg during r-tPA therapy with the use of agents such as labetalol or nicardipine.[69] Neurologic deterioration during thrombolytic infusion should raise suspicion of **hemorrhagic transformation;** the infusion should be stopped immediately, and the head CT should be repeated. If hemorrhagic transformation is present, reversal of r-tPA is achieved with administration of cryoprecipitate (10 units) with the goal of maintaining a serum fibrinogen level above 150 mg/dL. The added benefit of platelet transfusion is not clear. If cryoprecipitate is not available, tranexamic acid 1 gram intravenously may be administered.[73]

Patients with ischemic stroke who are not candidates for r-tPA therapy should receive aspirin (162 to 325 mg/day) for 1 to 2 weeks; subsequently, the dose may be decreased to 100 mg/day.[74] Deep vein thrombosis prophylaxis with unfractionated heparin should also be started on admission unless contraindicated. Outcome data related to blood pressure management in patients with acute ischemic stroke are inconsistent. In 2018 the AHA and the American Stroke Association recommended that, in patients who are not receiving thrombolytic therapy, emergency antihypertensive medication should be withheld unless the blood pressure is higher than 220/120 mm Hg.[69] This recommendation does not apply to women with ischemic stroke in the presence of preeclampsia, in whom current guidelines recommend treatment with antihypertensive agents if the blood pressure is greater than 160/110 mm Hg. If the patient has received thrombolytic therapy, aspirin and prophylactic doses of heparin should be withheld for 24 hours after completion of the infusion. Fever should be aggressively treated to achieve normothermia. Blood glucose control with a target between 140 to 180 mg/dL is recommended in the setting of ischemic stroke. Intravenous insulin may be used as needed. Seizure prophylaxis in ischemic stroke is not recommended.[69]

Cerebral sinus and vein thrombosis may occur during pregnancy and the puerperium, but most cases occur postpartum. The practitioner should suspect cerebral sinus thrombosis in the presence of severe headache, focal neurologic signs, and/or papilledema. The diagnostic test of choice is magnetic resonance venography (MRV). Most cases involve the transverse sinuses. Initial imaging reveals concomitant areas of hemorrhage in as many as 40% of these cases. Despite the latter, treatment involves immediate therapeutic anticoagulation with unfractionated heparin or low-molecular-weight heparin unless massive hemorrhage is present.[74,75]

Ischemic strokes that involve more than 50% of the territory of the middle cerebral artery are known as "malignant strokes." They occur more commonly in young people. In the vast majority of cases, these patients require early decompression hemicraniectomy because the stroke is usually associated with massive cerebral edema that frequently is not responsive to medical therapy.[76]

Hemorrhagic Stroke

Pregnancy typically is accompanied by a 40% to 50% increase in both cardiac output and effective blood volume. These changes, coupled with hormone-induced increased fragility of vessel wall structures (secondary to increased levels of estrogen, progesterone, matrix metalloproteinases, and relaxin), may render pregnant patients more susceptible to hemorrhagic stroke resulting in intracerebral and subarachnoid hemorrhage.[77]

Intracerebral hemorrhage. Intracerebral hemorrhage is usually a secondary complication of hypertensive emergencies (e.g., preeclampsia, hypertensive encephalopathy). Clinical presentation is similar to that in nonpregnant individuals. The diagnosis is confirmed with non–contrast-enhanced CT.

As in any other stroke victim, initial management involves securing the airway and facilitating oxygenation and ventilation. Intracranial pressure monitoring should be considered in patients with a GCS score less than 8, clinical evidence of transtentorial herniation, and evidence of significant intraventricular hemorrhage or hydrocephalus.[78]

Blood pressure control in the setting of intracerebral hemorrhage is controversial. Past evidence suggested that

acute blood pressure control with the aim of reducing systolic pressure to 140 mm Hg is safe and could be associated with improved functional outcomes.[78,79] However, evidence from recent clinical trials does not support benefit from strict blood pressure control (systolic blood pressure goal below 140 mm Hg) compared with traditional management (systolic blood pressure goal below 180 mm Hg).[80] In some studies, patients randomized to strict blood pressure control had a higher risk for acute kidney injury.[80] Blood pressure control is currently recommended in patients with intracerebral hemorrhage and a systolic blood pressure above 160 to 200 mm Hg.[81] In cases of intracerebral hemorrhage associated with preeclampsia, most practitioners recommend maintenance of systolic and diastolic blood pressures between 140 to 160 mm Hg and 90 to 110 mm Hg, respectively, to maintain uteroplacental perfusion pressure (see Chapter 35). Blood pressure should be monitored invasively and treated with a titratable intravenous agent such as labetalol or nicardipine.

In the setting of intracerebral hemorrhage secondary to the use of warfarin, rapid reversal of the anticoagulation effect is of paramount importance. Vitamin K (10 mg intravenously over a minimum of 20 minutes) should be administered, along with **prothrombin complex concentrate,** which contains the vitamin K–dependent clotting factors II, VII, IX, and X.[81] Advantages of prothrombin complex concentrate compared with plasma transfusion to replete vitamin K–dependent clotting factors include no requirement for blood typing and cross-matching, a lower risk for bloodborne infection, fewer complications, faster correction of the international normalized ratio (INR), and little risk for volume overload.[81] Prothrombin complex concentrate can be infused over 15 to 30 minutes. The role of recombinant activated factor VII (rFVIIa) in this setting is limited, and its use cannot be recommended at this time.[81]

The risk for seizures after intracerebral hemorrhage is higher in cases of lobar hemorrhage; the risk is small if hemorrhage is localized to the basal ganglia, and even less if limited to the posterior fossa. Unless clinical seizures are observed or nonconvulsive activity is noted on the electroencephalogram (EEG), routine seizure prophylaxis in patients with intracerebral hemorrhage is not recommended; therapy may be associated with poorer long-term functional outcome.[78] The exception is intracerebral hemorrhage in the setting of preeclampsia, for which magnesium is indicated for seizure prophylaxis. As with most brain injuries, glucose control is paramount in the management of intracerebral hemorrhage. Blood glucose should be maintained between 140 and 180 mg/dL in critically ill patients with brain injuries.[78,81] Once bleeding cessation is documented by repeat imaging, deep vein thrombosis prophylaxis with unfractionated heparin or low-molecular-weight heparin should be initiated (usually 1 to 4 days after the intracerebral hemorrhage). Patients should also receive mechanical prophylaxis with sequential compression devices.

Subarachnoid hemorrhage. A subarachnoid hemorrhage may be traumatic or nontraumatic. This discussion is limited to nontraumatic forms of subarachnoid hemorrhage. The most common cause of nontraumatic subarachnoid hemorrhage is rupture of a berry **aneurysm.** The clinical presentation varies from the complaint of the "worst headache in my life" to profound coma. The diagnosis is made by CT followed by cerebral angiography to locate the source of the bleeding; CT angiography detects aneurysms as small as 2 mm. Abdominal shielding is essential during all radiographic procedures to limit fetal radiation exposure.[53,54] Once the aneurysm is located, two management options exist. Craniotomy with clipping of the aneurysm has been the traditional treatment. More recently, coiling of the aneurysm has emerged as a less invasive option. Controversy exists regarding which option results in the most favorable outcome. A large randomized study comparing both treatment modalities found that endovascular coiling resulted in a lower risk for death at 5 years[82]; however, the risk for rebleeding was higher in the endovascular coiling group. Endovascular coiling is currently the preferred treatment option as it has been associated with better long-term neurologic outcomes and less mortality.[83] Endovascular coiling has not been specifically studied in the pregnant population, although several cases of successful endovascular treatment of ruptured intracranial aneurysms in pregnant women have been reported.

Regardless of the treatment modality, it is crucial to secure the aneurysm as early as possible. Before the aneurysm is secured, blood pressure control should target a systolic blood pressure below 160 mm Hg.[83]

Delayed vasospasm is one of the most serious complications of subarachnoid hemorrhage. The onset is usually 3 to 5 days after the hemorrhage and manifests as worsening of the neurologic examination (either new focal symptoms or decreased level of consciousness). If a change in the neurologic status is noted, immediate CT should be performed to rule out rebleeding or hydrocephalus; if absent, vasospasm is likely. Vasospasm is confirmed with cerebral angiography. All patients should be treated with nimodipine (60 mg orally every 4 hours for 21 days) as prophylaxis against delayed-onset ischemia secondary to cerebral vasospasm.[83] Nimodipine is the only agent that has shown improved outcomes in the treatment of delayed cerebral ischemia. Recent data do not lend support to the efficacy of magnesium sulfate[84] or statins.[85]

Once surgical or endovascular treatment is completed, blood pressure control may be less rigorous because hypertension may be a compensatory mechanism to maintain cerebral perfusion pressure in the setting of vasospasm. During pregnancy, extremely high blood pressure may lead to placental abruption and should be avoided. Maintaining a systolic blood pressure below 160 mm Hg may be reasonable during pregnancy after securing the aneurysm.

Historically, patients presenting with symptomatic delayed cerebral vasospasm have been treated with "triple H therapy." Triple H therapy consists of inducing *hypervolemia* (through administration of crystalloids or colloids), leading to *hemodilution,* accompanied by induced *hypertension* (by using vasopressors) in an attempt to increase cerebral perfusion. Evidence of the efficacy of triple H therapy is extremely limited.[86]

The use of hypervolemia and subsequent hemodilution may even be detrimental as a result of a decrease in arterial oxygen content.[87] Instead, many practitioners recommend induced hypertension with intravenous infusion of norepinephrine, phenylephrine, or dopamine, and titration of systolic blood pressure to measurements higher than 180 mm Hg (MAP > 120 mm Hg). However, during pregnancy, the use of high-dose vasopressors to induce hypertension may lead to uteroplacental vasoconstriction and hypoperfusion and subsequent fetal demise. Additionally, the hypertension may increase the risk for placental abruption. Pregnant patients requiring induced hypertension for delayed vasospasm present a significant clinical dilemma. If the fetus is sufficiently mature (e.g., more than 32 weeks' gestation), it may be advisable to deliver the fetus before initiation of induced hypertension. If delivery is not an option, balloon angioplasty of the constricted vessels by an interventional radiologist may be considered in lieu of induced hypertension.

Subarachnoid hemorrhage may also lead to extracerebral manifestations, the most common of which are hyponatremia, cardiac dysfunction, and neurogenic pulmonary edema. Hyponatremia occurs secondary to increased secretion of atrial and ventricular natriuretic peptides (cerebral salt-wasting syndrome).[88] Treatment with isotonic sodium replacement (0.9% saline) usually suffices. Rarely, hypertonic saline may be required.

The massive liberation of catecholamines that accompanies subarachnoid hemorrhage is believed to cause subendocardial ischemia, leading to "cardiac stunning" with concomitant arrhythmias and decreased cardiac output. Patients may require inotropic support and antiarrhythmic therapy. Neurogenic pulmonary edema usually occurs within hours of the bleeding event, and has both a hydrostatic component (from cardiac stunning and pulmonary venous constriction as a result of increased catecholamine secretion) and a noncardiogenic component (from endothelial injury owing to activation of the inflammatory cascade secondary to the presence of severe brain injury). Treatment of neurogenic pulmonary edema is supportive and requires low tidal volume ventilation strategies and the use of PEEP to improve oxygenation.

Subarachnoid hemorrhage may also occur secondary to rupture of brain **arteriovenous malformations.**[89] General intensive care provided to these patients is similar to that used in aneurysmal subarachnoid hemorrhage, with a few exceptions. The risk for vasospasm after subarachnoid hemorrhage from arteriovenous malformations is lower and rarely warrants therapy. Once removed (surgically), adjacent brain tissue will be exposed to increased cerebral blood flow leading to cerebral edema. Localized cerebral edema may be prevented by avoidance of severe hypertension. The decision to surgically treat a ruptured arteriovenous malformation is controversial and depends on the location and type of venous drainage (superficial or deep).[89] The risk for rebleeding during pregnancy is increased, and treatment (e.g., surgical resection, embolization) is commonly recommended for accessible lesions.[90]

As with intracerebral hemorrhage in general, normothermia should be maintained and the maximum blood glucose level should be maintained between 140 and 180 mg/dL. Seizure prophylaxis in the setting of subarachnoid hemorrhage is controversial. Prolonged use of phenytoin has been associated with poor neurologic outcomes and should be avoided.[91] A systematic review suggested that 3 days of seizure prophylaxis therapy provides similar seizure prevention with more favorable outcomes compared with longer-term treatment.[91] In general, widespread use of seizure prophylaxis in subarachnoid hemorrhage is not recommended.

Status Epilepticus

Status epilepticus is defined as a continuous, generalized convulsive seizure lasting more than 5 minutes or two or more seizures with no return to baseline consciousness between the seizures.[92] Status epilepticus may be caused by noncompliance with antiepileptic medications, stroke, brain tumor, central nervous system infection, head trauma, metabolic derangements (e.g., uremia, hepatic encephalopathy, electrolyte abnormalities), cerebral hypoxia, and hypoglycemia/hyperglycemia. Rarely, eclamptic seizures may progress to status epilepticus.

Initial management should include protecting the airway and arresting the epileptic convulsions. Intravenous access should be obtained and hypoglycemia ruled out promptly. If in doubt, a 50-mL bolus of intravenous 50% dextrose with 100 mg of thiamine should be administered. Adequate hydration is of paramount importance because seizure-induced muscle breakdown may lead to myoglobin-induced kidney injury.[92] Initial pharmacologic therapy includes an intravenous benzodiazepine (e.g., lorazepam 0.1 mg/kg) followed by a standard intravenous antiepileptic agent (e.g., phenytoin, valproic acid). If intravenous access is difficult, intramuscular drug administration is an option. Intramuscular midazolam (10 mg) is at least as effective as intravenous lorazepam in the prehospital management of status epilepticus.[93] If seizure control is not achieved, a continuous infusion of propofol, midazolam, or a barbiturate may be required.[94] There is no agreement on the recommended EEG titration goal (burst suppression versus seizure control).[94] Many practitioners recommend 24 to 48 hours of seizure control documented by EEG before slowly weaning the infusion.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a severe form of noncardiogenic pulmonary edema; it is a common cause of mortality in the critically ill obstetric patient. ARDS is defined as the acute onset (within 7 days of known clinical insult) of noncardiogenic pulmonary edema (usually secondary to an inflammatory insult) with bilateral pulmonary infiltrates and a partial pressure of oxygen to inspired fraction of oxygen ratio (P/F ratio) less than 300 with PEEP of at least 5 cm H_2O.[95] Mild ARDS is defined as a P/F ratio between 200 and 300, moderate ARDS between 100 and 200, and severe ARDS as a ratio below 100. The term *acute lung injury* is no

longer used. The mortality rate from severe ARDS is approximately 45%.[95]

ARDS may occur secondary to a pulmonary or extrapulmonary pathologic process. The common denominator is activation of the inflammatory cascade, leading to inflammation-induced endothelial/epithelial injury in the lung with subsequent leaking of protein-rich fluid into the alveoli. Direct (pulmonary) insults that may lead to ARDS include pneumonia, aspiration pneumonitis, pulmonary contusion, and smoke inhalation during burns. Indirect (extrapulmonary) causes include sepsis, pancreatitis, trauma, and massive transfusion. Similar to the nonobstetric population, the most common cause of ARDS in pregnant women is sepsis.[96] Certain obstetric conditions (e.g., placental abruption, amniotic fluid embolism, preeclampsia) may also cause ARDS because these conditions are associated with inflammation and subsequent diffuse endothelial injury. Also, patients with severe placental abruption or amniotic fluid embolism complicated by DIC are at increased risk for massive transfusion of blood products.

Initial treatment for the patient with acute hypoxemic respiratory failure of noncardiac origin falls into ventilatory and nonventilatory strategies (Box 54.7). Of vital importance, the underlying cause of the ARDS must be addressed simultaneously with institution of supportive measures (e.g., broad-spectrum antibiotics and surgical drainage if indicated in cases of sepsis-related ARDS; immediate delivery in patients with chorioamnionitis).

Ventilatory Strategies

The only intervention that has convincingly decreased mortality in ARDS is **lung-protective mechanical ventilation.**[97] ARDS is a heterogeneous disease in which some areas of the lung are affected (consolidated with edema) and others are not. During tidal volume delivery, gas flow is predominantly distributed to unaffected portions of the lung. If large tidal volumes are used, these "normal" areas of the lung are exposed to excessive volumes and pressures that lead to **volutrauma** and **barotrauma,** respectively. Overdistention of the lung provokes a local inflammatory response that further injures the lung parenchyma; locally produced inflammatory mediators (i.e., cytokines) may translocate to the systemic circulation and provoke worsening multiorgan failure **(biotrauma).**[98] If large tidal volumes are used with low PEEP, the constant opening and closing of the recruited alveoli **(atelectrauma)** will also worsen lung inflammation. These four insults (volutrauma, barotrauma, biotrauma, and atelectrauma) constitute what is known as **ventilator-induced lung injury.**[99]

In a randomized clinical trial involving 861 patients with ARDS, patients randomized to receive mechanical ventilation with a small tidal volume (6 mL/kg ideal body weight) and a limitation of plateau pressure to less than 30 cm H_2O had a mortality of 31% compared with 40% in the group randomized to receive a larger tidal volume (12 mL/kg ideal body weight).[97] Since the publication of this trial, intensivists have adopted strategies that limit tidal volumes to decrease ventilator-induced lung injury and improve outcomes in patients with ARDS. By limiting tidal volumes, minute ventilation is invariably decreased, leading to hypercarbia and respiratory acidemia. To improve minute ventilation, the operator may increase the respiratory rate up to 35 breaths per minute to maintain, ideally, an arterial pH above 7.3.[99]

Significant maternal hypercarbia may result in decreased removal of carbon dioxide from the fetus, leading to fetal acidemia. Tidal volumes from 6 to 8 mL/kg (ideal body weight) can be used to ventilate pregnant women with ARDS; attempts should be made to maintain maternal $Paco_2$ below 60 mm Hg. Because of decreased compliance of the chest wall during pregnancy, plateau pressures of up to 35 cm H_2O may

BOX 54.7 Management Strategies in Patients with Acute Respiratory Distress Syndrome during Pregnancy

Ventilatory Strategies

- Lung-protective mechanical ventilation
  - Limit tidal volume to 6 to 8 mL/kg (ideal body weight[a]). If possible, maintain $PaCO_2$ < 60 mm Hg. Limit plateau pressures to 30 to 35 cm H_2O.
- Oxygenation goals
  - Maintain PaO_2 ≥ 55 mm Hg and SpO_2 ≥ 88% as long as the electronic FHR tracing is reassuring. A higher PaO_2 may be required in patients with nonreassuring fetal status.
- Provide adequate PEEP
  - Titrate according to oxygen requirements.
- Rescue therapies
  - Prone ventilation, extracorporeal membrane oxygenation, airway pressure release ventilation, recruitment maneuvers.

