FHR variability, which typically is a good indicator of fetal well-being, is present by 25 to 27 weeks' gestation. Changes in the FHR baseline and variability caused by anesthetic agents or other drugs must be distinguished from changes that result from fetal hypoxia. Persistent severe fetal bradycardia typically indicates true fetal compromise.

BOX 17.2 Maneuvers for Intrauterine Resuscitation during Nonobstetric Surgery

- Increase left uterine displacement
- Increase oxygen concentration
- Treat hypotension or administer vasopressor to return blood pressure to baseline
- Release surgical retraction, manipulation, or abdominal insufflation
- Ensure appropriate end-tidal CO_2 level[a]
- Ensure appropriate acid-base status
- Check maternal hemoglobin
- Consider administering medications to improve uterine relaxation (e.g., increase volatile agent, nitroglycerin administration)

[a]28–32 mm Hg

Intraoperative FHR monitoring requires the presence of a provider who can interpret the FHR tracing. In addition, a multidisciplinary plan should address how to proceed in the event of persistent nonreassuring fetal status, including whether to interrupt ongoing surgery to perform an emergency cesarean delivery. Intraoperative FHR monitoring allows for the optimization of the maternal condition if the fetus shows signs of compromise (Box 17.2). For example, decreased FHR variability resulting from maternal hypoxemia resolved with improvement in maternal oxygenation (Fig. 17.5).[134] An unexplained change in FHR mandates the evaluation of maternal position, blood pressure, oxygenation, and acid-base status, and the inspection of the surgical site to ensure that neither surgeons nor retractors are impairing uteroplacental perfusion.

Fetal Effects of Anesthesia

Maintenance of Fetal Well-Being

The most serious fetal risk associated with maternal surgery during pregnancy is that of intrauterine asphyxia. Fetal oxygenation is critically dependent on the maintenance of normal maternal arterial oxygen tension, oxygen-carrying capacity, oxygen affinity, and uteroplacental perfusion.

Maternal and fetal oxygenation. Transient mild to moderate decreases in maternal Pao_2 are well tolerated by the fetus, primarily because fetal hemoglobin has a high affinity for oxygen. Severe maternal hypoxemia results in fetal hypoxia and, if persistent, may cause fetal death. Any complication that causes profound maternal hypoxemia (e.g., difficult tracheal intubation, esophageal intubation, pulmonary aspiration, total spinal anesthesia, local anesthetic systemic toxicity) is a potential threat to the fetus.

Studies of isolated human placental vessels suggest that **hyperoxia** may cause uteroplacental vasoconstriction, with potential impairment of fetal oxygen delivery.[135] This fear has proved to be unfounded. Studies in pregnant women have demonstrated better fetal oxygenation with increasing maternal Pao_2; however, fetal Pao_2 never exceeds 60 mm Hg, even when

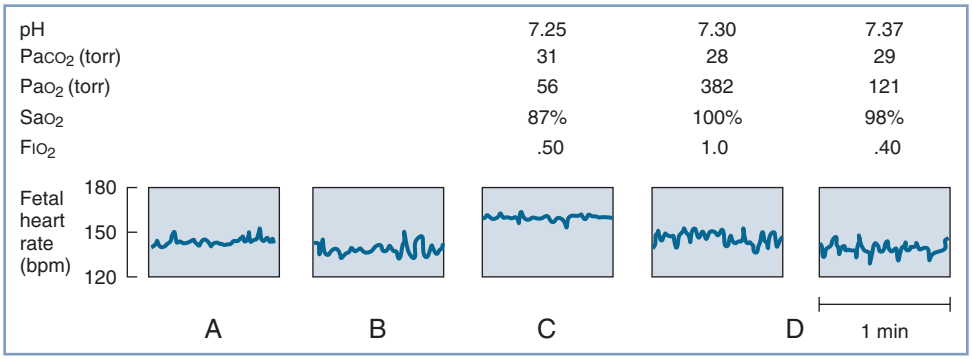

Fig. 17.5 Serial samples of the fetal heart rate tracing and corresponding maternal arterial blood gas measurements in a patient undergoing eye surgery. (A, B) Baseline fetal heart rate of 140 bpm with normal variability. (C) Fetal tachycardia and decrease in variability during inadvertent maternal hypoxemia (maternal Pao_2 = 56 mm Hg). (D) After correction of maternal ventilation, baseline fetal heart rate and variability return. (Redrawn from Katz JD, Hook R, Barash PG. Fetal heart rate monitoring in pregnant patients undergoing surgery. *Am J Obstet Gynecol.* 1976;125:267.)

maternal Pao_2 increases to 600 mm Hg. This physiologic limitation exists, in part, because of the low diffusion capacity of oxygen in the placenta, as well as the admixture of blood returning to the fetus from the placenta with deoxygenated blood from the fetal inferior vena cava (see Chapter 4). Thus, intrauterine retrolental fibroplasia and premature closure of the ductus arteriosus cannot result from high maternal Pao_2. McClaine et al.[137] observed that the maternal administration of general anesthesia for 4 hours in gravid ewes produced an initial—but not sustained—increase in fetal systemic oxygenation, but a sustained increase in cerebral oxygenation. The investigators hypothesized that the increase in fetal cerebral oxygenation resulted from greater cerebral perfusion, lower cerebral metabolic rate, or both. Histologic examination found no evidence of neurotoxicity.

Maternal carbon dioxide and acid-base status. Maternal hypercapnia can cause fetal acidosis, because fetal $Paco_2$ correlates directly with maternal $Paco_2$. Although mild fetal respiratory acidosis is of little consequence, severe acidosis can cause fetal myocardial depression and hypotension. Maternal hyperventilation with low maternal $Paco_2$ and high pH can adversely affect fetal oxygenation by means of several mechanisms.[138–140] Respiratory or metabolic alkalosis can compromise maternal-fetal oxygen transfer by causing umbilical artery constriction[138] and by shifting the maternal oxyhemoglobin dissociation curve to the left.[139] In addition, hyperventilation, independent of changes in $Paco_2$, may reduce uterine blood flow and cause fetal acidosis.[140] This decrease most likely is a consequence of mechanical ventilation, whereby increased intrathoracic pressure reduces venous return and cardiac output, which in turn decreases uteroplacental perfusion. Thus, hyperventilation should be avoided in the pregnant surgical patient. Rather, the $Paco_2$ should be kept in the normal range for pregnancy, which is lower than in the nonpregnant state.

Uteroplacental perfusion. Maternal hypotension from any cause can jeopardize uteroplacental perfusion and cause fetal asphyxia. The most common causes of hypotension in the pregnant patient undergoing surgery include (1) deep levels of general anesthesia, (2) sympathectomy with high sensory levels of spinal or epidural blockade, (3) aortocaval compression, (4) hemorrhage, and (5) hypovolemia. In monkeys, prolonged hypotension (i.e., systolic blood pressure less than 75 mm Hg) caused by deep halothane anesthesia resulted in fetal hypoxia, acidosis, and hypotension.[141] After experiencing as much as 5 hours of severe partial asphyxia *in utero* (pH less than 7.00 for at least 1 hour), neonatal monkeys were depressed and experienced seizures. Postnatal survival was poor, and pathologic brain changes included swelling, necrosis, and hemorrhage. The clinical course and neuropathologic findings in these animals resembled those in infants known to have suffered severe intrauterine asphyxia and who died within a few days of birth.

However, good fetal and neonatal outcomes have been reported following deliberate use of moderate degrees of hypotension, usually to facilitate performance of a neurosurgical procedure in otherwise healthy women[142]; maternal systolic blood pressures were maintained between 70 and 80 mm Hg, with transient periods as low as 50 mm Hg. These blood pressure parameters likely cannot be extrapolated to maternal conditions such as gestational hypertension, preeclampsia, or other conditions that predispose to uteroplacental insufficiency. In surgical circumstances necessitating maternal hypotension, the risk to the fetus must be balanced against the risk for uncontrolled maternal bleeding or stroke.

The multiple factors that influence uteroplacental blood flow are discussed in detail in Chapter 3. Of relevance to the pregnant surgical patient are drugs that cause uterine artery vasoconstriction. Preoperative anxiety and light anesthesia increase circulating catecholamines, possibly impairing uterine blood flow.[143] Drugs that cause uterine tachysystole (e.g., ketamine in early pregnancy in doses higher than 2 mg/kg,[144] toxic doses of local anesthetics[145]) may increase vascular resistance of the vessels perfusing the uterus and placenta, decreasing perfusion.

Although historically ephedrine was the preferred first-line agent for the treatment of hypotension during the administration of neuraxial anesthesia in obstetric patients, evidence

now supports the use of phenylephrine as the drug of choice for this purpose (see Chapter 26).[146] Human studies in women receiving neuraxial anesthesia, including those that directly evaluate uterine vascular resistance by Doppler ultrasonography, have demonstrated no differences in uterine blood flow parameters when ephedrine or phenylephrine infusions were used to maintain baseline mean arterial pressure.[147] Moreover, a meta-analysis of randomized controlled trials comparing ephedrine with phenylephrine for the treatment of hypotension during spinal anesthesia for cesarean delivery concluded the following: (1) there was no difference between phenylephrine and ephedrine for the prevention and treatment of maternal hypotension, (2) maternal bradycardia was more likely to occur with phenylephrine than with ephedrine, (3) women treated with phenylephrine had neonates with higher umbilical arterial blood pH measurements than those given ephedrine, and (4) there was no difference between the two vasopressors in the incidence of true fetal acidosis (i.e., umbilical arterial blood pH less than 7.20).[148]

Ngan Kee et al.[149] demonstrated that placental transfer was greater for ephedrine than phenylephrine, with less early metabolism and/or redistribution in the fetus. Fetal concentrations of lactate, glucose, and catecholamines were also higher with ephedrine than phenylephrine, thus supporting the hypothesis that the lower fetal pH observed with ephedrine is related to metabolic effects secondary to stimulation of fetal beta-adrenergic receptors. Recently, norepinephrine has been observed to successfully prevent and treat spinal anesthesia–induced maternal hypotension; further investigation of maternal and fetal effects, including comparison to other vasopressors, is necessary before widespread use can be recommended.[150]

Inhalation Agent Effects on the Fetus

The volatile halogenated anesthetic agents transfer readily across the placenta and can affect the fetus directly (by depressing the fetal cardiovascular system or CNS) or indirectly (by causing maternal hypoxia or hypotension). Studies in gravid ewes have shown minimal fetal effects with maternal administration of moderate concentrations of volatile agents.[151] During the inhalation of 1.0 and 1.5 MAC halothane or isoflurane, uterine artery vasodilation compensated for small decreases in maternal blood pressure to maintain uterine perfusion; however, the inhalation of 2.0 MAC concentrations for prolonged periods induced marked reductions in maternal blood pressure and uteroplacental blood flow, which resulted in fetal hypoxia, diminished fetal cardiac output, and fetal acidosis.[152]

The effects of anesthesia on the healthy fetal lamb may be minimal, but the effects on a stressed fetal lamb remain unclear. In one study, the administration of 1% halothane to the mothers of asphyxiated fetal lambs caused severe fetal hypotension, acidosis, and decreases in cerebral blood flow and oxygen delivery.[152] In other studies, acidosis that was less severe in magnitude or duration was associated with the maintenance of fetal cardiac output and a preservation of the balance between oxygen supply and demand.[153–155] The protective compensatory mechanisms that exist during asphyxia may be abolished by high but not low concentrations of volatile agents.

The relevance of these data to women undergoing surgery during pregnancy is unclear. Volatile anesthetic agents are a common component of general anesthesia; the depressant effect of these agents on uterine myometrial contractility may be beneficial for prevention of preterm labor. Provided that maternal hypotension is prevented, FHR decelerations are not expected, although diminished FHR variability may occur as the fetus becomes anesthetized. If intraoperative FHR monitoring shows signs of fetal compromise, corrective maneuvers should be considered and implemented (see Box 17.2); if these maneuvers fail, conversion to intravenous anesthetic agents may improve the fetal condition.

Systemic Agent Effects on the Fetus

Opioids and induction agents decrease FHR variability, possibly to a greater extent than the inhalation agents.[156,157] This finding most likely signals the presence of an anesthetized fetus and is not a cause for concern in the absence of maternal hypotension or other abnormalities. Fetal respiratory depression is relevant only if cesarean delivery is to be performed at the same time as the surgical procedure. Even then, high-dose opioid anesthesia need not be avoided if it is indicated for maternal reasons (e.g., anesthesia for patients with cardiac disease). The neonatologist should be informed of maternal drug administration so that preparations can be made to support neonatal respiration. Some data indicate that remifentanil may result in less neonatal depression than longer-acting opioids.[158]

Maternal administration of muscle relaxants and reversal agents typically is not problematic for the fetus. The rapid intravenous injection of an anticholinesterase agent could stimulate acetylcholine release and theoretically increase uterine tone and precipitate preterm labor.[159] Although this concern is unproven, slow administration of an anticholinesterase (after prior injection of an anticholinergic agent) is recommended. Atropine rapidly crosses the placenta and, when given in large doses, causes fetal tachycardia and loss of FHR variability.[160] Although neither atropine nor glycopyrrolate significantly affects FHR when standard clinical doses are administered,[161] glycopyrrolate is often recommended because it crosses the placenta less readily. Limited transplacental passage of neostigmine is expected, but mild fetal bradycardia was reported in one patient at 31 weeks' gestation when neostigmine was administered with glycopyrrolate during emergence from general anesthesia.[162] This problem did not occur during the administration of a second general anesthetic to the same patient 4 days later, when atropine was administered with neostigmine, presumably because atropine undergoes greater placental transfer than glycopyrrolate.

Sugammadex, an agent that rapidly reverses paralysis by forming a complex with neuromuscular blocking agents, has not been robustly investigated in pregnant women.[163] However, in a case series of 8 women who underwent a cesarean delivery with general anesthesia and rocuronium for

rapid-sequence induction, the dosing and response to sugammadex were similar to those in nonpregnant patients.[164] Consideration should be given to the known risks of anaphylaxis (0.3%), bradycardia, and cardiac arrest,[163] as well as the potential unknown risks for mother and fetus. Because the effects of all reversal agents are unpredictable, monitoring of FHR during maternal drug administration may be prudent.

Prevention of Preterm Labor

Most epidemiologic studies of women who undergo nonobstetric surgery during pregnancy have reported a higher incidence of abortion and preterm delivery.[1,108,110,165] Whether the surgery, manipulation of the uterus, or the underlying condition is responsible is unclear. In a study of 778 women who underwent appendectomy during pregnancy, Mazze and Källén[165] found that 22% of women who underwent surgery between 24 and 36 weeks' gestation delivered in the week after surgery. In the women in whom pregnancy continued beyond 1 week after surgery, there was no further increase in the rate of preterm birth. Although this study's database was unsuitable for determining the incidence of preterm delivery in women who had surgery before 24 weeks' gestation, a similar increase appeared likely. Second-trimester procedures and operations that do not involve uterine manipulation carry the lowest risk for preterm labor.

Although the volatile agents depress myometrial irritability and thus are theoretically advantageous for abdominal procedures, evidence does not show that any one anesthetic agent or technique positively or negatively influences the risk for preterm labor. Published evidence does not support the routine use of prophylactic tocolytic agents.[166] Whether greater surveillance and early tocolytic therapy will reduce the risk for preterm delivery after surgery during pregnancy is not known. Monitoring for uterine contractions may be performed intraoperatively with an external tocodynamometer (if technically feasible) and for several days postoperatively, allowing tocolytic therapy to be instituted, if appropriate. Additional surveillance is necessary in patients who receive potent postoperative analgesics, who may be unaware of mild uterine contractions.

Magnesium sulfate is among the most common drugs used in pregnancy as a tocolytic, anticonvulsant, or fetal neuroprotective agent. Antenatal magnesium sulfate has been shown to reduce the incidence and severity of cerebral palsy after very preterm birth (see Chapter 10).[167] Magnesium also has effects that are relevant to the delivery of anesthesia, including an increase in the rate of onset of neuromuscular blockade,[168] the reestablishment of neuromuscular blockade in patients recovering from a nondepolarizing muscle relaxant,[169] and a reduction in general anesthetic requirements.[170]

PRACTICAL CONSIDERATIONS

Timing of Surgery

The ACOG/ASA guidelines on nonobstetric surgery during pregnancy state that elective surgery should not be performed during pregnancy and that necessary surgery should not be denied because of trimester considerations; however, if surgery should be deemed necessary, the second trimester is preferred because of its association with the lowest risk for spontaneous abortion and preterm labor.[132] Urgent operations are often indicated for abdominal emergencies, some malignancies, and neurosurgical and cardiac conditions. The management and timing of most acute surgical procedures should mimic that for nonpregnant patients. Maternal appendicitis is associated with an increased risk for perinatal loss and preterm labor, particularly when the infection is advanced.[114] Appendicular perforation may be more common in pregnant than nonpregnant patients because diagnostic difficulties may delay surgery. Generalized peritonitis may also be more likely because increased corticosteroid levels during pregnancy may suppress the normal inflammatory response and prevent the "walling off" of the appendix by the omentum.[171]

In the event of a serious maternal illness necessitating emergency surgery, the remote fetal risks associated with anesthesia and surgery are of secondary importance. The primary goal is to preserve the life of the mother. Successful neonatal outcomes in complex, high-risk procedures requiring induced hypothermia, induced hypotension, and cardiopulmonary bypass have been reported. The decision to perform simultaneous cesarean delivery depends on several factors, including the gestational age, the risk to the mother of a trial of labor at a later date, and the presence of intra-abdominal sepsis. Cesarean delivery may be performed immediately before the surgical procedure to avoid fetal risks associated with special patient positioning (e.g., the sitting or prone position), prolonged anesthesia, major intraoperative blood loss, maternal hyperventilation, deliberate hypotension, or cardiopulmonary bypass.

Emergency Abdominal Surgery

Acute abdominal disease occurs infrequently in pregnancy; the most common causes include appendicitis (1 in 500 to 1 in 2000 pregnancies), cholecystitis (1 in 1600 to 1 in 10,000 pregnancies), and bowel obstruction (1 in 1500 to 1 in 16,000 pregnancies).[172,173] Accurate diagnosis, especially of an acute abdominal crisis (e.g., appendicitis, cholecystitis), can be very difficult during pregnancy, and several conditions must be considered in the differential diagnosis (Box 17.3).[171] Nausea, vomiting, constipation, and abdominal distention are common symptoms of both normal pregnancy and acute abdominal disease. Abdominal tenderness may be indistinguishable from ligamentous or uterine contraction pain. The expanding uterus makes the physical examination of the abdomen difficult. For example, the appendix rotates counterclockwise; thus, as term approaches, the tip typically lies over the right kidney.[174] Because the white blood cell count in normal pregnancy may reach 15,000/mm^3, it must be markedly elevated to be diagnostically helpful. Additional delay may result from the reluctance to perform imaging studies involving radiation or contrast medium. In 1991, Mazze and Källén[165] reported the misdiagnosis of appendicitis during pregnancy in 36% of cases, with a lower rate (23%) during

BOX 17.3 Nonobstetric Abdominal Crises in Pregnancy

Medical Conditions

- Abdominal crises caused by systemic disease
  - Sickle cell disease
  - Diabetic ketoacidosis
  - Porphyria
- Renal disease
  - Glomerulonephritis
  - Pyelonephritis
- Pulmonary disease
  - Basal pneumonia with pleurisy
- Cholecystitis and pancreatitis (early, uncomplicated)
- Myocardial infarction, pericarditis
- Drug addiction (withdrawal symptoms)

Surgical Conditions

Gynecologic Problems

- Ovarian cyst/tumor
  - Rupture
  - Torsion
  - Hemorrhage
  - Infection
- Torsion of a fallopian tube
- Tubo-ovarian abscess
- Uterine myoma
  - Degeneration
  - Infection
  - Torsion

Nongynecologic Problems

- Acute appendicitis
- Acute cholecystitis and its complications
- Acute pancreatitis and its complications
- Intestinal obstruction
- Trauma with visceral injury or hemorrhage
- Vascular accidents (e.g., ruptured abdominal aneurysm)
- Peptic ulcer

Modified from Fainstat T, Bhat N. Surgical resolution of nonobstetric abdominal crises complicating pregnancy. In Baden JM, Brodsky JB, eds. *The Pregnant Surgical Patient*. Mount Kisco, NY: Futura Publishing; 1985:154.

the first trimester than during the last two trimesters (43%). However, using more recent data from the American College of Surgeons NSQIP from 2005 to 2009, Silvestri et al.[175] found no difference in 30-day postoperative morbidity or mortality in 857 pregnant and 20,029 nonpregnant appendectomy cases, and 436 pregnant and 32,915 nonpregnant cholecystectomy cases. Moore et al.[17] used 2006 to 2011 data from the NSQIP to compare 2764 (0.5%) pregnant and 516,705 (99.5%) nonpregnant women undergoing general surgery. No difference in 30-day postoperative mortality or morbidity were noted between groups, but pregnant women tended to be younger, have fewer comorbidities than the general population, and were more likely to be undergoing emergency surgery. There is likely significant overlap in the data from these NSQIP studies.[17,175] Although it is reassuring that the risk to the mother is comparable to nonpregnant women undergoing similar surgical procedures, the severity of disease significantly affects fetal outcomes in pregnant women with acute abdominal disease.[114]

Laparoscopy

Laparoscopy is performed during pregnancy for both diagnostic and therapeutic indications with increasing frequency.[176–179] Concerns exist about the effects of laparoscopy on fetal well-being, especially the risks for (1) uterine or fetal trauma, (2) fetal acidosis from absorbed carbon dioxide, and (3) decreased maternal cardiac output and uteroplacental perfusion resulting from an iatrogenic increase in intra-abdominal pressure. In some animal studies, maternal and fetal acidosis and tachycardia have occurred during intra-abdominal insufflation, perhaps because maternal ventilation was guided by measurements of end-tidal rather than arterial carbon dioxide levels.[180] Uteroplacental perfusion decreased by 61% in one study in which gravid ewes were subjected to a CO_2 pneumoperitoneum at a pressure of 20 mm Hg (although there were no adverse fetal consequences).[181] It is unclear whether the severity of acidosis and decrement in uteroplacental perfusion are related to insufflation pressure.[180]

Many practitioners believe, however, that the potential benefits of laparoscopic surgery compared with open abdominal surgery outweigh the risks. Potential benefits include (1) shorter hospitalization, (2) less postoperative pain, (3) decreased risk for thromboembolic and wound complications, and (4) faster return to normal activities, including earlier return of normal gastrointestinal function, less uterine irritability, and less fetal depression.[176] In a 1994 survey of laparoendoscopic surgeons, Reedy et al.[177] obtained data from 413 laparoscopic procedures performed during pregnancy and reviewed an additional 55 previously published cases. Among the procedures surveyed, 48% were cholecystectomies, 28% were adnexal operations, 16% were appendectomies, and 8% were diagnostic procedures. Thirty-two percent of operations were performed in the first trimester, 54% in the second, and 13% in the third. Several principally retrospective trials comparing open and laparoscopic interventions reported no maternal and fetal outcome differences.[178,179]

Human clinical studies and experience suggest that the fetal effects of the CO_2 pneumoperitoneum and increased intra-abdominal pressure are limited. In one clinical study, there were no differences in the maternal pH, $Paco_2$, or arterial–to–end-tidal CO_2 pressure gradients before, during, or after termination of the pneumoperitoneum during laparoscopy.[182] Steinbrook and Bhavani-Shankar[183] used thoracic electrical bioimpedance cardiography to measure changes in cardiac output in four pregnant women undergoing laparoscopic cholecystectomy. They observed hemodynamic changes similar to those that typically occur during laparoscopic surgery in nonpregnant patients (i.e., decrease in cardiac index with concurrent increases in mean arterial pressure and systemic vascular resistance).

Reported clinical experiences with laparoscopy during pregnancy generally have been favorable with the rare

BOX 17.4 Selected Guidelines for Laparoscopic Surgery during Pregnancy

Diagnosis and Workup

- Ultrasonography is safe and useful to identify etiology of abdominal pain.
- Ionizing radiation: Timely and accurate diagnosis takes precedence over risk associated with ionizing radiation. (Attempt to limit dose to 5–10 rads.)
- Computed tomography (CT): Contemporary multidetector CT protocols deliver a low radiation dose to the fetus and may be used judiciously.
- Magnetic resonance imaging without gadolinium can be performed at any stage of pregnancy.
- Nuclear medicine: Administration of radionucleotides for diagnostic studies is generally safe for the mother and fetus.
- Intraoperative and endoscopic cholangiography: Exposes the mother and fetus to minimal radiation and may be used selectively during pregnancy. (Use protective shielding on the lower abdomen.)

Surgical Techniques

- Diagnostic laparoscopy is safe and effective when used selectively in pregnancy.
- Laparoscopic treatment of acute abdominal disease has the same indications in pregnant and nonpregnant patients.
- Laparoscopy can be safely performed during any trimester of pregnancy.
- Initial port placement can be safely performed with an open (Hasson) technique, Veress needle, or optical trocar.
- Insufflation pressure of 10–15 mm Hg can be safely used.

Disease

- Gallbladder disease: Laparoscopic cholecystectomy is the treatment of choice in the pregnant patient, regardless of trimester.
- Choledocholithiasis: May be managed with preoperative endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy followed by laparoscopic cholecystectomy, laparoscopic common bile duct exploration, or postoperative ERCP.
- Appendectomy: Laparoscopic appendectomy may be performed safely in pregnant patients with appendicitis.
- Solid-organ resection: Laparoscopic adrenalectomy, nephrectomy, splenectomy, and mesenteric cyst excision are safe procedures in pregnant patients.
- Cystic adnexal mass: Laparoscopy is a safe and effective treatment. Observation is acceptable for all other cystic lesions provided ultrasonography is not concerning for malignancy and tumor markers are normal. Initial observation is warranted for most cystic lesions <6 cm in size.
- Adnexal torsion: Laparoscopy is recommended for both diagnosis and treatment unless clinical severity warrants laparotomy.

Modified from Pearl, J. Price R, Fanelli R, Society of American Gastrointestinal Endoscopic Surgeons. Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy. *Surg Endosc.* 2011;25:3479–3492.

occurrence of complications, such as intraoperative perforation of the uterus with the Veress needle.[177] Nonetheless, Amos et al.,[184] in a case series, reported fetal deaths following four of seven laparoscopic procedures. Some practitioners have suggested the use of gasless laparoscopic techniques to avoid the potential fetal effects of CO_2 pneumoperitoneum.[185,186]

Careful selection and conduct of surgical and anesthetic techniques can assist in avoiding complications associated with laparoscopic surgery during pregnancy. The surgeon should be experienced with the technique, and the anesthesia provider must be aware of the accompanying physiologic alterations, including the cardiorespiratory implications. In 2011, the Society of American Gastrointestinal Endoscopic Surgeons[187] published "Guidelines for Diagnosis, Treatment, and Use of Laparoscopy for Surgical Problems during Pregnancy" (Box 17.4). The guidelines emphasized that the indications for laparoscopic surgery in pregnant patients do not differ from those for nonpregnant patients and may be performed during any trimester of pregnancy.