Nonventilatory Strategies

- Limit fluid administration
  - Avoid excessive fluids, especially after the initial phase of resuscitation.
- Neuromuscular blockade (cisatracurium)
  - May consider early use of cisatracurium for 48 hours. Avoid coadministration of corticosteroids and aminoglycosides.
- Corticosteroids (no consistent evidence of improved survival)
  - Methylprednisolone 1 mg/kg bolus over 30 minutes followed by a continuous infusion of 1 mg/kg/day for 14 days. The dose is then decreased by half for 1 week, then decreased by half again for 4 days, and finally decreased by half one last time for 3 days.
- Inhaled prostacyclin/nitric oxide
  - Despite improvements in oxygenation, data on survival benefit are lacking. Avoid intravenous vasodilators (e.g., epoprostenol) because these drugs may worsen oxygenation by increasing the shunt fraction.

FHR, Fetal heart rate; *PEEP,* positive end-expiratory pressure.
[a]Ideal body weight in kilograms (females) = 45.5 + 0.91 (height in centimeters – 152.4).

be tolerated. Continuous electronic FHR monitoring is recommended because abnormal FHR patterns may occur during periods of fetal acidemia.

The use of low tidal volumes to limit ventilator-induced lung injury must be accompanied by the use of adequate levels of PEEP to recruit alveolar units. A discussion of optimization of PEEP is beyond the scope of this chapter, but the reader may access F_{IO_2}-PEEP tables that titrate PEEP according to oxygen requirements.[100] Alternatively, PEEP may be increased gradually provided it does not result in increased plateau pressures (as this indicates overdistention as opposed to recruitment). The oxygenation goal is to achieve a Pa_{O_2} of at least 55 mm Hg or higher with an Sa_{O_2} (as measured by pulse oximetry) of at least 88% or higher.[100] The use of high PEEP (levels up to 15 cm H_2O or higher) has been associated with decreased mortality in the subset of patients with the most severe forms of ARDS.[101]

When patients with ARDS are turned from the supine to the prone position, oxygenation often greatly improves, likely secondarily to anterior displacement of the heart with resultant recruitment of the posterior lung segments and improved ventilation-perfusion matching. Decreased mortality from ARDS was observed in patients with P/F ratios less than 150 when prone ventilation was applied early in the course of the disease and for at least 16 hours per day.[102] Use of prone ventilation during the second half of pregnancy is obviously technically demanding (and may not be possible) because of the enlarged gravid uterus. Currently, prone ventilation is recommended as one of the strategies in severe ARDS that is associated with decreased mortality.

Other ventilatory strategies that may be used in ARDS, but have not been associated with reduced mortality, include the use of recruitment maneuvers, airway pressure release ventilation, high-frequency oscillatory ventilation (HFOV), and extracorporeal membrane oxygenation (ECMO).[100,103,104] HFOV is not recommended as it has been associated with either no benefit or increased mortality.[105] Evidence regarding the use of ECMO for treatment of ARDS is inconclusive; a large ongoing trial will answer whether or not venous ECMO improves outcomes compared with lung protective mechanical ventilation. Delivery of the fetus has not been shown to improve maternal oxygenation; however, in cases of life-threatening hypoxemia with a viable fetus and nonreassuring fetal status (especially after 32 weeks' gestation), delivery to prevent stillbirth may be warranted.

Nonventilatory Strategies

Nonventilatory strategies play an important role in the management of patients who suffer ARDS (see Box 54.7). The early use of neuromuscular blockade improves survival in patients with ARDS.[106] A possible advantage of cisatracurium is its significant antiinflammatory activity; the infusion should be limited to the first 48 hours of mechanical ventilation.[106] Pregnancy is not a contraindication to application of this treatment, if required.

Because ARDS occurs secondary to inflammation-mediated lung injury, interest has risen regarding the possible benefits of corticosteroid therapy. Theoretically, low-dose corticosteroids could be immunomodulatory (not immunosuppressive), leading to downregulation of excessive inflammation, and thus limiting acute lung injury.[107] Overall, published evidence indicates that low-dose corticosteroids reduce systemic inflammation, improve oxygenation, reduce multiorgan dysfunction, and decrease the duration of mechanical ventilation and ICU stay in patients with ARDS.[107] If used, low-dose corticosteroids (see Box 54.7) should be initiated before day 14 of the disease; after day 14, corticosteroid therapy is not recommended. The effect on survival is controversial, although some evidence suggests that corticosteroids decrease mortality in patients with ARDS.[108] Interestingly, the use of these low doses has not been associated with an increased risk for gastrointestinal hemorrhage, hyperglycemia, nosocomial infection, or myopathy.[107] At the current time, the use of steroids cannot be universally recommended in ARDS as the effects on mortality are not consistent. During pregnancy, the physician should consider the possible risk for fetal cleft lip (with and without cleft palate) associated with corticosteroid administration during the first trimester of pregnancy.[109]

Management of fluid balance is fundamental in the care of patients with ARDS. A randomized trial found that conservative fluid management (mean fluid balance in the first 7 days, –136 mL) was associated with a shorter duration of mechanical ventilation and a shorter length of stay in the ICU than liberal fluid management (mean fluid balance, +6992 mL).[110] At the time of enrollment, most patients had been fluid resuscitated and were hemodynamically stable. The incidence of adverse effects (e.g., shock, need for renal dialysis) did not differ between groups.

Fluid restriction in patients with ARDS is usually initiated on day 2 to 3 of the disease process; the first several days are commonly associated with hypotension and shock that invariably requires fluid resuscitation. Provided shock has resolved and vasopressors are not required to support blood pressure, fluids should be restricted to the amount required to maintain hemodynamic stability. Enteral feeding should be the main source of fluids in lieu of "maintenance fluids." If a diuretic is used to achieve a negative fluid balance, judicious use is recommended. Continuous electronic FHR monitoring is recommended to assess the adequacy of uteroplacental perfusion.

Right ventricular failure may be seen in up to 25% of patients with ARDS. Alveolar "flooding" limits oxygenation with resultant hypoxic pulmonary vasoconstriction. The increase in pulmonary vascular resistances may lead to acute cor pulmonale and right ventricular failure, accompanied by a severe decrease in cardiac output (from both right-sided failure and left ventricular diastolic dysfunction). The administration of an inhaled pulmonary vasodilator such as nitric oxide or prostacyclin often leads to improved oxygenation and right ventricular function. However, there is no evidence that these interventions improve survival.[111] Pregnancy is not a contraindication for pulmonary vasodilator therapy. Pharmaconutritional therapy for ARDS (e.g., omega-3 fatty acids,

linolenic acid, antioxidants) has not been shown to be beneficial and is not recommended.[112]

Nutrition and Glucose Control

Critically ill patients require nutrition to heal. Early aggressive enteral nutrition is of paramount importance and should be implemented within 24 to 48 hours of admission to the ICU.[113] Enteral nutrition (either through a nasogastric tube or a Dobhoff tube with the tip placed in the duodenum) helps maintain gut barrier integrity, thus preventing bacterial and cytokine translocation from the intestine. Enteral nutrition is generally preferred over parenteral nutrition because it is associated with less infectious morbidity and mortality. Enteral nutrition should be discontinued in patients requiring high doses of vasopressors because of a possible increase in the risk for bowel ischemia.[113]

The total amount of calories needed during critical illness is unknown.[114] More than 200 formulas exist to calculate daily energy requirements while in the ICU; many of these formulas coincide with a simple calculation of 25 Kcal/kg/day (ideal body weight).[113] An extra 300 Kcal/day should be added during pregnancy (500 Kcal/day in patients with multiple gestation). Overfeeding should be avoided because it may lead to fatty liver, volume overload, excessive carbon dioxide production, hyperglycemia, infection, and immunosuppression. Protein delivery should not be restricted, and critically ill patients should receive 1.2 to 2.0 g/kg/day of protein.[113] Most available enteral feeding formulas do not contain sufficient protein; it may be necessary to add additional protein to standard formulas. In the setting of ARDS, either trophic feeding or full-calorie feeding is acceptable during the first week of the disease.

Stress hyperglycemia refers to the elevation in blood glucose concentration associated with critical illness. Stress hyperglycemia is caused by multiple factors, including massive catecholamine release and systemic inflammation. Hyperglycemia is commonly worsened with initiation of nutritional support. Hyperglycemia worsens oxidative injury and potentiates inflammation and clotting. In 2001, a landmark study suggested that tight glycemic control during critical illness (intravenous use of an insulin infusion to maintain blood glucose level between 80 and 110 mg/dL) was associated with decreased mortality and other benefits.[115] These findings were not replicated in later studies; the largest available randomized controlled trial actually found that tight glucose control led to a 2.6% increase in mortality compared with less stringent glucose control. Maintaining blood glucose between 80 and 110 mg/dL commonly leads to episodes of iatrogenic hypoglycemia, which may worsen outcome.[116] Current guidelines recommend a target blood glucose level between 140 and 180 mg/dL in ICU patients.[113]

Transfusion Triggers

Most PRBC transfusions in the ICU are used to treat anemia in hemodynamically stable patients who are not actively bleeding.[117] The efficacy of such an approach has not been demonstrated. Anemia in the critically ill patient commonly results from inflammation-induced inhibition of erythropoiesis and excessive phlebotomy.[117] Administration of PRBCs theoretically leads to an increase in arterial blood oxygen content, oxygen delivery, and, ultimately, oxygen consumption. Unfortunately, no clear evidence indicates that PRBC transfusions improve oxygen consumption.[118,119] In reality, significant risks are associated with transfusion of blood products in the ICU (Table 54.2).[119]

The largest published trial to date evaluating the role of PRBC transfusion in hemodynamically stable ICU patients found no difference in outcome between patients randomized to a liberal transfusion strategy (transfuse to maintain hemoglobin greater than 10 g/dL) or a restrictive strategy (transfuse to maintain a hemoglobin greater than 7 g/dL).[120] A subgroup analysis revealed that mortality was *increased* with the liberal transfusion strategy in the subgroup of patients younger than 50 years of age and with less severe disease (Acute Physiology and Chronic Health Evaluation II [APACHE II] score less than 20). Based on these findings, most intensivists do not transfuse hemodynamically stable patients in the ICU until the hemoglobin level is less than 7 g/dL. (In patients with acute coronary syndrome, the threshold may be higher at 8 g/dL.[117]) Although each case should be individualized, it seems reasonable to apply these guidelines to critically ill pregnant patients. Plasma, cryoprecipitate, and platelets should not be transfused for the sole purpose of correcting laboratory measurements in patients who are not actively bleeding and are not undergoing an invasive procedure.

Sepsis

Sepsis occurs as the result of a maladaptive systemic inflammatory response to an infectious insult. It is the leading cause of mortality in ICUs in developed countries, and the incidence is increasing worldwide.[121] Sepsis is also one of the leading causes of maternal mortality.[122] The incidence of death from sepsis in obstetric patients is lower than that in nonobstetric patients. This likely reflects the fact that pregnant women are younger and have fewer co-existing medical pathologic processes.

Pregnancy affects both humoral and cell-mediated immunologic functions. The white blood cell count rises as pregnancy progresses, and some authors have described neutrophils in pregnant patients as "activated," thus favoring severe inflammatory reactions to infectious stimuli.[123] Cellular immunity is altered as a consequence of a decline in T-helper type 1 cell and natural killer cell function. The impaired cellular immunity may predispose pregnant women to infections from viruses and parasites. In contrast, antibody-mediated immunity is enhanced in pregnancy despite depressed levels of immunoglobulins (likely from hemodilution). Pregnancy is not a state of generalized immunosuppression; rather, it is a state of *immunomodulation* with compromised cellular and enhanced humoral immunity. Unfortunately, published information regarding the management of sepsis in pregnant women is limited; pregnant women typically have been excluded from large trials that have guided the evolution of the management of sepsis over the past several decades.

TABLE 54.2 Potential Complications Associated with Transfusion of Blood Products

Transfusion-related acute lung injury (TRALI)	Noncardiogenic pulmonary edema that occurs within 6 hours of transfusion Risk higher after platelet and fresh frozen plasma transfusions Supportive treatment
Transfusion-related circulatory overload (TACO)	Hydrostatic pulmonary edema secondary to volume overload
Transfusion-related immunomodulation (TRIM)	After transfusion, decreased immunity with increased risk for nosocomial infections
Infectious complications	Viral (hepatitis B and C, HIV, cytomegalovirus, parvovirus B19, West Nile virus, human T-lymphotropic virus) or bacterial (*Staphylococcus* species, *E. coli, Pseudomonas* species, *Yersinia*) Bacterial infections more common
Febrile reactions	Secondary to leukocytes and cytokines accumulated during storage. May decrease with leukoreduction.
Allergic nonhemolytic reactions	Urticaria and pruritus, secondary to soluble antigens in the donor plasma
Hemolytic reactions	Secondary to preexisting recipient alloantibodies against donor erythrocytes Sudden onset of fever and chills, back pain, hypotension, dyspnea, renal injury, and DIC
Posttransfusion purpura	Purpura and bleeding manifestations after transfusion of blood products Usually seen in patients with antibodies that react against the human platelet antigen-1 from donor platelets Treat with intravenous immunoglobulin
Increased risk for multiorgan system failure	Likely secondary to cytokines contained in stored blood products
Graft-versus-host reaction	Lymphocytes transfused to patient not recognized as foreign; such cells react against host tissues, leading to pancytopenia, rash, hepatitis, and diarrhea Mainly seen in patients with profound immunosuppression or in patients receiving blood products from close relatives who share human leukocyte antigens May be prevented with leukoreduction and gamma radiation of blood products.

DIC, Disseminated intravascular coagulopathy; *HIV,* human immunodeficiency virus.

Definitions

Sepsis is currently defined as an inflammatory response secondary to an infectious insult that results in organ dysfunction. The Sequential Organ Failure Assessment (SOFA) score evaluates dysfunction of the brain, kidney, liver, lung, platelet count, and mean arterial blood pressure.[124] Organ dysfunction is defined as an acute increase by two or more points in the SOFA score (see Table 36.1). The term *severe sepsis* is no longer used. **Septic shock** is defined as sepsis-induced hypotension requiring the use of vasopressors with a serum lactate level greater than 2 mEq/L. A recently introduced term is the *quick SOFA score*. The quick score does not define sepsis but has been used to identify patients with potential sepsis at risk for developing complications. Patients are deemed at risk if they have two or more of confusion, tachypnea (respiratory rate above 22/min), and hypotension (systolic blood pressure below 100 mm Hg).[124]

SOFA score thresholds for defining organ dysfunction may require modifications during pregnancy. For example, a serum creatinine level greater than 0.8 mg/dL may be abnormal in pregnancy (the SOFA score considers kidney injury if above 1.2 mg/dL). Similarly, a mean arterial blood pressure below 70 mm Hg (considered abnormal in the SOFA score) may be normal in mid-pregnancy. The other SOFA parameters used to define organ dysfunction (GCS less than 15, P/F ratio less than 400, platelet count less than 150,000/mm^3, and bilirubin greater than 1.2 mg/dL) likely do not require significant modification during gestation.

Pathophysiology

The pathophysiology of sepsis is complicated and not fully understood. After exposure to a microorganism (bacteria, virus, parasite, fungus), the inflammatory cascade is activated. Massive production and release of inflammatory cytokines (interleukin-1 beta [IL-1β], tumor necrosis factor-alpha [TNF-α], IL-6, IL-8), antiinflammatory cytokines (IL-4, IL-10), endothelial factors (nitric oxide), and other mediators (prostaglandins, leukotrienes, complement) result in loss of vasomotor tone, profound vasodilation, and increased vascular permeability (secondary to cytokine-induced injury of both the endothelium and the glycocalix). Fluids subsequently move out of the vascular space, resulting in so-called "third spacing."[121]

The profound decrease in systemic vascular resistance and accompanying tachycardia results in the so-called "hyperdynamic state" seen in septic patients. However, myocardial function is profoundly altered by the actions of nitric oxide, IL-1, oxygen-derived free radicals, and TNF-α. Up to 60% of patients with sepsis have an ejection fraction less than 45%. Both systolic and diastolic dysfunction may occur. Not

infrequently, myocyte injury from proinflammatory cytokines may lead to leakage of troponins. Typically, patients with systolic dysfunction tend to present with biventricular dilation. This dilation appears to be an adaptive response that allows for increased intracavitary filling, leading to an increased stroke volume despite a decrease in ejection fraction (preload recruitment). These cardiac changes tend to resolve spontaneously among survivors of sepsis.

Almost all patients with sepsis have coagulation abnormalities, ranging from asymptomatic changes to severe DIC.[125] Activation of the clotting cascade results from tissue factor expression by macrocytes, neutrophils, and the endothelium as part of the inflammatory response. Tissue factor expressed on the surface of these cells binds factor VII, thus activating the clotting cascade. Excessive activation of the clotting cascade may lead to consumptive coagulopathy and the development of DIC. Development of DIC contributes to organ hypoperfusion (secondary to microvascular occlusion) and multiorgan system failure.

Natural anticoagulant proteins are often consumed in patients with severe sepsis[121]; alterations in protein C, antithrombin III, and plasminogen activator inhibitor have been described. Consumption of activated protein C has been associated with poor outcomes in septic patients. Protein C is activated secondary to the interaction of thrombin (generated as a result of clotting activation) with the endothelial surface receptor thrombomodulin. Activated protein C inhibits factors V and VIII, promotes fibrinolysis, and has anti-inflammatory properties. Thus, the decrease in activated protein C observed in severe sepsis results in amplified inflammation and a disruption in the normal balance between procoagulant and anticoagulant activity.

Mitochondrial dysfunction is also common in severe sepsis.[126] Even in the presence of adequate oxygen delivery, oxygen consumption cannot be guaranteed if the mitochondria are dysfunctional and cannot extract oxygen and use it in oxidative respiration. This pathologic process explains why patients with sepsis may have normal or above-normal oxyhemoglobin saturation in the central or pulmonary circulation despite poor tissue oxygen utilization.