General anesthesia has been used in most laparoscopic procedures, although the use of epidural anesthesia has also been described.[177] Steinbrook et al.[188] described their anesthetic technique for 10 cases of laparoscopic cholecystectomy during pregnancy. They administered general anesthesia with a rapid-sequence induction followed by tracheal intubation and positive-pressure ventilation to maintain end-tidal CO_2 between 32 and 36 mm Hg. Anesthesia was maintained with a nondepolarizing muscle relaxant, an opioid, and a volatile halogenated agent, but nitrous oxide was avoided to prevent bowel distention and to allow administration of a higher concentration of inspired oxygen. The pneumoperitoneum resulted in increased peak airway pressure (Fig. 17.6) and

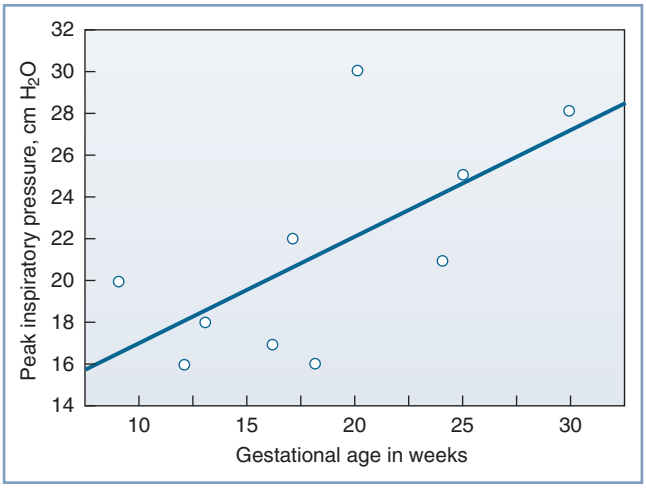

Fig. 17.6 Peak inspiratory pressure during laparoscopic cholecystectomy during pregnancy as a function of gestational age. The best-fit line by linear regression is shown ($y = 12.1 + 0.5x$; $R^2 = 0.43$). Peak inspiratory pressure tends to increase with advancing gestation. (Modified from Steinbrook RA, Brooks DC, Datta S. Laparoscopic cholecystectomy during pregnancy. *Surg Endosc.* 1996;10:511–515.)

decreased total lung compliance, which were progressively greater with advancing gestation.

The Trendelenburg position exacerbates decreases in FRC and increases in hypoxemia from airway closure. Hyperventilation, which may be necessary to maintain normal maternal $Paco_2$, may reduce uteroplacental perfusion and affect fetal oxygenation. Hypotension may result from pneumoperitoneum, aortocaval compression, or use of the reverse Trendelenburg position, and a vasopressor may be needed to maintain maternal blood pressure.[188] As with open surgery, fetal well-being is best preserved by maintaining maternal oxygenation, acid-base status, and hemodynamic parameters within normal pregnancy limits. The FHR and uterine tone should be monitored before and after surgery (see earlier discussion).

Anesthetic Management

Preoperative Management

Appropriate preoperative management of the pregnant patient undergoing nonobstetric surgery includes ensuring that these surgeries will be performed at an institution where qualified, multidisciplinary personnel are readily available.[132] Following a physical examination and informed anesthetic consent, including a discussion on the risks and benefits of maternal and fetal anesthetic exposure, premedication may be necessary to allay maternal anxiety. Pregnant women are at increased risk for acid aspiration after 18 to 20 weeks' gestation (see earlier discussion). Pharmacologic precautions against acid aspiration may include preanesthetic administration of a $histamine_2$-receptor antagonist, metoclopramide, and a clear nonparticulate antacid such as sodium citrate.

Choice of Anesthesia

Maternal indications and consideration of the site and nature of the surgery should guide the choice of anesthesia. No study has found an association between improved fetal outcome and any specific anesthetic technique, except for a single retrospective medical record analysis in which the use of general anesthesia was associated with a significantly lower birth weight despite similar gestational age at delivery.[189] When possible, however, local or regional anesthesia (with the exception of paracervical block) is preferred, because it permits the administration of drugs with no laboratory or clinical evidence of teratogenesis. In addition, maternal airway and respiratory complications occur less frequently with local and regional anesthetic techniques. These techniques are suitable for cervical cerclage and urologic or extremity procedures. Most abdominal operations require general anesthesia, because the incision typically extends to the upper abdomen. This situation may create an unacceptably high risk for aspiration in a pregnant patient with an unprotected airway.

Prevention of Aortocaval Compression

Beginning at 18 to 20 weeks' gestation, the pregnant patient should be transported on her side, and the uterus should be displaced leftward when she is positioned on the operating table.

Monitoring

Maternal monitoring should include noninvasive or invasive blood pressure measurement, electrocardiography, pulse oximetry, capnography, temperature monitoring, and the use of a peripheral nerve stimulator. The FHR and uterine activity should be monitored before and after surgery. Intraoperative FHR monitoring may be considered when technically feasible, depending on the ease of monitoring, the type and site of surgery, and gestational age (see earlier discussion).

Anesthetic Technique

Most anesthesiologists agree that general anesthesia mandates tracheal intubation beginning at 18 to 20 weeks' gestation or if the stomach is full. Two recent retrospective studies (combined $n = 3700$) reported using supraglottic airway devices with esophageal drains in pregnant women undergoing elective cesarean delivery with no reported cases of aspiration.[190,191] Women in these studies followed fasting guidelines and had normal body mass index, and the airway devices were placed using aspiration precautions (i.e., preoperative antacid administration, cricoid pressure, and rapid-sequence induction). Although these studies do not definitively demonstrate safety, these devices may be an alternative airway management technique for women for whom avoidance of tracheal intubation or neuromuscular paralysis is desirable (e.g., professional singer, patient with myotonic dystrophy). Denitrogenation (i.e., preoxygenation) should precede the induction of anesthesia. Although rapid-sequence induction with the application of cricoid pressure has been a long-standing practice for the induction of general anesthesia, some experts suggest that it is unnecessary in fasted pregnant women undergoing elective surgery and may make tracheal intubation more challenging.[192] Drugs with a history of safe use during pregnancy include thiopental, propofol, morphine, fentanyl, succinylcholine, and the nondepolarizing muscle relaxants.

A commonly used technique employs a high concentration of oxygen, a muscle relaxant, and an opioid and a moderate concentration of a volatile halogenated agent. Scientific evidence does not support avoidance of nitrous oxide during pregnancy, particularly after the sixth week of gestation.[193] Omission of nitrous oxide may increase fetal risk if inadequate anesthesia occurs or if a high dose of a volatile agent results in maternal hypotension. A cautious approach is to restrict nitrous oxide administration to a concentration of 50% or less and to limit its use in extremely long operations. Hyperventilation should be avoided; rather, end-tidal CO_2 should be maintained in the normal range (28 to 32 mm Hg) for pregnancy.

Rapid intravenous infusion of crystalloid or colloid fluids during the initiation of spinal or epidural anesthesia with prophylactic vasopressor administration or early treatment of hypotension is prudent. Hypotension should be treated aggressively, and practitioners should be vigilant to the signs of high neuraxial blockade and local anesthetic systemic toxicity.

Regardless of the anesthetic technique, steps to avoid hypoxemia, hypotension, acidosis, and hyperventilation are the most critical elements of anesthetic management.

Postoperative Management

The FHR and uterine activity should be monitored during recovery from anesthesia. Adequate analgesia should be ensured with systemic or neuraxial opioids, acetaminophen, or neural blockade. Nonsteroidal anti-inflammatory drugs should be avoided in pregnancy, especially in the first and third trimesters. Maternal safety organizations recommend mechanical compression devices for thromboembolism prophylaxis in all women undergoing cesarean delivery and pharmacologic prophylaxis in women with additional risk factors, including obesity, thrombophilia, prolonged immobility, and any condition that may increase a pregnant woman's risk for venous thromboembolism.[25,26] Many of the principles recommended in these guidelines should be applied to pregnant patients in the nonobstetric surgery setting.

Maternal Cardiac Arrest and Resuscitation

Although Standard Basic Life Support (BLS) and Advanced Cardiac Life Support (ACLS) principles apply to these patients, the anatomic and physiologic changes of pregnancy, and the presence of a fetus, require several specific modifications to the resuscitation protocol (see Boxes 41.9 and 54.5).[194] Left uterine displacement should be maintained during resuscitation, optimally performed using two hands to pull the uterus to the left (see Fig. 54.2).[195] Perimortem cesarean delivery (resuscitative hysterotomy) is an essential aspect of maternal resuscitation in the second half of gestation.[196] The primary purpose of the hysterotomy is to improve the chance of maternal survival, but early delivery will also improve the likelihood of fetal survival.[194,196] Thus, if initial resuscitative efforts are unsuccessful, perimortem cesarean delivery should be initiated within 4 minutes of the arrest with the goal of delivering the fetus within 5 minutes.[194] The neonatal resuscitation team should be part of the maternal cardiac arrest team, as the fetus will likely need immediate resuscitation upon delivery. The reversible causes of cardiac arrest during pregnancy are similar to those in nonpregnant patients; however, additional causes specific to pregnancy include amniotic fluid embolism, eclampsia, placental abruption, and hemorrhage.

KEY POINTS

- A significant number of women undergo anesthesia and surgery during pregnancy for procedures unrelated to delivery.
- Maternal risks are associated with the anatomic and physiologic changes of pregnancy (e.g., difficult intubation, aspiration) and with the underlying maternal disease.
- The diagnosis of abdominal conditions may be delayed during pregnancy, increasing the risk for maternal and fetal morbidity.
- Maternal catastrophes involving severe hypoxia, hypotension, and acidosis pose the greatest acute risk to the fetus.
- Other fetal risks associated with surgery include fetal loss, preterm labor, growth restriction, and low birth weight. Clinical studies suggest that anesthesia and surgery during pregnancy do not increase the risk for congenital anomalies.
- It is unclear whether adverse fetal outcomes result from the anesthetic, the operation, or the underlying maternal disease.
- No anesthetic agent is a proven teratogen in humans, although some anesthetic agents, specifically nitrous oxide, are teratogenic in animals under certain conditions.
- Many anesthetic agents have been used for anesthesia during pregnancy, with no demonstrable differences in maternal or fetal outcome.
- The anesthetic management of the pregnant surgical patient should focus on the avoidance of hypoxemia, hypotension, acidosis, and hyperventilation.

Obstetric Management of Labor and Vaginal Delivery

Akila Subramaniam, MD, MPH, Alan T. N. Tita, MD, PhD, Dwight J. Rouse, MD, MSPH

CHAPTER OUTLINE

THE PROCESS OF LABOR AND DELIVERY

Labor, which is also called *parturition,* is the process by which sufficiently frequent and strong uterine contractions cause thinning (i.e., effacement) and dilation of the cervix, thereby permitting passage of the fetus from the uterus through the birth canal.

Onset of Labor

Timing

Fewer than 10% of pregnancies end on the expected date of delivery (EDD), although the majority of births occur within 7 days of the EDD. In the United States, approximately 10% of births occur preterm (before 37 weeks' gestation), and approximately 5% to 7% of pregnancies remain undelivered at 42 weeks' gestation (14 days after the EDD, known as postterm). These rates are lower for carefully dated pregnancies.

Mechanism

The cause of the onset of labor in women—either term or preterm—remains unknown. In other mammalian species, a decrease in serum progesterone concentration in association with an increase in estrogen concentration is followed by increases in prostaglandin production, oxytocin receptors, and myometrial gap junction formation. In sheep, the fetus apparently triggers parturition through a surge in fetal cortisol production. In women, progesterone concentrations do not decline before the onset of labor, and no surge in fetal cortisol secretion occurs. The laboring human uterus does manifest increases in prostaglandin production, oxytocin receptors, and myometrial gap junction formation.[1,2] As more is learned, perhaps a unifying concept of the onset of mammalian labor will emerge. Preterm and postterm deliveries both constitute important obstetric problems; and when more is understood about the mechanism of the onset of labor, new approaches to preventing the preterm and postterm onset of parturition may evolve.

Stages of Labor

By convention, labor is divided into three stages. The first stage begins with the maternal perception of regular, painful uterine contractions and ends with the complete dilation of the cervix. Complete cervical dilation is the dilation necessary to allow movement of the fetus from the uterus into the vagina. At term gestation, 10 cm approximates complete cervical dilation. Preterm fetuses require less than 10 cm of cervical dilation. The second stage of labor begins with the complete dilation of the cervix and ends with the birth of the infant. The third stage begins with the birth of the infant and ends with the delivery of the placenta. The first stage of labor can be considered the cervical stage, the second stage the pelvic stage (reflecting the descent of the fetus through the pelvis), and the third stage the placental stage. Some authorities identify a fourth stage of labor, corresponding to the first postpartum hour, during which postpartum hemorrhage is most likely to occur.

TABLE 18.1 Features Determined by Clinical Pelvimetry as Related to Pelvic Type

	PELVIC TYPE			
Suboptimal Features	**Gynecoid**	**Android**	**Anthropoid**	**Platypelloid**
Promontory reached (diagonal conjugate ≤ 12 cm)	–	±	–	+
Sacrum flat/forward (versus curved)	–	+	–	+
Spines prominent (found by medical student)	–	+	+	–
Sacrosciatic notch narrow (≤ 2 fingerbreadths)	–	+	–	–
Subpubic arch narrow (acute angle)	–	+	+	–

+, Present; –, absent; ±, variable.

From Zlatnik FJ. Normal labor and delivery and its conduct. In Scott JR, DiSaia PJ, Hammond CB, Spellacy WN, eds. *Danforth's Obstetrics and Gynecology,* 6th ed. Philadelphia, PA: JB Lippincott; 1990:161–188.

Components of Labor and Delivery

When the events that occur during labor and vaginal delivery are considered, it is helpful to think about the following three components of the process: (1) the **powers** (uterine contractions and, in the second stage, the addition of voluntary maternal expulsive efforts); (2) the **passageway** (the bony pelvis and the soft tissues contained therein); and (3) the **passenger** (the fetus). The interaction of these three components determines the success or failure of the process.

The Powers

The uterus, which is a smooth muscle organ, contracts throughout gestation with variable frequency. The parturient verifies the onset of labor when she perceives regular, uncomfortable uterine contractions. In some women, the uterus remains relatively quiescent until the abrupt onset of labor. In others, the uterus contracts several times per hour for days without causing pain or even a clear perception of uterine contractions.

During labor, the frequency, duration, and intensity of uterine contractions increase. During early labor, the contractions may occur every 5 to 7 minutes, last 30 to 40 seconds, and develop intrauterine pressures (intensity) of 20 to 30 mm Hg above basal tone (10 to 15 mm Hg). Late in the first stage of labor, contractions typically occur every 2 to 3 minutes, last 50 to 70 seconds, and are 40 to 60 mm Hg in intensity. This higher intensity reflects a more widespread propagation of the contractions, with the recruitment of more myometrial cells.

Retraction accompanies contraction as the myometrial cells shorten. The walls of the upper, contractile portion of the uterus thicken. Cervical dilation and effacement reflect the traction placed on the cervix by the contracting uterus. The passive lower uterine segment enlarges and becomes thinner as cervical tissue is pulled over the fetal presenting part by traction from the upper portion of the uterus. At the end of the first stage of labor, no cervix is palpable on vaginal examination (corresponding to complete cervical dilation). If there is no mechanical obstruction, additional uterine contractions force the fetus to descend through the birth canal. At this time, the parturient perceives an urge to defecate (reflecting pressure on the rectum). Her expulsive efforts add to the force of uterine contractions to hasten descent and shorten the second stage of labor.

The Passageway

The fetus must be of such size and conformation that there is no mechanical mismatch with the bony pelvis. At times, an ovarian or uterine tumor (e.g., leiomyoma), cervical cancer, or a vaginal septum may impede passage of the fetus through the birth canal, but these situations are unusual.

Four pelvic types have been described on the basis of the shape of the pelvic inlet (the plane bounded by the upper inner pubic symphysis, the linea terminalis of the iliac bones, and the sacral promontory) (Table 18.1).[3] The type and size of the pelvis constitute important predictors of the success of vaginal delivery.

The most common pelvic type and the one theoretically best suited for childbirth is the **gynecoid** pelvis. The flexed fetal head presents a circle to the bony pelvis; a pelvis with gynecoid features best accommodates this circle. The inlet is round or oval, with the transverse diameter only slightly greater than the anteroposterior diameter. The pelvic sidewalls are straight and do not converge, the ischial spines are not prominent, the sacrum is hollow, and the subpubic arch is wide. The absence of prominent ischial spines is an important feature, because the distance between them—the transverse diameter of the mid-pelvis—is the narrowest pelvic dimension. The other pelvic types are less favorable for vaginal delivery.

Radiographic pelvimetry provides much more information regarding pelvic dimensions and features than can be obtained by clinical pelvimetry alone. However, it has only a limited place in clinical management because of its poor ability to predict a successful vaginal birth. In the absence of a history of pelvic fracture or musculoskeletal disease (e.g., a dwarfing condition), there are few circumstances in which the apparent pelvic anatomy precludes a trial of labor. A pelvis with smaller-than-average dimensions may be adequate for a particular fetus if the head is well-flexed, sufficient molding (i.e., overlapping of the unfused skull bones) has occurred, and the labor is strong; thus, radiographic pelvimetry does not always predict the presence or absence of cephalopelvic disproportion.[4] Further, some risk is associated with radiographic pelvimetry. In addition to the potential for point

mutations in the maternal oocytes and fetal germ cells, there is a small but apparently real increase in the incidence of malignancy and leukemia in children who were exposed to diagnostic radiation *in utero*. Some obstetricians use radiographic pelvimetry in cases of fetal breech presentation to assess whether fetal presentation, position, and lie are appropriate for vaginal delivery. The hope is to save a parturient from a long, futile labor and a hazardous delivery. Computed tomography and magnetic resonance imaging are associated with less or no ionizing radiation exposure, respectively; these methods are also more accurate than conventional radiographic pelvimetry. However, these methods also have limited ability to predict a successful vaginal delivery.

The Passenger

Fetal size and the relationship of the fetus to the maternal pelvis affect labor progress. The **lie** of the fetus (the relationship of the long axis of the fetus to the long axis of the mother) can be transverse, oblique, or longitudinal. In the first two, vaginal delivery is impossible unless the fetus is very immature.

The **presentation** denotes that portion of the fetus overlying the pelvic inlet. The presentation may be cephalic, breech, or shoulder. Cephalic presentations are further subdivided into vertex, brow, or face presentations, according to the degree of flexion of the neck. In more than 95% of labors at term, the presentation is cephalic and the fetal head is well flexed (i.e., vertex presentation).

The **position** of the fetus denotes the relationship of a specific presenting fetal bony point to the maternal pelvis. In vertex presentations, that bony point is the occiput. During vaginal examination, palpation of the sagittal suture and fontanels permits determination of the fetal position. Positions of the occiput in early labor are listed in Box 18.1. Other markers for position are the sacrum for breech presentation, the mentum for face presentation, and the acromion for shoulder presentation. (See Chapter 34 for a discussion of nonvertex presentations.)

The Mechanism of Labor

The *mechanism of labor* refers to the changes in fetal conformation and position (cardinal movements; Box 18.2) that occur during descent through the birth canal during the late first stage and the second stage of labor.

BOX 18.1 Positions of the Occiput in Early Labor, Listed in Order of Decreasing Frequency

- Left occiput transverse (LOT)
- Right occiput transverse (ROT)
- Left occiput anterior (LOA)
- Right occiput posterior (ROP)
- Right occiput anterior (ROA)
- Left occiput posterior (LOP)
- Occiput anterior (OA)
- Occiput posterior (OP)

BOX 18.2 The Cardinal Movements of Labor

- Engagement
- Descent
- Flexion
- Internal rotation
- Extension
- External rotation
- Expulsion

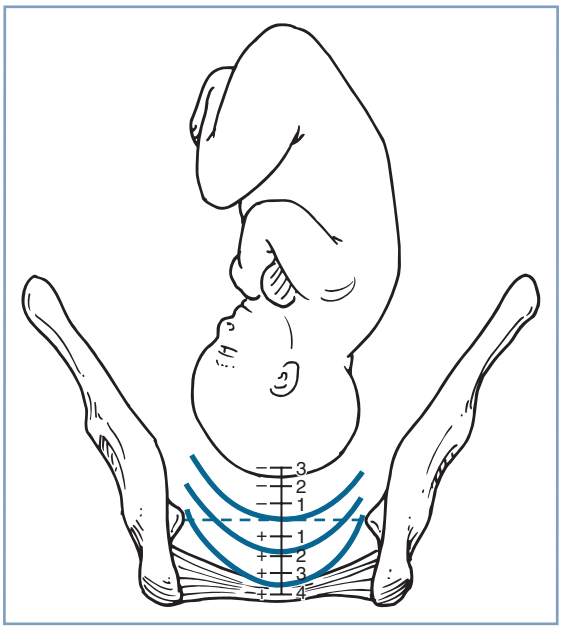

Fig. 18.1 Stations of the fetal head. (Redrawn from Zlatnik FJ. Normal labor and delivery and its conduct. In Scott JR, DiSaia PJ, Hammond CB, Spellacy WN, eds. *Danforth's Obstetrics and Gynecology,* 7th ed. Philadelphia, PA: JB Lippincott; 1994:116.)

The first cardinal movement is **engagement,** which denotes passage of the biparietal diameter (BPD) (i.e., the widest transverse diameter of the fetal head) through the plane of the pelvic inlet. A direct clinical determination of engagement cannot be made, but obstetricians assume that engagement has occurred if the leading bony point of the fetal head is palpable at the level of the ischial spines. This is true because the distance between the leading bony point and the BPD is typically less than the distance between the ischial spines and the plane of the pelvic inlet. If the leading bony point is at the level of the spines, the vertex is said to be at zero station. If the leading bony point is 1 cm above the level of the spines, the station is designated as –1. Similarly, +1, +2, and +3 indicate that the leading bony point is 1, 2, and 3 cm below the ischial spines, respectively (Fig. 18.1). At +5 station, delivery is imminent. *Station* refers to palpation of the leading bony point. Often marked edema of the scalp (i.e., caput succedaneum) occurs during labor. In such cases, the bony skull may be 2 to 3 cm higher than the scalp.

The second cardinal movement is **descent,** although it is artificial to separate descent from the other movements because descent occurs throughout the birth process. The third cardinal movement is **flexion.** A very small fetus can negotiate the average maternal pelvis without increased flexion. However, under the usual circumstances at term, the force from above and resistance from below enhance flexion of the occiput (Fig. 18.2).

The fourth cardinal movement is **internal rotation.** At the level of the mid-pelvis, the fetus meets the narrowest pelvic dimension, which is the transverse diameter between the ischial spines. Because the BPD of the fetal head is slightly smaller than the suboccipitobregmatic diameter, in most labors the vertex negotiates the mid-pelvis with the sagittal suture in an anteroposterior direction. If this did not occur, a larger-than-necessary diameter would be forced to pass through the narrowest portion of the pelvis. Internal rotation describes the change in the position of the vertex from occiput transverse or oblique to anteroposterior. The occiput tends to rotate to the roomiest part of the pelvis; thus, in gynecoid pelvises, the fetus is delivered in an occiput anterior position.

The next cardinal movement is **extension,** which occurs as the fetal head delivers (Fig. 18.3). Subsequently, the occiput rotates to the side of the back (**external rotation**) as the shoulders pass through the mid-pelvis in an oblique diameter.

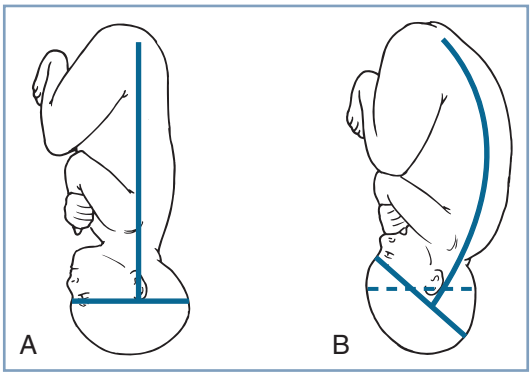

Fig. 18.2 (A) Relation of the head to the vertebral column before flexion. (B) Relation of the head to the vertebral column after flexion. (Redrawn from Zlatnik FJ. Normal labor and delivery and its conduct. In Scott JR, DiSaia PJ, Hammond CB, Spellacy WN, eds. *Danforth's Obstetrics and Gynecology,* 6th ed. Philadelphia, PA: JB Lippincott; 1990:174.)

The anterior shoulder moves under the pubic symphysis. With gentle downward traction, it passes from the birth canal, and **expulsion** of the remainder of the fetus occurs.

This description recounts events in the typical gynecoid pelvis. Abnormalities of the pelvis affect the mechanism of labor in specific ways. In an **anthropoid** pelvis, the anteroposterior diameter of the pelvic inlet exceeds the transverse diameter. Often internal rotation to the occiput posterior position rather than the occiput anterior position occurs. Because the pelvis is narrow transversely, further descent of the vertex occurs with the occiput in the posterior position. Delivery occurs with the occiput in the posterior position, or rotation to the occiput anterior position occurs just before delivery. In cases of persistent occiput posterior position, delivery occurs by flexion rather than extension of the fetal head (see Fig. 18.3).

In **platypelloid** pelvises, internal rotation may not take place. The widest diameter is the transverse diameter, and descent of the vertex may occur with the occiput in the transverse position; rotation to the occiput anterior position occurs only at delivery.

Clinical Course

Admission

When a patient enters the labor and delivery unit, the first question that must be asked is "why?" Did she come because of regular, painful uterine contractions; decreased fetal activity; vaginal bleeding; ruptured membranes; or some other reason? If the tentative diagnosis is labor, is she at term?

The time of the onset of labor and the presumed status of the membranes should be determined. Observation of the patient's demeanor coupled with the assessment of cervical effacement and dilation will signal whether the patient is in early or advanced labor. Examination of the cervix is deferred in patients with vaginal bleeding in the second half of pregnancy, unless placenta previa has been ruled out by ultrasonography, to avoid exacerbation of bleeding. To prevent infection, cervical examination may also be deferred in patients with premature rupture of membranes and no labor.

The obstetrician also directs attention to the second patient: the fetus. Abdominal examination or ultrasonography is used to establish presentation and an estimate of fetal size. With most obstetric services, external electronic fetal heart rate (FHR) monitoring is used on admission to assess

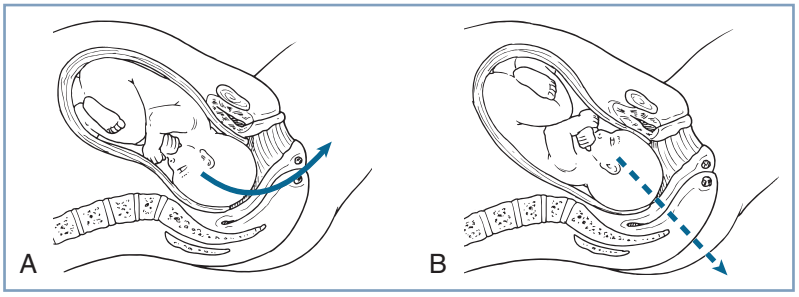

Fig. 18.3 Vertex presentations. (A) Occiput anterior position. (B) Occiput posterior position. (Redrawn from Zlatnik FJ. Normal labor and delivery and its conduct. fetal condition. The baseline rate and variability and the presence or absence of accelerations and decelerations are of interest.

Subsequent Care

The maternal vital signs and FHR are recorded periodically. In some obstetric services, continuous electronic FHR monitoring is used universally; with other services, it is monitored via intermittent auscultation. In low-risk patients, recording the FHR every 30 minutes in the first part of the first stage of labor, every 15 minutes in the latter part of the first stage, and every 5 minutes in the second stage is perfectly acceptable. During early labor, the patient may ambulate or assume any position of comfort on the labor bed or in a chair. During advanced labor, many women choose to lie down. Choices concerning analgesia or anesthesia are made according to the patient's wishes. Fig. 18.4 shows a flow sheet (partogram) that may be useful for charting the course of labor.

During labor, those providing obstetric care must focus on the following two critical questions:

1. Is the fetus tolerating labor in a satisfactory fashion, or is there evidence of fetal compromise (see Chapter 8)?
2. Is the labor progress normal?

Labor Progress: The Labor Curve

One of the central tasks of those providing intrapartum care is to determine whether labor is progressing normally and, if not, to determine the significance of the delay and what the response should be. Parity is an important determinant of labor length. (*Parity* refers to previous pregnancies of at least 20 weeks' gestation. A pregnant woman who is gravida 2, para 1, is pregnant for the second time, and her first pregnancy resulted in delivery after 20 weeks' gestation.)

A generation of obstetricians is indebted to Emanuel Friedman, whose landmark studies of labor provide a framework for judging labor progress. Friedman's approach was straightforward: He graphed cervical dilation on the *y*-axis and elapsed time on the *x*-axis for thousands of labors. He considered nulliparous and parous patients separately, and he determined the statistical limits of normal.[5] The curve of cervical dilation over time is sigmoid shaped (Fig. 18.5).

Most authorities consider Friedman's most important contribution to be his separation of the latent phase from the active phase of the first stage of labor. Many hours of regular, painful uterine contractions may take place with little appreciable change in the cervix. During this latent (or preparatory) phase, the cervix may efface and become softer. Quite abruptly, the active (or dilation) phase begins, and regular increases in cervical dilation are expected over time. The transition from the latent to the active phase of the first stage of labor does not occur at an arbitrary cervical dilation but rather is known—in retrospect—by change in slope of the cervical dilation curve. Peisner and Rosen[6] evaluated the progress of labor for 1060 nulliparous women and 639 parous

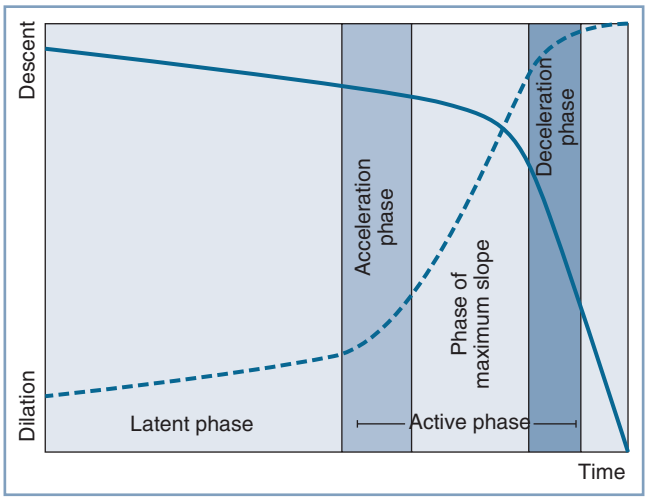

Fig. 18.5 The Friedman curve. (From Friedman EA. Patterns of labor as indicators of risk. *Clin Obstet Gynecol.* 1973;16:172–183.)

TABLE 18.2 Rate of Spontaneous Cervical Dilatation by Parity

Cervical Dilation	Nulliparous Median Time (h) (95th Percentile)	Parous Median Time (h) (95th Percentile)
First Stage		
4 to 5 cm	1.3 (6.4)	1.4 (7.1)
5 to 6 cm	0.8 (3.2)	0.8 (3.4)
6 to 7 cm	0.6 (2.2)	0.5 (1.8)
7 to 8 cm	0.5 (1.6)	0.4 (1.2)
8 to 9 cm	0.5 (1.4)	0.3 (1.0)
9 to 10 cm	0.5 (1.8)	0.3 (0.9)
Second Stage		
10 cm to delivery (epidural)	1.1 (3.6)	0.4 (2.0)
10 cm to delivery (no epidural)	0.6 (2.8)	0.2 (1.3)

Modified from Zhang J, Landy HJ, Branch DW, et al.; for the Consortium on Safe Labor. Contemporary patterns of spontaneous labor with normal neonatal outcomes. *Obstet Gynecol.* 2010;116:1281–1287.

women. After excluding women with protracted or arrested labor, these researchers noted that 60% of the women had reached the latent-active phase transition by 4 cm of cervical dilation and 89% did so by 5 cm.

A *nulliparous* woman may labor for 20 hours without achieving appreciable cervical dilation; 14 hours is the limit of the latent phase in the *parous* woman. Difficulty in assigning length to the latent phase lies not with its end (determined from the change in slope of the cervical dilation curve) but rather with its beginning. The onset of labor is self-reported by the parturient. The uterus contracts throughout gestation, and the level of prelabor uterine activity and its perception are variable. Often both the patient and the physician are uncertain as to exactly when labor started.

According to Friedman, in the active phase of the first stage of labor, a nulliparous woman's cervix should dilate at a rate of at least 1.2 cm per hour, and a parous woman's cervix should dilate at least 1.5 cm per hour. (The slopes of the dilation curves in Fig. 18.5 represent the lower limits of normal.) If a woman's cervix fails to dilate at the appropriate rate during the active phase of labor, she is said to have **primary dysfunctional labor.** Graphically, her cervical dilation "falls off the curve." If cervical dilation ceases during a 2-hour period in the active phase of labor, **secondary arrest of dilation** has occurred.

More recent studies have reported slower rates of cervical dilation and engendered an ongoing transition toward the use of the "contemporary labor curve."[7,8] These newer data have been adopted into new labor management practice guidelines.[9] These curves reveal that cervical dilation is particularly slow prior to 6 cm and that the deceleration phase described by Friedman is usually absent. Therefore, 6 cm rather than 4 cm of cervical dilation more accurately reflects the start of the active phase in contemporary labor curves—and should be used to define the active phase for labor management.[8,9] Furthermore, in the active phase, absence of cervical change over at least 4 hours rather than 2 hours is a better definition of labor arrest. Estimates of contemporary rates of cervical dilation from 4 cm (when patients are often admitted) by parity are presented (Table 18.2). Nulliparous women have a slower cumulative rate of cervical dilation overall. However, before 6 cm of dilation, the times required to dilate 1 cm are similar between nulliparous and parous women. While these "contemporary labor curves" have been emphasized in new practice guidelines, it is important to note that there is an ongoing need for prospective evaluation of these new criteria.

Abnormalities of the latent phase and active phase differ in associated factors, apparent causes, and significance. A prolonged latent phase is more likely if labor begins "before the cervix is ready."[5] Just as there is a wide range of prelabor uterine activity, so too is there a wide range of cervical softness, effacement, and dilation at the start of labor. In some women, appreciable cervical softening, effacement, and dilation take place in late pregnancy; thus, when clinical labor begins, the cervix may already be 3 to 4 cm dilated and completely effaced. Alternatively, in other women, there is no cervical effacement or dilation at the start of labor. Given these differences, it is not surprising that varying amounts of uterine contractile work are needed to cause dilation of the cervix. The most common factor associated with a prolonged latent phase is an "unripe" cervix at the start of labor. Some women with a prolonged latent phase are not in true labor at all but are in "false labor"; this diagnosis is made in retrospect. After hours of regular, painful contractions, uterine activity may cease without the occurrence of appreciable cervical dilation. Several hours or days later, the patient reappears in true labor. During the latent phase of labor, it is not known with certainty whether a woman is in true or false labor.

Recent studies refute the dictum that a prolonged latent phase alone is not associated with fetal compromise or cephalopelvic disproportion.[10,11] An increased risk for cesarean delivery, chorioamnionitis, endometritis, excessive blood loss, depressed Apgar scores, and need for neonatal resuscitation have all been associated with a prolonged latent phase. An ongoing increase in the use of labor induction may be a mediating factor. Primary dysfunctional labor and arrest of dilation during the active phase may also indicate cephalopelvic disproportion.[5,12,13] Friedman's original work suggested that an arrest of dilation during the active phase was associated with the need for cesarean delivery nearly half of the time. Later studies suggest a lower percentage, but it is clear that women who experience active-phase arrest of dilation are more likely to require cesarean delivery than women with normal labor progress during the active phase. Friedman's analysis suggested that active-phase abnormalities pose a threat to the fetus, especially if they are combined with operative vaginal delivery.[14] A later study of women who delivered in the modern era of electronic FHR monitoring and decreased frequency of mid-forceps deliveries suggested that arrest disorders by themselves do not have adverse perinatal consequences.[13]

In summary, the contemporary view is that delays in the latent phase of the first stage of labor may be associated with fetopelvic disproportion or the need for cesarean delivery, but this requires confirmation.[11] Delays in the active phase predict fetopelvic disproportion, although not with precision. Given current obstetric practice and fetal monitoring techniques, it is unclear whether first-stage labor abnormalities are intrinsically associated with neonatal depression at delivery.[15,16]

Amniotomy

The intact amnion serves as the vessel that contains the amniotic fluid and helps protect the uterine contents from the microbial flora of the vagina. The amniotic fluid provides mechanical protection for the fetus and umbilical cord and allows growth and movement.

In the absence of intervention, the membranes generally rupture at the onset of labor or near full cervical dilation. If the membranes are intact, should they be artificially ruptured during the course of labor? If so, when? Because there is concern about infection once the membranes are ruptured, the performance of an amniotomy commits the mother to delivery. The traditional thought was that amniotomy should not be done early in the labor course. However, newer data suggest early amniotomy (i.e., amniotomy at cervical dilation less than 4 cm or soon after cervical ripening with Foley balloon) decreases the time to complete dilation and vaginal delivery, especially in nulliparous women, without an increase in adverse perinatal outcomes.[17,18]

Advantages of amniotomy during the first stage of labor are that (1) the ruptured membranes permit the placement of a fetal electrocardiographic electrode, which can provide more consistent information than external FHR monitoring; (2) the amniotic fluid can be inspected for the presence or absence of meconium; and (3) amniotomy shortens time to delivery.[17,18] Disadvantages of amniotomy during the first stage of labor are that it may result in increased scalp edema (i.e., caput succedaneum, which has no clinical significance) and that there may be a greater likelihood of variable decelerations of the FHR. If there is a nonvertex presentation or the vertex is high in the pelvis and not well applied to the cervix, amniotomy is deferred to decrease the risk for prolapse of the umbilical cord.

Second Stage of Labor

When the cervix has been completely retracted to form the lower uterine segment and is therefore not palpable on vaginal examination, full or complete dilation has been achieved, and the second stage of labor begins. Strong uterine contractions coupled with voluntary expulsive efforts by the parturient cause the fetal presenting part to descend through the pelvis, resulting in delivery. At complete cervical dilation, there is frequently an increase in bloody show, the parturient may vomit, and, in the absence of anesthesia, she may complain that she needs to defecate. This sensation of needing to "bear down" encourages strong Valsalva maneuvers during uterine contractions. The effect of this sensation on the efficiency of "pushing" efforts during the second stage is reflected by the suggestion that the duration of the second stage of labor varies not only according to parity but also with the presence or absence of epidural analgesia.[15] According to current guidelines, a second stage longer than 3 hours may be considered prolonged for a nulliparous woman without epidural analgesia, but 4 hours are granted if the patient has epidural analgesia. For the parous woman, the time limits are 2 and 3 hours, respectively.[9]

The contemporary obstetrician, although less concerned about the elapsed time during the second stage of labor than were earlier obstetricians, continues to balance the risks of prematurely performing a cesarean delivery with the risks of adverse outcomes associated with a prolonged second stage. A generation ago, the teaching was that a long second stage meant trouble.[19] It often did, for at least two reasons. First, if cephalopelvic disproportion existed, the second stage was prolonged; this often resulted in a difficult operative vaginal delivery and serious fetal trauma. Second, umbilical cord compression may become severe with descent of the presenting part during the second stage of labor. If FHR monitoring was not performed conscientiously, considerable fetal/neonatal compromise could occur in association with delayed delivery. Umbilical cord arterial blood pH varies inversely with the length of the second stage of labor. While multiple studies have shown that a second-stage duration longer than recommended is associated with an increase in maternal obstetric trauma, postpartum hemorrhage, infection, birth depression, and admission to the neonatal intensive care unit in both nulliparous and parous women, the contemporary view is that the second stage of labor does not need to be terminated at any arbitrary time provided that progress in descent continues and the FHR pattern is reassuring.[20,21] Thus, given recent guidelines, a longer second-stage duration is recommended to decrease the cesarean delivery rate.[7,9]

If the parturient is allowed to choose her own position during labor and delivery, she does not need to stay in one place.[22] Without instruction from birth attendants, the parturient frequently chooses to walk or sit in a chair during early labor. Late in the first stage, however, she often returns to the labor bed. During the second stage of labor, some women assume the squatting position, whereas others, with their legs supported by the nurse and the father of the baby, assume a semi-sitting position. The goal is to achieve a position in which the parturient's bearing-down efforts are most effective. The patient should avoid the supine position, which results in aortocaval compression. Aortocaval compression seems to be less severe with the patient in the semi-sitting position, and it is avoided altogether with the patient in the lateral position. Indeed, it is perfectly acceptable for the patient to push and deliver while remaining in the left lateral position. A vaginal examination during a contraction may provide information as to which position is best for a particular individual.

In the past, as the fetal head distends the perineum shortly before delivery, an episiotomy was often performed. An episiotomy is an incision extending either directly posteriorly from 6 o'clock (midline) or in a 45-degree angle to either side (mediolateral). The former causes less discomfort, is more anatomic, and is easier to repair than the latter. The mediolateral episiotomy's advantage is that extension through the anal sphincter and rectal mucosa is less likely to occur, but its major disadvantage is that it may cause more bleeding or severe postpartum pain. (If the patient has an epidural catheter, the anesthesia provider may give additional epidural local anesthetic or opioid to provide postpartum analgesia.)

The role of episiotomy in contemporary obstetrics is limited.[23] In the past, episiotomy was advocated not only to shorten labor but also to protect the woman against the subsequent development of uterine prolapse, cystocele, and rectocele. An episiotomy hastens delivery, but only by a few minutes. Tears involving the anal sphincter (third degree) and rectal mucosa (fourth degree) are more common after midline episiotomy than if episiotomy is not performed; in the absence of an episiotomy, however, anterior periurethral lacerations are common. Although the latter rarely cause immediate problems, scientifically valid data on long-term outcome are lacking. Given the recognized association between midline episiotomies and third- and fourth-degree tears, the fact that these tears may be associated with long-term morbidity, and the failure to observe any benefits to routine episiotomy, more restrictive use of this incision is now recommended.[23,24] For example, an episiotomy may be indicated in some instances of operative vaginal delivery of a large infant, with suspected fetal compromise, or to manage shoulder dystocia.

Third Stage of Labor

The third stage of labor begins with the delivery of the infant and ends with the delivery of the placenta. The placenta typically separates from the uterine wall within a few contractions after delivery of the infant, and expulsion follows a few minutes later. Signs of placental separation are listed in Box 18.3.

BOX 18.3 Signs of Placental Separation

- The uterus rises in the maternal abdomen.
- The shape of the uterus changes from discoid to globular.
- The umbilical cord lengthens.
- A gush of blood frequently occurs.

When the placenta has separated from the uterine wall, gentle traction on the umbilical cord, coupled with suprapubic pressure to elevate the uterus, serves to deliver the placenta and membranes. In the absence of excessive bleeding, the obstetrician waits for the signs of placental separation before attempting to deliver it. If traction is exerted on the umbilical cord before the placenta has separated, problems result. The least serious—but nonetheless embarrassing—complication involves separating the umbilical cord from the placenta. This tear in the cord leads to bleeding, which is of no concern because the blood is fetoplacental blood that would be discarded; however, the obstetrician's reputation for gentleness suffers because the detached segment of umbilical cord is held with the placenta remaining *in situ*. A much more serious problem is uterine inversion, which can occur in a case of fundal implantation of the placenta. If the placenta has not separated and the umbilical cord does not break, excessive traction turns the uterus inside out, resulting in severe hemorrhage (see Chapter 37).

If the placenta does not separate in a timely fashion after delivery (prolonged third stage) or if significant bleeding occurs, manual removal of the placenta is indicated. Although some obstetricians advocate performing this procedure with sedation or systemic analgesia, neuraxial or general anesthesia is ideal. The obstetrician's hand is then passed into the uterine cavity, and the edge of the placenta is identified. The hand is used as a trowel to separate the placenta from the uterine wall. If the obstetrician cannot easily develop a plane between the placenta and the uterine wall, the diagnosis of **placenta accreta** should be considered. Placenta accreta typically results in severe hemorrhage, which frequently mandates emergency hysterectomy (see Chapter 37). Classically, a duration of 30 minutes has been used to define a prolonged third stage; however, recent data suggest that increased postpartum hemorrhage may occur when the third stage of labor duration exceeds 20 minutes.[25] However, in the absence of significant bleeding, more time may be allowed for placental separation, particularly at earlier gestational ages when it may be difficult to access the uterus.

After delivery, and either before or after the placenta has been removed, uterotonic agents are administered to reduce bleeding. **Oxytocin** is given intravenously in a dilute solution (e.g., starting at an infusion rate of 20 to 80 units/h), or 10 units are given intramuscularly. Bolus intravenous injection of oxytocin can cause hypotension and should be avoided (see Chapter 37).[26]

If the uterus does not respond to oxytocin, other agents can be tried. **Methylergonovine** (Methergine, 0.2 mg every 2 to 4 hours) has long been available for intramuscular administration. It contracts vascular smooth muscle and may cause hypertension. Methylergonovine should not be given intravenously except in cases of severe, life-threatening hemorrhage. In such cases, the physician should give the drug slowly and carefully monitor the maternal blood pressure.

15-Methylprostaglandin $F_{2\alpha}$ (carboprost, Hemabate) is a newer ecbolic agent. Given intramuscularly, 0.25 mg (every 15 to 90 minutes, with a maximum of 8 doses) of 15-methylprostaglandin $F_2\alpha$ has been demonstrated to be an effective uterotonic agent when other drugs have failed.[27] It can also cause hypertension, but the hypertension is typically not as severe as that associated with administration of methylergonovine. More important, 15-methylprostaglandin $F_{2\alpha}$ may cause bronchospasm and is relatively contraindicated in patients with asthma.

Most obstetricians in the United States do not use ecbolic agents until the placenta has been delivered, whereas European obstetricians typically administer an ecbolic agent immediately after delivery of the infant or even with delivery of the anterior shoulder. The timing probably does not matter.[28] Immediately after the delivery of the placenta, if the obstetrician suspects an abnormality, the hand can be passed into the uterine cavity. Within several minutes, however, the cervix and birth canal contract. Subsequent uterine exploration typically requires the administration of anesthesia.

Fourth Stage of Labor

Many obstetricians consider the first 60 minutes after delivery of the placenta to be the fourth stage of labor. Labor is completed, but this designation emphasizes that the patient must be watched carefully for bleeding. More than 90% of cases of postpartum hemorrhage result from uterine atony. If uterine atony is not identified during the first hour after delivery, it is unlikely to occur subsequently. The patient should be evaluated frequently to be certain that excessive bleeding is not occurring and that the uterus remains contracted. Considerable blood loss can occur in the presence of "normal" vital signs; a modest increment in additional blood loss can then be followed by profound shock. Uterine relaxation and excessive bleeding after delivery are initially treated with uterine massage and further ecbolic drug administration (see Chapter 37). Management options for persistent hemorrhage include uterine tamponade, surgery, and vascular embolization.

LABOR PROGRESS: FIVE MANAGEMENT QUESTIONS

The purpose of this section is to provide a step-by-step approach to the management of the laboring woman by serially posing and answering the following five critical questions:

1. *Is the patient in labor?* If the answer is "Yes," certain factors must be considered before proceeding. Is the patient at term? If she is preterm, is she a candidate for antenatal corticosteroids and tocolytic therapy? If the patient is at term, are there medical or obstetric conditions that affect management? Abnormal fetal size or presentation, twin gestation, preeclampsia, and vaginal bleeding are obstetric factors that may alter management of labor from the outset. If a singleton vertex presentation is identified in a patient without complications, the physician proceeds to the following question.
2. *Is the labor progress abnormal?* If progress is normal according to the labor curve, no problem exists. If progress is abnormal, the physician proceeds to the following question.
3. *Is the abnormality in the active phase?* An apparent prolongation of the latent phase may represent false labor. In the absence of some other indication for effecting delivery, the obstetrician should not administer oxytocin or perform amniotomy, which would involve committing the patient to labor. However, if the decision is to proceed with delivery, augmentation with oxytocin or early amniotomy can be considered to expedite entry into the active phase of labor.[9] Long latent phases do increase patient anxiety and fatigue; reassurance is essential. At this point, ambulation and sedation are alternatives that may be selected on an individual basis, with input from the woman. If false labor has occurred, contractions will cease over time, or the patient will enter the active phase. Specifically, a diagnosis of failed induction in the latent phase should require at least 12 to 24 hours after rupture of membranes. If primary dysfunctional labor is the diagnosis or if a secondary arrest of dilation has occurred during the active phase (6 cm cervical dilation), the physician is faced with an abnormality that may indicate cephalopelvic disproportion, a mechanical obstruction to delivery. The next question can then be asked.
4. *Is the fetus tolerating labor?* Although the FHR pattern should be monitored from admission until delivery, a delay in the active phase of labor calls for a reassessment. If the FHR pattern is nonreassuring, the physician should effect delivery. If not, the next question is asked.
5. *Does the pelvis appear to be adequate for the infant?* An active-phase delay indicates either insufficient uterine contractile effort to dilate the cervix or a mechanical obstruction to delivery. Obviously this is a critical issue, because the therapeutic alternatives are very different. If the pelvis is clinically small and/or the fetus is large and the labor seems strong (e.g., intense uterine contractions occurring every 2 minutes), the choice is cesarean delivery. If the fetopelvic relationship is favorable for vaginal delivery and the contractions are infrequent, the choice is intravenous oxytocin, amniotomy, or both. In the vast majority of cases, however, the obstetrician is uncertain as to whether oxytocin augmentation will result in successful vaginal delivery or whether cesarean delivery will ultimately be required despite oxytocin augmentation. Given the uncertainty about whether mechanical obstruction or insufficient uterine activity is the problem, the proper choice typically is to administer oxytocin to correct the

latter, a decision that recognizes that, if the former is present, the attempt will ultimately fail. Data support longer periods of oxytocin augmentation for nonprogressive active-phase labor (at least 4 to 6 hours) provided the FHR pattern is reassuring.[29]

The benefit of intravenous oxytocin administration for labor arrest during the active phase of the first stage of labor is that the majority of the time it succeeds and cesarean delivery is avoided.[12] The risks associated with oxytocin stimulation are both maternal and fetal. If mechanical obstruction to delivery exists, greater uterine activity predisposes the patient to uterine rupture, which is one of the gravest obstetric complications. Multiparity and a scarred uterus are additional predisposing factors to uterine rupture. Oxytocin has an antidiuretic effect, and in the past there were reports of water intoxication with seizures and even coma and death as iatrogenic complications of its use. In these cases, oxytocin was administered over many hours (often days) in electrolyte-free solutions, with little attention paid to maternal urine output; infusion of electrolyte-containing solutions and close attention to the parturient's fluid balance should make this a theoretical rather than a practical concern. However, *uterine tachysystole with FHR decelerations* is a real concern when infusing oxytocin. The force generated during uterine contractions interrupts blood flow through the intervillous space because placental perfusion occurs during periods of uterine relaxation, and uterine contractions can be regarded as episodes of "fetal breath-holding." If the contractions are occurring very frequently (e.g., at intervals less than 2 minutes apart, defined as uterine tachysystole), there may be insufficient time between contractions for placental gas exchange, the fetus may become hypoxemic, and fetal compromise may result. Continuous observation permits a timely diagnosis of uterine tachysystole. Decreasing the infusion rate, temporarily stopping the infusion, or, rarely, giving terbutaline promptly corrects the problem.

Currently, in the United States, oxytocin for inducing or augmenting labor is given intravenously, typically by infusion pump. Continuous electronic FHR monitoring is used, and a physician or nurse constantly monitors the FHR pattern. Although the foregoing procedures are quite uniform from service to service, the selected doses of oxytocin are not.

The variability in protocols for oxytocin induction or augmentation of labor reflects confusion in the literature.[30–34] The goal is to increase uterine activity efficiently to dilate the cervix without causing fetal compromise as a result of uterine tachysystole. However, the best way to do this is unclear. Recommended starting doses of oxytocin vary from 1 to 6 mU/min, and additional drug is administered until a satisfactory labor pattern is achieved. Dosage increments typically vary from 1 to 6 mU at intervals of 15 to 40 minutes. High-dose oxytocin regimens involve the use of higher starting doses and incremental doses of 4 mU/min or greater. A systematic review of available trials suggests that the use of a higher dose regimen for labor augmentation is associated with shortened labor and a decrease in the incidence of cesarean delivery.[35,36]

The Active Management of Labor

Dystocia, which is also called abnormal labor progress, both directly and indirectly (through subsequent repeat cesarean deliveries) is the single most important reason for the high rate of cesarean delivery in the United States. Concern for the high cesarean delivery rate has created interest in the remarkable results achieved in the 1980s with the use of active management of labor at the National Maternity Hospital in Dublin, Ireland.[30,37] Components of the active management of labor include (1) a rigorous definition of labor; (2) early amniotomy; (3) constant nursing attendance; (4) the demand for continued progress in cervical dilation (1 cm or more per hour); (5) vigorous oxytocin stimulation for lack of progress; and (6) a "guarantee" that the parturient's stay in the labor unit will last no longer than 12 hours. In Dublin, these practices were associated with a cesarean birth rate of less than 5%; however, the rate has been higher in more recent years.

The introduction of the active management of labor in other obstetric services has been associated with lower cesarean delivery rates than those among historic controls. One randomized trial indicated that active management shortened labor, reduced the incidence of cesarean delivery for dystocia, and resulted in fewer maternal infectious complications without increasing maternal or neonatal morbidity.[38] However, data from other clinical trials and a Cochrane review suggest that active labor management is associated with little or no decrease in the cesarean delivery rate.[39,40] Nonetheless, in order to decrease the rate of cesarean delivery, recent efforts have been made to specifically create new guidelines for the active management of labor.[9]

SPECIAL SITUATIONS

Premature Rupture of Membranes

Premature rupture of the membranes (PROM) is defined as a rupture of the fetal membranes (i.e., the chorioamnion) before the onset of labor. It may occur preterm (before 37 weeks' gestation) or at term.

Preterm Premature Rupture of Membranes

The most significant complication of preterm PROM is preterm birth.[41] Although the length of the *latent period* (the interval between membrane rupture and the onset of labor) is inversely related to gestational age, only one in five women with preterm PROM have latent periods exceeding 1 week. Indeed, PROM is the precipitating factor in nearly one-third of preterm deliveries. Other risks for preterm PROM include chorioamnionitis and prolapse of the umbilical cord. If membrane rupture occurs during the second trimester and if the fetus experiences a long exposure to oligohydramnios, there is risk for pulmonary hypoplasia, perinatal death, neonatal sepsis, and orthopedic deformities.

Current management of preterm PROM is conservative. After the diagnosis is confirmed by inspection and nitrazine and fern testing (or rarely by ultrasound-guided instillation of dye into the amniotic fluid and observation of its passage

TABLE 18.3 Natural History of Premature Rupture of the Membranes at Term

Element	Percentage
Prevalence	10
Spontaneous labor within 24 hours	90
If cervix is unfavorable and no labor at 6 hours, percent laboring by 24 hours	60
Chorioamnionitis:	
Latent period < 24 hours	1–2
Latent period > 24 hours	5–10
Significant neonatal infection if chorioamnionitis is present	10

vaginally),[42] electronic FHR monitoring is used to identify variable FHR decelerations that signal umbilical cord compression. The mother is also evaluated for fever and uterine tenderness, which may indicate chorioamnionitis. If these are absent, the clinician awaits the onset of labor or the subsequent development of infection. The adjunctive use of maternally administered corticosteroids to enhance fetal pulmonary maturity and antibiotics to prevent chorioamnionitis and delay the onset of labor is indicated.[42–44] Current evidence does not support the use of tocolytic therapy to prolong pregnancy.[45] Delivery is recommended routinely at 34 weeks (a point beyond which the rate of severe neonatal morbidity and mortality is very low).[42]

Term Premature Rupture of Membranes

Approximately 8% of term pregnancies are complicated by PROM; the natural history is summarized in Table 18.3.[42,46]

Although chorioamnionitis is more likely to occur preterm than at term with PROM, no clear relationship exists between the length of the latent period and chorioamnionitis in the preterm patient.[47] By contrast, chorioamnionitis at term is more likely if the latent period exceeds 24 hours. The relationship between prolonged latency and chorioamnionitis accounts for the usual practice in the United States of oxytocin induction of labor for a woman with PROM at term if she is not already in active labor. Expectant management is only acceptable for women who decline induction with adequate counseling regarding the risks associated with prolonged rupture of membranes.[42]

Chorioamnionitis

If chorioamnionitis develops, the uterus must be emptied. Intrapartum antibiotic administration improves the outcome for both the mother and infant.[48] Ampicillin and gentamicin are often chosen to combat group B streptococcus and *Escherichia coli,* which are important neonatal pathogens. Because no relationship exists between the number of hours that chorioamnionitis has been present and perinatal outcome, chorioamnionitis alone is not an indication for cesarean delivery.[49-51] Antibiotics, oxytocin, and close observation of the mother and fetus are indicated.