Management

Of pivotal importance in the management of sepsis is achieving early infection source control and instituting adequate antibiotic therapy and resuscitation. Infected fluid collections or tissues should be drained/excised if clinically indicated.[127] Broad-spectrum antibiotics should be initiated quickly (ideally after cultures have been obtained); narrow-spectrum antibiotic administration should follow once culture results are available.

Fluid management. The cornerstone of resuscitation in sepsis is early fluid therapy. Premature initiation of vasopressors may worsen tissue ischemia. Current guidelines recommend the early administration of 30 mL/kg of crystalloid solution; vasopressors are indicated if a mean arterial blood pressure of at least 65 mm Hg is not achieved.[127] The placenta should be regarded as the maternal end organ that is most sensitive to hypoperfusion. For this reason, FHR decelerations are often an early sign of maternal hypoperfusion.

Fluid resuscitation improves tissue perfusion by increasing driving pressure and modulating early inflammation by decreasing concentrations of proinflammatory cytokines. Crystalloids (normal saline, lactated Ringer's solution, PlasmaLyte) have an intravascular half-life of 30 to 60 minutes compared with 16 hours for colloids such as albumin. Theoretically, the use of colloid leads to a more efficient resuscitation. The largest published trial comparing the use of crystalloids and colloids in critically ill patients found no difference in outcomes between groups.[29] However, a subgroup analysis suggested that patients with sepsis might benefit from albumin administration.[29] A recent randomized clinical trial found no benefit of albumin use in sepsis.[128] Currently, there is no evidence that colloids (mainly albumin) are superior to crystalloids for fluid resuscitation in septic patients.

The use of hydroxyl ethyl starch in septic patients is associated with increased rates of kidney injury and mortality, and is not recommended.[129,130] The use of balanced crystalloid solutions (lactated Ringer's solution and PlasmaLyte) is currently recommended; normal saline is associated with increased adverse renal effects among critically ill patients.[31]

In the past, early goal-directed therapy (defined as "adjustments in cardiac preload, afterload, and contractility to balance oxygen delivery with oxygen demand" to achieve a normal central venous mixed oxygen concentration) was advocated. More recent evidence shows that this approach does not improve outcomes, and may be harmful as it introduces the risks associated with central line insertion.[131,132]

Excessive fluid resuscitation and a positive fluid balance have consistently been associated with increased mortality in critically ill patients. A trial in patients with ARDS showed that *after* the initial phase of resuscitation, patients who were randomized to receive a conservative fluid regimen had improved lung function and a shorter duration of mechanical ventilation and ICU stay compared with patients who received a liberal fluid regimen.[110] The study did not have sufficient power to identify a difference in 60-day mortality.

Thus, it appears that early in sepsis (the first 6 hours), patients benefit more from aggressive initial fluid resuscitation. Later, a conservative fluid strategy may be beneficial, with fluid administration guided by *dynamic* rather that static measurements of preload.[133] For example, in mechanically ventilated patients with sinus rhythm and who are not triggering the ventilator, pulse pressure variation above 13% accurately predicts fluid responsiveness. Similarly, in nonintubated patients or patients not in sinus rhythm, an increase in stroke volume (usually 10% to 15%) as assessed by transthoracic echocardiography or noninvasive cardiac output monitoring during passive leg raising (or after administration of a fluid bolus) accurately predicts fluid responsiveness.[133]

Vasopressors and inotropes. If a MAP greater than 65 mm Hg is not achieved with fluid therapy alone, vasopressors are indicated.[127] The vasopressor of choice in septic shock is norepinephrine. Norepinephrine increases blood pressure primarily by increasing systemic vascular resistance.

Obstetricians have traditionally expressed concern regarding the potential adverse effects of vasopressors on uteroplacental perfusion. However, in the setting of septic shock, restoration of maternal organ perfusion pressure is essential for fetal survival. Multiple case reports have described improved fetal status with the use of vasopressors to increase MAP.

Vasopressin is a peptide hormone synthesized in the hypothalamus and stored in the pituitary gland. A relative deficiency of vasopressin has been described during septic shock. Vasopressin causes direct vascular smooth muscle constriction via stimulation of V_1 receptors. It also increases the response to catecholamines, likely by increasing cortisol secretion through its action on V_3 receptors in the pituitary gland. Additionally, vasopressin causes vasoconstriction by closing ATP-dependent potassium channels. Observational studies have shown that the addition of low-dose vasopressin (0.03 U/min) to traditional vasopressor therapy can raise blood pressure in vasopressor-refractory septic shock. A large randomized clinical trial reported no difference in mortality in patients with vasopressor-dependent septic shock who were randomized to receive either vasopressin or norepinephrine in addition to open-label vasopressor therapy.[134] However, the trial did not address the use of vasopressin as rescue therapy for septic shock that is resistant to conventional vasopressors. Vasopressin is commonly used in catecholamine-refractory septic shock and in patients who experience significant tachyarrythmias with the use of catecholamines.

No good data exist regarding the use of vasopressin during septic shock in pregnant women. Theoretically, it may activate uterine V_{1a} receptors, leading to uterine contractions. Caution is recommended if this agent is used during pregnancy.

Myocardial contractility is compromised in septic shock (see earlier discussion). **Septic cardiomyopathy** may be "unmasked" when vasopressors are used to increase systemic vascular resistance. Assessment of cardiac output (e.g., bedside transthoracic echocardiography) is beneficial when vasopressors (primarily norepinephrine and vasopressin) are used without concomitant inotropic support. If worsening cardiac output is noted after initiating vasoconstrictor therapy, inotropic support (dobutamine or milrinone) may be beneficial.

Anecdotal data suggest that catecholamines may not be effective in patients with severe acidemia. However, data do not support the use of sodium bicarbonate therapy during resuscitation. In septic patients, bicarbonate therapy is not indicated if the pH is above 7.15.[127] If the pH is less than 7.15, the use of sodium bicarbonate should be individualized. Particular care should be taken if the practitioner chooses to use bicarbonate during pregnancy because bicarbonate does not cross the placenta, but the carbon dioxide generated from its administration crosses the placenta to the fetal compartment, leading to potential fetal acidemia.

Corticosteroids. Approximately 50% to 75% of patients with sepsis/septic shock have **critical illness–related corticosteroid insufficiency.** Cytokines lead to a dysfunctional hypothalamic-pituitary-adrenal axis with a consequent decrease in cortisol secretion. Cortisol plays a pivotal role in the upregulation of catecholamine receptors at the vascular level (leading to an increased response to endogenous and exogenous catecholamines).

The use of corticosteroid therapy in patients with septic shock has long been controversial. In the past, large doses of corticosteroids were used; however, evidence suggested that the use of high-dose corticosteroids in patients with sepsis/septic shock may be harmful. Studies performed in the past decade suggest that low-dose corticosteroids (hydrocortisone 200 mg/day) may be beneficial.[135] Currently, physiologic doses of corticosteroids are recommended in patients who fail to respond to catecholamine therapy.[127,136] The agent of choice is hydrocortisone (50 mg bolus intravenously every 6 hours or a continuous intravenous infusion at 10 mg/h) together with oral fludrocortisone 50 μg daily. This low dose of glucocorticoid is believed to be immunomodulatory; the excessive inflammatory response that leads to shock is downregulated without causing immunosuppression. Once begun, treatment should be maintained for 7 days; tapering is not necessary. The practitioner should be cognizant of the possible association between corticosteroid use during the first trimester of pregnancy and the development of fetal cleft lip and palate.[109] The adrenocorticotropic hormone (ACTH) stimulation test should not be used to identify patients with septic shock who should receive glucocorticoids.

Monitoring resuscitation. Traditionally, the main goal of resuscitation efforts in sepsis has been to achieve "normal" vital signs (MAP greater than 65 mm Hg, urine output greater than 0.5 mL/kg/h, normal heart rate).[127] Unfortunately, clinical signs and symptoms lack sensitivity for detection of tissue hypoperfusion. Patients may have normal vital signs and still have organ hypoperfusion and anaerobic metabolism. Different strategies have been proposed to detect these patients with "occult shock." Resuscitation may be guided by blood lactate levels. Patients with persistent lactic acidosis, despite apparently normal vital signs, may require further resuscitation to increase tissue oxygen delivery.

Another option is to optimize hemodynamic support using central ($Sc\bar{v}o_2$) and mixed venous ($S\bar{v}o_2$) oxyhemoglobin saturation monitoring. $S\bar{v}o_2$ is the saturation of hemoglobin obtained from blood sampled from the pulmonary artery. It requires placement of a pulmonary artery catheter; a normal value is greater than 65%. Pregnancy *per se* does not alter the $S\bar{v}o_2$.[137]

$Sc\bar{v}o_2$ is the oxyhemoglobin saturation of a blood sample obtained from the junction of the superior vena cava and the right atrium. This measurement is readily achieved by obtaining a blood sample from a central venous catheter. The normal value is greater than 70%. To our knowledge, normal values for $Sc\bar{v}o_2$ during pregnancy have not been described. Patients with tissue hypoperfusion will extract more oxygen in an attempt to increase aerobic metabolism. The increased extraction will lead to a decrease in the oxygen saturation of hemoglobin returning to the central circulation.

The Fetus during Critical Maternal Illness

In the vast majority of cases, therapeutic interventions in the critically ill pregnant patient should not be withheld because of fetal concerns. When the alternative is death or severe injury, very few drugs or diagnostic or therapeutic maneuvers are contraindicated. Most medications (sedatives, neuromuscular blocking agents, corticosteroids, vasopressors, inotropes, antibiotics) may be used safely (or with minimal risks that are commonly outweighed by the benefits) during pregnancy. Some of the common agents used in the ICU setting, and the associated fetal risks, are listed in Table 54.3.

Imaging studies should be performed as needed with the use of abdominal shielding to limit fetal radiation exposure. When possible, ultrasonography and magnetic resonance imaging (MRI) are preferred because no ionizing radiation is used. Radiation exposure from common studies, such as a chest or abdominal radiography or CT of the head or chest, are all below the upper limit of safety (5 rads) recommended by the American College of Obstetricians and Gynecologists (ACOG).[54] Similarly, the use of radiopaque (iodide containing) or paramagnetic contrast media during pregnancy is acceptable, provided the study is considered fundamental to the care of the patient.[54]

Critically ill pregnant patients should receive continuous electronic FHR monitoring after 24 weeks' gestation (lower age limit of viability) to continuously evaluate fetal well-being. The presence of fetal bradycardia, tachycardia, or persistent FHR decelerations may signal uterine hypoperfusion that requires improved resuscitation efforts. Each case should be evaluated individually with the aid of a maternal-fetal medicine specialist. Pregnant women beyond 20 weeks' gestation should be positioned either in the left or right decubitus position to avoid uterine compression of the inferior vena cava, which results in a decrease in cardiac preload.

Acknowledgment

We would like to acknowledge the contributions of Dr. Paul Howell to a previous edition of this chapter.

TABLE 54.3 Common Medications Used during Critical Illness

Medication	Comments
Norepinephrine	Uterine vessels are very sensitive to vasoconstriction because they are rich in alpha-adrenergic receptors. As with any vasopressor, this agent may be used after adequate volume resuscitation and with continuous electronic FHR monitoring. Norepinephrine is the preferred agent in sepsis.
Dopamine	Dopamine is associated with more tachyarrhythmias than norepinephrine. As with norepinephrine, it should be used after adequate fluid resuscitation and with continuous electronic FHR monitoring. Not currently recommended as a first-line pressor in critical care.
Vasopressin	Low doses used for the treatment of diabetes insipidus have not been associated with fetal harm. No data exist on its use as a continuous infusion for septic shock in pregnancy. Potentially, vasopressin may lead to activation of V_{1a} receptors and uterine contractions; thus, extreme caution is recommended if used during pregnancy. Continuous electronic FHR monitoring is highly desirable.
Dobutamine	Provides inotropic support
Milrinone	Provides inotropic support
Phenylephrine	Pure vasopressor, no inotropic support
Epinephrine	Both vasopressor and inotropic support
Hydrocortisone	Some data suggest an association between corticosteroid use during the first trimester and fetal cleft lip/palate. However, if required to improve maternal outcomes, use should not be deferred.
Midazolam	No clear correlation between the use of midazolam and fetal anomalies has been described. Use of any sedative close to the time of delivery is associated with neonatal depression.
Lorazepam	Limited data have associated prolonged use with fetal anomalies. It is unlikely that its use during a few days of critical illness outside the first trimester is teratogenic.
Propofol	May result in hypotension
Dexmedetomidine	This agent crosses the placenta, but no published studies link dexmedetomidine to fetal malformations.
Cisatracurium	May have antiinflammatory properties (beneficial in treatment of ARDS)
Vecuronium	Accumulates in renal and/or liver failure
Morphine	Histamine release may result in hypotension
Fentanyl	Minimal hemodynamic disturbances
Hydromorphone	Minimal hemodynamic disturbances
Haloperidol	Commonly used to treat agitated delirium

FHR, Fetal heart rate.

KEY POINTS

- Trauma is the most common nonobstetric cause of maternal death.
- Head injury and hemorrhagic shock are the most common causes of death in the pregnant trauma victim.
- Even minor trauma increases the risk for placental abruption and preterm labor.
- Resuscitation of the critically ill or injured obstetric patient should be based on the premise that optimized maternal resuscitation will be most beneficial to the fetus.
- Care of the pregnant trauma patient should be based on Advanced Trauma Life Support principles. Additional attention should be given to complications that are specific to pregnancy, such as uterine rupture and placental abruption.
- In addition to standard Advanced Cardiac Life Support guidelines for cardiac arrest, considerations for resuscitation of the pregnant patient include maintenance of left uterine displacement and evacuation of the uterus. If spontaneous circulation does not return within 4 minutes of cardiac arrest, immediate hysterotomy or cesarean delivery should be performed if the gestational age is 20 weeks or greater, aiming for delivery within 5 minutes of cardiac arrest.
- Neurologic emergencies during pregnancy require prompt intensive care to avoid secondary brain injury caused by hypoxia, hypercarbia, seizures, hyponatremia, hyperglycemia, and rebleeding episodes.
- Patients with ARDS should receive lung-protective mechanical ventilation. When possible, excessive fluid administration should be avoided.
- Early enteral nutrition and glucose control are basic tenants of contemporary critical care.
- Transfusion of blood products in critically ill patients should follow a restrictive strategy.
- Prompt diagnosis, infection source control, adequate antibiotic therapy, and early fluid resuscitation are fundamental principles of the early management of sepsis.
- Fetal heart rate monitoring is indicated in pregnant trauma victims and critically ill obstetric patients beginning at 24 weeks' gestation; altered fetal heart rate patterns can serve as a valuable indicator of inadequate resuscitation.

A APPENDIX

American Society of Anesthesiologists Guidelines for Neuraxial Anesthesia in Obstetrics*[1]

COMMITTEE OF ORIGIN: OBSTETRIC ANESTHESIA

These guidelines apply to the use of neuraxial anesthesia and labor anesthesia or analgesia in which local anesthetics are administered to the parturient during labor and delivery. They are intended to encourage quality patient care but cannot guarantee any specific patient outcome. Because the availability of anesthesia resources may vary, members are responsible for interpreting and establishing the guidelines for their own institutions and practices. These guidelines are subject to revision from time to time as warranted by the evolution of technology and practice.

GUIDELINE I
NEURAXIAL ANESTHESIA SHOULD BE INITIATED AND MAINTAINED ONLY IN LOCATIONS IN WHICH APPROPRIATE RESUSCITATION EQUIPMENT AND DRUGS ARE IMMEDIATELY AVAILABLE TO MANAGE PROCEDURALLY RELATED PROBLEMS.

Resuscitation equipment should include, but is not limited to: sources of oxygen and suction, equipment to maintain an airway and perform endotracheal intubation, a means to provide positive pressure ventilation, and drugs and equipment for cardiopulmonary resuscitation.

GUIDELINE II
NEURAXIAL ANESTHESIA SHOULD BE INITIATED AND MAINTAINED BY A PHYSICIAN WITH APPROPRIATE PRIVILEGES OR UNDER THE MEDICAL DIRECTION[2] OF SUCH AN INDIVIDUAL.

Physicians should be approved through the institutional credentialing process to initiate and direct the maintenance of obstetric anesthesia and to manage procedurally related complications.

GUIDELINE III
NEURAXIAL ANESTHESIA SHOULD NOT BE ADMINISTERED UNTIL: (1) THE PATIENT HAS BEEN EXAMINED BY A QUALIFIED INDIVIDUAL[3]; AND (2) A PHYSICIAN WITH OBSTETRIC PRIVILEGES TO PERFORM OPERATIVE VAGINAL OR CESAREAN DELIVERY, WHO HAS KNOWLEDGE OF THE MATERNAL AND FETAL STATUS AND THE PROGRESS OF LABOR AND WHO AGREES WITH THE INITIATION OF LABOR ANESTHESIA, IS READILY AVAILABLE TO SUPERVISE THE LABOR AND MANAGE ANY OBSTETRIC COMPLICATIONS THAT MAY ARISE.

Under circumstances defined by department protocol, qualified personnel may perform the initial pelvic examination. The physician responsible for the patient's obstetric care should be informed of her status so that a decision can be made regarding present risk and further management.[3]

GUIDELINE IV
AN INTRAVENOUS INFUSION SHOULD BE ESTABLISHED BEFORE THE INITIATION OF NEURAXIAL ANESTHESIA AND MAINTAINED THROUGHOUT THE DURATION OF THE NEURAXIAL ANESTHETIC.

GUIDELINE V
NEURAXIAL ANESTHESIA FOR LABOR AND/OR VAGINAL DELIVERY REQUIRES THAT THE PARTURIENT'S VITAL SIGNS AND THE FETAL HEART RATE BE MONITORED AND DOCUMENTED BY A QUALIFIED INDIVIDUAL. MONITORING TECHNIQUE, FREQUENCY OF RECORDING, AND ADDITIONAL MONITORING SHOULD BE CHOSEN WITH REGARD TO THE CLINICAL CONDITION OF THE PARTURIENT AND FETUS AND IN ACCORDANCE WITH INSTITUTIONAL POLICY. WHEN EXTENSIVE NEURAXIAL

*Approved by the ASA House of Delegates on October 12, 1988, and last amended on October 16, 2013.

[1]Guidelines for Neuraxial Anesthesia in Obstetrics/2013 is reprinted with permission of the American Society of Anesthesiologists, 520 N. Northwest Highway, Park Ridge, IL 60068-2573.

[2]The Anesthesia Care Team (Approved by ASA House of Delegates October 18, 2006, and last amended October 21, 2009).

[3]American Academy of Pediatrics and American College of Obstetricians and Gynecologists. *Guidelines for Perinatal Care*. 7th ed. Elk Grove Village, IL: AAP; Washington, DC: ACOG, 2002.

BLOCKADE IS ADMINISTERED FOR COMPLICATED VAGINAL DELIVERY, THE STANDARDS FOR BASIC ANESTHETIC MONITORING[4] SHOULD BE APPLIED.

GUIDELINE VI
NEURAXIAL ANESTHESIA FOR CESAREAN DELIVERY REQUIRES THAT THE STANDARDS FOR BASIC ANESTHETIC MONITORING[4] BE APPLIED AND THAT A PHYSICIAN WITH PRIVILEGES IN OBSTETRICS BE IMMEDIATELY AVAILABLE.

GUIDELINE VII
QUALIFIED PERSONNEL, OTHER THAN THE ANESTHESIA PROVIDER ATTENDING THE MOTHER, SHOULD BE IMMEDIATELY AVAILABLE TO ASSUME RESPONSIBILITY FOR RESUSCITATION OF THE NEWBORN.[4]

The primary responsibility of the anesthesia provider is to provide care to the mother. If the anesthesia provider is also requested to provide brief assistance in the care of the newborn, the benefit to the child must be compared to the risk to the mother.

GUIDELINE VIII
A PHYSICIAN WITH APPROPRIATE PRIVILEGES SHOULD REMAIN READILY AVAILABLE DURING THE NEURAXIAL ANESTHETIC TO MANAGE ANESTHETIC COMPLICATIONS UNTIL THE PATIENT'S POSTANESTHESIA CONDITION IS SATISFACTORY AND STABLE.

GUIDELINE IX
ALL PATIENTS RECOVERING FROM NEURAXIAL ANESTHESIA SHOULD RECEIVE APPROPRIATE POSTANESTHESIA CARE. FOLLOWING CESAREAN DELIVERY AND/OR EXTENSIVE NEURAXIAL BLOCKADE, THE STANDARDS FOR POSTANESTHESIA CARE[5] SHOULD BE APPLIED.

GUIDELINE X
THERE SHOULD BE A POLICY TO ASSURE THE AVAILABILITY IN THE FACILITY OF A PHYSICIAN TO MANAGE COMPLICATIONS AND TO PROVIDE CARDIOPULMONARY RESUSCITATION FOR PATIENTS RECEIVING POSTANESTHESIA CARE.

[4]Standards for Basic Anesthetic Monitoring (Approved by ASA House of Delegates October 21, 1986, and last amended October 20, 2010).

[5]Standards for Postanesthesia Care (Approved by ASA House of Delegates October 27, 2004, and last amended October 21, 2009).

B APPENDIX

Practice Guidelines for Obstetric Anesthesia: an Updated Report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia and the Society for Obstetric Anesthesia and Perinatology[a]

- What other guidelines are available on this topic?
  - These Practice Guidelines update the "Practice Guidelines for Obstetric Anesthesia: An Updated Report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia," adopted by the American Society of Anesthesiologists (ASA) in 2006 and published in 2007.[1]
  - Other guidelines on the topic for the anesthetic management of the parturient have been published by the American College of Obstetricians and Gynecologists in 2002 and reaffirmed in 2010 and 2013.[2]
- Why was this guideline developed?
  - In October 2014, the ASA Committee on Standards and Practice Parameters, in collaboration with the Society for Obstetric Anesthesia and Perinatology, elected to collect new evidence to determine whether recommendations in the existing practice guidelines continue to be supported by current evidence. The resultant guidelines, presented in this issue, incorporate an analysis of current scientific literature and expert consultant survey results.
- How does this statement differ from existing guidelines?
  - This statement presents new findings from the scientific literature since 2006 and surveys of both expert consultants and randomly selected ASA members.
  - This document represents the first practice guideline to be developed as a collaborative effort between the ASA and a subspecialty society (Society for Obstetric Anesthesia and Perinatology) with content expertise relevant to the recommendations.
- Why does the statement differ from existing guidelines?
  - The American College of Obstetricians and Gynecologists Practice Bulletin focuses on limited aspects of cesarean anesthesia (e.g., when an anesthesiology consult is appropriate) and of labor analgesia (e.g., parenteral opioids) that an obstetrician would use to counsel their patients.
  - These guidelines also include perianesthetic management of other obstetric procedures and emergencies.

PRACTICE guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to the clinical needs and constraints and are not intended to replace local institutional policies. In addition, practice guidelines developed by the American Society of Anesthesiologists (ASA) are not intended as standards or absolute requirements, and their use cannot guarantee any specific outcome. Practice

Links to the digital files are provided in the HTML text of this article on the journal's website (www.anesthesiology.org). A complete bibliography used to develop these updated guidelines, arranged alphabetically by author, is available as supplemental digital content 1. http://links.lww.com/ALN/B219.

Submitted for publication October 28, 2015. Accepted for publication October 28, 2015. Approved by the ASA House of Delegates on October 28, 2015.

guidelines are subject to revision as warranted by the evolution of medical knowledge, technology, and practice. They provide basic recommendations that are supported by a synthesis and analysis of the current literature, expert and practitioner opinion, open-forum commentary, and clinical feasibility data.

This document updates the "Practice Guidelines for Obstetric Anesthesia: An Updated Report by the ASA Task Force on Obstetric Anesthesia," adopted by ASA in 2006 and published in 2007.[b]

METHODOLOGY

Definition of Perioperative Obstetric Anesthesia

For the purposes of these updated guidelines, *obstetric anesthesia* refers to peripartum anesthetic and analgesic activities performed during labor and vaginal delivery, cesarean delivery, removal of retained placenta, and postpartum tubal ligation.

Purposes of the Guidelines

The purposes of these guidelines are to enhance the quality of anesthetic care for obstetric patients, improve patient safety by reducing the incidence and severity of anesthesia-related complications, and increase patient satisfaction.

Focus

These guidelines focus on the anesthetic management of pregnant patients during labor, nonoperative delivery, operative delivery, and selected aspects of postpartum care and analgesia (i.e., neuraxial opioids for postpartum analgesia after neuraxial anesthesia for cesarean delivery). The intended patient population includes, but is not limited to, intrapartum and postpartum patients with uncomplicated pregnancies or with common obstetric problems. The guidelines do not apply to patients undergoing surgery during pregnancy, gynecological patients, or parturients with chronic medical disease (e.g., severe cardiac, renal, or neurologic disease). In addition, these guidelines do not address (1) postpartum analgesia for vaginal delivery, (2) analgesia after tubal ligation, or (3) postoperative analgesia after general anesthesia (GA) for cesarean delivery.

Application

These guidelines are intended for use by anesthesiologists. They also may serve as a resource for other anesthesia providers and health care professionals who advise or care for patients who will receive anesthetic care during labor, delivery, and the immediate postpartum period.

Task Force Members and Consultants

In 2014, the ASA Committee on Standards and Practice Parameters requested that the updated guidelines published in 2007 be reevaluated. This current update consists of a literature evaluation and the reporting of new survey findings of expert consultants and ASA members. A summary of recommendations is found in Appendix l.

This update was developed by an ASA-appointed Task Force of 11 members, consisting of anesthesiologists in both private and academic practices from various geographic areas of the United States, and consulting methodologists from the ASA Committee on Standards and Practice Parameters. The Task Force developed these updated guidelines by means of a multistep process. First, original published research studies from peer-reviewed journals published subsequent to the previous update were reviewed. Second, a panel of expert consultants was asked to (1) participate in opinion surveys on the effectiveness of various anesthetic management strategies and (2) review and comment on a draft of the update developed by the Task Force. Third, survey opinions about the guideline recommendations were solicited from a random sample of active members of the ASA. Finally, all available information was used to build consensus within the Task Force to finalize the update.

Availability and Strength of Evidence

Preparation of these guidelines followed a rigorous methodologic process. Evidence was obtained from two principal sources: scientific evidence and opinion-based evidence.

Scientific Evidence

Scientific evidence used in the development of these updated guidelines is based on cumulative findings from literature published in peer-reviewed journals. Literature citations are obtained from PubMed and other healthcare databases, direct Internet searches, Task Force members, liaisons with other organizations, and manual searches of references located in reviewed articles.

Findings from the aggregated literature are reported in the text of the guidelines by evidence category, level, and direction. Evidence categories refer specifically to the strength and quality of the *research design* of the studies. Category A evidence represents results obtained from randomized controlled trials (RCTs), and Category B evidence represents observational results obtained from nonrandomized study designs or RCTs without pertinent comparison groups. When available, Category A evidence is given precedence over Category B evidence for any particular outcome. These evidence categories are further divided into evidence levels. Evidence levels refer specifically to the strength and quality of the summarized study *findings* (i.e., statistical findings, type of data, and the number of studies reporting/replicating the findings within the evidence categories). In this document, only the highest level of evidence is included in the summary report for each intervention–outcome pair, including a directional designation of benefit, harm, or equivocality for each outcome.

Category A. Randomized controlled trials report comparative findings between clinical interventions for specified outcomes. Statistically significant ($P < 0.01$) outcomes are

[b]Practice guidelines for obstetric anesthesia: An updated report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia. *Anesthesiology* 2007;106:843-863.

designated as either beneficial (B) or harmful (H) for the patient; statistically nonsignificant findings are designated as equivocal (E).

Level 1: The literature contains a sufficient number of RCTs to conduct meta-analysis,[c] and meta-analytic findings from these aggregated studies are reported as evidence.

Level 2: The literature contains multiple RCTs, but the number of RCTs is not sufficient to conduct a viable meta-analysis for the purpose of these updated guidelines. Findings from these RCTs are reported separately as evidence.

Level 3: The literature contains a single RCT, and findings are reported as evidence.

Category B. Observational studies or RCTs without pertinent comparison groups may permit *inference* of beneficial or harmful relations among clinical interventions and clinical outcomes. Inferred findings are given a directional designation of beneficial (B), harmful (H), or equivocal (E). For studies that report statistical findings, the threshold for significance is a *P* value of less than 0.01.

Level 1: The literature contains observational comparisons (e.g., cohort and case-control research designs) with comparative statistics between clinical interventions for a specified clinical outcome.

Level 2: The literature contains noncomparative observational studies with associative statistics (e.g., relative risk, correlation, or sensitivity/specificity).

Level 3: The literature contains noncomparative observational studies with descriptive statistics (e.g., frequencies and percentages).

Level 4: The literature contains case reports.

Insufficient literature. The lack of sufficient scientific evidence in the literature may occur when the evidence is either unavailable (i.e., no pertinent studies found) or inadequate. Inadequate literature cannot be used to assess relations among clinical interventions and outcomes because a clear interpretation of findings is not obtained due to methodologic concerns (e.g., confounding of study design or implementation), or the study does not meet the criteria for content as defined in the "Focus" of the guidelines.

Opinion-Based Evidence.

All opinion-based evidence (e.g., survey data, Internet-based comments, letters, and editorials) relevant to each topic was considered in the development of these updated guidelines. However, only the findings obtained from formal surveys are reported in the current update. Identical surveys were distributed to expert consultants and a random sample of ASA members who practice obstetric anesthesia.

Category A: Expert opinion. Survey responses from Task Force-appointed expert consultants are reported in summary form in the text, with a complete listing of the consultant survey responses reported in Appendix 2.

Category B: Membership opinion. Survey responses from active ASA members are reported in summary form in the text, with a complete listing of ASA member survey responses reported in Appendix 2.

Survey responses from expert and membership sources are recorded using a 5-point scale and summarized based on median values.[d]

Strongly Agree: Median score of 5 (at least 50% of the responses are 5)

Agree: Median score of 4 (at least 50% of the responses are 4 or 4 and 5)

Equivocal: Median score of 3 (at least 50% of the responses are 3, or no other response category or combination of similar categories contain at least 50% of the responses)

Disagree: Median score of 2 (at least 50% of responses are 2 or 1 and 2)

Strongly Disagree: Median score of 1 (at least 50% of responses are 1)

Category C: Informal opinion. Open-forum testimony obtained during the development of these guidelines, Internet-based comments, letters, and editorials are all informally evaluated and discussed during the formulation of guideline recommendations. When warranted, the Task Force may add educational information or cautionary notes based on this information.

GUIDELINES

Perianesthetic Evaluation and Preparation

Perianesthetjc evaluation and preparation topics include (l) a focused history and a physical examination, (2) an intrapartum platelet count, (3) a blood type and screen, and (4) perianesthetic recording of fetal heart rate patterns.

History and Physical Examination

Literature findings. Although it is a well-accepted clinical practice to review medical records and conduct a physical examination, comparative studies are insufficient to directly evaluate the impact of these practices. Studies with observational findings suggest that certain patient or clinical characteristics (e.g., hypertensive disorders of pregnancy such as preeclampsia and hemolysis, elevated liver enzymes, and low platelet count syndrome, obesity, and diabetes mellitus) may be associated with obstetric complications (*Category B2/B3-H evidence*).[3-14]

Survey findings. The consultants and ASA members both strongly agree (l) to conduct a focused history and physical examination before providing anesthesia care and (2) that a communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.

[c]All meta-analyses are conducted by the ASA methodology group. Meta-analyses from other sources are reviewed but not included as evidence in this document.

[d]When an equal number of categorically distinct responses are obtained, the median value is determined by calculating the arithmetic mean of the two middle values. Ties are calculated by a predetermined formula.

Intrapartum Platelet Count

Literature findings. The literature is insufficient to assess whether a routine platelet count can predict anesthesia-related complications in uncomplicated parturients. An observational study reported that platelet count and fibrinogen values are associated with the frequency of postpartum hemorrhage (*Category B2 evidence*).[15] Other observational studies and case reports suggest that a platelet count may be useful for diagnosing hypertensive disorders of pregnancy, such as preeclampsia; hemolysis, elevated liver enzymes, and low platelet count syndrome; and other conditions associated with coagulopathy (*Category B3/B4-B evidence*).[16-23]

Survey findings. The consultants and ASA members strongly agree that the anesthesiologist's decision to order or require a platelet count should be individualized and based on a patient's history (e.g., preeclampsia with severe features), physical examination, and clinical signs.

Blood Type and Screen

Literature findings. The literature is insufficient to determine whether obtaining a blood type and screen is associated with fewer maternal anesthetic complications. In addition, the literature is insufficient to determine whether a blood cross-match is necessary for healthy and uncomplicated parturients.

Survey findings. The ASA members agree and the consultants strongly agree that (1) a routine blood cross-match is not necessary for healthy and uncomplicated parturients for vaginal or operative delivery and (2) the decision whether to order or require a blood type and screen or cross-match should be based on maternal history, anticipated hemorrhagic complications (e.g., placenta accreta in a patient with placenta previa and previous uterine surgery), and local institutional policies.

Perianesthetic Recording of Fetal Heart Rate Patterns

Literature findings. Studies with observational findings and case reports indicate that fetal heart rate patterns may change after the administration of neuraxial anesthetics (*Category B3/B4 evidence*).[24-31]

Survey findings. The consultants and ASA members strongly agree that fetal heart rate patterns should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor.

Recommendations for Perianesthetic Evaluation and Preparation

History and Physical Examination

- Conduct a focused history and physical examination before providing anesthesia care.
  - This should include, but is not limited to, a maternal health and anesthetic history, a relevant obstetric history, a baseline blood pressure measurement, and an airway, heart, and lung examination, consistent with the ASA "Practice Advisory for Preanesthesia Evaluation."[e]
  - When a neuraxial anesthetic is planned, examine the patient's back.
  - Recognition of significant anesthetic or obstetric risk factors should encourage consultation between the obstetrician and the anesthesiologist.
- A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.

Intrapartum Platelet Count

- The anesthesiologist's decision to order or require a platelet count should be individualized and based on a patient's history (e.g., precclampsia with severe features), physical examination, and clinical signs.[f]
  - A routine platelet count is not necessary in the healthy parturient.

Blood Type and Screen

- A routine blood cross-match is not necessary for healthy and uncomplicated parturients for vaginal or operative delivery.
- The decision whether to order or require a blood type and screen or cross-match should be based on maternal history, anticipated hemorrhagic complications (e.g., placenta accreta in a patient with placenta previa and previous uterine surgery), and local institutional policies.

Perianesthetic Recording of Fetal Heart Rate Patterns

- Fetal heart rate patterns should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor.
  - *Continuous* electronic recording of fetal heart rate patterns may not be necessary in every clinical setting and may not be possible during placement of a neuraxial catheter.[g]

Aspiration Prevention

Aspiration prevention includes (l) clear liquids, (2) solids, and (3) antacids, H_2-receptor antagonists, and metoclopramide.

Clear Liquids

Literature findings. There is insufficient published literature to examine the relation between fasting times for clear liquids and the risk of emesis/reflux or pulmonary aspiration during labor.

---

[e]Practice advisory for preanesthesia evaluation: An updated report by the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. *Anesthesiology* 2012;116:522-538.

[f]A specific platelet count predictive of neuraxial anesthetic complications has not been determined.

[g]American College of Obstetricians and Gynecologists: ACOG Practice Bulletin No. 106: Intrapartum fetal heart rate monitoring: Nomenclature, interpretation, and general management principles. *Obstet Gynecol* 2009;114:192-202.

Survey findings. ASA members agree and the consultants strongly agree that (1) oral intake of moderate amounts of clear liquids may be allowed for uncomplicated laboring patients and (2) the uncomplicated patient undergoing elective surgery (e.g., scheduled cesarean delivery or postpartum tubal ligation) may have moderate amounts of clear liquids up to 2 h before induction of anesthesia.

Solids

Literature findings. A specific fasting time for solids that is predictive of maternal anesthetic complications has not been determined. There is insufficient published literature to address the safety of *any* particular fasting period for solids in obstetric patients.

Survey findings. The consultants and ASA members strongly agree that (1) the patient undergoing elective surgery (e.g., scheduled cesarean delivery or postpartum tubal ligation) should undergo a fasting period for solids of 6 to 8 h depending on the type of food ingested (e.g., fat content); (2) laboring patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes mellitus, and difficult airway) or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis; and (3) solid foods should be avoided in laboring patients.