Induction of Labor

Induction of labor can be defined as a surgical or medical intervention that leads to uterine contractions that progressively dilate the cervix. Because elective and indicated inductions differ in terms of eligibility criteria and the methods used, they are considered separately.

Elective Induction

The rationale for elective induction of labor is convenience, both for the patient and for the physician. Because it is elective, the delivery should be easily accomplished and the risks should approach zero. Factors associated with the success of elective induction of labor include (1) a parous patient; (2) a singleton vertex presentation; (3) a certain gestation of at least 39 weeks; (4) a favorable cervix; and (5) no contraindications to labor and vaginal delivery. The Bishop score (Table 18.4) helps quantitate the favorability of the cervix; the higher the score, the shorter the labor and the less likely induction will fail.[52] Bishop[52] observed that a score of 9 or greater was not associated with failure. With the modified Bishop score, cervical length replaces cervical effacement. Friedman et al.[53] determined that the Bishop score primarily predicts the latent phase of labor. This finding is not surprising, because a high Bishop score indicates that the cervix is ready to dilate with uterine contractions (i.e., the cervix will soon enter the active phase). By contrast, a low score suggests that many hours of uterine contractions may be needed to soften and efface the cervix. When the components of the Bishop score are considered separately in terms of their effects on the latent phase, dilation is most critical. Effacement (or length), station, and consistency are each half as important, and position has little effect.[53]

With a favorable cervix, elective induction is begun by performance of an amniotomy with or without concomitant oxytocin administration, which some obstetricians reserve for the patient who is not experiencing uterine contractions 4 to 6 hours after amniotomy. Amniotomy is typically performed early in the morning and is followed by delivery in the afternoon. Elective inductions have been criticized by some

physicians because of the possibilities of induction failure and iatrogenic prematurity.[54] However, a recent British study noted no increase in the risk for cesarean delivery or adverse perinatal outcomes in women older than 35 years of age undergoing elective induction of labor at 39 weeks' gestation.[55] A large multicenter randomized trial recently found that elective induction of labor in low-risk nulliparous women at 39 weeks' gestation did not result in a greater frequency of adverse perinatal outcomes than expectant management, and it resulted in a lower frequency of cesarean delivery.[56]

Indicated Induction

Indicated induction of labor is performed when delivery is indicated for maternal or fetal reasons and both the mother and fetus can tolerate labor and vaginal delivery. An indicated induction of labor often arises in the setting of a medical or obstetric complication such as diabetes mellitus, preeclampsia, fetal growth restriction (also known as intrauterine growth restriction), or the postterm pregnancy. By definition, the physician is dealing with a complicated pregnancy when performing an indicated induction of labor; therefore, close maternal and fetal monitoring is indicated. When considering the critical question whether induction should be undertaken, the obstetrician must weigh the perinatal risks of continued intrauterine versus extrauterine existence and must also consider the potential adverse maternal consequences of induction, including a higher risk for infection and/or cesarean delivery.

If the Bishop score is favorable, amniotomy or oxytocin administration suffices as a means of inducing labor. Often, however, the cervix is not favorable, and induction is typically initiated with application of cervical ripening agents (prostaglandin E analogues) or use of a Foley catheter bulb to mechanically dilate the cervix.[57] Both osmotic cervical dilators and pharmacologic techniques are effective in improving the Bishop score.[58] Alternatively, a Foley catheter bulb may also be used for mechanical dilation. Typically these adjunctive measures are instituted the evening before the planned induction. A common pharmacologic method involves the topical application of prostaglandin E_2, either in the vagina or in the cervical canal. **Prostaglandin E_2** has a local effect in the initiation of softening, effacement, and dilation of the cervix, and it also has an oxytocin-like effect on the myometrium. Women treated with prostaglandin E_2 commonly experience contractions and labor before amniotomy or oxytocin administration. The same is true for **misoprostol,** a prostaglandin E_1 analogue that is now widely used for cervical ripening and labor induction.[59] Prostaglandins should not be administered to induce labor in women with a prior cesarean delivery, because their use is associated with an increased risk for uterine rupture. Overall, mechanical dilation with a Foley catheter bulb (16 to 20 French, filled 30 to 60 mL saline) or prostaglandin E analogues are considered equally efficacious methods of cervical ripening.

Operative Vaginal Delivery

Cesarean delivery has become a too frequent solution to labor room problems. This safe operation is certainly preferable to the continuation of labor in the setting of genuine fetal compromise or to the performance of a difficult and traumatic vaginal delivery. Unfortunately, however, more traditional obstetric interventions (e.g., labor, additional labor, operative vaginal delivery) are often bypassed in favor of cesarean delivery, perhaps more for medicolegal than for medical concerns. The appropriate use of operative vaginal delivery techniques requires an accurate assessment of the situation, technical skills, and an honest and humble physician.

BOX 18.4 Classification of Forceps Delivery

Outlet Forceps Delivery
- Scalp is visible.
- Skull has reached the pelvic floor, and head is on the perineum.
- Sagittal suture is in the anteroposterior diameter or within 45 degrees (e.g., occiput anterior, left occiput anterior, right occiput posterior).

Low Forceps Delivery
- Station is +2 or greater.
- Hollow of the sacrum is filled.

Mid-Forceps Delivery
- Vertex is engaged, but the station is 0 or +1.

Vertex Presentation

Carefully selected and performed forceps or vacuum-assisted delivery shortens the second stage of labor in cases of nonreassuring fetal status, maternal illness or exhaustion, and/or undue prolongation of labor with little or no progress (Box 18.4). The station of the presenting vertex is critical to the safety of the procedure for mother and infant. The current American College of Obstetricians and Gynecologists classification permits a more rational approach to operative vaginal delivery than was available previously.[60,61]

For any operative vaginal delivery, adequate anesthesia is required. Outlet operative deliveries are perfectly safe for both mother and fetus. The low station effectively rules out cephalopelvic disproportion, and little traction is required. Outlet operative deliveries shorten the second stage by only a few minutes. Sustained fetal bradycardia is a common indication for outlet operative delivery. An experienced physician may safely perform low-station operative deliveries in cases of fetal compromise or maternal illness or exhaustion. The higher the head, the harder the pull. Rotations increase the likelihood of vaginal tears.[61]

Mid-pelvic deliveries reflect a more complicated problem.[62,63] If the station is overestimated, the vertex may be barely engaged. The hollow of the sacrum is incompletely filled. Midpelvic deliveries should be regarded as "trials." The obstetrician must avoid excessive traction and must be willing to abandon the attempt in favor of cesarean delivery if vaginal delivery does not proceed easily.

Although operative vaginal delivery was traditionally accomplished with obstetric forceps, there has been interest in the soft plastic cup vacuum extractor.[64–67] Neither is uniformly better. The vacuum extractor is easier to apply, especially if the obstetrician is uncertain of the position of the occiput, and most likely it is associated with less maternal trauma. Forceps—but not the vacuum extractor—permit the correction of deflection or slight abnormalities of position that may impede progress. The vacuum extractor is more likely to slip off; whether this feature enhances safety is unknown. Neonatal results are comparable, but retinal hemorrhages, which are of unclear significance, are more likely with vacuum extraction. The obstetrician should be trained in both techniques and should individualize their use. A recent study observed that mandating resident competency in use of forceps before beginning training with vacuum extraction was associated with greater use of epidural analgesia, more forceps deliveries, fewer cases of postpartum hemorrhage, and no increase in perineal injury or neonatal morbidity.[68]

Persistent occiput-posterior positions often occur in anthropoid and android pelvises. In modern obstetrics, the infants in most of these cases are delivered with the occiput posterior. Extension of the episiotomy is a common complication in this circumstance, which argues for the consideration of a mediolateral episiotomy.

Deep transverse arrests of the occiput were traditionally managed with rotation and delivery with Kielland's forceps. Current trainees typically have little experience with this instrument, and they are more likely to select the vacuum extractor in this circumstance.

Nonvertex Presentations

A persistent brow presentation or a transverse lie mandates cesarean delivery. Most face presentations and selected breech presentations can be safely delivered vaginally.[69] However, in response to a large international multicenter trial in which planned vaginal delivery was associated with worse perinatal outcomes than planned cesarean delivery,[70] the American College of Obstetricians and Gynecologists now recommends cesarean delivery for the persistent singleton breech presentation at term as the preferred mode of delivery for most physicians, particularly in light of diminishing experience in vaginal breech deliveries.[71]

Fetal Death

If fetal death has occurred, the obstetrician no longer has two patients, making maternal safety the only concern. Although placenta previa or absolute cephalopelvic disproportion may indicate cesarean delivery, the obstetrician is often more willing to choose a more complicated operative vaginal delivery than if the fetus were living.

Shoulder Dystocia

With vertex presentations, most mechanical difficulties are resolved with delivery of the head; once the head is delivered, the remainder of the fetus follows easily. In as many as 3% of vaginal deliveries, this is not the case. After the (often large) head is delivered, it seems to be "sucked" back into the perineum (the turtle sign). With maternal pushing and gentle traction, nothing happens. In this case, the anterior shoulder is trapped above the pubic symphysis. This serious complication is called *shoulder dystocia.* Recognition that shoulder dystocia exists is often followed by equanimity giving way to panic. If delivery is not accomplished soon, umbilical cord compression may result in asphyxia. Excessive traction on the fetal head may result in damage to the brachial plexus (e.g., Erb palsy), which may be permanent or temporary. During the manipulations undertaken to effect delivery, a fracture of the clavicle or humerus may result.

BOX 18.5 Risk Factors for Shoulder Dystocia

- Fetal macrosomia
- Maternal diabetes mellitus
- Delayed active phase of labor
- Prolonged second stage of labor
- Operative vaginal delivery

Risk factors for shoulder dystocia are those that predict or reflect mechanical difficulty (Box 18.5).[72–75] Women with diabetes mellitus are predisposed to shoulder dystocia, not only because fetal macrosomia is more common but also because the fetus of a mother with diabetes has a shoulder circumference that is disproportionately large relative to the head circumference. Desultory labor may be a harbinger of mechanical mismatch, and operative vaginal delivery can exacerbate the situation. Although risk factors are known, it is important to recognize that shoulder dystocia cannot be accurately predicted or prevented.[75]

Appropriate management of shoulder dystocia begins with the recognition that there is sufficient time to deliver the infant safely. Neuraxial anesthesia is ideal but not essential. Extension of the episiotomy should be considered. The anterior shoulder is stuck behind the pubic symphysis. Although greater posterior room does not directly permit delivery, it does permit vaginal manipulations that may be necessary to effect delivery. Table 18.5 lists a personal plan of management for shoulder dystocia, but other choices are available.[72,75,76] Emergency drills and simulation training may improve proficiency in the management of shoulder dystocia.

If suprapubic pressure (directed toward the floor) coupled with gentle traction on the head is not efficacious, the mother's thighs are removed from their supports and are hyperflexed alongside her abdomen. This maneuver (i.e., the McRoberts maneuver) elevates the symphysis in a cephalad direction and often frees the impacted shoulder and allows easy delivery. If the McRoberts maneuver is not successful, recent guidelines now recommend attempts to deliver the posterior arm as the next step.[75] Despite previous assumptions to the contrary, vaginal delivery of the head does not necessarily commit one

TABLE 18.5 Management of Shoulder Dystocia

Maneuver	Desired Result
Suprapubic pressure	Anterior shoulder dislodged from above pubic symphysis
Hyperflexion of maternal thighs alongside abdomen (McRoberts maneuver)	Cephalad rotation of pubic symphysis
Intravaginal pressure on posterior shoulder	Anteroposterior position of shoulders transformed to oblique position
Delivery of posterior arm	Once accomplished, added room permits delivery
Cephalic replacement (Zavanelli maneuver)	Cesarean delivery

to vaginal birth of the infant. Cephalic replacement (i.e., the Zavanelli maneuver) must be kept in mind as a last resort. If all measures have failed, the "tape is rewound," and the mechanism of labor is reversed. The position of the vertex is rotated back to the position prior to external rotation (usually occiput anterior), flexion is achieved, and the head is elevated, which may be facilitated by tocolysis (e.g., sublingual or intravenous nitroglycerin 100 μg, subcutaneous or intravenous terbutaline 0.25 mg, or general anesthesia with a volatile anesthetic agent). After the fetal head has been placed back into the vagina, prompt cesarean delivery is performed.[76]

KEY POINTS

- The outcome of labor reflects the interaction of three components: the powers, the passageway, and the passenger.
- Assuming that the fetus is tolerating labor satisfactorily, the most important obstetric determination is whether the patient is in the latent or the active phase of the first stage of labor.
- Amniotomy shortens labor.
- Oxytocin is the most valuable obstetric drug, and judicious use of a higher dose regimen may increase vaginal birth and shorten labor.
- Expectant management is the standard choice for the very preterm patient with premature rupture of membranes; induction of labor is generally undertaken in patients exhibiting this condition at term.
- Elective induction of labor is an appropriate choice for a patient with a favorable cervix.
- The declining numbers of operative vaginal deliveries reflect medicolegal concerns rather than new scientific information.

Trial of Labor and Vaginal Birth after Cesarean Delivery

David H. Chestnut, MD

CHAPTER OUTLINE

In 1916, Edward Cragin[1] stated, "Once a cesarean, always a cesarean." This edict has had a profound effect on obstetric practice in the United States. The cesarean delivery rate increased from 5.5% of all deliveries in 1970 to 24.7% in 1988 (Fig. 19.1). Much of the increase in the cesarean delivery rate resulted from performance of repeat cesarean deliveries. In contemporary practice, elective repeat cesarean deliveries account for one-third of all cesarean deliveries. Cesarean delivery is the most frequently performed major surgery in the United States.

For many years, most US physicians ignored Cragin's subsequent statement, "Many exceptions occur."[1] In 1981, the National Institute of Child Health and Human Development Conference on Childbirth concluded that vaginal birth after cesarean (VBAC) is an appropriate option for many women.[2] In 1991, Rosen et al.[3] modified Cragin's original dictum as follows: "Once a cesarean, a trial of labor should precede a second cesarean except in the most unusual circumstances." In 1988 and again in 1994, the American College of Obstetricians and Gynecologists (ACOG)[4] concluded:

> *"The concept of routine repeat cesarean birth should be replaced by a specific decision process between the patient and the physician for a subsequent mode of delivery.… In the absence of a contraindication, a woman with one previous cesarean delivery with a lower uterine segment incision should be counseled and encouraged to undergo a trial of labor in her current pregnancy."*

The VBAC rate increased from 2% in 1970 to 28% in 1995. This change in practice helped reduce the overall cesarean delivery rate from 24.7% in 1988 to 20.7% in 1996 (see Fig. 19.1). Subsequently, the safety of a trial of labor after cesarean (TOLAC) underwent further scrutiny and criticism, and the VBAC rate sharply declined.[5] The VBAC rate in the United States dropped from 28% in 1995 to 9% in 2004. In 2009, the overall cesarean delivery rate rose to 32.9%, the highest rate ever recorded in this country.[6] Subsequently the cesarean delivery rate declined slightly to 32.0% in 2015.[6]

PRIMARY CESAREAN DELIVERY: CHOICE OF UTERINE INCISION

Obstetric practice in 1916 hardly resembled obstetric practice today. In 1916, only 1% to 2% of all infants were delivered by cesarean delivery. Most cesarean deliveries were performed in patients with a contracted bony pelvis, and obstetricians uniformly performed a classic uterine incision (i.e., a long

vertical incision in the upper portion of the uterus) (Fig. 19.2). A patient with a classic uterine incision is at high risk for catastrophic uterine rupture during a subsequent pregnancy. Such uterine rupture may occur before or during labor, and it often results in maternal and perinatal morbidity or mortality.

In 1922, De Lee and Cornell[7] advocated the performance of a vertical incision in the lower uterine segment. Unfortunately, low-vertical incisions rarely are confined to the lower uterine segment. Such incisions often extend to the body of the uterus, which does not heal as well as the lower uterine segment. Kerr[8] later advocated the performance of a low-transverse uterine incision (see Fig. 19.2). A low-transverse uterine incision results in less blood loss and is easier to repair than a classic uterine incision.[9] Further, a low-transverse uterine incision is more likely to heal satisfactorily and to maintain its integrity during a subsequent pregnancy. Thus, obstetricians prefer to make a low-transverse uterine incision during most cesarean deliveries.

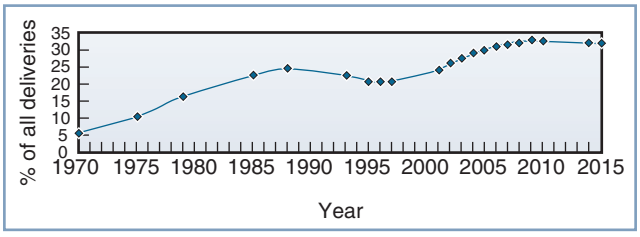

Fig. 19.1 Incidence of cesarean delivery in the United States.

Obstetricians reserve the low-vertical incision for patients whose lower uterine segment does not have enough width to allow safe delivery. Preterm parturients may have a narrow lower uterine segment. In these patients, delivery through a transverse uterine incision may cause an extension of the incision into the vessels of the broad ligament. For example, a patient with preterm labor at 26 weeks' gestation may undergo cesarean delivery because of a breech presentation, and the obstetrician may perform a low-vertical incision to facilitate an atraumatic delivery of the fetal head.

Obstetricians rarely perform a classic uterine incision in modern obstetric practice. An obstetrician may perform a classic uterine incision when the need for extensive

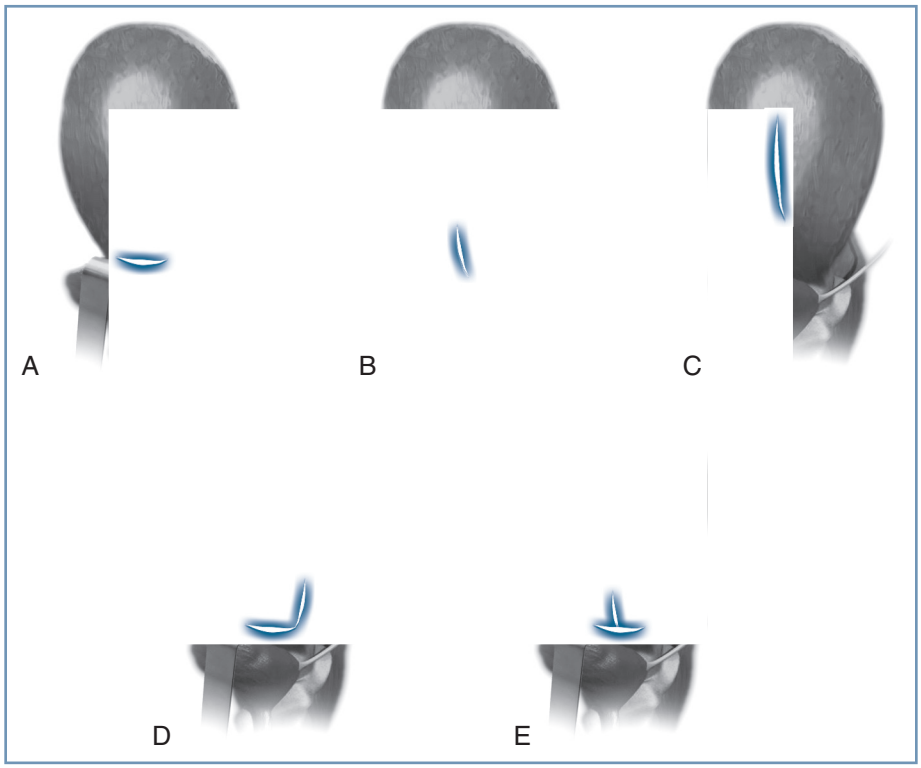

Fig. 19.2 Uterine incisions for cesarean delivery. (A) Low-transverse incision. The bladder is retracted downward, and the incision is made in the lower uterine segment, curving gently upward. If the lower segment is poorly developed, the incision also can curve sharply upward at each end to avoid extending into the ascending branches of the uterine arteries. (B) Low-vertical incision. The incision is made vertically in the lower uterine segment after reflection of the bladder, with avoidance of extension into the bladder below. If more room is needed, the incision can be extended upward into the upper uterine segment. (C) Classic incision. The incision is entirely within the upper uterine segment and can be at the level shown or in the fundus. (D) J-shaped incision. If more room is needed when an initial transverse incision has been made, either end of the incision can be extended upward into the upper uterine segment and parallel to the ascending branch of the uterine artery. (E) T-shaped incision. More room can be obtained in a transverse incision by an upward midline extension into the upper uterine segment. (Modified from Landon MB. Cesarean delivery. In Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics: Normal and Problem Pregnancies.* 5th ed. Philadelphia, PA: Churchill Livingstone; 2007:493.)

intrauterine manipulation of the fetus (e.g., delivery of a fetus with a transverse lie) is anticipated. Some obstetricians prefer a classic uterine incision in patients with an anterior placenta previa. In such cases, the performance of a classic incision allows the obstetrician to avoid cutting through the placenta, which might result in significant hemorrhage. The obstetrician may perform a classic uterine incision in morbidly obese women in whom it is difficult to expose the lower uterine segment, especially when the skin incision is supra-umbilical.

MATERNAL AND NEONATAL OUTCOMES

Multiple studies have demonstrated that TOLAC results in a successful VBAC in 60% to 80% of women in whom a low-transverse uterine incision was made for a previous cesarean delivery.[10–14] A 2010 National Institutes of Health (NIH) consensus development panel[15] concluded that although the TOLAC rate has declined dramatically in recent years, the VBAC rate after TOLAC has remained constant at approximately 74%. In 2015, the Royal College of Obstetricians and Gynaecologists (RCOG)[16] concluded that the success rate of planned VBAC is 72% to 75%. The NIH panel[15] also noted that a history of vaginal delivery, either before or after a prior cesarean delivery, is consistently associated with an increased likelihood of successful VBAC.

Maternal Outcomes

Flamm et al.[10] performed a prospective multicenter study of TOLAC. Of the 7229 patients, 5022 (70%) underwent TOLAC and 2207 underwent elective repeat cesarean delivery. Some 3746 (75%) of the women who opted for TOLAC delivered vaginally. The incidence of uterine rupture was 0.8%. The incidence of postpartum transfusion, the incidence of postpartum fever, and the duration of hospitalization were significantly lower in the TOLAC group than in the elective repeat cesarean group. Likewise, in a 1991 meta-analysis of 31 studies, Rosen et al.[3] noted that maternal febrile morbidity was significantly lower among women who attempted VBAC than among those who underwent elective repeat cesarean delivery.

In contrast, McMahon et al.[17] performed a population-based longitudinal study of 6138 women in Nova Scotia who had previously undergone cesarean delivery and who delivered a single live infant between 1986 and 1992. Some 3249 women attempted VBAC, and 2889 women chose a repeat cesarean delivery. There was no difference between the two groups in the incidence of "minor complications" (e.g., puerperal fever, transfusion, wound infection). However, "major complications" (e.g., hysterectomy, uterine rupture, operative injury) were nearly twice as common among women who attempted VBAC than among women who underwent elective repeat cesarean delivery.

Landon et al.[11] subsequently conducted a prospective 4-year observational study of all parturients with a singleton gestation and a prior cesarean delivery at 19 academic medical centers. Among the 17,898 women who attempted VBAC, 13,139 (73.4%) delivered vaginally. Symptomatic uterine rupture occurred in 124 (0.7%) women who underwent a trial of labor. The rate of endometritis was higher in women who underwent a trial of labor than in women who had an elective repeat cesarean delivery (2.9% versus 1.8%), as was the rate of blood transfusion (1.7% versus 1.0%).[17]

In a 2004 systematic review of published studies of attempted VBAC, Guise et al.[18] observed no significant difference in the incidence of maternal death or hysterectomy between women who attempted a trial of labor and those who underwent repeat cesarean delivery. Uterine rupture was more common in the women who attempted a trial of labor, but the rates of asymptomatic uterine dehiscence did not differ.

Wen et al.[19] performed a retrospective cohort comparison of outcomes after TOLAC or elective repeat cesarean delivery in 308,755 Canadian women with a history of previous cesarean delivery. These investigators observed that the rates of uterine rupture (0.65%), transfusion (0.19%), and hysterectomy (0.10%) were significantly higher in the TOLAC group. However, the maternal in-hospital death rate was significantly lower in the TOLAC group (1.6 per 100,000) than in the elective cesarean delivery group (5.6 per 100,000). Similarly, Guise et al.[20] observed a lower maternal mortality rate in women who underwent TOLAC than in women who underwent elective repeat cesarean delivery (0.004% versus 0.013%, respectively).

Cahill et al.[21] performed a multicenter cohort study in which they concluded that among TOLAC candidates who had a prior vaginal delivery, those who attempted VBAC had a lower risk for overall major maternal morbidities, as well as maternal fever and transfusion, than women who chose repeat cesarean delivery. These investigators concluded that women who have had a prior vaginal delivery have "less composite maternal morbidity if they attempt VBAC compared with [those] undergoing an elective repeat cesarean delivery." Further, they concluded that a trial of labor is "a safer overall option for women who have had a prior vaginal birth."[21]

Rossi and D'Addario[12] performed a meta-analysis of studies published from 2000 to 2007 that compared maternal morbidity in women who underwent TOLAC versus women who underwent elective repeat cesarean delivery. Successful VBAC occurred in 17,905 (73%) of 24,349 women who underwent TOLAC. Overall maternal morbidity did not differ between women who underwent TOLAC and women who underwent elective repeat cesarean delivery. Likewise, the incidence of blood transfusion and hysterectomy did not differ between the two groups. The incidence of uterine rupture was higher in the TOLAC group (1.3% versus 0.4%). Further, maternal morbidity, uterine rupture, blood transfusion, and hysterectomy were more common in women who had a *failed* TOLAC.

The 2010 NIH consensus development panel[15] noted that the overall benefits of TOLAC "are directly related to having a [successful] VBAC as these women typically have the lowest morbidity." Likewise, the panel noted that the harms of TOLAC "are associated with an unsuccessful trial of labor

resulting in cesarean delivery because these deliveries have the highest morbidity." However, the panel concluded that women who undergo TOLAC, regardless of the ultimate mode of delivery, are at decreased risk for maternal mortality compared with women who undergo elective repeat cesarean delivery. The panel also cited low-grade evidence of a shorter hospitalization overall for women attempting TOLAC compared with women undergoing elective repeat cesarean delivery.

Neonatal Outcomes

Lydon-Rochelle et al.[22] conducted a population-based, retrospective cohort analysis of obstetric outcomes for all 20,095 nulliparous women who gave birth to a live singleton infant by cesarean delivery in civilian hospitals in Washington between 1987 and 1996 and who subsequently delivered a second singleton child during the same period. These investigators observed that spontaneous labor was associated with a tripling of the risk for uterine rupture (i.e., a uterine rupture rate of 5.2 per 1000 women who had spontaneous onset of labor versus 1.6 per 1000 women who underwent elective repeat cesarean delivery without labor). Further, the incidence of infant death was more than 10 times higher among the 91 women who experienced uterine rupture than among the 20,004 who did not (i.e., a 5.5% incidence of infant death versus a 0.5% incidence, respectively).[22]

In the study performed by McMahon et al.[17] there was no difference between the two groups in perinatal mortality or morbidity. However, two perinatal deaths occurred after uterine rupture in the TOLAC group. Landon et al.[11] observed that hypoxic-ischemic encephalopathy occurred in no infants whose mothers underwent elective repeat cesarean delivery and in 12 infants delivered at term whose mothers underwent a trial of labor ($P < .001$).

The 2010 NIH consensus development panel[15] concluded that the perinatal mortality rate (death between 20 weeks' gestation and 28 days of life) is increased with TOLAC when compared with elective repeat cesarean delivery (i.e., 130 deaths per 100,000 infants compared with 50 deaths per 100,000 infants, respectively). Likewise, the panel concluded that the neonatal mortality rate (death in the first 28 days of life) is also increased with TOLAC when compared with elective repeat cesarean delivery (110 deaths per 100,000 infants versus 50 deaths per 100,000 infants, respectively).[15]

On the other hand, elective cesarean delivery results in some cases of iatrogenic neonatal respiratory sequelae, including respiratory distress syndrome and transient tachypnea of the newborn. Kamath et al.[23] observed that newborns born after elective repeat cesarean delivery had significantly higher rates of respiratory morbidity and neonatal intensive care unit admission—and a longer length of hospital stay—than infants whose mothers attempted VBAC. However, the 2010 NIH consensus development panel[15] concluded that there is insufficient evidence to determine whether substantial differences in respiratory outcomes occur in infants born via elective repeat cesarean delivery compared with infants born after TOLAC.

ELIGIBILITY AND SELECTION CRITERIA

Most studies suggest a high likelihood of success with TOLAC, even in women in whom the indication for previous cesarean delivery was dystocia or failure to progress in labor. Rosen and Dickinson[24] performed a meta-analysis of 29 studies of attempted VBAC. Among women whose previous cesarean deliveries were performed for dystocia or cephalopelvic disproportion, the average rate of successful VBAC was 67%. Later studies have concluded that a history of previous vaginal delivery (especially previous VBAC) is the greatest predictor for successful VBAC and is associated with a VBAC success rate of 85% to 90%.[16,25]

The highest risk for maternal morbidity and mortality is associated with unsuccessful TOLAC.[15] The ACOG[13,14] concluded that women with at least a 60% to 70% chance of successful VBAC have equal or less maternal morbidity when they undergo TOLAC than women who undergo elective repeat cesarean delivery. Conversely, the ACOG[13,14] noted that women who have a lower than 60% probability of successful VBAC have a greater likelihood of morbidity than women who undergo elective repeat cesarean delivery. Thus, the ability to identify women with a high likelihood of successful VBAC would improve the safety of TOLAC. Investigators have developed scoring systems for predicting the success or failure of TOLAC. Grobman et al.[26] developed a nomogram specifically for women undergoing TOLAC at term gestation with one previous low-transverse cesarean delivery, a singleton gestation, and a vertex fetal presentation. The nomogram incorporates six variables that may be ascertained at the first prenatal visit; those variables include maternal age, body mass index, ethnicity, prior vaginal delivery, prior VBAC, and a recurring indication for cesarean delivery. This model was validated in a subsequent study,[27] and a VBAC calculator is now available online.[28] Mardy et al.[29] subsequently developed a prediction model for *preterm* women undergoing TOLAC between 26 and 36 weeks' gestation. They identified eight predictive variables: chronic hypertension, hypertensive disease of pregnancy, diabetes (pregestational or gestational), any prior vaginal delivery, prior VBAC, dilation on admission cervical examination, a recurring indication for prior cesarean delivery, and a need for induction of labor. A preterm VBAC prediction calculator is now available online.[30]

The ACOG[13,14] concluded that "most women with one previous cesarean delivery with a low-transverse incision are candidates for and should be counseled about and offered TOLAC." A history of dystocia, a need for induction of labor, and maternal obesity are associated with a lower likelihood of successful VBAC.[26,31–33]

History of More Than One Cesarean Delivery

Studies that have assessed outcomes of TOLAC in women with a history of more than one cesarean delivery have not demonstrated consistent conclusions. One large multicenter study found no increased risk for uterine rupture (0.9% versus 0.7%) in women with more than one previous cesarean delivery, when compared with women with only one previous

cesarean delivery.[34] A second large study observed that the risk for uterine rupture increased from 0.9% to 1.8% during TOLAC in women with two previous cesarean deliveries.[35] Both studies observed that TOLAC was associated with some increase in maternal morbidity in women with more than one previous cesarean delivery, although the absolute magnitude of the difference in morbidity was relatively small.[34,35] The ACOG[13,14] concluded that it is reasonable to consider TOLAC for women with two previous low-transverse cesarean deliveries. In 2015, the RCOG[16] stated that "women who have had two or more prior lower segment caesarean deliveries may be offered VBAC after counselling by a senior obstetrician." Data regarding the risk for TOLAC in women with more than two previous cesarean deliveries are limited.[13,14]

Previous Low-Vertical Incision

Some obstetricians allow a trial of labor after a previous low-vertical uterine incision, provided that there is documentation that the uterine incision was confined to the lower uterine segment. (Low-vertical uterine incisions often extend above the lower uterine segment, especially when performed in preterm patients.) Naef et al.[36] retrospectively reviewed outcomes for 174 women who attempted VBAC after a previous low-vertical cesarean delivery; 144 (83%) women delivered vaginally. Uterine rupture occurred in 2 (1.1%) of the patients. These investigators concluded that "the likelihood of successful outcome and the incidence of complications are comparable to those of published experience with a trial of labor after a previous low-segment transverse incision."[36] Adair et al.[37] made similar observations. The ACOG[13,14] concluded that there is no consistent evidence of an increased risk for uterine rupture in women with a previous low-vertical uterine incision, and that obstetricians and patients may choose to undergo TOLAC in the presence of a documented prior low-vertical uterine incision.

Twin Gestation

Some obstetricians believe that uterine overdistention, which occurs with twin gestation, increases the risk for uterine rupture in patients with a history of previous cesarean delivery. Early reports suggested otherwise, but these studies were limited by the small number of patients.[38,39] Cahill et al.[40] performed a retrospective cohort study of 25,005 obstetric patients with at least one previous cesarean delivery, which included 535 patients with a twin pregnancy. The investigators observed that women with a twin gestation were less likely to attempt VBAC but were no more likely to have a failed VBAC or to experience major morbidity than women with a singleton gestation.

Likewise, a report from the Maternal-Fetal Medicine Unit Cesarean Registry[41] included outcome measures for 186 women with a twin gestation who attempted VBAC. Some 120 (64.5%) women delivered vaginally. Women who attempted a trial of labor with twin gestation had no higher risk for transfusion, endometritis, intensive care unit admission, or uterine rupture than women who underwent elective repeat cesarean delivery. The investigators concluded that a trial of labor in women with a twin gestation after previous cesarean delivery does not appear to be associated with a higher risk for maternal morbidity.[41]

Ford et al.[42] subsequently examined outcomes for 6555 women with a twin gestation who delivered between 1993 and 2002. Among 1850 women who underwent a trial of labor, 836 (45.2%) delivered vaginally. The rate of uterine rupture was higher in the trial-of-labor group than in the elective cesarean delivery group (0.9% versus 0.1%), but the rate of wound complications was lower in the trial-of-labor group (0.6% versus 1.3%).

The ACOG[14] concluded that "women with one previous cesarean delivery with a low-transverse [uterine] incision, who are otherwise appropriate candidates for twin vaginal delivery, are considered candidates for TOLAC." In contrast, the RCOG[16] stated that "there is uncertainty about the safety and efficacy of planned VBAC in pregnancies complicated by … twin gestation."

Unknown Uterine Scar

For some patients, there is no documentation of the type of uterine incision performed during a previous cesarean delivery. Some obstetricians require documentation of the type of previous uterine incision before they allow a patient to attempt VBAC. At least two studies have concluded that a trial of labor does not significantly increase maternal or perinatal mortality in patients with an unknown uterine scar.[43,44] Perhaps this conclusion is true because most patients with an unknown uterine scar had a low-transverse uterine incision at previous cesarean delivery. Ultrasonography may help the obstetrician confirm the presence of a low-transverse uterine scar in the pregnant woman with an unknown uterine scar.[45] The ACOG[14] concluded that "women with one previous cesarean delivery with an unknown uterine scar type may be candidates for TOLAC, unless there is a high clinical suspicion of a previous classical uterine incision such as cesarean delivery performed at an extremely preterm gestational age."

Suspected Macrosomia

In 1994, the ACOG[4] concluded that an estimated fetal weight of more than 4000 g does not contraindicate TOLAC. However, in 1999, the ACOG[46] included suspected macrosomia on the list of TOLAC eligibility criteria that are controversial. In 2004, the ACOG[47] noted that macrosomia is associated with a lower likelihood of successful VBAC but did not include a specific recommendation regarding TOLAC in cases of suspected macrosomia. However, the ACOG cited one report that observed that the rate of uterine rupture appeared to be higher only in women without a previous vaginal delivery.[48] A report from the Maternal-Fetal Medicine Unit Cesarean Registry[49] concluded that for women with a history of previous cesarean delivery for dystocia, a higher birth weight in a subsequent pregnancy (relative to the first pregnancy birth weight) diminishes the chances of successful VBAC. In 2010, the ACOG[13] concluded that "suspected macrosomia alone should not preclude the possibility of TOLAC."

Gestation beyond 40 Weeks

Studies have consistently demonstrated decreased rates of successful VBAC in women who undergo TOLAC after 40 weeks' gestation.[50–52] One study observed an increased incidence of uterine rupture in women undergoing TOLAC beyond 40 weeks' gestation,[52] but other studies (including the largest study[51] that has assessed this risk factor) have not confirmed an increased risk for uterine rupture in these patients. The ACOG[14] concluded that although the likelihood of successful VBAC may be diminished in more advanced gestations, a "gestational age greater than 40 weeks alone should not preclude TOLAC."

Breech Presentation and External Cephalic Version

Breech presentation itself does not increase the risk for uterine rupture. In contemporary practice, most obstetricians do not allow a trial of labor in *any* patient with a breech presentation. Thus, most patients with a breech presentation undergo elective cesarean delivery, with or without a history of previous cesarean delivery. The ACOG[13,14] concluded that external cephalic version is not contraindicated in women with a previous low-transverse uterine incision who are at low risk for adverse maternal and neonatal outcomes from external cephalic version and TOLAC.

Size of Hospital

Most studies of VBAC have been conducted in university or tertiary care hospitals with in-house obstetricians, anesthesia providers, and operating room staff. In 1999, the ACOG[46] noted that "the safety of [a] trial of labor is less well documented in smaller community hospitals or facilities where resources may be more limited." A 2007 study[53] evaluated outcomes for women who attempted VBAC in 17 diverse hospitals, including six university hospitals, five community hospitals with an obstetrics-gynecology residency program, and six community hospitals without an obstetrics-gynecology residency program. The incidence of uterine rupture with attempted VBAC was significantly higher in community hospitals than in university hospitals (1.2% versus 0.6%, respectively). However, the rates of maternal blood transfusion and composite adverse maternal outcome were identical in community and university hospitals.[53] The ACOG and the Society for Maternal-Fetal Medicine have recommended that attempted VBAC should occur in a level I center or higher.[54]

Contraindications

Contraindications to planned TOLAC include[13,14,47]:

- Previous classic or T-shaped incision or extensive transfundal uterine surgery
- Previous uterine rupture
- Medical or obstetric complication that precludes labor and vaginal delivery
- Inability to perform emergency cesarean delivery because of unavailable surgeon, anesthesia provider, or operating room staff

Social and Economic Factors

Why do most eligible patients choose to undergo elective repeat cesarean delivery? The low frequency of TOLAC has resulted, in part, from both physician and patient preference. VBAC requires more physician effort than elective repeat cesarean delivery. In some cases, physician reimbursement is greater for elective repeat cesarean delivery than for VBAC, despite the fact that VBAC requires greater physician effort.

Stafford[55] reviewed the impact of nonclinical factors on the performance of repeat cesarean delivery in California. He observed that "proprietary hospitals, with the greatest incentive to maximize reimbursement, had the highest repeat cesarean [delivery] rates." Nonteaching hospitals and hospitals with low-volume obstetric services had lower VBAC rates than teaching hospitals and hospitals with high-volume obstetric services. Likewise, Hueston and Rudy[56] found that women who undergo elective repeat cesarean delivery are more likely to have private insurance than women who attempt VBAC. Stafford[55] concluded: "Because a cesarean [delivery] is nearly twice as costly as a vaginal birth,… the higher repeat cesarean [delivery] rates associated with proprietary hospitals, non-teaching hospitals, and low-volume hospitals contribute to increased health care expenditures."

In contrast, after assessing both the direct and indirect costs of VBAC, Clark et al.[57] concluded that "any economic savings for the healthcare system of a policy of trial of labor are at best marginal, even in a tertiary care center with a success rate for vaginal birth after cesarean of 70%." Further, they stated that "a policy of trial of labor does not result in any cost saving under most birthing circumstances encountered in the United States today."[57] The ACOG[46] had earlier acknowledged that "the difficulty in assessing the cost-benefit of VBAC is that the costs are not all incurred by one entity." In 2004, the ACOG[47] made the following conclusion:

> *A true analysis of the cost-effectiveness of VBAC should include hospital and physician costs, the method of reimbursement, potential professional liability expenses, and the probability that a woman will continue with childbearing after her first attempt at VBAC. Higher costs may be incurred by a hospital if a woman has a prolonged labor or has significant complications or if the newborn is admitted to a neonatal intensive care unit.*

Some women reject TOLAC because they have experienced prolonged, painful labor during a previous pregnancy. They fear that they will again experience a prolonged, painful labor and ultimately need a repeat cesarean delivery. This fear is more common in women who have delivered in smaller hospitals without the availability of neuraxial analgesia during labor. Other women reject TOLAC because they prefer to schedule the date of elective repeat cesarean delivery. (A scheduled, elective cesarean delivery allows the patient to arrange for a relative or friend to provide child care.) Kirk et al.[58] questioned 160 women regarding factors affecting their choice between VBAC and elective repeat cesarean delivery. These investigators concluded that "social exigencies

appeared to play a more important role than an assessment of the medical risks in making these decisions." Similarly, Joseph et al.[59] observed that fear and inconvenience are the most common deterrents to attempted VBAC. Finally, some women reject a trial of labor because of their concern about the adverse effects of labor and vaginal delivery on the maternal pelvic floor, with the risk for subsequent problems such as urinary and fecal incontinence.

Some insurance carriers previously required that eligible women with a history of previous cesarean delivery attempt VBAC in subsequent pregnancies. These carriers denied partial or full reimbursement to women who chose elective repeat cesarean delivery unless there was a medical reason to perform repeat cesarean delivery. The ACOG and others have agreed that hospitals and insurers should *not* mandate a trial of labor for pregnant women with a history of previous cesarean delivery.[60] In 2004, the ACOG[47] concluded, "After thorough counseling that weighs the individual benefits and risks of VBAC, the ultimate decision to attempt this procedure or undergo a repeat cesarean delivery should be made by the patient and her physician."

Bernstein et al.[61] found that TOLAC-eligible women undergoing either TOLAC or elective repeat cesarean delivery were not adequately informed about the risks and benefits of the two options, and they also found that provider preference drove the decision regarding the planned mode of delivery. Cox[62] emphasized and discussed the importance of shared decision-making when choosing the mode of delivery after a previous cesarean. It is important to discuss with the patient her family planning goals, as the risk for a morbidly adherent placenta and major hemorrhage in subsequent pregnancies increases with each cesarean delivery (see Chapter 37).[63] A patient who is planning to have several children should take this factor into consideration when deciding between TOLAC and repeat cesarean delivery.

Medicolegal Factors

What is the risk for uterine rupture during VBAC? A lower uterine segment scar is relatively avascular, and massive hemorrhage rarely follows separation of a lower segment scar. In contrast, rupture of a classic uterine scar may result in massive intraperitoneal bleeding. Unfortunately, there is some inconsistency and confusion in reports of the incidence of asymptomatic uterine scar dehiscence as opposed to frank uterine rupture. **Uterine scar dehiscence** may be defined as a uterine wall defect that does not result in fetal compromise or maternal hemorrhage and that does not require emergency cesarean delivery or postpartum laparotomy. In contrast, **uterine rupture** may be accompanied by extrusion of the fetus or placenta and results in fetal compromise, maternal hemorrhage, or both, sufficient to require cesarean delivery or postpartum laparotomy.[64]

Some obstetricians have suggested that earlier studies underestimated the risks associated with TOLAC. Scott[65] reported 12 women from Salt Lake City, Utah, who experienced clinically significant uterine rupture during TOLAC. Some of the women did not experience optimal obstetric management. For example, Scott's series included two women whose labor occurred at home.[65] Of interest, the number of home VBACs in the United States increased from 664 in 2003 to approximately 1000 in 2008, perhaps as a result of restricted access to TOLAC in some hospitals.[66]

Obstetricians understandably fear that they will be found liable if an adverse event occurs during TOLAC. In one case, a jury awarded a verdict of $98.5 million because of a delayed diagnosis of uterine rupture.[67] Phelan[68] cited another court decision that he predicted would have a "chilling effect on the future of VBAC." In this case, the fetal heart rate (FHR) was normal until it abruptly decreased to 80 beats per minute at a cervical dilation of 9 cm. The interval between the onset of the FHR deceleration and emergency cesarean delivery was 27 minutes. At delivery, the fetal head was found in the left adnexa. The mother required transfusion, and the child suffered from developmental delay and cerebral palsy. The court found that the defendants were negligent in their failure to deliver the infant in a timely manner and to provide adequate informed consent. The court also concluded that "the ACOG 30-minute rule represented the maximum period of elapse" and did not represent the minimum standard of care. As a result of this verdict, Phelan[68] proposed the use of a VBAC consent form that includes the following statement: "I understand that if my uterus ruptures during my VBAC, there may not be sufficient time to operate and to prevent the death of or permanent brain injury to my baby." Flamm[69] responded that "widespread implementation of this or similar consent forms essentially would mean the end of VBAC."

Greene[70] wrote a sobering editorial on the risks associated with attempted VBAC. Observing that the study performed by Lydon-Rochelle et al.[22] was an observational study that reflected "broad experience in a wide range of clinical-practice settings," he stated that "there is no reason to believe that improvements in clinical care can substantially reduce the risks of uterine rupture and perinatal mortality." Greene[70] concluded his editorial as follows:

> *After a thorough discussion of the risks and benefits of attempting a vaginal delivery after cesarean section, a patient might ask, "But doctor, what is the safest thing for my baby?" Given the findings of Lydon-Rochelle et al., my unequivocal answer: elective repeated cesarean section.*

In an earlier editorial, Pitkin[71] made the following statement regarding VBAC: "Many women with previous cesareans can be delivered vaginally, and thereby gain substantial advantage, but neither the decision for trial [of] labor nor management during that labor should be arrived at in a cavalier or superficial manner."

PROFESSIONAL SOCIETY PRACTICE GUIDELINES

In 1999, the ACOG[46] issued guidelines stating that because uterine rupture may be catastrophic, VBAC should be attempted in institutions equipped to respond to emergencies with physicians *immediately* available to provide emergency

care. Likewise, the RCOG[16] has stated that planned VBAC should be conducted in a facility "with resources available for immediate caesarean delivery and advanced neonatal resuscitation." The ACOG[72] defended their "immediately available" recommendation by noting that "VBAC is a completely elective procedure that allows for reasonable precautions in assuming this small but significant risk [of uterine rupture]." In contrast, other obstetric catastrophes (e.g., placental abruption, umbilical cord prolapse) cannot be predicted. The ACOG[72] has also noted that "the operational definition of 'immediately available' personnel and facilities remains the purview of each local institution." However, this requirement for the immediate availability of physicians and other personnel clearly represents a more stringent standard than the "readily available" requirement in other published guidelines for obstetric care.

Earlier, Zlatnik[73] made the following comments regarding VBAC in a community hospital: "If a timely cesarean [delivery] cannot be performed in a community hospital, VBAC is out of the question, but the larger question is: Should obstetrics continue to be practiced there? Timely cesarean [delivery] is an essential option for all laboring women."

In contrast, the American Academy of Family Physicians (AAFP)[74] published the following recommendations:

> *Women with one previous cesarean delivery with a low transverse incision are candidates for and should be offered a trial of labor (TOL).…Trial of labor after cesarean (TOLAC) should not be restricted only to facilities with available surgical teams present throughout labor since there is no evidence that these additional resources result in improved outcomes. At the same time, it is clinically appropriate that a management plan for uterine rupture and other potential emergencies requiring rapid cesarean section should be documented for each woman undergoing TOLAC.*

The AAFP[74] has argued that the ACOG guidelines suggest that "one rare obstetrical catastrophe (e.g., uterine rupture) merits a level of resource that has not been recommended for other rare obstetrical catastrophes that may actually be more common." The AAFP has acknowledged that these other complications are "largely not predictable," whereas a TOLAC is a "planned event that may demand a different degree of preparedness." Nonetheless, they stated that their recommendations significantly differ from ACOG guidelines because they could find "no evidence to support a different level of care for TOLAC patients."[74]

In response, Dr. Gary Hankins, Chair of the ACOG Committee on Obstetric Practice, made the following statement[75]:

> *It's very troubling when people who may not even be qualified to perform a cesarean section start issuing guidelines about the safety of this kind of thing.… Their argument is that the available data don't prove it's unsafe—they're not arguing that it is safe.…Our main concern is with having the best possible outcome for mother and baby. If women are given the true numbers about the bad outcomes that can be associated with VBAC, no woman is going to take the chance [of laboring without immediately available surgical support].*

The 2010 NIH consensus development panel[15] noted that approximately one-third of hospitals and one-half of obstetric physicians in the United States no longer offer TOLAC largely because of fear of liability and litigation. The panel[15] expressed concern that practice guidelines have created barriers that prevent women from choosing TOLAC. The panel concluded that TOLAC remains "a reasonable option for many pregnant women with one prior low-transverse uterine incision." The panel acknowledged that decision-making may be difficult, because the benefit of TOLAC for the woman may come at the price of increased risk for the infant. The panel stated that pregnant women should be given the opportunity to make informed decisions about the risks and benefits of TOLAC versus elective repeat cesarean delivery. The panel also urged professional societies to reassess the requirement for immediate availability of surgical and anesthesia providers.

Subsequently the ACOG[14] stated that restricting access was not the intention of their "immediately available" requirement. The ACOG[14] noted that "much of the data concerning the safety of TOLAC is from centers capable of performing a timely emergency cesarean delivery." Further, they stated that "although there is reason to think that more rapid availability of cesarean delivery may provide a small incremental benefit in safety, comparative data examining in detail the effect of alternate systems and response times are not available." A 2012 study[64] evaluated neonatal outcome after 36 cases of uterine rupture that occurred among 11,195 cases of TOLAC between 2000 and 2009. None of the 17 infants who were delivered less than 18 minutes after the identification of uterine rupture had either an umbilical arterial blood pH less than 7.0 or evidence of neurologic injury. In contrast, three infants who were delivered more than 30 minutes after the diagnosis of uterine rupture had an umbilical arterial blood pH less than 6.8 and suffered neonatal neurologic injury.[64]

In 2017 the ACOG[14] modified their practice bulletin as follows:

> *Because of the risks associated with TOLAC, and [because] uterine rupture and other complications may be unpredictable, ACOG recommends that TOLAC be attempted in facilities that can provide cesarean delivery for situations that are immediate threats to the life of the woman or fetus. When resources for immediate cesarean delivery are not available, ACOG recommends that obstetricians or other obstetric care providers and patients considering TOLAC discuss the hospital's resources and availability of obstetric, pediatric, anesthesiology, and operating room staff.…The decision to offer and pursue TOLAC in a setting in which the option of emergency cesarean delivery is limited should be carefully considered by patients and their obstetricians or other obstetric care providers. In such situations the best alternative may be to refer patients to a facility with available resources.*

Further, the ACOG[14] also encouraged respect for patient autonomy, as follows:

> *Respect for patient autonomy also dictates that even if a center does not offer TOLAC, such a policy cannot be used to force women to have cesarean delivery or to deny care to women in labor who decline to have a repeat cesarean delivery.*

Birnbach et al.[76] reviewed the impact of anesthesia provider availability on the incidence of VBAC in the United States. They concluded that the "immediately available" requirement necessitates having an in-hospital anesthesia provider who is not performing another simultaneous anesthetic. Their economic analysis prompted a conclusion that "the minimum requirement to provide immediate anesthesia care for all deliveries would be to have all deliveries at facilities with greater than 1500 deliveries annually."

OBSTETRIC MANAGEMENT

Intravenous Access and Availability of Blood

It seems prudent to recommend the early establishment of intravenous access in women who undergo TOLAC. Resources for transfusion of blood and blood products should be readily available.

Fetal Heart Rate Monitoring

The RCOG[16] recommends "continuous electronic [FHR] monitoring for the duration of planned VBAC." Continuous electronic FHR monitoring represents the best means of detecting uterine rupture.[77–79] Rodriguez et al.[78] reviewed 76 cases of uterine rupture at their hospital. A nonreassuring FHR pattern occurred in 59 of the 76 patients and was the most reliable sign of uterine rupture.

Intrauterine Pressure Monitoring

The intrauterine pressure catheter provides a quantitative measurement of uterine tone both during and between contractions. In the past, some obstetricians contended that an intrauterine pressure catheter should be used in all patients who undergo TOLAC, arguing that a loss of intrauterine pressure and cessation of labor will signal the occurrence of uterine rupture. In one study,[78] 39 patients had an intrauterine pressure catheter at the time of uterine rupture. None of these patients experienced an apparent decrease in resting uterine tone or cessation of labor, but 4 patients experienced an increase in baseline uterine tone. In these 4 patients, the increase in baseline uterine tone was associated with severe variable FHR decelerations that prompted immediate cesarean delivery. The authors concluded that the information obtained from the use of the intrauterine pressure catheter did not help obstetricians make the diagnosis of uterine rupture.[78]

Use of Prostaglandins

Lydon-Rochelle et al.[22] observed a uterine rupture rate of 24.5 per 1000 women who attempted VBAC with prostaglandin-induced labor. The ACOG[13] cited evidence from small studies that observed an increased risk for uterine rupture after the use of misoprostol (prostaglandin E_1) in women who attempted VBAC. The ACOG[13,80] has concluded that "misoprostol should not be used for third trimester cervical ripening or labor induction in patients who have had a cesarean delivery or major uterine surgery." The RCOG[16] concluded that "induction of labor using mechanical methods (amniotomy or Foley catheter) is associated with a lower risk for scar rupture compared with induction using prostaglandins."

Induction and Augmentation of Labor

Induction of labor is less likely to result in successful VBAC than spontaneous labor.[31] A 2015 study concluded that induction of labor in women with one prior cesarean delivery is associated with an increased risk for failed TOLAC, when compared with expectant management.[81]

Studies of outcomes after the use of **oxytocin augmentation** of labor during TOLAC have demonstrated conflicting results.[3,22,82–84] In a 1991 meta-analysis, Rosen et al.[3] noted that the use of oxytocin did not increase the risk for uterine scar dehiscence or rupture during VBAC. In contrast, in one large retrospective study of more than 20,000 women, uterine rupture was nearly five times more common among women undergoing induction of labor with oxytocin than in those who had an elective repeat cesarean delivery.[22] Zelop et al.[83] observed a higher rate of uterine rupture in women undergoing oxytocin induction of labor for attempted VBAC than in similar women attempting VBAC with spontaneous labor. Further, the rate of uterine rupture was also higher in women receiving oxytocin for augmentation of labor, but the difference was not statistically significant. The ACOG[13] has concluded that "the varying outcomes of available studies and small absolute magnitude of the risk reported in those studies support that oxytocin augmentation may be used in patients undergoing TOLAC."

ANESTHETIC MANAGEMENT

In the past, some obstetricians contended that epidural analgesia might mask the pain of uterine scar separation or rupture and thereby delay the diagnosis of uterine scar dehiscence or rupture.[85,86] Plauché et al.[85] stated, "Regional anesthesia, such as epidural anesthesia, blunts the patient's perception of symptoms and the physician's ability to elicit signs of early uterine rupture." Others have argued that the sympathectomy associated with epidural anesthesia might attenuate the maternal compensatory response to the hemorrhage associated with uterine rupture. For example, sympathectomy might prevent the compensatory tachycardia and vasoconstriction that occur during hemorrhage. However, consensus now exists that these concerns do not preclude administration of neuraxial analgesia during TOLAC, for several reasons.