Antacids, H_2-Receptor Antagonists, and Metoclopramide

Literature findings. Randomized controlled trials indicate that preoperative nonparticulate antacids (e.g., sodium citrate and sodium bicarbonate) are associated with higher gastric pH values during the peripartum period (*Category A2-B evidence*)[32-35] and are equivocal regarding gastric volume (*Category A2-E evidence*).[32-33] Randomized placebo-controlled trials indicate that H_2-receptor antagonists are associated with higher gastric pH values in obstetric patients (*Category A2-B evidence*) and are equivocal regarding gastric volume (*Category A2-E evidence*).[36-38] Randomized placebo-controlled trials indicate that metoclopramide is associated with reduced peripartum nausea and vomiting (*Category A2-B evidence*).[39-43] Literature is not available that examines the relation between reduced gastric acidity and the frequency of pulmonary aspiration, emesis, morbidity, or mortality in obstetric patients who have aspirated gastric contents.

Survey findings. The consultants and ASA members both agree that before surgical procedures (e.g., cesarean delivery or postpartum tubal ligation), consider the timely administration of nonparticulate antacids, H_2-rcceptor antagonists, and/or metoclopramide for aspiration prophylaxis.

Recommendations for Aspiration Prevention[h]

Clear Liquids

- The oral intake of moderate amounts of clear liquids may be allowed for uncomplicated laboring patients.
- The uncomplicated patient undergoing elective surgery may have clear liquids up to 2 h before induction of anesthesia.
  - Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, black coffee, and sports drinks.
  - The volume of liquid ingested is less important than the presence of particulate matter in the liquid ingested.
- Laboring patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes mellitus, and difficult airway) or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis.

Solids

- Solid foods should be avoided in laboring patients.
- The patient undergoing elective surgery (e.g., scheduled cesarean delivery or postpartum tubal ligation) should undergo a fasting period for solids of 6 to 8 h depending on the type of food ingested (e.g., fat content).[i]

Antacids, H_2-Receptor Antagonists, and Metoclopramide

- Before surgical procedures (e.g., cesarean delivery or postpartum tubal ligation), consider the timely administration of nonparticulate antacids, H_2-receptor antagonists, and/or metoclopramide for aspiration prophylaxis.

Anesthetic Care for Labor and Vaginal Delivery

Anesthetic care for labor and vaginal delivery includes (1) timing of neuraxial analgesia and outcome of labor, (2) neuraxial analgesia and trial of labor after prior cesarean delivery, and (3) anesthetic/analgesic techniques. Appendix 3 contains an overview of anesthetic care for labor and vaginal delivery.[j]

Timing of Neuraxial Analgesia and Outcome of Labor

Literature findings. Meta-analyses of RCTs report equivocal findings for spontaneous, instrumented, and cesarean delivery when comparing early administration (i.e., cervical dilations of less than 4 or 5 cm) with late administration (i.e., cervical dilations of greater than 4 or 5 cm) of epidural analgesia (*Category A1-E evidence*).[44-48] An RCT comparing cervical dilations of less than 2 cm with greater than or equal to 2 cm also reports equivocal findings (*Category A3-E evidence*).[49] Finally, RCTs comparing early versus late combined spinal-epidural (CSE) analgesia administration report equivocal findings for cesarean, instrumented, and spontaneous delivery (*Category A2-E evidence*).[50,51]

[h]The Task Force recognizes that in laboring patients the timing of delivery is uncertain; therefore, adherence to a predetermined fasting period before nonelective surgical procedures is not always possible.

[i]Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: An updated report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology* 2011;114:495-511.

[j]Note that statements in Appendix 3 are intended to provide an overview and are not recommendations.

Survey findings. The consultants and ASA members strongly agree to (1) provide patients in early labor (i.e., less than 5 cm dilation) the option of neuraxial analgesia when this service is available; (2) offer neuraxial analgesia on an individualized basis; and (3) not withhold neuraxial analgesia on the basis of achieving an arbitrary cervical dilation.

Neuraxial Analgesia and Trial of Labor after Prior Cesarean Delivery

Literature findings. Nonrandomized comparative studies are equivocal regarding mode of delivery, duration of labor, and adverse outcomes when epidural analgesia is used in a trial of labor for previous cesarean delivery patients (*Category B1-E evidence*).[52-56]

Survey findings. The consultants and ASA members strongly agree (1) to offer neuraxial techniques to patients attempting vaginal birth after previous cesarean delivery and (2) that for these patients, it is appropriate to consider early placement of a neuraxial catheter that can be used later for labor analgesia or for anesthesia in the event of operative delivery.

Analgesia/anesthetic techniques. Considerations for analgesic/anesthetic techniques include (l) early insertion of a neuraxial (i.e., spinal or epidural) catheter for complicated parturients, (2) continuous infusion epidural (CIE) analgesia, (3) epidural local anesthetics combined with opioids, (4) higher versus lower concentrations of local anesthetics, (5) single-injection spinal opioids with or without local anesthetics, (6) pencil-point spinal needles, (7) CSE analgesia, and (8) patient-controlled epidural analgesia (PCEA).

Early Insertion of a Neuraxial Catheter for Complicated Parturients

Literature findings. The literature is insufficient to assess whether, when caring for the complicated parturient, the early insertion of a neuraxial catheter, with immediate or later administration of analgesia, improves maternal or neonatal outcomes.

Survey findings. The consultants and ASA members strongly agree to consider early insertion of a neuraxial catheter for obstetric (e.g., twin gestation or preeclampsia) or anesthetic indications (e.g., anticipated difficult airway or obesity) to reduce the need for GA if an emergent procedure becomes necessary.

CIE Analgesia

Literature findings. Randomized controlled trials indicate that CIE local anesthetics are associated with reduced maternal pain and discomfort compared with single-shot IV opioids during labor (*Category A2-B evidence*).[57,58] The literature is insufficient to evaluate CIE compared with continuous infusion of IV opioids. An RCT reports greater pain relief during labor for CIE when compared with intramuscular opioids (*Category A3-B evidence*), with equivocal findings for duration of labor and mode of delivery (*Category A3-E evidence*).[59] A nonrandomized comparative study reports equivocal findings for duration of labor and mode of delivery when CIE local anesthetics are compared with single-injection spinal opioids (*Category B1-E evidence*).[60]

Survey findings. The consultants and ASA members strongly agree that (1) continuous epidural infusion may be used for effective analgesia for labor and delivery, and (2) when a continuous epidural infusion of local anesthetic is selected, an opioid may be added.

Analgesic Concentrations

Literature findings. Meta-analyses of RCTs report improved analgesic quality[61-65] when comparing epidural local anesthetics combined with opioids versus equal concentrations of epidural local anesthetics without opioids (*Category A1-B evidence*). Findings were equivocal for frequency of spontaneous delivery, hypotension, pruritus, and 1-min Apgar scores (*Category A1-E evidence*).[62-73]

Randomized controlled trials are equivocal for analgesic efficacy and duration of labor when continuous epidural infusion of low concentrations of local anesthetics with opioids are compared with higher concentrations of local anesthetics without opioids for maintenance of analgesia (*Category A2-E evidence*).[74-79] Meta-analyses of RCTs are also equivocal regarding spontaneous delivery and neonatal Apgar scores when continuous epidural infusion of low concentrations of local anesthetics with opioids are compared with higher concentrations of local anesthetics without opioids (*Category A1-E evidence*).[74-80] A lower frequency of motor block was found for lower concentrations of local anesthetics (*Category A1-B evidence*).[74-76,78-80,k] The literature is insufficient to determine the effects of epidural local anesthetics with opioids on other maternal outcomes (e.g., hypotension, nausea, pruritus, respiratory depression, and urinary retention).

Survey findings. The consultants and ASA members strongly agree to use dilute concentrations of local anesthetics with opioids to produce as little motor block as possible.

Single-Injection Spinal Opioids with or without Local Anesthetics

Literature findings. An RCT reports a longer duration of analgesia when a spinal opioid is compared with an IV opioid (*Category A1-B evidence*).[81] Nonrandomized comparisons are equivocal for duration of labor, mode of delivery, and other adverse outcomes such as nausea, vomiting, headache, and pruritus (*Category B1-E evidence*).[82-84] The literature is not sufficient to compare single-injection spinal opioids with local anesthetics versus single-injection spinal opioids without local anesthetics.

Survey findings. The consultants and ASA members agree that single-injection spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor when spontaneous vaginal delivery is anticipated. The ASA members agree and the consultants strongly agree that a local anesthetic may be added

[k]The Task Force notes that the addition of an opioid to a local anesthetic infusion allows an even lower concentration of local anesthetic for providing equally effective analgesia.

to a spinal opioid to increase duration and improve quality of analgesia.

Pencil-Point Spinal Needles

Literature findings. Meta-analysis of RCTs indicate that the use of pencil-point spinal needles reduces the frequency of postdural puncture headache when compared with cutting-bevel spinal needles (*Category A1-B evidence*).[85-89]

Survey findings. The consultants and ASA members strongly agree to use pencil-point spinal needles instead of cutting-bevel spinal needles to minimize the risk of postdural puncture headache.

CSE Analgesia

Literature findings. Meta-analyses of RCTs report improved analgesia and a faster onset time (*Category A2-B evidence*) when CSE local anesthetics with opioids are compared with epidural local anesthetics with opioids,[90-96] with equivocal findings for maternal satisfaction with analgesia, mode of delivery, hypotension, pruritus, and 1-min Apgar scores (*Category A1-E evidence*).[90-101] Meta-analysis of RCTs report an increased frequency of motor block with CSE (*Category A1-H evidence*).[90,92,93,96,101]

Survey findings. The consultants and ASA members strongly agree that (1) if labor is expected to last longer than the analgesic effects of the spinal drugs chosen, or if there is a good possibility of operative delivery, then consider a catheter technique instead of a single-injection technique and (2) CSE techniques may be used to provide effective and rapid onset of analgesia for labor.

Patient-Controlled Epidural Analgesia

Literature findings. Meta-analysis of RCTs report reduced analgesic consumption (*Category A1-B evidence*) when PCEA is compared with CIE.[102-107] Meta-analysis of RCTs report equivocal findings for duration of labor, mode of delivery, motor block, and 1- and 5-min Apgar scores when PCEA is compared with CIE (*Category A1-E evidence*).[103-116] Meta-analysis of RCTs indicate greater analgesic efficacy for PCEA with a background infusion compared with PCEA without a background infusion (*Category A1-B evidence*)[117-121] and is equivocal regarding mode of delivery and frequency of motor block (*Category A1-E evidence*).[117-122]

Survey findings. The consultants and ASA members strongly agree that (l) PCEA may be used to provide an effective and flexible approach for the maintenance of labor analgesia and (2) the use of PCEA may be preferable to fixed-rate CIE for providing fewer anesthetic interventions and reducing dosages of local anesthetics. The consultants and ASA members agree that PCEA may be used with or without a background infusion.

Recommendations for Anesthetic Care for Labor and Vaginal Delivery

Timing of Neuraxial Analgesia and Outcome of Labor

- Provide patients in early labor (i.e., less than 5 cm dilation) the option of neuraxial analgesia when this service is available.
- Offer neuraxial analgesia on an individualized basis regardless of cervical dilation.
  - Reassure patients that the use of neuraxial analgesia does not increase the incidence of cesarean delivery.

Neuraxial Analgesia and Trial of Labor after Prior Cesarean Delivery

- Offer neuraxial techniques to patients attempting vaginal birth after previous cesarean delivery.
- For these patients, consider early placement of a neuraxial catheter that can be used later for labor analgesia or for anesthesia in the event of operative delivery.

Analgesia/Anesthetic Techniques

Early insertion of a neuraxial catheter for complicated parturients

- Consider early insertion of a neuraxial catheter for obstetric (e.g., twin gestation or preeclampsia) or anesthetic indications (e.g., anticipated difficult airway or obesity) to reduce the need for GA if an emergent procedure becomes necessary.
  - In these cases, the insertion of a neuraxial catheter may precede the onset of labor or a patient's request for labor analgesia.

CIE analgesia

- Continuous epidural infusion may be used for effective analgesia for labor and delivery.
- When a continuous epidural infusion of local anesthetic is selected, an opioid may be added to reduce the concentration of local anesthetic, improve the quality of analgesia, and minimize the motor block.

Analgesic concentrations

- Use dilute concentrations of local anesthetics with opioids to produce as little motor block as possible.

Single-injection spinal opioids with or without local anesthetics

- Single-injection spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor when spontaneous vaginal delivery is anticipated.
- If labor duration is anticipated to be longer than the analgesic effects of the spinal drugs chosen, or if there is a reasonable possibility of operative delivery, then consider a catheter technique instead of a single-injection technique.
- A local anesthetic may be added to a spinal opioid to increase duration and improve quality of analgesia.

Pencil-point spinal needles

- Use pencil-point spinal needles instead of cutting-bevel spinal needles to minimize the risk of postdural puncture headache.

CSE analgesia

- If labor duration is anticipated to be longer than the analgesic effects of the spinal drugs chosen, or if there is a reasonable possibility of operative delivery, then consider a catheter technique instead of a single-injection technique.
- CSE techniques may be used to provide effective and rapid onset of analgesia for labor.

Patient-controlled epidural analgesia

- Patient-controlled epidural analgesia may be used to provide an effective and flexible approach for the maintenance of labor analgesia.
- The use of PCEA may be preferable to fixed-rate CIE for administering reduced dosages of local anesthetics.
- PCEA may be used with or without a background infusion.

Removal of Retained Placenta

Techniques for removal of retained placenta include (l) anesthetic techniques for removal of retained placenta and (2) nitroglycerin for uterine relocation.

Anesthetic Techniques

Literature findings. The literature is insufficient to assess whether a particular anesthetic technique is more effective than another for removal of retained placenta.

Survey findings. The consultants and ASA members strongly agree (l) that the hemodynamic status should be assessed before administering neuraxial anesthesia and (2) if an epidural catheter is in place and the patient is hemodynamically stable, consider providing epidural anesthesia. The consultants and ASA members agree to consider aspiration prophylaxis. The consultants and ASA members strongly agree that (1) titration of sedation/analgesia should be performed carefully due to the potential risks of respiratory depression and pulmonary aspiration during the immediate postpartum period and (2) in cases involving major maternal hemorrhage with hemodynamic instability, GA with an endotracheal tube may be considered in preference to neuraxial anesthesia.

Nitroglycerin for Uterine Relaxation

Literature findings. Randomized controlled trials comparing IV or sublingual nitroglycerin with placebo for the purpose of uterine relaxation report inconsistent findings for the successful removal of retained placenta (*Category A2-E evidence*).[123-125] Observational studies and case reports indicate successful uterine relaxation and successful placental removal after IV or sublingual nitroglycerin administration (*Category B3/B4 evidence*).[126-130]

Survey findings. The ASA members agree and the consultants strongly agree that nitroglycerin may be used as an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue.

Recommendations for Removal of Retained Placenta

Anesthetic Techniques for Removal of Retained Placenta

- In general, there is no preferred anesthetic technique for removal of retained placenta.
  - If an epidural catheter is in place and the patient is hemodynamically stable, consider providing epidural anesthesia.
- Assess hemodynamic status before administering neuraxial anesthesia.
- Consider aspiration prophylaxis.
- Titrate sedation/analgesia carefully due to the potential risks of respiratory depression and pulmonary aspiration during the immediate postpartum period.
- In cases involving major maternal hemorrhage with hemodynamic instability, GA with an endotracheal tube may be considered in preference to neuraxial anesthesia.

Nitroglycerin for Uterine Relaxation

- Nitroglycerin may be used as an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue.
  - Initiating treatment with incremental doses of IV or sublingual (i.e., tablet or metered dose spray) nitroglycerin may be done to sufficiently relax the uterus.

Anesthetic Care for Cesarean Delivery

Anesthetic care for cesarean delivery consists of (1) equipment, facilities, and support personnel; (2) general, epidural, spinal, or CSE anesthesia; (3) IV fluid preloading or coloading; (4) ephedrine or phenylephrine; and (5) neuraxial opioids for postoperative analgesia after neuraxial anesthesia.

Equipment, Facilities, and Support Personnel

Literature findings. The literature is insufficient to evaluate the benefit of providing equipment, facilities, and support personnel in the labor and delivery operating suite comparable to that available in the main operating suite.

Survey findings. The consultants and ASA members strongly agree that (l) equipment, facilities, and support personnel available in the labor and delivery operating suite should be comparable to those available in the main operating suite; (2) resources for the treatment of potential complications (e.g., failed intubation, inadequate anesthesia, hypotension, respiratory depression, local anesthetic systemic toxicity, pruritus, and vomiting) should also be available in the labor and delivery operating suite; and (3) appropriate equipment and personnel should be available to care for obstetric patients recovering from major neuraxial or GA.

General, Epidural, Spinal, or CSE Anesthesia

Literature findings. Randomized controlled trials report higher Apgar scores at 1 and 5 min for epidural anesthesia when compared with GA (*Category A2-B evidence*)[131-135] and equivocal findings for umbilical artery pH values (*Category A2-E evidence*).[133,135-137] When spinal anesthesia is compared with GA, RCTs report equivocal findings for 1- and 5-min Apgar scores and umbilical artery pH values (*Category A1-E evidence*).[132,138-142] RCTs also are equivocal regarding total time in the operating room when epidural[137,140,143,144] or spinal[144,145] anesthesia is compared with GA (*Category A2-E evidence*).

When spinal anesthesia is compared with epidural anesthesia, RCTs are equivocal regarding induction-to-delivery times, hypotension, umbilical pH values, and Apgar scores (*Category A2-E evidence*).[132,144,146-153]

When CSE is compared with epidural anesthesia, RCTs report equivocal findings for the frequency of hypotension and for 1-min Apgar scores (*Category A2-E*

evidence).[133,135,154-158] RCTs report equivocal findings for delivery times, time in the operating room, hypotension, and l- and 5-min Apgar scores when CSE is compared with spinal anesthesia (*Category A2-E evidence*).[159-162]

Survey findings. The consultants and ASA members strongly agree that (1) the decision to use a particular anesthetic technique for cesarean delivery should be individualized, based on anesthetic, obstetric, or fetal risk factors (e.g., elective versus emergency), the preferences of the patient, and the judgment of the anesthesiologist; (2) uterine displacement (usually left displacement) should be maintained until delivery regardless of the anesthetic technique used; (3) consider selecting neuraxial techniques in preference to GA for most cesarean deliveries; (4) if spinal anesthesia is chosen, use pencil-point spinal needles instead of cutting-bevel spinal needles; (5) for urgent cesarean delivery, an indwelling epidural catheter may be used as an alternative to initiation of spinal anesthesia; and (6) GA may be the most appropriate choice in some circumstances (e.g., profound fetal bradycardia, ruptured uterus, severe hemorrhage, severe placental abruption, umbilical cord prolapse, and preterm footling breech).