First, pain, uterine tenderness, and tachycardia have low sensitivity as diagnostic symptoms and signs of lower uterine

segment scar dehiscence or rupture. Some uterine scars separate painlessly. Obstetricians occasionally discover an asymptomatic lower uterine segment scar dehiscence at the time of elective repeat cesarean delivery. Molloy et al.[87] reported 8 cases of uterine rupture among 1781 patients who attempted VBAC. None of these 8 patients had abdominal pain, but all had FHR abnormalities. Johnson and Oriol[79] reviewed 14 studies of VBAC published between 1980 and 1989. Among 10,967 patients who attempted VBAC, 1623 patients received epidural analgesia. Of those who experienced uterine rupture, 5 of 14 patients (35%) with epidural analgesia experienced abdominal pain, compared with 4 of 23 patients (17%) without epidural analgesia. FHR abnormalities represented the most common sign of uterine rupture among patients who did and did not receive epidural analgesia. None of these investigators observed that epidural analgesia delayed the diagnosis of uterine rupture.

Second, pain, uterine tenderness, and tachycardia have low specificity as diagnostic symptoms and signs of lower uterine segment scar dehiscence. Case et al.[88] reported 20 patients with a history of previous cesarean delivery in whom the indication for urgent repeat cesarean delivery was severe hypogastric pain, tenderness, or both. At surgery, they confirmed the presence of scar dehiscence in only one of the 20 patients. Eckstein et al.[89] suggested that the unexpected development of pain during previously successful epidural analgesia might be indicative of uterine rupture. Crawford[90] referred to this phenomenon as the "epidural sieve." Others have described patients who received epidural analgesia and subsequently complained of pain and tenderness secondary to uterine scar rupture.[91–94] I have provided epidural analgesia for several patients in whom the first suggestion of scar separation was the sudden and unexpected development of "breakthrough pain" despite the continuous epidural infusion of local anesthetic. A 2010 study[95] found evidence of "epidural dose escalation immediately before uterine rupture in women who attempted VBAC, when compared with women who did not have uterine rupture." The authors concluded that "clinical suspicion for uterine rupture should be high in women who require frequent epidural dosing during a VBAC trial."[95] Likewise, the RCOG[16] stated that "an increasing requirement for pain relief in labour should raise awareness of the possibility of an impending uterine rupture." Thus, epidural analgesia may improve the specificity of abdominal pain as a symptom of uterine scar separation or rupture.

Third, most cases of lower uterine segment scar dehiscence do not lead to severe hemorrhage. In one report of six cases of uterine scar dehiscence or rupture, only one patient had intrapartum vaginal bleeding.[77] However, if significant bleeding should occur, epidural anesthesia may attenuate the maternal compensatory response to hemorrhage. Vincent et al.[96] observed that epidural anesthesia (median sensory level of T9) significantly worsened maternal hypotension, uterine blood flow, and fetal oxygenation during untreated hemorrhage (20 mL/kg) in gravid ewes. Intravascular volume replacement promptly eliminated the differences between groups in maternal mean arterial pressure, cardiac output, and fetal Pao_2. Maternal heart rate did not change significantly during hemorrhage in the control animals. However, there was a significant drop in maternal heart rate during hemorrhage in the animals that received epidural anesthesia.[96]

Fourth, several published series have reported the successful use of epidural analgesia in women undergoing TOLAC.[44,77,90,97–101] There is little evidence that epidural analgesia either decreases the likelihood of vaginal delivery or adversely affects maternal or neonatal outcome in women who have uterine scar separation or rupture. Flamm et al.[100] reported a multicenter study of 1776 patients who attempted VBAC. Approximately 134 (74%) of 181 women who received epidural analgesia delivered vaginally, compared with 1180 (74%) of 1595 women who did not receive epidural analgesia. A 2017 retrospective study from Israel reported a slightly higher rate of successful VBAC in women who received labor epidural analgesia than in women who did not (91.2% *versus* 88.3%), but women in the epidural group were more likely to undergo instrumental vaginal delivery (11.7% versus 2.8%). Phelan et al.[97] reported that among patients who received both oxytocin augmentation and epidural analgesia, 69% delivered vaginally. This did not differ from the incidence of vaginal delivery among patients who received oxytocin without epidural analgesia. Other investigators have reported results of smaller studies suggesting a lower rate of successful VBAC among patients who received epidural analgesia.[98,99] However, this effect was limited to patients who received oxytocin for the induction or augmentation of labor. These investigators concluded that epidural analgesia does *not* decrease the likelihood of successful VBAC.

Fifth, in the past some obstetricians favored the use of epidural analgesia because it facilitates postpartum uterine exploration to assess the integrity of the uterine scar. Meehan et al.[102] earlier supported routine postpartum palpation of the uterine scar. However, Meehan et al.[103] subsequently acknowledged that it is not necessary to repair all such defects. Many obstetricians manage asymptomatic uterine scar dehiscence with "expectant observation." Thus, they argue that routine palpation of the uterine scar is unnecessary after successful VBAC.[9]

Sixth, epidural analgesia provides rapid access to safe, surgical anesthesia if cesarean delivery or postpartum laparotomy should be required.[104]

Finally, it is inhumane to deny effective analgesia to women who undergo TOLAC. Further, the ACOG[13,14] has concluded that adequate pain relief may encourage more women to choose TOLAC. Thus, the availability and use of neuraxial analgesia may decrease the incidence of unnecessary repeat cesarean delivery.

The ACOG[13,14] has stated that good and consistent scientific evidence supports a conclusion that epidural analgesia may be used during TOLAC. In my judgment, the availability of neuraxial analgesia is an essential component of a successful VBAC program. It seems reasonable to provide analgesia—but not total anesthesia—during labor in patients attempting VBAC.

KEY POINTS

- Cesarean delivery is the most commonly performed major operation in the United States, and previous cesarean delivery is the most common indication.
- A trial of labor is successful in 72% to 75% of women in whom a low-transverse uterine incision was made during a previous cesarean delivery.
- A previous vaginal delivery is the greatest predictor for successful vaginal birth after cesarean delivery (VBAC). A history of dystocia, the need for induction of labor, and/or maternal obesity are associated with a lower likelihood of successful VBAC.
- Hospitals and insurers should not mandate a trial of labor for pregnant women with a history of previous cesarean delivery.
- The American College of Obstetricians and Gynecologists has recommended that resources for performing emergency cesarean delivery should be immediately available in women attempting a trial of labor after previous cesarean delivery (TOLAC). Other groups have argued that this guideline is too restrictive and has created barriers that prevent women from choosing TOLAC.
- Continuous electronic fetal heart rate monitoring represents the best means of detecting uterine rupture.
- Women are more likely to undergo TOLAC if they know that they will receive effective analgesia during labor.
- Epidural analgesia does not delay the diagnosis of uterine rupture or decrease the likelihood of successful VBAC.

The Pain of Childbirth and Its Effect on the Mother and the Fetus

Peter H. Pan, MD, Jessica L. Booth, MD

CHAPTER OUTLINE

The gate control theory of pain, described more than 50 years ago by Melzack and Wall,[1] has revolutionized the understanding of the mechanisms responsible for pain and analgesia. Originally explained as the regulation of pain signals from the peripheral nerve to the spinal cord by the activity of other peripheral nerves, interneurons in the spinal cord, and central supraspinal centers (Fig. 20.1), the theory has been refined with the concept of a neuromatrix, a remarkably dynamic system capable of undergoing rapid change.[2] Neural circuits and intraneural mechanisms regulate sensitivity at peripheral afferent terminals; along the conducting axons of peripheral nerves; in the spinal cord, pons, medulla, and thalamus; and at cortical sites of pain transmission and projection. For example, the peripheral application of capsaicin to the skin alters spinal gating mechanisms within 10 minutes, resulting in a light touch signal being interpreted as burning pain.[3]

Despite extensive research (initiated by the gate control theory) into the mechanisms and treatments for chronic pain, virtually no research on the neurophysiologic basis or therapies for labor pain has been performed. This discrepancy in focus has led to vastly different approaches to the treatment of patients with chronic versus obstetric pain. A patient with chronic pain typically undergoes a sophisticated physical assessment of sensory function; is offered therapies, on the basis of the assessment, from nearly a dozen different classes of analgesics; and can benefit from the enormous resources expended by the pharmaceutical industry to introduce agents that act on novel receptors or enzymes. By contrast, a laboring woman receives no physical assessment of sensory function and is offered only a handful of systemic drugs that act primarily through the anatomic blockade of neural traffic.

In this chapter, this paradox in the approach to labor pain is examined and the basis for current therapy (anatomy), the basis for future therapy (neurophysiology), and the effects of labor pain on the mother and the infant are reviewed.

MEASUREMENT AND SEVERITY OF LABOR PAIN

The recognition and acceptance of chronic pain, which frequently lacks an obvious outward cause, contrasts to the recurrent denial of labor pain, which is accompanied by visible tissue injury. Dick-Read[4] suggested that labor is a natural process not considered painful by women in primitive cultures that should be handled with education and preparation rather than through pain medications. Lamaze[5] popularized psychoprophylaxis as a method of birth preparation; this method now forms the basis for prepared childbirth training in the developed world. Although childbirth training acknowledges the existence of pain during labor, some scientific-thought leaders still consider labor pain to be minor.

The severity of labor pain has been recognized previously. Melzack,[6] using a questionnaire developed to assess the intensity and emotional impact of pain, observed that nulliparous women with no prepared childbirth training rated

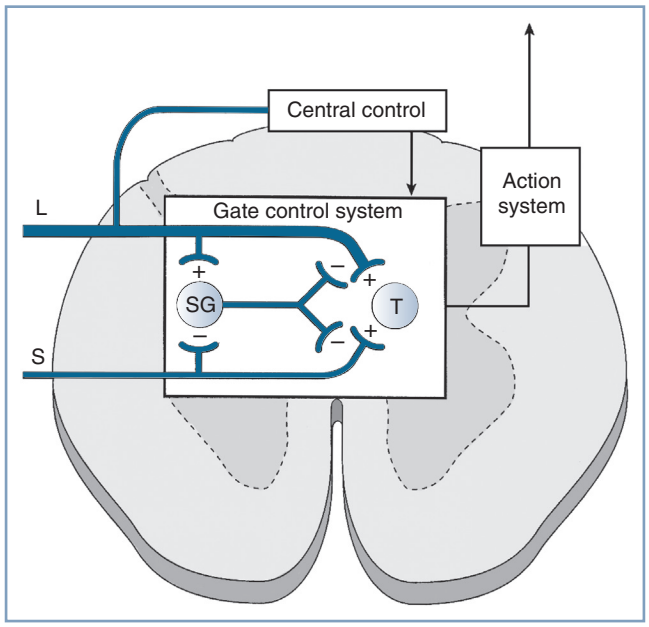

Fig. 20.1 Gate control theory of pain. Activity in small-diameter afferents *(S)* stimulates transmission cells in the spinal cord *(T),* which send signals supraspinally and results in the perception of pain. Small-diameter afferents also inhibit cells in the spinal cord substantia gelatinosa *(SG),* the activity of which reduces excitatory input to T cells. Activity in large-diameter afferents *(L)* also stimulates T cells in a manner that is perceived as nonpainful and excites SG cells to "close the gate" and reduce small-diameter afferent activation of T cells. The gate mechanism is under regulation by central sites. (From Melzack R, Wall PD. Pain mechanisms: a new theory. *Science.* 1965;150:971–975.)

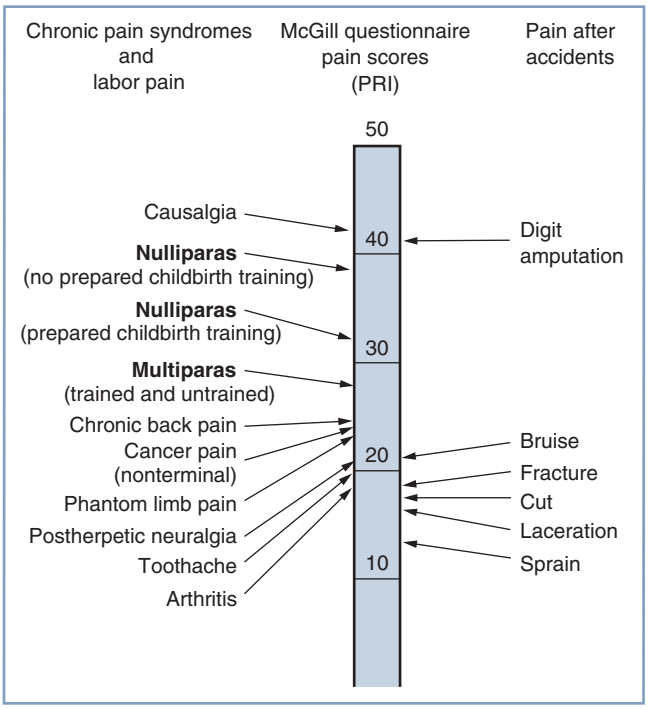

Fig. 20.2 A comparison of pain scores obtained through the McGill Pain Questionnaire. Scores were collected from women in labor, patients in a general hospital clinic, and patients in the emergency department after accidents involving traumatic injury. Note the modest difference in pain scores between nulliparous women with and without prepared childbirth training. *PRI,* Pain rating index, which represents the sum of the rank values of all the words chosen from 20 sets of pain descriptors. (Modified from Melzack R. The myth of painless childbirth [The John J. Bonica Lecture]. *Pain.* 1984;19: 321–337.)

labor pain to be as painful as a digit amputation without anesthesia (Fig. 20.2).[6] More than 30 years before Melzack's quantification of pain, Javert and Hardy[7,8] trained subjects to reproduce the intensity of labor pain with the sensation of noxious heat applied to the skin from a radiant heat source. In these experiments, several women achieved "ceiling pain"—resulting in second-degree burns to the skin—when they attempted to match the intensity of uterine contraction pain.[7] Individual women also reported a close positive correlation between cervical dilation and pain intensity. Logistic regression analysis of the investigators' original data[7] indicates a high likelihood of severe pain as labor progresses, with a time course closely associated with cervical dilation (Fig. 20.3). Other investigators have noted that uterine pressure during contractions accounts for more than 90% of the variability in labor pain intensity.[9] These observations are consistent with the conclusion that cervical distention is the primary cause of pain during the first stage of labor.

In an effort to objectively measure pain in laboring women, Charier et al.[10] studied the physiologic fluctuations of the iris, which is dependent on the input from the sympathetic and parasympathetic systems. By measuring the variation coefficient of the pupillary diameter (VCPD) as a mathematical extraction of pupil size fluctuation in 40 laboring women, researchers were able to demonstrate a stronger correlation

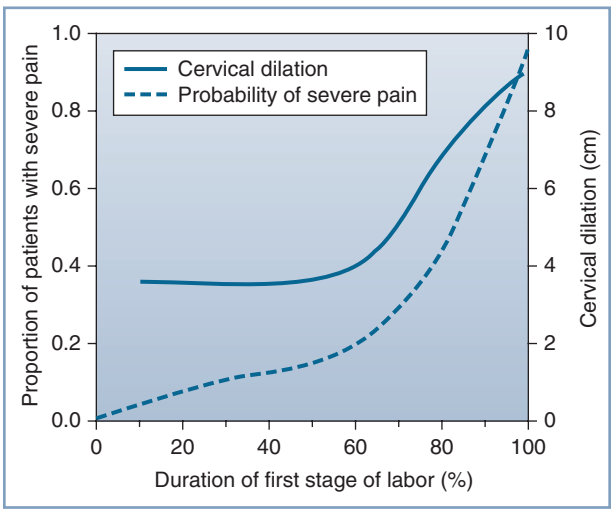

Fig. 20.3 Likelihood of severe pain during labor. A significant minority of women (approximately one-third) have severe pain in early labor, and the proportion of women with severe pain increases to nearly 90% later in labor, in close relationship with cervical dilation. (Data from Hardy JD, Javert CT. Studies on pain: measurements of pain intensity in childbirth. *J Clin Invest.* 1949;28:153–162.)

($r = .77$ versus $r = .42$) with numerical pain scores in labor during a uterine contraction than pupillary diameter alone.

However, there is considerable variability in the rated intensity of pain during labor. Nulliparous women rate labor pain as more severe than do parous women; however, the differences are small and of questionable clinical relevance.[11] There is a correlation between the intensity of menses and labor pain, especially back discomfort,[11] although the reason for this relationship is unknown. It is possible that the rated intensity of labor pain reflects individual differences in the perception of all types of pain. In a study of factors affecting labor pain, 10 of 97 subjects reported that they had never experienced pain before childbirth; these women reported significantly less pain during labor and delivery compared with women who had previously experienced pain.[12] In other studies, the variability of pain after cesarean delivery could be predicted with preoperative quantitative sensory testing (such as rating the intensity of pain with a standardized noxious thermal stimulus), psychological constructs, and their combinations.[13,14]

The mechanism by which people perceive different levels of pain from the same stimulus remains unclear. A study involving brain imaging and a fixed acute noxious heat stimulus showed a strong correlation between verbal pain assessment and the level of activation of various cortical brain regions, especially the contralateral somatosensory cortex and anterior cingulate cortex.[15] The investigators also found that the degree of activation of the thalamus was essentially identical in all subjects, suggesting that differences in perceived pain resulted from modulation at suprathalamic levels rather than in the peripheral nerves or spinal cord. The situation in labor may be more complex. For example, a large genetic polymorphism regulates cytokine production and function as well as pregnancy outcome.[16] It is possible that interindividual differences in labor pain may partially reflect genetic differences in cytokine production or response.

In evaluating and studying labor pain and its treatment, most studies have tended to assess labor pain by using a set of discrete pain scores. However, labor pain is a complex, subjective, multidimensional, and dynamically changing experience with both sensory and affective components that are influenced by many factors. As a result, there are substantial individual differences in labor pain. Therefore, better identification of the covariates that affect labor progress and its associated pain is needed. Conell-Price et al.[17] developed and validated a dynamic model to account for labor progress in the assessment of labor pain. Subsequently, Debiec et al.,[18] at the same institution, combined a biexponential model that describes labor progress with a sigmoidal labor pain model to assess the influence of patient covariates on labor pain.[18] Both studies used retrospective patient data to develop and test their models. In the former study,[17] the prediction error for the pain scores was large, but the purpose of the model was to identify and remove variability associated with labor progress so that other factors (e.g., genetic polymorphisms) can be quantitatively studied. In this study,[17] cervical dilation accounted for only 16% to 20% of the variability in reported pain. In the latter study,[18] the covariate of ethnicity was found to have a statistically significant but clinically trivial effect on labor progress. The modeling described by these investigators provides a useful quantitative tool for future studies to identify and assess the effect—or the lack of effect—of patient and/or environmental covariates on labor progress, labor pain, and therapeutic responses. Better understanding of underlying causes of interindividual variability in labor progress, labor pain, and therapeutic responses is likely to lead to more tailored therapy.

In summary, although significant variability exists in the rated intensity of pain during labor and delivery, the majority of women experience more than minimal pain. The close correlation between cervical dilation and the rated severity of pain implies the existence of a causal relationship and increases the likelihood that a parturient will request analgesia as labor progresses.

PERSONAL SIGNIFICANCE AND MEANING

The International Association for the Study of Pain (IASP) has defined pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[19] Recognition of an intensity-discriminatory component and an emotional-cognitive component, with powerful interactions between the two, has fostered current interventions heavily weighted toward the first component and assumes that labor pain is severe and in need of pharmacologic treatment. Largely ignored are coping strategies and the personal meaning of labor pain, which varies considerably among women.[20] Williams and Craig[21] suggested that the definition of pain should include the often overlooked cognitive and social elements, and Whitburn et al.[22] suggested a further extension to etiologies that do not include tissue damage. These alterations would make the experience and study of pain more relevant to the labor experience; nociceptive pain intensity increases with cervical dilation, despite the absence of tissue damage.

Although many women rate the pain of labor and delivery as severe, the terms used to more fully describe this pain reflect an emotional meaning. In a pioneering study of the quantification of pain from experimental dilation of the cervix, Bajaj et al.[23] compared pain descriptors in women who were in labor, had experimental cervical dilation, were undergoing spontaneous abortion, or who had dysmenorrhea (Table 20.1). Women with dysmenorrhea used words that indicate suffering, such as "punishing" and "wretched," whereas those in labor did not. Some researchers have drawn parallels between the pain derived from mountain climbing, which is associated with a sense of euphoria, and the pain of labor.[20] As noted by one woman, "You mature and become a stronger personality when you've had a baby and have gone through the pain. I think that is the purpose of it, what the meaning of life is … to protect our children, to be stronger."[24] However, other women have found no deeper meaning to the pain of labor or reasons why it should not be treated. Many conditions that involve pain (e.g., trauma, severe dental

TABLE 20.1 Word Descriptors from the McGill Pain Questionnaire Used to Describe Pain from the Uterus and Cervix

Pain Descriptors	TYPE/SOURCE OF PAIN			
	Balloon Distention of the Cervix[a]	Labor[b]	Abortion[c]	Dysmenorrhea[a]
Sensory	Shooting, boring, sharp, hot, dull, taut	Throbbing, shooting, sharp, cramping, aching, taut	Cutting, cramping, tugging, pulling, aching	Pulsing, beating, shooting, pricking, boring, drilling, sharp, cutting, pinching, pressing, cramping, tugging, pulling, hot, stinging, dull, hurting, heavy, taut
Affective		Exhausting, tiring, frightening, grueling	Tiring	Tiring, sickening, punishing, wretched
Evaluative	Annoying		Intense	Annoying, intense
Miscellaneous	Drawing, squeezing	Tearing	Numb, squeezing	Piercing, drawing, squeezing, nagging

disease, cancer) are considered a "normal" part of human life without a spiritual meaning, thereby making labor pain unique.

In summary, there are large interindividual differences in how women experience the personal significance or meaning of labor pain. These different perceptions can lead to a long-term sense of failure and guilt when pharmacologic pain relief is accepted or emotional trauma when it is withheld. The use of educational interventions and improved management of labor expectations may improve the birth experience by creating realistic pain expectations during labor and delivery.[25]

ANATOMIC BASIS

First Stage of Labor

Several lines of evidence suggest that the pain experienced during the first stage of labor is transduced by afferents with peripheral terminals in the cervix and lower uterine segment rather than the uterine body, as is often depicted (Fig. 20.4). Uterine body afferents fire in response to distention, but in the absence of inflammation, uterine body distention has no or minimal effect on the behavior of laboratory animals.[26,27] These observations suggest that uterine body afferents may be an important site of chronic inflammatory disease and chronic pelvic pain but are much less relevant to acute obstetric and uterine cervical pain. In addition, afferents to the uterine body regress during normal pregnancy, whereas those to the cervix and lower uterine segment do not.[28] This denervation of the myometrium may protect against preterm labor by limiting α_1-adrenergic receptor stimulation by locally released norepinephrine. Javert and Hardy[7] reproduced the pain of uterine contractions in women during labor by manual distention of the cervix. Bonica and Chadwick[29] later confirmed that women undergoing cesarean delivery under a local anesthetic field block experience pain from cervical distention (which mimics that of labor pain) but do not experience pain from uterine distention.[29]

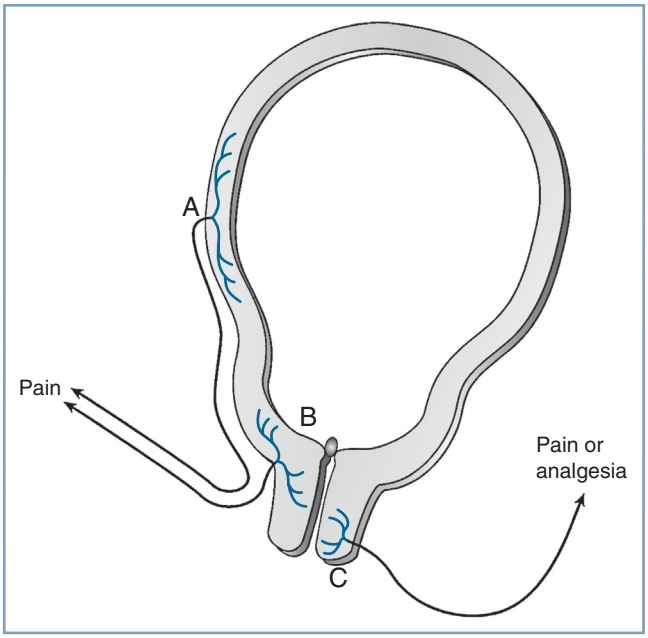

Fig. 20.4 Uterocervical afferents activated during the first stage of labor. Uterine body afferents (A) partially regress during pregnancy and may contribute to the pain of the first stage of labor. However, the major input is from afferents in the lower uterine segment and endocervix (B). By contrast, at least in animals, the activation of afferents that innervate the vaginal surface of the cervix (C) results in analgesia, not pain, and they enter the spinal cord in sacral areas rather than at the site of referred pain in labor.

The uterine cervix has dual innervation; afferents innervating the endocervix and lower uterine segment have cell bodies in thoracolumbar dorsal root ganglia (DRG), whereas

afferents innervating the vaginal surface of the cervix and upper vagina have cell bodies in sacral DRG.[30] These two innervations result in different sensory input and referral of pain. Pelvic afferents that innervate the vaginal surface of the cervix are almost exclusively C fibers, with the majority containing the peptides substance P and calcitonin gene–related peptide (CGRP). These afferents express alpha and beta estrogen receptors and have an innervation pattern that is not affected by pregnancy.[31–33] Stimulation of the vaginal surface of the cervix in rats results in antinociception, lordosis, ovulation, and a hormonal state of pseudopregnancy, all of which are related to mating behaviors in this species.[34] In rats, these vaginal afferent terminals are activated only during delivery and not during labor, which suggests that they are not relevant to the pain of the first stage of labor.[35] By contrast, dilation of the endocervix in rats results in the activation of afferents entering the lower thoracic spinal cord and nociception rather than antinociception. These afferents, which are mostly or exclusively C fibers,[36] are activated during the first stage of labor, suggesting that they are relevant to pain during this period.

More than 80 years ago, experiments in dogs allowed Cleland[37] to identify T11 to T12 as the segmental level of entry into the spinal cord of afferents that transmit the pain of the first stage of labor. Because dysmenorrhea could be treated through the destruction of the superior or inferior hypogastric plexus,[38] Cleland reasoned that the sensory afferents and sympathetic efferents were likely intermingled; he subsequently demonstrated that the bilateral blockade of the lumbar paravertebral sympathetic chain could produce analgesia during the first stage of labor.[37] First-stage labor pain is transmitted by afferents that have cell bodies in T10 to L1 DRG and pass through the paracervical region, the hypogastric nerve and plexus, and the lumbar sympathetic chain.

Classical teaching states that pain-transmitting C and A-delta nerve fibers enter the spinal cord through the dorsal roots and terminate in a dense network of synapses in the ipsilateral superficial laminae (I and II) of the dorsal horn, with minimal rostrocaudal extension of fibers. Whereas this characterization is true for somatic afferents, visceral C fiber afferents enter the cord primarily—but not exclusively—through the dorsal roots and terminate in a loose network of synapses in the superficial and deep dorsal horn and the ventral horn. These afferents also cross to the contralateral dorsal horn, with extensive rostrocaudal extension of fibers. This anatomic distinction underlies the precise localization of somatic pain and the diffuse localization of visceral pain, which may cross the midline; it may also determine the potency or efficacy of drugs that must reach afferent terminals, such as intrathecal opioids.

Pain-transmitting neurons in the spinal cord dorsal horn send axons to the contralateral ventral spinothalamic tract (stimulating thalamic neurons) with further projections to the somatosensory cortex, where pain is perceived. These spinal neurons also send axons through the spinoreticular and spinomesencephalic tracts to provide signals to the areas of vigilance (locus coeruleus, reticular formation), cardiorespiratory regulation (nucleus tractus solitarius, caudal medulla), and reflex descending inhibition (periaqueductal gray, locus coeruleus and subcoeruleus, nucleus raphe magnus, rostral medial medulla, cerebellum). Thalamic activation from painful stimuli results in the activation not only of the somatosensory cortex but also areas of memory (prefrontal cortex), motor response (M1 motor cortex), and emotional response (insular cortex, anterior cingulate cortex). Supraspinal pain pathways activated by pain of the first stage of labor can be briefly described sequentially, starting with the ascending pathways projecting to the pons and the medulla, thereby activating centers of cardiorespiratory control and descending pathways as well as the thalamus, which in turn sends projections to the anterior cingulate, motor, somatosensory, and limbic regions.

The anatomic basis for pain of the first stage of labor implies that amelioration of pain should occur after blockade of peripheral afferents (by paracervical, paravertebral, lumbar sympathetic, or epidural [T10 to L1 dermatome] block) or after blockade of spinal cord transmission (by intrathecal injection of local anesthetic and/or opioid) (Fig. 20.5). In addition, the widespread distribution of visceral synapses in the spinal cord implies that intrathecally administered drugs (e.g., opioids) must have physicochemical properties that facilitate deep penetration into the cord to reach the terminals responsible for pain transmission.

Second Stage of Labor

Pain during the second stage of labor is transmitted by the same afferents activated during the first stage of labor but with additional afferents that innervate the cervix (vaginal surface), vagina, and perineum. These additional afferents course through the pudendal nerve DRG at S2 to S4 and are somatic. Thus, the pain specific to the second stage of labor is precisely localized to the vagina and perineum and reflects distention, ischemia, and frank injury, either by stretching to the point of disruption or by surgical incision. Studies in nonpregnant women indicate a minor analgesic effect of mechanical self-stimulation of the vaginal surface of the cervix[39]; this effect may result from the stimulation of C fibers, because in women with a high oral intake of capsaicin, the activity of such fibers is reduced.[40] The relevance of this minor effect in reducing the pain of the second stage of labor is questionable and has not been examined; however, it does appear to provide evidence that noxious input during labor may activate endogenous analgesia (see later discussion).

The anatomic basis for pain of the second stage of labor implies that analgesia can be obtained through a combination of methods used to treat the pain of the first stage with a pudendal nerve block or extension of the epidural blockade from T10 to S4 (see Fig. 20.5).

NEUROPHYSIOLOGIC BASIS

Peripheral Afferent Terminals

Visceral nociceptors, such as those that transduce the pain of the first stage of labor, are activated by stretching and

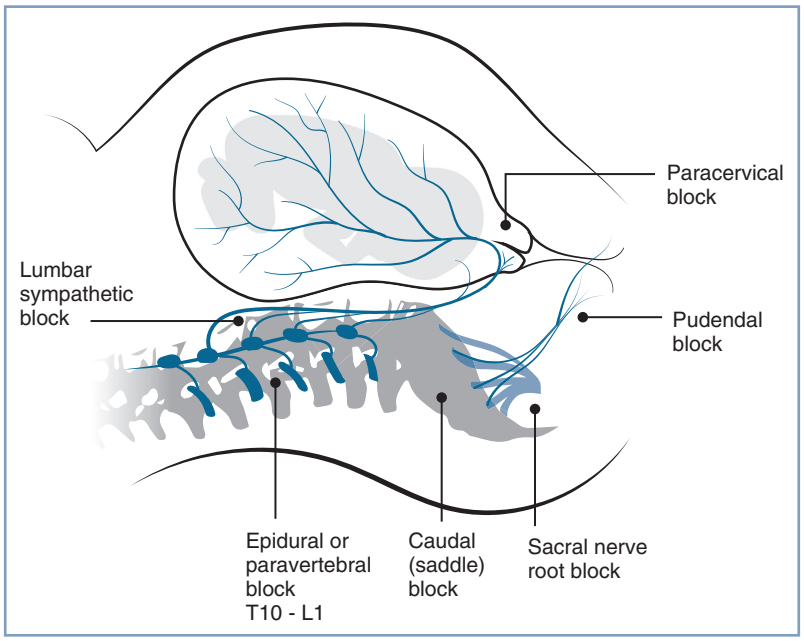

Fig. 20.5 Transmission and blockade of labor pain. Labor pain has a visceral component (e.g., release of potassium, bradykinin, histamine, and serotonin) and a somatic component (e.g., mechanoreceptors). Noxious stimuli invoke nociceptive responses in the paracervical region and the pelvic and hypogastric plexus, as well as the lumbar sympathetic chain. Through the white rami communicantes of the T10, T11, T12, and L1 spinal nerves, nociceptive signals enter the dorsal horn of the spinal cord. Blockade at different levels along this path (sacral nerve root block of S2-4, pudendal block, paracervical block, low caudal or true saddle block, lumbar sympathetic block, segmental epidural block of T10-L1, and paravertebral block T10-L1) can alleviate the visceral and somatic components of labor pain. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

distention. However, unlike somatic afferents, they are not activated by cutting. With each uterine contraction, pressure is transmitted to distort and stretch the uterine cervix, thereby leading to the activation of these nerve terminals. How mechanical distention results in the depolarization of the nerve terminal and the generation of an action potential is not entirely known, but the following three mechanisms are likely:

1. A variety of ion channels respond to the distortion of the cell membrane, and one of them—brain sodium channel-1 (BNC-1) or acid-sensing ion channel-2 (ASIC-2)—is exclusively expressed in sensory afferents and might directly depolarize the nerve terminal by opening its channel when the membrane is distorted (Fig. 20.6).[41]
2. Mechanical distortion may result in the acute release of a short-acting neurotransmitter that directly but transiently stimulates ion channel receptors on nerve terminals. Although this process has not yet been examined in the uterine cervix, studies have observed that stretching the bladder urothelium releases adenosine triphosphate, which directly stimulates a type of ligand-gated ion channel—P2X3—on sensory afferents in the bladder wall.[42] Because P2X3 receptors are widely expressed in C fibers,[43] this mechanism might be responsible for the pain that results from the acute distention of the uterine cervix.
3. Local ischemia during contractions may result in gated or spontaneous activity of other ion channels. Some of these ion channels—the ASIC family—respond directly to the low pH that occurs during ischemia,[44] whereas other classes of ion channels may be activated to open spontaneously. For example, the vanilloid receptor type 1 (VR-1) can be stimulated by capsaicin. It is likely that VR-1 receptors (which also respond to noxious heat) are expressed on visceral afferent terminals, given that the application of capsaicin or heat to the distal esophagus in humans results in pain.[45] VR-1 receptor–gated ion channels are not normally open in the absence of high temperature or capsaicin-like ligands; however, in the presence of low pH, the temperature response of these receptors shifts so that their channels open at body temperature.[46]

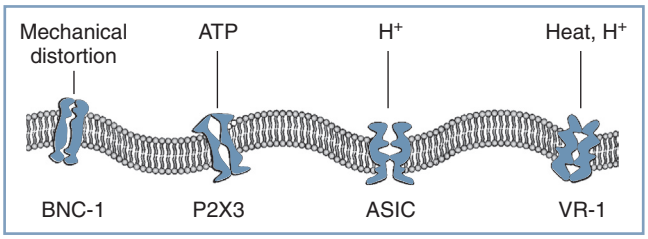

Fig. 20.6 Afferent nerve endings contain multiple excitatory ligand-gated ion channels, including those that respond to mechanical distortion: *BNC-1,* brain sodium channel-1; *ATP,* adenosine triphosphate; *P2X3,* purinergic receptor; *H+,* hydrogen ion; *ASIC,* acid-sensing ion channel; *VR-1,* vanilloid receptor type 1.

Uterine cervical afferents (including the C fibers that innervate the vaginal surface of the cervix) contain substance P, CGRP, and the enzyme nitric oxide synthase.[47] C fibers can be divided into two groups: (1) those that contain substance P and CGRP and respond to nerve growth factor through actions on tyrosine kinase A receptors and (2) those that contain somatostatin, instead of substance P and CGRP, and respond to glially derived growth factor through actions on a c-ret complex.[48] Some overlap exists between these rough classifications, and further definition of C fiber subtypes will likely occur as more markers and neuropeptides are examined. Other compounds commonly contained in C fiber terminals include glutamate, vasoactive intestinal peptide, and neuropeptide Y. The variable role of C fiber subtypes in the transmission of pain is also unclear. Given that somatostatin typically inhibits substance P release and pain transmission,[49,50] the net transmission of nociception at the spinal cord level may reflect a complex interaction between excitatory and inhibitory C fiber subtypes.

The peripheral afferent neurophysiology of pain during the first stage of labor suggests that the largely unexplored multiple ion channels that transduce the mechanical signal of cervical stretching to an electrical signal generating the perception of pain may represent important new targets for local or systemic analgesic drug delivery. In addition, the understanding of the classification, function, and relevance to pain of different C fiber subtypes remains in its infancy. Research involving endocervical C fiber subtypes may identify new targets for the treatment of labor pain.

Role of Sensitization

Peripheral afferent terminals, like other parts of the sensory system, can change their properties in response to various conditions. Afferent terminals can be directly stimulated by the low pH associated with inflammation (Fig. 20.7), and selective ligand-gated ion channels on these terminals can be stimulated by the release of bradykinin.[51] In addition, peripheral inflammation sensitizes afferent terminals by changing their properties; this process can result, over a short time, in a change in gene expression by these nerve fibers, thereby leading to a large amplification of pain signaling.

Although peripheral inflammation is most commonly associated with the pain that results from acute postoperative and chronic arthritic conditions, it may also play an essential role in labor pain. The cervical ripening process and labor itself both result from local synthesis and release of a variety of inflammatory products. The clinical implications of these inflammatory pathways include the application of inflammatory mediators (e.g., prostaglandin E_2 [PGE_2]) to prepare the cervix for labor induction and the administration of inflammatory mediator inhibitors (e.g., indomethacin) to stop preterm labor.

PGE_2 is an especially important sensitizing agent for uterine cervical afferents. In most species, the onset of labor is triggered by a sudden decrease in circulating estrogen concentration. This decrease removes a tonic block on the expression of cyclooxygenase, leading to an increase in local

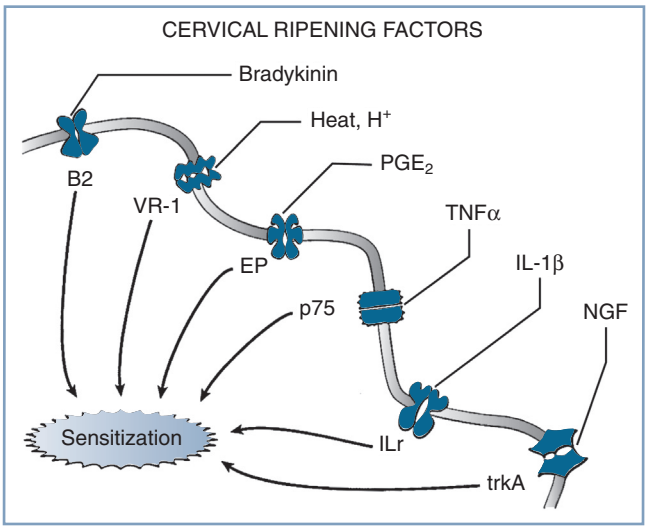

Fig. 20.7 Effects of inflammation from cervical ripening on afferent terminals. A variety of factors—including bradykinin, heat and hydrogen ions, prostaglandins (including *PGE_2*), tumor necrosis factor-α *(TNFα)*, interleukin-1 beta *(IL-1β)*, and nerve growth factor *(NGF)*—act on their cognate receptors to sensitize nerve endings and amplify the perception and severity of pain from nerve stimulation. *B2*, bradykinin-2 receptor; *EP*, prostaglandin E receptor; *ILr*, interleukin-1 receptor; *p75*, p75 tumor necrosis factor-α receptor; *trkA*, tyrosine kinase A; *VR-1*, vanilloid receptor type 1.

production of prostaglandins, especially PGE_2.[52] PGE_2 is central to a variety of processes that are activated to allow ripening and dilation of the uterine cervix. During the 24 to 72 hours preceding the onset of labor, collagen in the cervix becomes disorganized owing to the activation of prostaglandin receptors and the activity of inflammatory cytokines (mostly interleukin-1-beta [IL-1β] and tumor necrosis factor-alpha [TNF-α]) and matrix metalloproteinases (especially types 2 and 9).[53,54] A series of studies in the rat paw have demonstrated that PGE_2 induces peripheral sensitization in a sex-independent manner by activation of protein kinase A[55] and nitric oxide synthase.[56]

Cytokines and growth factors are also released into the uterine cervix immediately before and during labor. The cytokine IL-1β enhances cyclooxygenase activity and substance P release in the DRG and spinal cord.[57,58] TNF-α increases the spontaneous activity of afferent fibers[59] and enhances CGRP release and VR-1 receptor expression in DRG cells in culture.[60] Nerve growth factor also induces mechanical hypersensitivity.[61] These sensitizing substances (prostaglandins, cytokines, and growth factors) signal peripheral nerves in a manner that results in a host of changes in DRG cell number, peptide expression and release, receptor and ion channel expression, and biophysical properties. For example, inflammatory mediators alter the expression of sodium (Na+) channel subtypes,[62,63] thereby resulting in more rapid, repetitive firing capability[64] and spontaneous afferent activity.[65]

Estrogen receptor signaling can dramatically affect the structure of the uterine cervix and possibly modulate pain

responses. Long-term estrogen exposure sensitizes a subset of mechanosensitive afferents innervating the uterine cervix. The hypogastric afferents that innervate the uterine cervix are polymodal and contain high-threshold (HT) and low-threshold (LT) fibers. Long-term estrogen exposure increases the spontaneous activities of both HT and LT fibers, but only HT fibers show greater responses to uterine cervical distention.[66] Long-term estrogen exposure also increases the proportion of hypogastric afferents innervating the uterine cervix, which express transient receptor potential vanilloid type 1 (TRPV-1). Capsazepine, a TRPV-1 channel antagonist, reduces the hypogastric afferent responses to cervical distention in estrogen-treated animals but not in ovariectomized animals without estrogen replacement.[67,68] These data suggest that the TRPV-1 receptor is important for estrogen-induced sensitization and amplification of pain responses to uterine cervical distention, and that it may therefore represent a potential new target for preventing or treating such enhanced pain.

Implications of the peripheral sensitization of cervical afferents during labor are as follows:

1. Braxton-Hicks contractions, prior to the onset of this inflammatory process, may be as powerful as labor contractions but are painless.
2. Pain may increase with the progress of labor as a result of sensitization.
3. Inflammatory mediators may provide new targets to treat labor pain.

Inhibitory Receptors

Given the multiplicity of direct excitatory and sensitizing mechanisms on peripheral terminals, more plausible targets for peripheral pain treatment are the endogenous inhibitory receptors expressed on the afferent terminals (Fig. 20.8).

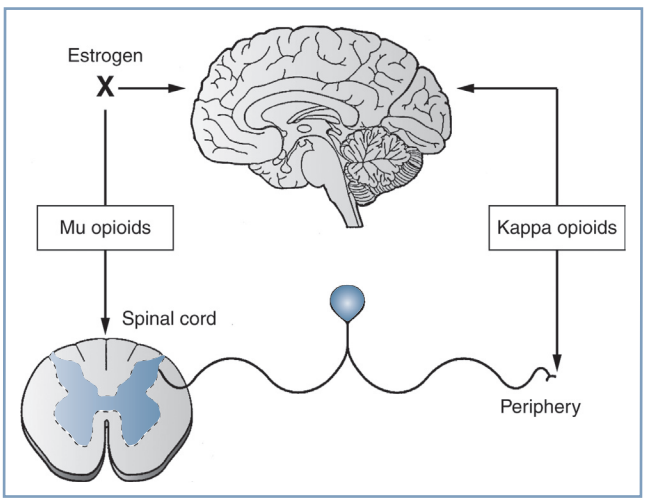

Fig. 20.8 κ-Opioid receptor agonists act primarily at visceral afferent terminals in the periphery and in the supraspinal central nervous system to provide analgesia during the first stage of labor, whereas μ-opioid receptor agonists act in the spinal cord and the supraspinal central nervous system. Estrogens block the effect of μ-opioid receptor agonists at supraspinal sites.

Opioid receptors have achieved the widest attention. Although μ-opioid receptors are expressed in some afferents in the setting of inflammation,[69] the efficacy of morphine provided by local instillation has proved disappointing,[70] with the exception of an intra-articular injection.[71] Similarly, μ-opioid receptor agonists produce antinociception to uterine cervical distention through actions in the central nervous system but not in the periphery.[72]

κ-Opioid receptor agonists may effectively treat visceral pain owing to the presence of these receptors in visceral, but not somatic afferents, at least in the gastrointestinal tract.[73] κ-Opioid receptor agonists can also produce antinociception in response to uterine cervical distention through actions in the peripheral nervous system.[32,72] Pharmaceutical firms are developing drugs of this class that are restricted to the periphery, have few central side effects,[74,75] and presumably express little potential for placental transfer; potentially, such agents would be useful for labor analgesia. One of these new agents has been observed to effectively treat chronic visceral pain from pancreatitis in patients receiving poor analgesia from μ-opioid receptor agonists.[76]

Estrogen and progesterone can alter the analgesic response to opioids. In most cases involving somatic stimulation, tonic estrogen treatment reduces the efficacy of μ-opioid but not κ-opioid receptor agonists.[77] Further, κ-opioid receptor agonists have greater analgesic efficacy in women than in men.[78] In animals, tonic estrogen exposure reduces the inhibitory responses to uterine cervical distention by morphine but not to the κ-opioid receptor agonist U-50488.[79] In contrast, the inhibitory action of *intrathecal* morphine against responses to uterine cervical distention is unaffected by tonic estrogen exposure,[80] which is consistent with the observation that intrathecal opioids relieve the pain of the first, but not second, stage of labor.

Implications of inhibitory receptors on afferent terminals are that κ- but not μ-opioid receptor agonists may produce pain relief through their actions in the periphery. Selective, peripherally restricted drugs are under development for the systemic treatment of visceral pain. In addition, estrogen-dependent inhibition of the supraspinal (but not the spinal) analgesic action of μ-opioid receptor agonists may underlie the limited analgesic effect produced by systemic opioids,[81] a finding that is in contrast to the efficacy of intrathecal opioids[82] in relieving the pain of the first stage of labor.

Peripheral Nerve Axons

The current approach to labor analgesia relies primarily on an understanding of the afferent axons and their level of entry into the spinal cord and on the administration of local anesthetics to block afferent traffic conduction. Traditionally, axons have been considered conduits that allow for the propagation of action potentials by the transitory opening of sodium channels. More recent investigations have confirmed the existence of a variety of sodium channel subtypes and axons that modulate transmission through other ion channels.

Although a number of voltage-gated sodium channel subtypes exist, most studies have focused on three specific subtypes that are expressed in sensory afferents.[83] Two of these, NaV1.8 and NaV1.9, are relatively resistant to blockade by tetrodotoxin (TTX-R); NaV1.9 is often referred to as "persistent," owing to its very slow inactivation kinetics.[84] Inflammation and injury to nerves decrease the TTX-R current density in afferent cell bodies.[85] Some investigators have suggested that NaV1.8 is selectively trafficked to the periphery after injury and inflammation[85] and that a reduction of its expression reduces hypersensitivity.[86] Other investigators, using sucrose gap measurements of compound action potentials, have demonstrated a shortened refractory period and a decrease in delayed depolarization after nerve injury[87,88] that are consistent with the greater expression of rapidly repriming tetrodotoxin-sensitive (TTX-S) channels and the decreased expression of kinetically slow TTX-R channels. To date, these studies have focused primarily on peripheral nerve injury models of chronic pain, and neither the subtypes nor their change during the cervical inflammation of labor has been studied.

Several pharmaceutical firms have discovery programs to produce sodium channel subtype-selective blockers that could improve both the safety and efficacy of the treatment of labor pain, because such agents would not interact with sodium channels in the brain, heart, or motor nerve fibers. Some investigators have observed that injection of the antidepressant amitriptyline, an agent known to block the NaV1.8 sodium channel, around the peripheral nerves provides a neural blockade twofold to fivefold longer than that provided by injection of long-acting local anesthetics.[89,90]

Another subject of current research is the extension of the duration of selective antinociception with no motor or sympathetic block by manipulation of the TRPV-1 receptor, which is a nonselective ligand-gated cation channel. TRPV-1 receptors are expressed in peripheral primary afferent neurons, the nociceptive C and A-delta fibers, and the dorsal root ganglia, as well as the structures involving the endogenous antinociceptive descending pathway. TRPV-1 receptors can be activated by capsaicin, heat, and endovanilloids, leading to release of substance P, which in turn excites inhibitory neurons in laminae I, III, and IV. Further, activation of the TRPV-1 receptors causes opening of the small TRPV-1 channels on the neurons and allows entry of co-administered charged molecules of certain sizes. Permanently charged local anesthetic, when applied alone, would not be able to cross the nerve membrane to exert its effect on sodium channels in small sensory neurons, but when applied in the presence of capsaicin or other TRPV-1 agonists, the permanently charged local anesthetic would become permeant to exert its local anesthetic effect. Binshtok et al.[91] reported the inhibition of nociceptors by TRPV-1–mediated entry of impermeant sodium channel blockers. However, stimulation of TRPV-1 receptors, such as with capsaicin alone, will also result in the induction of receptor-mediated acute pain. Therefore, these investigators subsequently performed another study in rodents, and they observed that the co-application of lidocaine and its quaternary permanently charged derivative QX-314 produces a prolonged, predominantly nociceptor-selective block by allowing QX314 entry through the TRPV-1 channels without the nocifensive behavior associated with capsaicin when lidocaine is used instead to activate the TRPV-1 receptors.[92] The issues of pain elicited with administration of TRPV-1 agonists such as capsaicin and, more importantly, the neurotoxicity of permanently charged Na+ channel blockers remain to be overcome and require further research. Additional investigations of the exploitation of new targets may allow provision of safer and prolonged selective antinociception. Should future research prove the absence of toxicity, it is conceivable that amitriptyline or other agents that interact with Na+ channel subtypes and/or TPRV-1 receptors could be considered for single-injection techniques to produce prolonged and selective analgesia for labor pain and postoperative pain relief.

Interactions within the large number of ion channels expressed on axons can alter neural conduction. An example is the transient refractory period caused by the membrane hyperpolarization that follows a short burst of nerve firing. This phenomenon results from activation of the Na+/K+ exchange pump and dampens high-frequency nerve activity. The Na+/K+ exchange pump activity, in turn, can be reduced by a hyperpolarization-induced current termed I_h. Drugs that block the I_h current enhance the hyperpolarization caused by the Na+/K+ exchange pump and ultimately serve to reduce nerve traffic[93] and provide prolonged analgesia.[94] A second example is the desensitization of VR-1 receptors present on the axons of C fibers. The perineural injection of drugs that desensitize these receptors without first stimulating them avoids the induction of receptor-mediated acute pain and instead produces very long periods of selective sensory analgesia without motor effects.[95] The mechanism by which VR-1 receptor desensitization alters the transmission of action potentials is under investigation.

Implications of the neurophysiology of axonal transmission of labor pain are that sodium channel subtype–selective agents—or those that affect other ion channels expressed on axons—may provide safer and more selective tools for regional analgesic techniques.

Spinal Cord

When action potentials invade the central terminals of C and A-delta fiber afferents in the spinal cord, voltage-gated calcium channels open and cause intracellular calcium concentration to increase; this increase triggers a multistep process of neurotransmitter docking and fusion with the plasma membrane, which results in neurotransmitter release.[96] Inhibition of these calcium channels produces analgesia. Studies in animals suggest that at least one agent that affects the calcium channels, gabapentin, produces antinociception to visceral stimulation.[97]

A nociceptive stimulus can result in the release of multiple excitatory neurotransmitters, including amino acids (glutamate, aspartate) and peptides (especially substance P, CGRP, and neurokinin A) that interact with specific receptors on

spinal cord neurons. Although the stimulation of neurokinin receptors is necessary for the perception of moderate to severe pain,[98] a complex and poorly understood interplay exists among these released neurotransmitters.

Neurotransmitter release at sensory afferent terminals is controlled by presynaptic receptors that act primarily by altering the flux of intracellular calcium when an action potential arrives. Some of these neurotransmitters are excitatory; for example, the action of acetylcholine on nicotinic acetylcholine receptors amplifies further neurotransmitter release.[99] Gamma-aminobutyric acid (GABA) is the key endogenous inhibitory neurotransmitter in the nervous system, and stimulation of GABA receptors significantly reduces the afferent terminal release of other neurotransmitters.[100] Multiple compounds produce analgesia by enhancing the release of GABA at afferent terminals in the spinal cord. The existence of excitatory and inhibitory systems can make the response to a neurotransmitter or an exogenously-administered agent (such as a local anesthetic drug given intrathecally) difficult to predict. For example, acetylcholine can enhance or reduce the afferent terminal release of neurotransmitters by actions on nicotinic and muscarinic receptors, respectively.[101,102] The net effect of acetylcholine appears to be inhibitory, which is indicated by the analgesic effect of intrathecal administration of the cholinesterase inhibitor neostigmine.[103]

The primary mechanism of action of the neurotransmitter enkephalin, which is released by spinal cord interneurons, and of norepinephrine, which is released by axons descending from pontine centers, is the inhibition of neurotransmitter release from primary afferent terminals. These substances act on μ-opioid and α_2-adrenergic receptors, respectively,[104,105] and may produce some of the similar effects observed after the intrathecal administration of opioids and α_2-adrenergic agonists for the treatment of labor pain.

Amino acids and peptides released from sensory afferents stimulate a heterogeneous group of spinal cord neurons, including neurons that project to supraspinal structures, interneurons that modulate transmission at the afferent terminal itself (the "gate" of the control theory), and interneurons that stimulate motor and sympathetic nervous system reflexes. Large and sustained glutamate release from an intensely noxious stimulus can activate *N*-methyl-D-aspartate (NMDA) receptors, resulting in sustained depolarization and enhanced excitability of projection neurons (Fig. 20.9).[106] Although the intrathecal injection of NMDA receptor antagonists (e.g., ketamine) has been restricted because of neurotoxicity concerns,[107] systemic infusion of magnesium sulfate has been observed to produce postoperative analgesia.[108] Magnesium is an endogenous inhibitory modulator of NMDA receptors, and it is conceivable that magnesium sulfate administered systemically for obstetric indications may have a minor effect on labor pain.

Prolonged and intense nociceptive stimuli can produce sensitization and amplification of pain signaling at the spinal cord level like the peripheral sensitization that occurs as a result of inflammation. Some of these processes are a direct

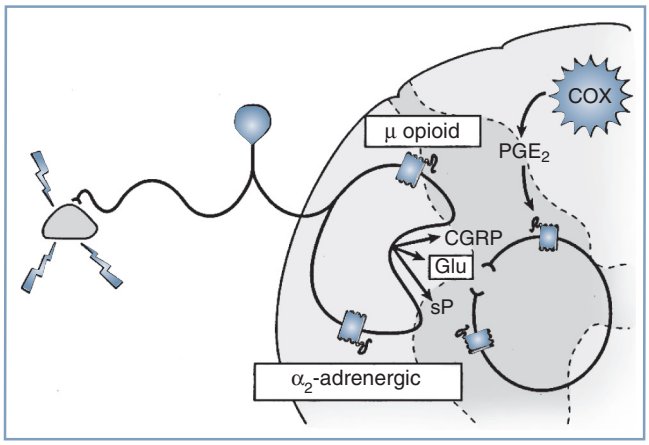

Fig. 20.9 Pain transmission in the spinal cord. Excitatory transmission occurs directly by release of amino acids such as glutamate *(Glu)* and peptides (*sP* [substance P], *CGRP* [calcitonin gene–related peptide]) and indirectly via activation of enzymes such as cyclooxygenase *(COX)* in nearby glia, which synthesize prostaglandins, including prostaglandin E_2 *(PGE_2)*. Inhibitory mechanisms are primarily presynaptic, with μ-opioid and α_2-adrenergic receptors being the most common (or at least the most studied).

consequence of receptors (e.g., NMDA receptors) that are activated only with highly intense and prolonged stimulation or by the long-term release of neurotransmitters that simultaneously activate the glutamate and substance P receptors on the same cell. Others reflect the synthesis and release of classic "inflammatory" substances by the spinal cord glial cells in response to prolonged afferent stimulation from nitric oxide and prostaglandins, especially PGE_2. Some non-opioid analgesic drugs produce analgesia by actions exclusively (e.g., acetaminophen [paracetamol]) or primarily (e.g., aspirin) in the central nervous system (especially the spinal cord).[109]

Spinal sensitization processes represent a novel target for the treatment of labor pain. More than 80 years ago, Cleland[37] noted the presence of hypersensitivity to light touch on the skin of dermatomes T11 and T12 in laboring women, which likely represents the enhanced sensitivity of spinal cord neurons receiving both visceral input from the cervix and skin input at those levels.[110] When the visceral stimulation to these dermatomes was blocked by a paravertebral local anesthetic injection, Cleland[37] observed that the hypersensitivity was ablated; this observation is consistent with the later finding that ongoing C fiber input is required for hypersensitivity to occur.[111] Uterine cervical distention (UCD) results in a pattern of spinal cord neuronal activation similar to that witnessed during labor and delivery. In a study in rats reported by Tong et al.,[112] UCD significantly increased c-fos immunoreactivity in the spinal cord from T12 to L2, with most of the c-fos expression occurring in the deep dorsal horn and central canal regions. UCD-evoked c-fos expression was prevented by prior infiltration of lidocaine into the cervix or by intrathecal administration of ketorolac (a cyclooxygenase [COX] inhibitor) in a dose-dependent manner.[112] Intrathecal administration of indomethacin (a nonspecific COX inhibitor) and the selective COX-2 inhibitor SC-58238 effectively ablated

UCD-induced electromyographic activity without altering the hemodynamic response to UCD. By contrast, the selective COX-1 inhibitor SC-58360 was ineffective in ablating UCD-induced electromyographic activity, as was ketorolac, an agent with higher affinity for COX-1 than COX-2.[113] Together, these data suggest that targeting COX-2 is necessary to treat the acute visceral pain often associated with brief infrequent contractions in late pregnancy; therefore, intrathecal ketorolac would be predicted to be ineffective. However, in the setting of sustained, frequent, and repetitive contractions for a prolonged period (as occurs during active labor), intrathecal ketorolac might be effective. The intrathecal injection of ketorolac has been introduced into experimental human trials[114] and warrants examination as a potential modality for selective treatment of labor pain.