IV Fluid Preloading or Coloading

Literature findings. Randomized controlled trial findings are inconsistent regarding the frequency of maternal hypotension when IV fluid preloading or coloading for spinal anesthesia is compared with no fluids (*Category A2-E evidence*).[163-169] Meta-analyses of RCTs are equivocal for maternal hypotension when IV fluid preloading is compared with coloading (*Category A2-E evidence*).[168,170-176]

Survey findings. The consultants and ASA members agree that IV fluid preloading may be used to reduce the frequency of maternal hypotension after spinal anesthesia for cesarean delivery. The ASA members agree and the consultants strongly agree that, although fluid preloading reduces the frequency of maternal hypotension, it does not delay the initiation of spinal anesthesia in order to administer a fixed volume of IV fluid.

Ephedrine or Phenylephrine

Literature findings. Meta-analysis of double-blind placebo-controlled RCTs report reduced maternal hypotension during anesthesia for cesarean delivery when IV ephedrine is administered compared with placebo (*Category A1-B evidence*).[177-181] RCTs are equivocal for hypotension when intramuscular ephedrine is compared with placebo (*Category A2-E evidence*).[182-184] RCTs comparing phenylephrine with placebo report a lower frequency of hypotension when higher dosages of phenylephrine are administered (*Category A2-B evidence*) and equivocal findings when lower dosages are administered (*Category A2-E evidence*).[182,185-187] Meta-analysis of double-blind RCTs report lower frequencies of patients with hypotension when infusions of phenylephrine are compared with ephedrine (*Category A1-B evidence*)[188-193]; higher umbilical artery pH values are reported for phenylephrine when compared with ephedrine (*Category A1-H evidence*).[194-199]

Survey findings. The consultants and ASA members strongly agree that IV ephedrine and phenylephrine both may be used for treating hypotension during neuraxial anesthesia.

Neuraxial Opioids for Postoperative Analgesia

Literature findings. Randomized controlled trials comparing epidural opioids with intermittent injections of IV or intramuscular opioids report improved postoperative analgesia for epidural opioids after cesarean delivery (*Category A2-B evidence*)[200-206]; meta-analysis of RCTs reports equivocal findings for nausea, vomiting, and pruritus (*Category A1-E evidence*).[200-204,206-211] RCTs report improved postoperative analgesia when PCEA is compared with IV patient-controlled analgesia (*Category A2-B evidence*) with equivocal findings for nausea, vomiting, pruritus, and sedation (*Category A2-E evidence*).[208,211]

Survey findings. The consultants and ASA members strongly agree that for postoperative analgesia after neuraxial anesthesia for cesarean delivery, selecting neuraxial opioids rather than intermittent injections of parenteral opioids should be considered.

Recommendations for Anesthetic Care for Cesarean Delivery

Equipment, Facilities, and Support Personnel

- Equipment, facilities, and support personnel available in the labor and delivery operating suite should be comparable to those available in the main operating suite.
- Resources for the treatment of potential complications (e.g., failed intubation, inadequate analgesia/anesthesia, hypotension, respiratory depression, local anesthetic systemic toxicity, pruritus, and vomiting) should also be available in the labor and delivery operating suite.
- Appropriate equipment and personnel should be available to care for obstetric patients recovering from neuraxial or GA.

General, Epidural, Spinal, or CSE Anesthesia

- The decision to use a particular anesthetic technique for cesarean delivery should be individualized, based on anesthetic, obstetric, or fetal risk factors (e.g., elective versus emergency), the preferences of the patient, and the judgment of the anesthesiologist.
  - Uterine displacement (usually left displacement) should be maintained until delivery regardless of the anesthetic technique used.
- Consider selecting neuraxial techniques in preference to GA for most cesarean deliveries.
- If spinal anesthesia is chosen, use pencil-point spinal needles instead of cutting-bevel spinal needles.
- For urgent cesarean delivery, an indwelling epidural catheter may be used as an alternative to initiation of spinal or GA.
- GA may be the most appropriate choice in some circumstances (e.g., profound fetal bradycardia, ruptured uterus, severe hemorrhage, and severe placental abruption).

IV Fluid Preloading or Coloading

- IV fluid preloading or coloading may be used to reduce the frequency of maternal hypotension after spinal anesthesia for cesarean delivery.
- Do not delay the initiation of spinal anesthesia in order to administer a fixed volume of IV fluid.

Ephedrine or Phenylephrine

- Either IV ephedrine or phenylephrine may be used for treating hypotension during neuraxial anesthesia.
- In the absence of maternal bradycardia, consider selecting phenylephrine because of improved fetal acid-base status in uncomplicated pregnancies.

Neuraxial Opioids for Postoperative Analgesia

- For postoperative analgesia after neuraxial anesthesia for cesarean delivery, consider selecting neuraxial opioids rather than intermittent injections of parenteral opioids.

Postpartum Tubal Ligation

Literature findings. The literature is insufficient to evaluate the benefits of neuraxial anesthesia compared with GA for postpartum tubal ligation. In addition, the literature is insufficient to evaluate the impact of the timing of a postpartum tubal ligation on maternal outcome.

Survey findings. The consultants and ASA members strongly agree (l) that before postpartum tubal ligation, the patient should have no oral intake of solid foods within 6 to 8 h of the surgery, depending on the type of food ingested (e.g., fat content), and (2) that both the timing of the procedure and the decision to use a particular anesthetic technique (i.e., neuraxial versus general) should be individualized based on anesthetic risk factors, obstetric risk factors (e.g., blood loss), and patient preferences. The ASA members agree and the consultants strongly agree to consider selecting neuraxial techniques in preference to GA for most postpartum tubal ligations.

Recommendations for Postpartum Tubal Ligation

- Before a postpartum tubal ligation, the patient should have no oral intake of solid foods within 6 to 8 h of the surgery, depending on the type of food ingested (e.g., fat content).[i]
- Consider aspiration prophylaxis.
- Both the timing of the procedure and the decision to use a particular anesthetic technique (i.e., neuraxial versus general) should be individualized, based on anesthetic and obstetric risk factors (e.g., blood loss), and patient preferences.
- Consider selecting neuraxial techniques in preference to GA for most postpartum tubal ligations.
  - Be aware that gastric emptying will be delayed in patients who have received opioids during labor.
  - Be aware that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals.
  - If a postpartum tubal ligation is to be performed before the patient is discharged from the hospital, do not attempt the procedure at a time when it might compromise other aspects of patient care on the labor and delivery unit.[l]

Management of Obstetric and Anesthetic Emergencies

Management of obstetric and anesthetic emergencies consists of (1) resources for management of hemorrhagic emergencies, (2) equipment for management of airway emergencies, and (3) cardiopulmonary resuscitation.

Resources for Management of Hemorrhagic Emergencies

Studies with observational findings and case reports suggest that the availability of resources for hemorrhagic emergencies may be associated with reduced maternal complications (*Category B3/B4-B evidence*).[212-219]

Survey findings. The consultants and ASA members strongly agree that institutions providing obstetric care should have resources available to manage hemorrhagic emergencies.

Equipment for Management of Airway Emergencies

Case reports suggest that the availability of equipment for the management of airway emergencies may be associated with reduced maternal, fetal, and neonatal complications (*Category B4-B evidence*).[220-228]

Survey findings. The consultants and ASA members strongly agree that labor and delivery units should have personnel and equipment readily available to manage airway emergencies consistent with the ASA Practice Guidelines for Management of the Difficult Airway, to include a pulse oximeter and carbon dioxide detector.

Cardiopulmonary Resuscitation

Literature findings. The literature is insufficient to evaluate the efficacy of cardiopulmonary resuscitation in the obstetric patient during labor and delivery. In cases of cardiac arrest, the American Heart Association has stated that 4 to 5 min is the maximum time rescuers will have to determine whether the arrest can be reversed by Basic Life Support and Advanced Cardiac Life Support interventions.[m] Delivery of the fetus may improve cardiopulmonary resuscitation of the mother by relieving aortocaval compression. The American Heart Association further notes that the best survival rate for infants more than 24 to 25 weeks in gestation occurs when the

[l]The American College of Obstetricians and Gynecologists (ACOG) has indicated that postpartum tubal ligation "should be considered an urgent surgical procedure given the consequences of a missed procedure and the limited time frame in which it may be performed." ACOG Committee Opinion No. 530: Access to postpartum sterilization. *Obstet Gynecol* 2012;120:212-215.

[m]2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation* 2010;122(18 suppl 3):S640-933.

delivery of the infant occurs no more than 5 min after the mother's heart stops beating.

Survey findings. The consultants and ASA members strongly agree that (1) basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units, and (2) if cardiac arrest occurs during labor and delivery, to initiate standard resuscitative measures with accommodations for pregnancy such as left uterine displacement and preparing for delivery of the fetus.

Recommendations for Management of Obstetric and Anesthetic Emergencies

Resources for Management of Hemorrhagic Emergencies

- Institutions providing obstetric care should have resources available to manage hemorrhagic emergencies (Box B.1).
  - In an emergency, type-specific or O-negative blood is acceptable.
  - In cases of intractable hemorrhage, when banked blood is not available or the patient refuses banked blood, consider intraoperative cell salvage if available.[n]

Equipment for Management of Airway Emergencies

- Labor and delivery units should have personnel and equipment readily available to manage airway emergencies consistent with the ASA Practice Guidelines for Management of the Difficult Airway[o] to include a pulse oximeter and carbon dioxide detector.
  - Basic airway management equipment should be immediately available during the provision of neuraxial analgesia (Box B.2).
  - Portable equipment for difficult airway management should be readily available in the operative area of labor and delivery units (Box B.3).
  - A preformulated strategy for intubation of the difficult airway should be in place.
  - When tracheal intubation has failed, consider ventilation with mask and cricoid pressure or with a supraglottic airway device (e.g., laryngeal mask airway, intubating laryngeal mask airway, or laryngeal tube) for maintaining an airway and ventilating the lungs.
  - If it is not possible to ventilate or awaken the patient, a surgical airway should be performed.

Cardiopulmonary Resuscitation.

- Basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units.

[n]Practice guidelines for perioperative blood management: An updated report by the American Society of Anesthesiologists Task Force on Perioperative Blood Management. *Anesthesiology* 2015; 122:241-275.

[o]Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology* 2013;118:251-270.

BOX B.1 Suggested Resources for Obstetric Hemorrhagic Emergencies

Large-bore IV catheters
Fluid warmer
Forced-air body warmer
Availability of blood bank resources
Massive transfusion protocol
Equipment for infusing IV fluids and blood products rapidly. Examples include, but are not limited to, hand-squeezed fluid chambers, hand-inflated pressure bags, and automatic infusion devices.

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health care facility.

BOX B.2 Suggested Resources for Airway Management during Initial Provision of Neuraxial Analgesia in a Labor Delivery Room Setting

Laryngoscope and assorted blades
Endotracheal tubes, with stylets
Oxygen source
Suction source with tubing and tonsil suction tip
Self-inflating bag and mask for positive-pressure ventilation
Medications for blood pressure support, muscle relaxation, and hypnosis

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and healthcare facility.

BOX B.3 Suggested Contents of a Portable Storage Unit for Difficult Airway Management for Cesarean Delivery Rooms

Rigid laryngoscope blades of alternate design and size
Videolaryngoscopic devices
Endotracheal tubes of assorted size
Endotracheal tube guides. Examples include (but are not limited to) semirigid stylets, light wands, and forceps designed to manipulate the distal portion of the endotracheal tube.
At least one device suitable for emergency nonsurgical airway ventilation consisting of a face mask or supraglottic airway device (e.g., laryngeal mask airway, intubating laryngeal mask airway, and laryngeal tube).
Equipment suitable for emergency surgical airway access (e.g., cricothyrotomy)

The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and healthcare facility.

Adapted from the Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology* 2013;118:251-270.

- If cardiac arrest occurs, initiate standard resuscitative measures.
  - Uterine displacement (usually left displacement) should be maintained.
  - If maternal circulation is not restored within 4 min, cesarean delivery should be performed by the obstetrics team.[p]

APPENDIX 1 SUMMARY OF RECOMMENDATIONS

PERIANESTHETIC EVALUATION AND PREPARATION

History and Physical Examination

- Conduct a focused history and physical examination before providing anesthesia care.
  - This should include, but is not limited to, a maternal health and anesthetic history, a relevant obstetric history, a baseline blood pressure measurement, and an airway, heart, and lung examination, consistent with the American Society of Anesthesiologists (ASA) "Practice Advisory for Preanesthesia Evaluation."[e]
  - When a neuraxial anesthetic is planned or placed, examine the patient's back.
  - Recognition of significant anesthetic or obstetric risk factors should encourage consultation between the obstetrician and the anesthesiologist.
- A communication system should be in place to encourage the early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.

Intrapartum Platelet Count

- The anesthesiologist's decision to order or require a platelet count should be individualized and based on a patient's history (e.g., preeclampsia with severe features), physical examination, and clinical signs.[q]
  - A routine platelet count is not necessary in the healthy parturient.

Blood Type and Screen

- A routine blood cross-match is not necessary for healthy and uncomplicated parturients for vaginal or operative delivery.
- The decision whether to order or require a blood type and screen or cross-match should be based on maternal history, anticipated hemorrhagic complications (e.g., placenta accreta in a patient with placenta previa and previous uterine surgery), and local institutional policies.

Perianesthetic Recording of Fetal Heart Rote Patterns

- Fetal heart rate patterns should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor.
  - *Continuous* electronic recording of fetal heart rate patterns may not be necessary in every clinical setting and may not be possible during placement of a neuraxial catheter.[g]

ASPIRATION PREVENTION

Clear Liquids

- The oral intake of moderate amounts of clear liquids may be allowed for uncomplicated laboring patients.
- The uncomplicated patient undergoing elective surgery may have clear liquids up to 2 h before induction of anesthesia.
  - Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, black coffee, and sports drinks.
  - The volume of liquid ingested is less important than the presence of particulate matter in the liquid ingested.
- Laboring patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes mellitus, and difficult airway) or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis.

Solids

- Solid foods should be avoided in laboring patients.
- The patient undergoing elective surgery (e.g., scheduled cesarean delivery or postpartum tubal ligation) should undergo a fasting period for solids of 6 to 8 h depending on the type of food ingested (e.g., fat content).[r]

Antacids, H_2-Receptor Antagonists, and Metoclopramide

- Before surgical procedures (e.g., cesarean delivery and postpartum tubal ligation), consider the timely administration of nonparticulate antacids, H_2-rcceptor antagonists, and/or metoclopramide for aspiration prophylaxis.

[p]More information on management of cardiac arrest can be found in: Lipman S, Cohen S, Einav S, et al.; Society for Obstetric Anesthesia and Perinatology: The Society for Obstetric Anesthesia and Perinatology consensus statement on the management of cardiac arrest in pregnancy. *Anesth Analg* 2014;118:1003-1016.

[q]A specific platelet count predictive of neuraxial anesthetic complications has not been determined.

[r]Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk or pulmonary aspiration: An updated report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology* 2011;114:495-511.

ANESTHETIC CARE FOR LABOR AND DELIVERY

Timing of Neuraxial Analgesia and Outcome of Labor

- Provide patients in early labor (i.e., less than 5 cm dilation) the option of neuraxial analgesia when this service is available.
- Offer neuraxial analgesia on an individualized basis regardless of cervical dilation.
  - Reassure patients that the use of neuraxial analgesia does not increase the incidence of cesarean delivery.

Neuraxial Analgesia and Trial of Labor after Prior Cesarean Delivery

- Offer neuraxial techniques to patients attempting vaginal birth after previous cesarean delivery.
- For these patients, consider early placement of a neuraxial catheter that can be used later for labor analgesia or for anesthesia in the event of operative delivery.

Analgesia/Anesthetic Techniques

Early Insertion of a Neuraxial (i.e., Spinal or Epidural) Catheter for Complicated Parturients

- Consider early insertion of a neuraxial catheter for obstetric (e.g., twin gestation or preeclampsia) or anesthetic indications (e.g., anticipated difficult airway or obesity) to reduce the need for general anesthesia if an emergent procedure becomes necessary.
  - In these cases, the insertion of a neuraxial catheter may precede the onset of labor or a patient's request for labor analgesia.

Continuous Infusion Epidural Analgesia

- Continuous epidural infusion may be used for effective analgesia for labor and delivery.
- When a continuous epidural infusion of local anesthetic is selected, an opioid may be added to reduce the concentration of local anesthetic, improve the quality of analgesia, and minimize motor block.

Analgesic Concentrations

- Use dilute concentrations of local anesthetics with opioids to produce as little motor block as possible.

Single-Injection Spinal Opioids with or without Local Anesthetics

- Single-injection spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor when spontaneous vaginal delivery is anticipated.
- If labor duration is anticipated to be longer than the analgesic effects of the spinal drugs chosen, or if there is a reasonable possibility of operative delivery, then consider a catheter technique instead of a single-injection technique.
- A local anesthetic may be added to a spinal opioid to increase duration and improve quality of analgesia.

Pencil-Point Spinal Needles

- Use pencil-point spinal needles instead of cutting-bevel spinal needles to minimize the risk of postdural puncture headache.

Combined Spinal-Epidural Analgesia

- If labor duration is anticipated to be longer than the analgesic effects of the spinal drugs chosen, or if there is a reasonable possibility of operative delivery, then consider a catheter technique instead of a single-injection technique.
- Combined spinal–epidural techniques may be used to provide effective and rapid onset of analgesia for labor.

Patient-Controlled Epidural Analgesia

- Patient-controlled epidural analgesia (PCEA) may be used to provide an effective and flexible approach for the maintenance of labor analgesia.
- The use of PCEA may be preferable to fixed-rate continuous infusion epidural analgesia for administering reduced dosages of local anesthetics.
- PCEA may be used with or without a background infusion.

REMOVAL OF RETAINED PLACENTA

Anesthetic Techniques

- In general, there is no preferred anesthetic technique for removal of retained placenta.
  - If an epidural catheter is in place and the patient is hemodynamically stable, consider providing epidural anesthesia.
- Assess hemodynamic status before administering neuraxial anesthesia.
- Consider aspiration prophylaxis.
- Titrate sedation/analgesia carefully due to the potential risks of respiratory depression and pulmonary aspiration during the immediate postpartum period.
- In cases involving major maternal hemorrhage with hemodynamic instability, general anesthesia with an endotracheal tube may be considered in preference to neuraxial anesthesia.

Nitroglycerin for Uterine Relaxation

- Nitroglycerin may be used as an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue.
  - Initiating treatment with incremental doses of IV or sublingual (i.e., tablet or metered dose spray) nitroglycerin may be done to sufficiently relax the uterus.

ANESTHETIC CARE FOR CESAREAN DELIVERY

Equipment, Facilities, and Support Personnel

- Equipment, facilities, and support personnel available in the labor and delivery operating suite should be comparable to those available in the main operating suite.
- Resources for the treatment of potential complications (e.g., failed intubation, inadequate analgesia/anesthesia, hypotension, respiratory depression, local anesthetic systemic toxicity, pruritus, and vomiting) should also be available in the labor and delivery operating suite.
- Appropriate equipment and personnel should be available to care for obstetric patients recovering from neuraxial or general anesthesia.

General, Epidural, Spinal, or Combined Spinal-Epidural Anesthesia

- The decision to use a particular anesthetic technique for cesarean delivery should be individualized, based on anesthetic, obstetric, or fetal risk factors (e.g., elective versus emergency), the preferences of the patient, and the judgment of the anesthesiologist.
  - Uterine displacement (usually left displacement) should be maintained until delivery regardless of the anesthetic technique used.
- Consider selecting neuraxial techniques in preference to general anesthesia for most cesarean deliveries.
- If spinal anesthesia is chosen, use pencil-point spinal needles instead of cutting-bevel spinal needles.
- For urgent cesarean delivery, an indwelling epidural catheter may be used as an alternative to initiation of spinal or general anesthesia.
- General anesthesia may be the most appropriate choice in some circumstances (e.g., profound fetal bradycardia, ruptured uterus, severe hemorrhage, severe placental abruption, umbilical cord prolapse, and preterm footling breech).

IV Fluid Preloading or Coloading

- IV fluid preloading or coloading may be used to reduce the frequency of maternal hypotension after spinal anesthesia for cesarean delivery.
- Do not delay the initiation of spinal anesthesia in order to administer a fixed volume of IV fluid.

Ephedrine or Phenylephrine

- Either IV ephedrine or phenylephrine may be used for treating hypotension during neuraxial anesthesia.
- In the absence of maternal bradycardia, consider selecting phenylephrine because of improved fetal acid-base status in uncomplicated pregnancies.

Neuraxial Opioids for Postoperative Analgesia

- For postoperative analgesia after neuraxial anesthesia for cesarean delivery, consider selecting neuraxial opioids rather than intermittent injections of parenteral opioids.

POSTPARTUM TUBAL LIGATION

- Before a postpartum tubal ligation, the patient should have no oral intake of solid foods within 6 to 8 h of the surgery, depending on the type of food ingested (e.g., fat content).[r]
- Consider aspiration prophylaxis.
- Both the timing of the procedure and the decision to use a particular anesthetic technique (i.e., neuraxial versus general) should be individualized, based on anesthetic and obstetric risk factors (e.g., blood loss) and patient preferences.
- Consider selecting neuraxial techniques in preference to general anesthesia for most postpartum tubal ligations.
  - Be aware that gastric emptying will be delayed in patients who have received opioids during labor.
  - Be aware that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals.
  - If a postpartum tubal ligation is to be performed before the patient is discharged from the hospital, do not attempt the procedure at a time when it might compromise other aspects of patient care on the labor and delivery unit.[l]

MANAGEMENT OF OBSTETRIC AND ANESTHETIC EMERGENCIES

Resources for Management of Hemorrhagic Emergencies

- Institutions providing obstetric care should have resources available to manage hemorrhagic emergencies (Box B.l).
  - In an emergency, type-specific or O-negative blood is acceptable.
  - In cases of intractable hemorrhage, when banked blood is not available or the patient refuses banked blood, consider intraoperative cell salvage if available.[n]

Equipment for Management of Airway Emergencies

- Labor and delivery units should have personnel and equipment readily available to manage airway emergencies consistent with the ASA Practice Guidelines for Management of the Difficult Airway,[o] to include a pulse oximeter and carbon dioxide detector.
  - Basic airway management equipment should be immediately available during the provision of neuraxial analgesia (Box B.2).
  - Portable equipment for difficult airway management should be readily available in the operative area of labor and delivery units (Box B.3).
  - A preformulated strategy for intubation of the difficult airway should be in place.
  - When tracheal intubation has failed, consider ventilation with mask and cricoid pressure or with a supraglottic airway device (e.g., laryngeal mask airway,

intubating laryngeal mask airway, and laryngeal tube) for maintaining an airway and ventilating the lungs.
- If it is not possible to ventilate or awaken the patient, a surgical airway should be performed.

Cardiopulmonary Resuscitation

- Basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units.
- If cardiac arrest occurs, initiate standard resuscitative measures.
  - Uterine displacement (usually left displacement) should be maintained.
  - If maternal circulation is not restored within 4 min, cesarean delivery should be performed by the obstetrics team.[p]

APPENDIX 2 METHODS AND ANALYSES

For these updated guidelines, a review of studies used in the development of the previous update was combined with studies published subsequent to approval of the update in 2006.[b] The scientific assessment of these guidelines was based on evidence linkages or statements regarding potential relations between clinical interventions and outcomes. The interventions listed below were examined to assess their relation to a variety of outcomes related to obstetric anesthesia.[s]

PREANESTHETIC EVALUATION AND PREPARATION

- Conducting a focused history (patient condition)
- Conducting a physical examination
- Communication between anesthetic and obstetric providers
- Laboratory tests
  - Routine intrapartum platelet count
  - Platelet count for suspected preeclampsia or coagulopathy
  - Blood type and screen or cross-match
- Recording of fetal heart rate patterns

ASPIRATION PREVENTION

- Oral intake of clear liquids for laboring patients
- Oral intake of solids for laboring patients
- A fasting period for solids of 6 to 8 h before an elective cesarean
- Nonparticulate antacids versus no antacids before operative procedures (excluding operative vaginal delivery)
- H_2-receptor antagonists (e.g., cimetidine, ranitidine, or famotidine) versus no H_2 antagonists before operative procedures (excluding operative vaginal delivery)
- Metoclopramide versus no metoclopramide before operative procedures (excluding operative vaginal delivery)

ANESTHETIC CARE FOR LABOR AND VAGINAL DELIVERY

- Early versus late administration of neuraxial analgesia (e.g., cervical dilations of less than 5 versus greater than 5 cm or less than 4 versus greater than 4 cm)
- Neuraxial techniques for labor for patients attempting vaginal birth after prior cesarean delivery
- Prophylactic neuraxial catheter insertion for obstetric (e.g., twin gestation or preeclampsia) or anesthetic indications (e.g., anticipated difficult airway or obesity)
- Continuous infusion epidural (CIE) of local anesthetics
  - CIE of local anesthetics (with or without opioids) versus intramuscular opioids for labor
  - CIE of local anesthetics (with or without opioids) versus IV opioids for labor
  - CIE of local anesthetics with or without opioids versus spinal opioids with or without local anesthetics for labor
- Analgesic concentrations
  - Induction of epidural analgesia using local anesthetics with opioids versus equal concentrations of epidural local anesthetics without opioids for labor
  - Induction of epidural analgesia using local anesthetics with opioids versus higher concentrations of epidural local anesthetics without opioids for labor
  - Maintenance of epidural infusion of lower concentrations of local anesthetics with opioids versus higher concentrations of local anesthetics without opioids for labor
  - Maintenance of epidural infusion with bupivacaine concentrations less than 0.125% with opioids versus bupivacaine concentrations greater than 0.125% without opioids for labor
- Single-injection spinal opioids
  - Single-injection spinal opioids with or without local anesthetics versus parenteral opioids for labor
  - Single-injection spinal opioids with local anesthetics versus spinal opioids without local anesthetics for labor
- Pencil-point spinal needles
  - Pencil-point spinal needles versus cutting-bevel spinal needles
- Combined spinal-epidural (CSE) local anesthetics with opioids
  - CSE local anesthetics with opioids versus epidural local anesthetics with opioids for labor
- Patient-controlled epidural analgesia (PCEA)
  - PCEA versus CIE for labor
  - PCEA with a background infusion versus PCEA without a background infusion for labor
- Removal of retained placenta
  - Anesthetic techniques
  - Administration of nitroglycerin for uterine relaxation

[s]Unless otherwise specified, outcomes for the listed interventions refer to the reduction of maternal, fetal, and neonatal complications.

ANESTHETIC CARE FOR CESAREAN DELIVERY

- Equipment, facilities, and support personnel
  - Availability of equipment, facilities, and support personnel
- General, epidural, spinal, or CSE anesthesia
  - General anesthesia (GA) versus epidural anesthesia
  - Epidural versus spinal anesthesia
  - CSE anesthesia versus epidural anesthesia
  - CSE anesthesia versus spinal anesthesia
  - *In situ* epidural catheter versus no epidural anesthesia in hemodynamically stable patients for removal of retained placenta
  - GA versus neuraxial anesthesia in cases involving major maternal hemorrhage for removal of retained placenta
- IV fluid preloading or coloading
  - IV fluid preloading or coloading versus no IV fluid preloading or coloading for spinal anesthesia to reduce maternal hypotension
  - IV fluid preloading versus coloading
- Ephedrine or phenylephrine
  - Ephedrine versus placebo or no ephedrine
  - Phenylephrine versus placebo or no ephedrine
  - Ephedrine versus phenylephrine
- Neuraxial opioids for postoperative analgesia
  - Neuraxial opioids versus intermittent injections of parenteral opioids for postoperative analgesia after neuraxial anesthesia for cesarean
  - PCEA versus IV patient-controlled analgesia for postoperative analgesia after neuraxial anesthesia for cesarean
  - Addition of nonsteroidal antiinflammatory drugs versus no nonsteroidal antiinflammatory drugs for postoperative analgesia after neuraxial anesthesia for cesarean

POSTPARTUM TUBAL LIGATION

- A fasting period for solids of 6 to 8 h before postpartum tubal ligation
- Aspiration prophylaxis for postpartum tubal ligation
- Neuraxial anesthesia versus GA for postpartum tubal ligation
- Postpartum tubal ligation within 8 h of delivery

MANAGEMENT OF OBSTETRIC AND ANESTHETIC EMERGENCIES

Resources for Management of Hemorrhagic Emergencies

- Equipment, facilities, and support personnel available in the labor and delivery suite comparable to that available in the main operating suite
- Resources for management of hemorrhagic emergencies (e.g., red blood cells, platelets, and cell salvage)
- Invasive hemodynamic monitoring for severe preeclamptic patients

Resources for Management of Airway Emergencies

- Equipment for management of airway emergencies

Cardiopulmonary Resuscitation

- Basic and advanced life-support equipment in the labor and delivery suite

State of the Literature

For the literature review, potentially relevant clinical studies were identified via electronic and manual searches of the literature. The updated searches covered an 11-yr period from January 1, 2005 to July 31, 2015. New citations were reviewed and combined with pre-2005 articles used in the previous update, resulting in a total of 478 articles that contained direct linkage-related evidence. Search terms consisted of the interventions indicated above guided by the appropriate inclusion/exclusion criteria as stated in the "Focus" section of these Guidelines. A complete bibliography used to develop these guidelines, organized by section, is available as Supplemental Digital Content 2, http://links.lww.com/ALN/B220.

Each pertinent outcome reported in a study was classified by evidence category and level, and designated as either beneficial, harmful, or equivocal. Findings were then summarized for each evidence linkage. Literature pertaining to 13 evidence linkages contained enough studies with well-defined experimental designs and statistical information sufficient to conduct meta-analyses. These linkages were (1) early versus late epidural anesthetics, (2) epidural local anesthetics with opioids versus equal concentrations of epidural local anesthetics without opioids, (3) CIE of local anesthetics with opioids versus higher concentrations of local anesthetics without opioids, (4) pencil-point versus cutting-bevel spinal needles, (5) CSE local anesthetics with opioids versus epidural local anesthetics with opioids, (6) PCEA versus CIE anesthetics, (7) PCEA with a background infusion versus PCEA, (8) GA versus epidural anesthesia for cesarean delivery, (9) CSE anesthesia versus epidural anesthesia for cesarean delivery, (10) fluid preloading versus coloading for cesarean delivery, (11) ephedrine versus placebo for cesarean delivery, (12) ephedrine versus phenylephrine for cesarean delivery, and (13) neuraxial versus parenteral opioids for postoperative analgesia.

General variance-based effect-size estimates or combined probability tests were obtained for continuous outcome measures, and Mantel–Haenszel odds ratios were obtained for dichotomous outcome measures. Two combined probability tests were used as follows: (l) the Fisher combined test, producing chi-square values based on logarithmic transformations of the reported *P* values from the independent studies, and (2) the Stouffer combined test, providing weighted representation of the studies by weighting each of the standard normal deviates by the size of the sample. An odds ratio procedure based on the Mantel–Haenszel method for combining study results using 2 x 2 tables was used with

outcome frequency information. An acceptable significance level was set at a *P* value of less than 0.01 (one tailed). Tests for heterogeneity of the independent studies were conducted to assure consistency among the study results. DerSimonian–Laird random-effects odds ratios were obtained when significant heterogeneity was found ($P < 0.01$). To control for potential publishing bias, a "fail-safe n" value was calculated. No search for unpublished studies was conducted, and no reliability tests for locating research results were done. To be accepted as significant findings, Mantel–Haenszel odds ratios must agree with combined test results whenever both types of data are assessed. In the absence of Mantel–Haenszel odds ratios, findings from both the Fisher and weighted Stouffer combined tests must agree with each other to be acceptable as significant.

For the previous update, interobserver agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a κ statistic for two-rater agreement pairs were as follows: (l) type of study design, $\kappa = 0.83$ to 0.94; (2) type of analysis, $\kappa = 0.71$ to 0.93; (3) evidence linkage assignment, $\kappa = 0.87$ to 1.00; and (4) literature inclusion for database, $\kappa = 0.74$ to 1.00. Three-rater chance-corrected agreement values were as follows: (l) study design, Sav = 0.884, Var (Sav) = 0.004; (2) type of analysis, Sav = 0.805, Var (Sav) = 0.009; (3) linkage assignment, Sav = 0.911, Var (Sav) = 0.002; (4) literature database inclusion, Sav = 0.660, Var (Sav) = 0.024. These values represent moderate to high levels of agreement.

Consensus-Based Evidence

For the previous update, consensus was obtained from multiple sources, including (1) survey opinion from consultants who were selected based on their knowledge or expertise in obstetric anesthesia or maternal and fetal medicine, (2) survey opinions solicited from active members of the American Society of Anesthesiologists (ASA), (3) testimony from attendees of publicly-held open forums at two national anesthesia meetings, (4) Internet commentary, and (5) Task Force opinion and interpretation. The survey rate of return was 75% (n = 76 of 102) for the consultants, and 2,326 surveys were received from active ASA members. Results of the surveys are reported in the guidelines.

The consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the guidelines were instituted. The rate of return was 35% (n = 36). The percent of responding consultants expecting *no change* associated with each linkage were as follows: perianesthetic evaluation: 97%; aspiration prophylaxis: 83%; anesthetic care for labor and delivery: 89%; removal of retained placenta: 97%; anesthetic choices for cesarean delivery: 97%; postpartum tubal ligation: 97%; and management of complications: 94%. Ninety-seven percent of the respondents indicated that the guidelines would have *no effect* on the amount of time spent on a typical case. One respondent indicated that there would be an increase of 5 min in the amount of time spent on a typical case with the implementation of these guidelines.

APPENDIX 3 OVERVIEW OF ANESTHETIC CARE FOR LABOR AND DELIVERY[t]

Not all women require anesthetic care during labor or delivery. For women who request pain relief for labor and/or delivery, there are many effective analgesic techniques available. Maternal request represents sufficient justification for pain relief. In addition, maternal medical and obstetric conditions may warrant the provision of neuraxial techniques to improve maternal and neonatal outcome.

The choice of analgesic technique depends on the medical status of the patient, progress of labor, and resources at the facility. When sufficient resources (e.g., anesthesia and nursing staff) are available, neuraxial catheter techniques should be one of the analgesic options offered. The choice of a specific neuraxial technique should be individualized and based on anesthetic risk factors, obstetric risk factors, patient preferences, progress of labor, and resources at the facility.

When neuraxial techniques are used for analgesia during labor or vaginal delivery, the primary goal is to provide an adequate maternal analgesia with minimal motor block (e.g., achieved with the administration of local anesthetics at low concentrations with or without opioids).

When a neuraxial technique is chosen, appropriate resources for the treatment of complications (e.g., hypotension, systemic toxicity, and high spinal anesthesia) should be available. If an opioid is added, treatments for related complications (e.g., pruritus, nausea, and respiratory depression) should be available. An IV infusion should be established before the initiation of neuraxial analgesia or general anesthesia and maintained throughout the duration of the neuraxial analgesic or anesthetic. However, administration of a fixed volume of IV fluid is not required before neuraxial analgesia is initiated.

Acknowledgments

Support was provided solely from institutional and/or departmental sources.

Optimal Goals for Anesthesia Care in Obstetrics[a]

COMMITTEE OF ORIGIN: OBSTETRIC ANESTHESIA

Abstract: Good obstetric care requires the availability of qualified personnel and equipment to administer general or neuraxial anesthesia. The extent and degree to which anesthesia services are available varies widely among hospitals. However, for any hospital providing obstetric care, certain optimal anesthesia goals should be sought. These include the following:

I. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary. For many women, neuraxial anesthesia (epidural, spinal, or combined spinal-epidural) will be the most appropriate anesthetic.
II. Availability of a licensed practitioner who is credentialed to maintain support of vital functions in any obstetric emergency.
III. Availability of anesthesia and surgical personnel to permit the start of a cesarean delivery in a timely manner in accordance with clinical needs and local resources.
IV. Because the risks associated with trial of labor after cesarean delivery (TOLAC) and uterine rupture may be unpredictable, the immediate availability of appropriate facilities and personnel (including obstetric anesthesia; nursing personnel; and a physician capable of monitoring labor and performing cesarean delivery, including an emergency cesarean delivery) is optimal. When resources for immediate cesarean delivery are not available, patients considering TOLAC should discuss the hospital's resources and availability of obstetric, anesthetic, pediatric, and nursing staff with their obstetric provider[1]; patients should be clearly informed of the potential increase in risk and the management alternatives. The definition of *immediately available personnel and facilities* remains a local decision based on each institution's available resources and geographic location.
V. Appointment of a qualified anesthesia provider to be responsible for all anesthetics administered. There are many obstetric units where physicians or physician-supervised nurse anesthetists administer labor anesthetics. The administration of general or neuraxial anesthesia requires both medical judgment and technical skills. Thus, a physician with privileges in anesthesiology should be readily available.

Persons administering or supervising obstetric anesthesia should be qualified to manage the infrequent but occasionally life-threatening complications of neuraxial anesthesia, such as respiratory and cardiovascular failure, toxic local anesthetic convulsions, or vomiting and aspiration. Mastering and retaining the skills and knowledge necessary to manage these complications requires adequate training and frequent application.

To ensure the safest and most effective anesthesia for obstetric patients, the physician Director of Anesthesia Services, with the approval of the medical staff, should develop and enforce written policies regarding provision of obstetric anesthesia. These include the following:

I. A qualified physician with obstetric privileges to perform operative vaginal or cesarean delivery who concurs with the patient's management and has knowledge of the maternal and fetal status and progress of labor should be readily available during administration of anesthesia. *Readily available* should be defined by each institution within the context of its resources and geographic location. Neuraxial and/or general anesthesia should not be administered until the patient has been examined and the fetal status and progress of labor evaluated by a qualified individual.
II. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite. This should include the availability of a properly equipped and staffed recovery room capable of receiving and caring for all patients recovering from neuraxial or general anesthesia. Birthing facilities, when used for labor anesthesia services or surgical anesthesia, must be appropriately equipped to provide safe anesthetic care during labor and delivery or postanesthesia recovery care.

[a]Approved by the ASA House of Delegates on October 17, 2007, and last amended on October 26, 2016.

III. Personnel, other than the surgical team, should be immediately available to assume care of the newborn. The obstetric provider and anesthesia provider are responsible for the mother and may not be able to leave her to care for the newborn.

In larger maternity units and those functioning as high-risk centers, 24-hour in-house anesthesia, obstetric, and neonatal specialists are usually available. Preferably, the obstetric anesthesia services should be directed by an anesthesia provider with special training or experience in obstetric anesthesia. These units will also frequently require the availability of more sophisticated monitoring equipment and specially trained nursing personnel.

Finally, good interpersonal relations between obstetric providers and anesthesia providers are important. Joint meetings between the two departments should be encouraged. Anesthesia providers should recognize the special needs and concerns of obstetric providers, who in turn should recognize the anesthesia provider as a consultant in the management of pain and life-support measures. Both should recognize the need to provide high-quality care for all patients.

Information Technology Resources for Obstetric Anesthesia Providers

Richard C. Month, MD, FASA, William Camann, MD, Larry F. Chu, MD, MS (BCHM), MS (Epidemiology)

A variety of information technology–based resources exist for obstetric anesthesia clinicians, offering information regarding clinical practice, ongoing research, and recent publications, and providing avenues for professional interaction among clinicians, patients, the media, and others. This appendix should serve as a brief guide to some of these resources, which include websites, mobile computing applications, and social media resources, including Facebook, Twitter,[a] and LinkedIn, where available. We have chosen to organize these resources into four sections for ease of navigation: (1) societies and organizations, (2) journals and online information resources, (3) multimedia learning resources, and (4) online communities of practice.

These sites were active at the time this guide was prepared (November, 2018). The authors of this appendix, and the editors and publisher of this textbook, bear no responsibility for the accuracy (or lack thereof) of any information found in these sites. Publication of this list does not imply endorsement of these sites.

For long web addresses, we have used URL-shortening (Bit.ly) to facilitate web browser entry.

Section I: Societies and Organizations
Obstetric anesthesia societies, other professional societies of interest including pediatrics and obstetrics and gynecology, and governmental regulatory organizations.

Section II: Journals and Online Information Resources
Leading obstetric anesthesia journals and related online information resources including pediatrics and obstetrics and gynecology journals.

Section III: Multimedia Learning Resources
Multimedia learning resources, including video, audio podcasts, and virtual reality screen-based simulation in obstetric anesthesia.

Section IV: Online Communities of Practice
Social media, communities of practice, and online groups of subject matter experts in obstetric anesthesia.

SECTION I: SOCIETIES AND ORGANIZATIONS

OBSTETRIC ANESTHESIA SOCIETIES

The Society for Obstetric Anesthesia and Perinatology (SOAP)

Web: http://soap.org

Facebook: http://www.facebook.com/soaphq

Twitter: @SOAPHQ

SOAP is a subspecialty anesthesiology society based in the United States that promotes excellence in research, education, and the clinical practice of obstetric anesthesiology and perinatology. Significant amounts of educational material are freely available for all users. Freely-available resources include the SOAP Consensus Statement on the Anesthetic Management of Pregnant and Postpartum Women Receiving Thromboprophylaxis or Higher Dose Anticoagulants, available at http://bit.ly/SOAPAnticoag.

The Obstetric Anaesthetists Association (OAA)

Web: http://www.oaa-anaes.ac.uk

Facebook: http://bit.ly/oaafacebook

Twitter: @OAAInfo

The OAA provides both education and training for anesthesia clinicians in the United Kingdom and other countries, and serves as a resource for women seeking information about analgesia for

[a] TWITTER, TWEET, RETWEET, and the Twitter logo are trademarks of Twitter, Inc. or its affiliates.

labor and anesthesia for cesarean delivery. Significant amounts of educational material are freely available for all users.

OTHER PROFESSIONAL SOCIETIES OF INTEREST

The American Academy of Pediatrics (AAP)

Web: http://www.aap.org

Facebook: https://www.facebook.com/AmerAcadPeds

Twitter: @AmerAcadPeds

LinkedIn: http://bit.ly/aaplinkedin

The AAP promotes the attainment of optimal physical, mental, and social health and well-being for all infants, children, adolescents, and young adults. Significant amounts of educational material are freely available.

The American College of Obstetricians and Gynecologists (ACOG)

Web: http://www.acog.org

Facebook: http://www.facebook.com/ACOGNational

Twitter: @ACOGNews

The ACOG promotes health care for women through policy and guideline development, education, and advocacy. A password is required for access to much of the online information, including committee opinions and practice bulletins and guidelines.

The American Society of Anesthesiologists (ASA)

Web: http://www.asahq.org

Facebook: https://www.facebook.com/AmericanSocietyofAnesthesiologists

Twitter: @ASALifeline

LinkedIn: http://www.linkedin.com/company/american-society-of-anesthesiologists

The ASA encourages education, research, and scientific progress in anesthesiology. The ASA strives to be an advocate for all patients who require anesthesia or relief from pain. The majority of documents, policies, and guidelines are freely available; some sections require a password for access. The ASA practice guidelines for obstetric anesthesia can be found at http://bit.ly/ASAOBGuidelines, and are included in Appendix B of this text.

The American Society of Regional Anesthesia and Pain Medicine (ASRA)

Web: http://www.asra.com

Facebook: http://bit.ly/ASRAFacebook

Twitter: @asra_society

LinkedIn: http://bit.ly/asralinkedin

The ASRA provides clinical and professional education for physicians and scientists, promotes excellence in patient care, and encourages research to advance the scientific basis of regional anesthesia and pain medicine. The ASA/ASRA practice advisory regarding infectious complications of neuraxial blockade can be found at http://bit.ly/ASAASRAInfectious.

The Anesthesia Patient Safety Foundation (APSF)

Web: http://www.apsf.org

Facebook: https://www.facebook.com/APSForg/

Twitter: @APSFOrg

The APSF seeks to improve patient safety during anesthesia care by encouraging and conducting research and education, programs and campaigns, and national and international exchange of information and ideas. Significant amounts of educational material are freely available for all users. The APSF Newsletter can be found at https://www.apsf.org/apsf-newsletter/.

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN)

Web: http://www.awhonn.org

Facebook: https://www.facebook.com/AWHONN

Twitter: @AWHONN

LinkedIn: https://www.linkedin.com/company/awhonn

The AWHONN seeks to improve the health of women and newborns, and to strengthen the nursing profession through advocacy, research, education, and provision of other professional and clinical resources for nurses and other health care professionals. Some content is freely available for all users. The AWHONN position statement on Nursing Support of Laboring Women is available at http://bit.ly/AWHONNSupport. The AWHONN position statement on the role of the registered nurse in the care of the pregnant woman receiving analgesia/anesthesia by neuraxial catheter techniques is available at http://bit.ly/AWHONN-Neuraxial.

The Canadian Anesthesiologists' Society (CAS)

Web: http://www.cas.ca

Facebook: https://www.facebook.com/CanadianAnesthesiologistsSociety/

Twitter: @CASUpdate

The CAS promotes science, vigilance, and compassion in the practice of anesthesiology. Significant amounts of information (including practice guidelines) are freely available for all users. The CAS guidelines for regional (neuraxial) analgesia in obstetric patients can be found as a section in the CAS Guidelines to the Practice of Anesthesia at http://www.cas.ca/English/Page/Files/97_Guidelines-2017.pdf.

The International Anesthesia Research Society (IARS)

Web: http://www.iars.org

The IARS encourages the development and dissemination of current, state-of-the-art basic and clinical research data and the newest advances in all areas of clinical anesthesia care.

The International Fetal Medicine and Surgery Society (IFMSS)

Web: http://ifmss.org

The IFMSS promotes education and research related to the field of fetal diagnosis and therapy.

The North American Society of Obstetric Medicine (NASOM)

Web: http://www.nasom.org

The NASOM promotes and supports research collaboration, communication, and teaching concerning the medical care of pregnant women. General internists from the United States and Canada form the core membership of the society.

The Society for Maternal-Fetal Medicine (SMFM)

Web: http://www.smfm.org

Facebook: http://bit.ly/SMFMFacebook

Twitter: @MySMFM

The SMFM seeks to promote and expand education and research in maternal-fetal medicine and encourages the exchange of new ideas and research concerning the most recent approaches and treatments for obstetric problems.

The Society of Obstetric Medicine of Australia and New Zealand (SOMANZ)

Web: http://www.somanz.org

The SOMANZ seeks to advance clinical and scientific knowledge of hypertensive diseases and medical disorders in pregnancy and to foster collaboration with other regional and international societies interested in hypertension in pregnancy and obstetric medicine.

GOVERNMENTAL REGULATORY ORGANIZATIONS

The Centers for Disease Control and Prevention (CDC)

Web: http://www.cdc.gov

Facebook: https://www.facebook.com/CDC

Twitter: @CDCgov

The CDC provides extensive information on most health-related subjects. For example, information is available on assisted reproductive technologies, birth rates, birth defects, breast-feeding, medication use during pregnancy, nutrition in pregnancy, preterm labor, maternal mortality, and various disease processes in pregnancy.

Mothers and Babies: Reducing Risk Through Audits and Confidential Enquiries Across the UK (MBRRACE-UK)

Web: https://www.npeu.ox.ac.uk/mbrrace-uk

MBRRACE-UK has replaced CMACE as the organization through which severe maternal and perinatal morbidity and mortality are reported and studied in the United Kingdom. They provide extensive information on maternal and perinatal mortality statistics, including anesthesia-related deaths, in the United Kingdom.

SECTION II: JOURNALS AND ONLINE INFORMATION RESOURCES

JOURNALS AND SCIENTIFIC LITERATURE

Obstetric Anesthesia Journals

Anesthesia & Analgesia (the Official Journal of IARS and SOAP)

Web: http://www.anesthesiaanalgesia.org

Facebook: http://bit.ly/AnesAnalgFacebook

Twitter: @IARS_journals

App for iPad: http://bit.ly/AnesAnalgApp

Content more than 12 months old is freely available without a subscription or password.

The International Journal of Obstetric Anesthesia (the Official Journal of the OAA)

Web: http://www.obstetanesthesia.com

This is the only peer-reviewed journal devoted solely to obstetric anesthesia. A subscription is required for most text.

The Obstetric Anesthesia Digest

Web: http://journals.lww.com/obstetricanesthesia/

Facebook: http://bit.ly/OADFacebook

Twitter: @OBAnesDigest

Recent publications of interest to obstetric anesthesia providers are cited, reviewed, and discussed by a panel of experts. A subscription is required for access to full text.

Related Journals

The American Journal of Obstetrics and Gynecology (the Official Journal of the SMFM)

Web: http://www.ajog.org

Facebook: https://www.facebook.com/AJOGthegray

Twitter: @AJOGthegray

A subscription is required for most text.

Anesthesiology (the Official Journal of the ASA)

Web: http://www.anesthesiology.org

Facebook: https://www.facebook.com/ASAanesthesiology

Twitter: @ALNAnesthesia

Content more than 6 months old is freely available without a subscription or password.

The Canadian Journal of Anesthesia (the Official Journal of the CAS)

Web: https://link.springer.com/journal/12630

Content more than 12 months old is freely available without a subscription or password.

Obstetrics & Gynecology (the Official Journal of the ACOG)

Web: http://www.greenjournal.org

Facebook: https://www.facebook.com/greenjournal

Twitter: @greenjrnl

New or updated ACOG practice bulletins and committee opinions are frequently published in Obstetrics & Gynecology. A subscription is required for most text.

Pediatrics (the Official Journal of the AAP)

Web: http://pediatrics.aappublications.org

Facebook: https://www.facebook.com/aappeds

Twitter: @AAPJournals

Content more than 12 months old is freely available without a subscription or password (for a rolling 8-year period).

Other Information Sources

The Cochrane Collaboration

Web: http://www.cochrane.org

The Cochrane Collaboration provides frequently updated reviews of current literature in a variety of medical specialties, including anesthesiology and obstetrics. Most information in abstract form is freely available; however, a subscription is required for access to full-text documents.

LabourPains.com

Web: http://www.labourpains.com

Twitter: @labourpainsoaa

LabourPains.com is the public information site of the OAA. It is a source of accurate, unbiased patient information regarding delivery of obstetric anesthesia. In addition, it provides translations of much of this information, in the form of patient handouts/leaflets, into almost 50 languages.

Obstetric Anesthesia Fellowship Program Listings

Web: http://bit.ly/obanesfellows

This webpage is hosted by the Society for Obstetric Anesthesiology and Perinatology. It is a listing of obstetric anesthesia fellowship opportunities in the United States and Canada, and it was created to help residents interested in pursuing advanced training in obstetric anesthesiology.

PubMed (a Medical Literature Search Resource Supported by the National Institutes of Health)

Web: https://www.ncbi.nlm.nih.gov/pubmed

This site provides citations and abstracts; the user must go to the original source to obtain the full text of most articles.

SECTION III: MULTIMEDIA LEARNING RESOURCES

Anesthesia and Critical Care Reviews and Commentary

Web: http://accrac.com/

Created by Jed Wolpaw, MD, MEd, an anesthesiologist at Johns Hopkins University School of Medicine, this podcast series aims to help trainees who are preparing for their board certifications as well as provide a forum for interesting debates and interviews in the areas of anesthesiology and critical care medicine.

Anesthesia Illustrated–SOAP

Web: http://www.anesthesiaillustrated.com/soap/

This collaboration between Anesthesia Illustrated and SOAP includes a large number of obstetric anesthesia videos including many of the major presentations from the Sol Shnider and SOAP annual meetings. No registration or password is required. The website includes lectures from the 2015, 2016, and 2017 Sol Shnider annual meetings.

OpenAnesthesia

Web: http://www.openanesthesia.org

Facebook: http://bit.ly/OpenAnesthesiaFB

Twitter: @OpenAnesthesia

OpenAnesthesia is a wide-ranging multimedia educational platform sponsored by the IARS. The Obstetric Anesthesia Subspecialty section has extensive multimedia educational content including a well-developed online obstetric anesthesia curriculum, a library of virtual grand rounds, and a series of obstetric anesthesia podcasts.

California Maternal Quality Care Collaborative

Web: https://www.cmqcc.org/

The California Maternal Quality Care Collaborative uses research, quality improvement toolkits, statewide outreach collaboratives, and its innovative Maternal Data Center to improve health outcomes for mothers and infants. A variety of documents is available providing comprehensive advice on topics such as, but not limited to, preeclampsia, maternal hemorrhage, maternal cardiovascular disease, and venous thromboembolism.

SimStat–Labor and Delivery

Web: http://bit.ly/simstatLD

The ASA has created a novel screen-based simulation multimedia experience to evaluate how well participants manage a patient involved in an obstetric crisis. Examples of activities include development of a differential diagnosis and management therapies for hypertension during pregnancy, and demonstration of adherence to ACLS guidelines in a pregnant patient. Completion of the activity confers five Part II and IV activity points toward American Board of Anesthesiology (ABA) Maintenance of Certification in Anesthesiology (MOCA).

Neuraxial Ultrasound

Web: http://bit.ly/neuraxus

Brendan Carvalho, MBBCh, FRCA, MDCH, an obstetric anesthesiologist at Stanford University School of Medicine, shares his insights on "Neuraxial Ultrasound: Time to Learn and Not Get Left Behind," in this Sol Shnider lecture for the Society for Obstetric Anesthesiology and Perinatology (SOAP).

SECTION IV: ONLINE COMMUNITIES OF PRACTICE

Duke Anesthesiology Twitter Journal Club Series

Web: https://anesthesiology.duke.edu/?page_id=830505

Twitter: @Duke_Anesthesia #AnesJC

Duke Anesthesiology presents one of a growing number of Twitter-based journal clubs, allowing discussion of research articles from around the world. The website contains an archive of curated discussions of prior articles.

Obstetric Anesthesia Social Media Influencers List

Web: https://twitter.com/larrychu/lists/ob-anesthesia-list

This is a Twitter list compiled and maintained by Larry Chu, MD, MS, an anesthesiologist at Stanford University School of Medicine. It is based on social media metrics data of obstetric anesthesia influencers from the Symplur Signals database. The tweets posted by members of this social media list yield information that is highly relevant to obstetric anesthesia practice.

Obstetric Anesthesia Facebook Interest Page

Facebook: https://www.facebook.com/obstetricanesthesia/

This Facebook page is dedicated to the science, practice, and research of obstetric anesthesia. It is curated by Alex Butwick, MBBS, FRCA, an anesthesiologist at Stanford University School of Medicine.

Symplur Healthcare Hashtags

Web: https://www.symplur.com/healthcare-hashtags/

The Healthcare Hashtag project is a free and open platform presented by Symplur that allows interested parties (clinicians, patients, advocates, and others) to participate in social media discussions. It is an easy way to follow trending topics and conferences.