The neurophysiologic basis for labor pain in the spinal cord implies that purely inhibitory mechanisms (e.g., opioid and α_2-adrenergic receptors) can be mimicked by the intrathecal injection of agonists to these receptors. However, the administration of other agents (e.g., acetylcholine) in this location has less predictable results. Central sensitization mechanisms in the spinal cord most certainly occur during labor, and future treatments may target these mechanisms.

Ascending Projections

Spinal cord neurons project to multiple brainstem sites as well as the thalamus. Forty years ago, it was noted that descending systems—activated primarily by stimulation of the nucleus raphe magnus, the periaqueductal gray, and the locus coeruleus—could reduce pain transmission as described in the gate control theory.[115] Activation of descending pathways results in the spinal release of endogenous ligands for serotonergic, opioid, and α_2-adrenergic receptor–mediated analgesia. Spillover of neurotransmitters into the cerebrospinal fluid has been used as a measure of activation of these systems, and studies measuring these substances have shown no increase in enkephalin, but an increase in norepinephrine, in laboring women.[116] These descending systems can be activated by psychoprophylactic methods,[117] and agents that prolong or intensify the action of these ligands, such as enkephalinase inhibitors and blockers of monoamine reuptake, might further enhance analgesia.[118]

Brainstem activation by the pain of labor leads to other reflexes, such as increases in sympathetic nervous system activity and respiratory drive and, with prolonged activation, stimulation of descending pathways that amplify rather than reduce pain transmission at the spinal cord.[119,120] The circuitry and pharmacology of such pain-enhancing systems in the brainstem and their potential applications for treatment are under current investigation.

Our understanding of the areas of the brain activated during labor pain is limited, although studies of other types of experimental nociception in healthy volunteers indicate that visceral pain is considered more unpleasant than somatic pain; this difference reflects, in part, the greater activation of centers for negative emotions, including fear. Although distraction methods do not alter the thalamic activation from noxious stimulation, a reduction in cortical activation and the report of pain have been observed,[121] supporting a suprathalamic mechanism of psychoprophylaxis in the reduction of pain.

The neurophysiologic basis of labor pain and ascending projections suggests the activation of multiple supraspinal sites. Some of these sites stimulate potentially detrimental cardiorespiratory reflexes. Other sites, which send descending projections that either reduce or enhance pain transmission in the spinal cord, may be targeted for the provision of analgesia. In addition, suprathalamic modulation of pain signals appears to account for the interindividual differences in pain perception and for the relative efficacy of psychoprophylaxis in reducing the intensity of reported pain.

EFFECT ON THE MOTHER

Obstetric Course

Several aspects of labor pain can affect the course of labor and delivery (Fig. 20.10). Pain-induced increases in the activity of the sympathetic nervous system lead to higher plasma concentrations of catecholamines, especially epinephrine. The provision of labor analgesia reduces the plasma concentration of epinephrine and its associated beta-adrenergic tocolytic effects on the myometrium. This process may underlie the observations by some investigators who have noted, either anecdotally or under controlled conditions, a shift from dysfunctional to normal labor patterns in some women when analgesia is achieved with paravertebral[37] or epidural[122] blocks or with systemic meperidine (pethidine) analgesia.[123] The abrupt reduction in plasma epinephrine concentration that follows the rapid onset of intrathecal opioid analgesia may

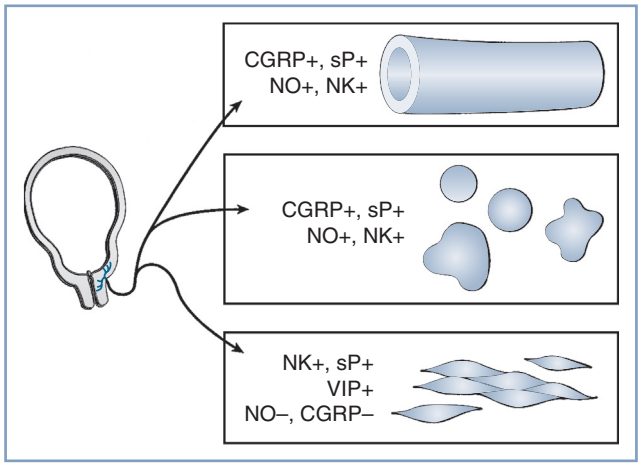

Fig. 20.10 Aspects of pain that may affect the course of labor. In addition to indirect effects (e.g., beta-adrenergic tocolysis from increased secretion of epinephrine, greater release of oxytocin via Ferguson's reflex), depolarization of afferent terminals in the lower uterine segment and cervix can directly alter aspects of labor. Substances released by nerve terminals include those that increase local blood flow (*CGRP* [calcitonin gene–related peptide], *sP* [substance P], *NO* [nitric oxide], *NK* [neurokinin]), those that stimulate immune cell function, and those that stimulate (+) or inhibit (–) myometrial smooth muscle activity, including vasoactive intestinal peptide *(VIP)*.

result in an acute reduction of beta-adrenergic tocolysis and a transient period of uterine hyperstimulation; in some cases, these changes may lead to transient fetal stress and fetal heart rate abnormalities.[124,125]

Ferguson's reflex involves neural input from ascending spinal tracts (especially from sacral sensory input) to the midbrain, thereby leading to enhanced oxytocin release. Although spontaneous labor and delivery occur in women with spinal cord injury (which disrupts this tract[126]), some investigators have argued that neuraxial analgesia can inhibit this reflex and prolong labor, especially the second stage. However, strong evidence for this does not exist. Some studies have noted a reduction in plasma oxytocin concentration with epidural local anesthetic[127] or intrathecal opioid[128] analgesia, whereas others have not noted such a reduction.[129]

Papka and Shew[28] suggested that afferent terminals in the lower uterine segment and cervix might have an important secretory (efferent) function in the regulation of labor. Afferent terminals contain many substances that can *stimulate* (substance P, glutamate, vasoactive intestinal peptide) or *inhibit* (CGRP, nitric oxide) myometrial activity, and these substances can be released locally into the cervix and lower uterine segment when terminals are depolarized by contraction-related tissue distortion. In addition, depolarization of the afferent terminal can result in an action potential that, upon reaching a site of nerve branching, invades adjacent branches and travels distally to depolarize distant terminals of the same nerve. This axon reflex has long been recognized to occur in somatic nerves; owing to the more extensive arborizations believed to exist in visceral nerves, local stimulation should result in more widespread release of these transmitters. Therefore, it is tempting to speculate that these axon reflexes are more profoundly affected when local anesthetic is administered closer to the terminals associated with cervical dilation and labor (e.g., as occurs with paracervical and paravertebral blocks) than occurs when local anesthetic is administered farther away from the terminals (e.g., with epidural block). This speculation would imply that the net effect of afferent terminal–released substances inhibits rather than accelerates labor.

In summary, neural stimulation through pain pathways leads to the release of substances that either increase (oxytocin) or inhibit (epinephrine) uterine activity and cervical dilation. Therefore, the effect of analgesia on the course of labor can vary between and within individuals. In addition, axon reflexes can result in the release of neurotransmitters from afferents into the lower uterine segment and cervix. It is hoped that future investigation will determine whether the proximity of local anesthetic deposition affects the response of cervical dilation and labor.

Cardiac, Respiratory, and Gastrointestinal Effects

Labor exerts stresses on the cardiovascular and respiratory systems. The elevated plasma catecholamine concentrations observed during labor pain can increase maternal cardiac output and peripheral vascular resistance and decrease

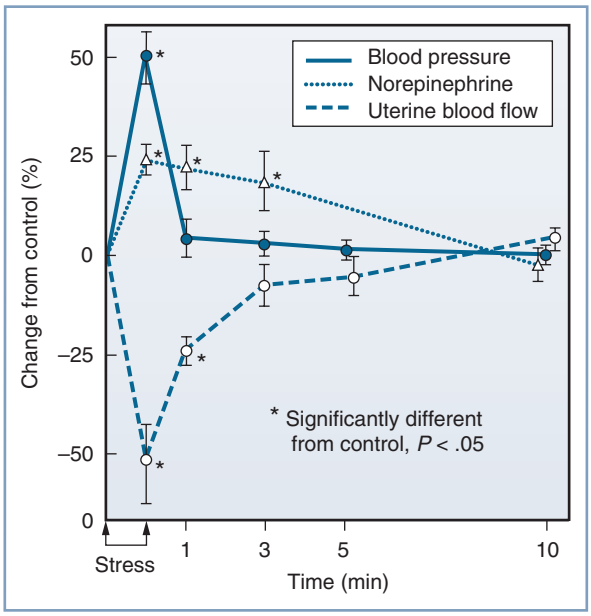

Fig. 20.11 Effect of a painful stimulus on the hind leg on maternal blood pressure, norepinephrine concentrations, and uterine blood flow in gravid ewes. The increase in blood pressure was transient, but plasma norepinephrine concentrations remained elevated for several minutes; the elevation is reflected in the slow return of uterine blood flow to normal. (From Shnider SM, Wright RG, Levinson G, et al. Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. *Anesthesiology*. 1979;50:524–527.)

uteroplacental perfusion. Even transient stress is associated with dramatic increases in plasma concentration of norepinephrine and subsequent decreases in uterine blood flow (Fig. 20.11). Plasma epinephrine concentrations in women with painful labor are similar to those observed after intravenous administration of a bolus of epinephrine 15 µg[130]; intravenous bolus injection of epinephrine 10 to 20 µg resulted in a significant (albeit transient) reduction in uterine blood flow in gravid ewes.[131] Effective neuraxial analgesia, provided by epidural local anesthetic[132] or intrathecal opioid administration,[133] significantly reduces (50%) maternal catecholamine concentrations. By contrast, neonatal catecholamine concentrations do not appear to be altered by maternal neuraxial anesthetic techniques; this relative independence of neonatal catecholamine responses may be important for the neonatal adaptation to extrauterine life.[134]

The intermittent pain of uterine contractions also stimulates the respiratory system and leads to periods of intermittent hyperventilation. In the absence of supplemental oxygen administration, compensatory periods of hypoventilation between contractions result in transient episodes of maternal, and even fetal, hypoxemia (Fig. 20.12). Treatment of labor pain with epidural analgesia minimizes the increase in net minute ventilation and the accompanying increase in oxygen consumption.[135] In general, the cardiovascular and respiratory system changes induced by labor pain are well tolerated by healthy parturients (with normal uteroplacental perfusion) and their fetuses. Some authors have concluded

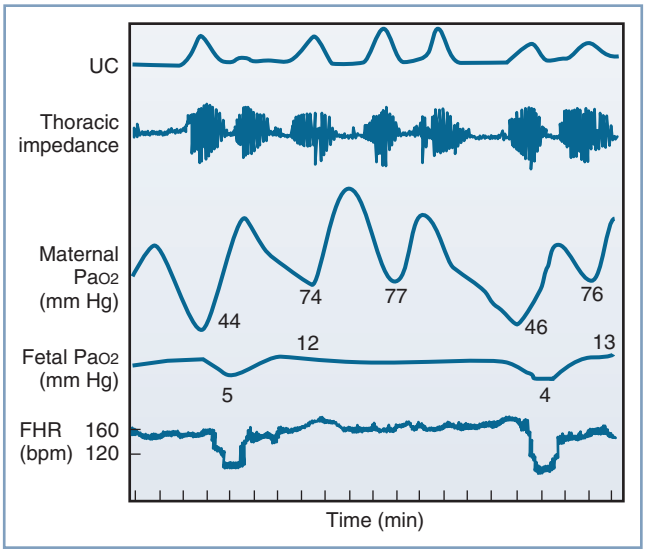

Fig. 20.12 Maternal and fetal hypoxemia during hypoventilation between uterine contractions *(UC),* which are associated with maternal hyperventilation. *FHR,* fetal heart rate. (From Bonica JJ. Labour pain. In Wall PD, Melzack R, eds. *Textbook of Pain.* Edinburgh: Churchill Livingstone; 1984, as redrawn from Huch A, Huch R, Schneider H, Rooth GL. Continuous transcutaneous monitoring of fetal oxygen tension during labour. *Br J Obstet Gynaecol.* 1977;84[Suppl]:1–39.)

that these changes are of no concern or relevance in uncomplicated labor.[20] However, when maternal or fetal disease or compromise is observed, significant cardiopulmonary alterations may lead to maternal or fetal decompensation; effective analgesia may be especially important in such cases.

Labor pain, anxiety, and emotional stress increase gastrin release and inhibit the segmental and suprasegmental reflexes of gastrointestinal and urinary motility. This in turn results in an increase in gastric acidity and volume and a delay in bladder emptying.[136] These changes are further aggravated by the recumbent position, opioids, and other depressant medications (e.g., barbiturates), putting laboring parturients at risk for pulmonary aspiration of gastric contents, especially during emergency induction of general anesthesia for cesarean delivery.

In summary, pain-induced activation of the sympathetic nervous system during labor is associated with cardiovascular, respiratory, and gastrointestinal effects that may alter maternal and fetal well-being. The provision of effective neuraxial analgesia may mitigate many of these cardiopulmonary effects.

Psychological Effects

The meaning of labor pain is greatly influenced by psychosocial and environmental factors (as previously discussed) and varies considerably among women. Although the acceptance of labor analgesia has a minor overall effect on maternal satisfaction with the labor and delivery process,[137] individual women can be profoundly influenced. It has been suggested that women who understand the origin of their pain and view the labor and delivery process as positive and nonthreatening may undergo pain without suffering.[20] Billewicz-Driemel and Milne[138] reported that a small proportion (< 5%) of women who requested and received epidural labor analgesia described a sense of deprivation from having missed the natural labor experience in its entirety; some of these women may subsequently seek psychiatric counseling.[139]

By contrast, unrelieved severe labor pain can have psychological and physical consequences, including depression and negative thoughts about sexual relationships.[6,11] In a 5-year study in Sweden, 43 women requested elective cesarean delivery owing to a fear of labor and vaginal delivery.[140] Some countries (e.g., Brazil) have an extremely high elective cesarean delivery rate (> 80%) among upper-class women because of their concerns about reduced sexual function after vaginal delivery. Frank psychotic reactions resembling posttraumatic stress disorder can occur after childbirth, although the incidence is rare (< 1%).[141]

Psychological effects of labor pain can occur in a small proportion of women. Psychological harm can be experienced through the provision or withholding of labor analgesia, underscoring the tremendous variability in the meaning of labor pain for different women.

Pain after Delivery

Many women undergo delivery without negative sequelae, but some may experience significant persistent postpartum pain and even depression. Studies of acute and chronic postpartum pain have shown a 7% incidence of perineal pain at 8 weeks after vaginal delivery,[142] and a 43% incidence of hyperalgesia at 48 hours and a 23% incidence of residual pain at 6 months after cesarean delivery.[143] In a multicenter, prospective, longitudinal cohort study of 1288 parturients delivering either by cesarean or vaginal delivery, Eisenach et al.,[144] using regression analyses and propensity adjustment, reported a 10.9% prevalence of severe acute pain within 36 hours postpartum, whereas the prevalence of persistent pain and depression at 8 weeks postpartum was 9.8% and 11.2%, respectively. The severity of acute postpartum pain, but not the mode of delivery, was independently related to risk for persistent pain and depression at 8 weeks postpartum, both of which also resulted in negative effects on activities of daily living and on sleep. Those women with severe acute postpartum pain had a 2.5- and 3.0-fold increased risk for persistent pain and depression, respectively, when compared with those with mild acute postpartum pain. These findings suggest these morbidities may not be related to degrees of physical tissue trauma but rather may be related to an individual's pain response to that injury.

Although there is significant interindividual variability with regard to acute postpartum pain,[14] the severity of acute postoperative pain in nonobstetric surgical patients has been correlated with the occurrence of chronic pain.[145] Whether the presence and severity of labor pain or the presence and severity of acute postpartum pain after either vaginal or cesarean delivery predicts the occurrence of chronic pain is under investigation. Studies in animals suggest that acute intervention at the time of tissue injury reduces the likelihood

of developing chronic pain.[146] It is likely that severity of the acute pain is not just a marker of chronic pain but rather an active participatory component in the pathophysiology of transitioning from acute to chronic pain.[144] In a prospective cohort study of 241 parturients undergoing a vaginal delivery, Ding et al.[147] reported that the use of epidural labor analgesia was associated with a decreased risk for postpartum depression (odds ratio 0.31, 95% confidence interval 0.12 to 0.82, $P = 0.018$). More careful attention to pain treatment and follow-up in days after childbirth may potentially reduce long-term morbidities and improve overall outcomes.

Reports on the incidence of chronic pain after delivery vary widely in part because of the difference in the definition and the inclusion or exclusion of types of chronic pain and not critically separating new pain after delivery from preexisting pain. Long-term follow up of postpartum patients showed that the incidence of chronic pain (defined as new pain that began at the time of labor and delivery) at 6 months and 1 year was remarkably low at 3% and 0.1%, respectively, compared with nonobstetric surgeries with similar tissue injury.[148] By using a sciatic nerve injury–induced neuropathic pain model in rats, it has been observed that the birthing process plus the nursing of the pups in combination, but not individually, may be protective of the development of surgical nerve injury–induced hypersensitivity to pain. This protection is likely mediated by spinal oxytocin because the protective effect is abolished by administration of spinal atosiban, an oxytocin antagonist.[149]

The majority of pain research examines pain scores at predefined time points in the postoperative or postpartum period, but neglects the day-to-day experiences of pain recovery following surgery. Houle et al.[150] applied growth curve modeling to patients undergoing cesarean delivery or lower limb total joint arthroplasty by evaluating daily pain scores; a Bayesian change-point model, rather than the traditional log (time) model, was observed to be a better fit to the diminution of postoperative pain scores and suggested that "meaningful subpopulations of experience may exist" wherein patients do not recover in the same manner after the same surgery.

Further research is needed to better define protective and/or predictive factors in patients who are at risk for developing severe acute and/or chronic postpartum pain. Persistent or chronic pain may be particularly difficult for postpartum patients owing to the multiple stresses (e.g., care of the neonate) and sequelae encountered. An association between pain and depression exists, and depression is the most common complication after delivery, affecting approximately 13% of postpartum women.[151] Postpartum patients with depression are among those who frequently do not disclose depression even though they desire assistance.[152,153] Immediate and effective postpartum pain management (after both vaginal and cesarean deliveries) with adequate long-term follow-up may potentially prevent long-term morbidity and improve overall outcomes. For example, one prospective study of 205 parturients evaluating risk factors for the development of persistent postcesarean pain did not find a relationship with maternal anxiety, but demonstrated an association with acute pain and postpartum depression.[153] Further detailed research is needed to better stratify risk factors that place parturients at risk for the development of persistent pain after delivery.

EFFECT ON THE FETUS

Because of the absence of direct neural connections from the mother to the fetus, maternal labor pain has no direct effects on the fetus. However, maternal labor pain can affect a number of systems that determine uteroplacental perfusion, as follows: (1) uterine contraction frequency and intensity, by the effect of pain on the release of oxytocin and epinephrine; (2) uterine artery vasoconstriction, by the effect of pain on the release of norepinephrine and epinephrine; and (3) maternal oxyhemoglobin desaturation, which may result from intermittent hyperventilation followed by hypoventilation, as discussed earlier. Although these effects are well tolerated in normal circumstances and are effectively blocked by analgesia, fetal well-being may be affected in situations of limited uteroplacental reserve.

SUMMARY

Pain during the first stage of labor results from the stimulation of visceral afferents that innervate the lower uterine segment and cervix, intermingle with sympathetic efferents, and enter the spinal cord at the T10 to L1 segments. Pain during the second stage of labor results from the additional stimulation of somatic afferents that innervate the vagina and perineum, travel within the pudendal nerve, and enter the spinal cord at the S2 to S4 segments. These pain signals are processed in the spinal cord and are transmitted to brainstem, midbrain, and thalamic sites, the last with projections to the cortex, resulting in the sensory-emotional experience of pain. Current obstetric anesthesia practice relies nearly exclusively on the blocking of pain transmission by deposition of local anesthetic—with or without adjuncts—along the afferent nerves from sites near the peripheral afferent terminals to sites near their central terminals.

The neurophysiology of visceral pain, especially in relation to labor pain, is currently under investigation, with considerable academic and pharmaceutical targeting of (1) the normal ionic transduction mechanisms and processes of sensitization in peripheral afferent terminals, (2) the mechanisms of inhibition available in the spinal cord and brainstem, and (3) the processes by which conscious distraction methods can be amplified and can relieve pain. Labor pain is an intensely variable and personal experience, and it is essential that the anesthesia provider play a flexible role within this context.

Acknowledgment

We would like to acknowledge the contributions of Dr. James C. Eisenach to the previous edition of this chapter.

KEY POINTS

- Labor pain exists and is severe in many women, with a close correlation between cervical dilation and pain during the first stage.
- The first stage of labor involves visceral pain from the lower uterine segment and endocervix, which results in hypersensitivity to convergent somatic dermatomes. This pain is most likely amplified over time as a result of the sensitization of peripheral and central pain-signaling pathways. The second stage of labor results in somatic pain from the vagina and perineum and is briefer than the first stage.
- Afferent terminals transduce a mechanical process into electrical signals, which are probably amplified by the release of prostaglandins, cytokines, and growth factors into the cervix as part of the normal disruption of collagen that allows the cervix to soften and dilate.
- Pain transmission in the spinal cord is not hardwired; it is remarkably and rapidly plastic, and it is altered by local neuronal activity that releases μ-opioid receptor agonists and descending pathways that release α_2-adrenergic and serotonergic receptor agonists.
- There are large individual differences in pain perception, which likely reflect differences at suprathalamic sites. The activation of suprathalamic sites is the primary mechanism of action for distraction methods of analgesia.
- Labor pain alters the obstetric course and the maternal cardiac and respiratory function in a complex manner that normally is well tolerated, can sometimes be detrimental to both mother and fetus, and is alleviated by analgesia.
- Labor pain carries meaning in distinction from most other causes of severe pain; the treatment of labor pain should be applied within this context.
- Acute postpartum pain after either vaginal or cesarean delivery deserves attention and treatment; the factors or mechanisms responsible for the development of persistent or chronic postpartum pain are under investigation.

Childbirth Preparation and Nonpharmacologic Analgesia

Rebecca D. Minehart, MD, MSHPEd, Marie E. Minnich, MD, MMM, MBA, CPE

CHAPTER OUTLINE

At their core, the experiences of labor and birthing a child are intensely personal, intimate processes for many women, regardless of culture or background. While anesthesia providers may have a particular view of what is important to a woman during childbirth, including pain management strategies, our goals should be to understand each woman's values and beliefs and to recommend therapies when appropriate, taking into account medical and obstetric considerations as well as personal wishes. Some women seek nonpharmacologic strategies to cope with the pain in labor; these strategies may be independent of, or complementary to, some of our more "traditional" forms of labor pain relief such as neuraxial analgesia. A 2014 meta-analysis of nonpharmacologic approaches for pain management during labor compared with "usual care" found that the nonpharmacologic strategies were associated with reductions in various obstetric interventions, indicating that these therapies will remain in the lexicon of patient-centered care.[1] While some of the evidence surrounding nonpharmacologic approaches is less rigorous than evidence supporting some of our more traditional forms of pain relief, many of these approaches are rooted in pain-based theories, including (1) the gate control theory (e.g., light massage, water immersion, ambulation, birthing balls); (2) diffuse noxious inhibitory control (DNIC) [e.g., sterile water injections, acupuncture, acupressure, transcutaneous electrical nerve stimulation (TENS)]; and (3) central nervous system control (e.g., antenatal education, continuous support during labor, meditation, hypnosis, aromatherapy).[1] This chapter aims to provide obstetric anesthesia providers with a comprehensive knowledge of nonpharmacologic labor strategies and how they may contribute to coping and management of labor pain. This information provides a basis for informed discussion of pain relief options among patients, nurses, obstetricians, and anesthesia providers.

In addition to referencing their own personal beliefs, pregnant women and their support person(s) obtain information about childbirth and analgesia from many sources. The more traditional sources of information include obstetricians, childbirth preparation classes, lay periodicals, books and pamphlets, and experiences of family and friends. The Internet has become the primary source of information for many patients, and according to the *Listening to Mothers III* survey published in 2014, 78% of women used childbirth websites or blogs to gain access to information.[2] Anesthesia providers should be familiar with the information that patients in the local area are using for decision-making, because this information influences their birth experiences. Knowledge of the information and biases held by patients helps anesthesia providers in their interactions with pregnant women.

PAIN PERCEPTION

Anesthesia providers are indebted to John Bonica and Ronald Melzack for their studies of the pain of childbirth. Investigators have used sophisticated questionnaires[3,4] and visual

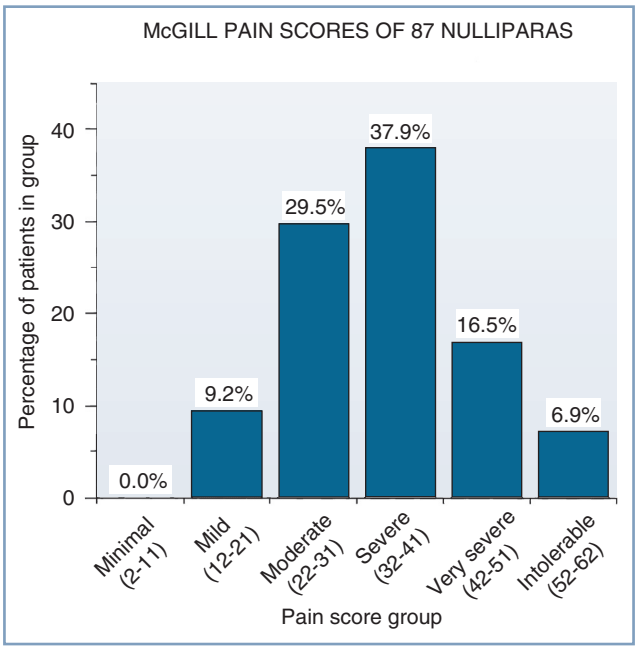

Fig. 21.1 The severity of pain during labor as assessed by the McGill Pain Questionnaire for 87 nulliparous women. (Modified from Melzack R, Taezner P, Feldman P, Kinch RA. Labour is still painful after prepared childbirth training. *Can Med Assoc J.* 1981; 125:357–363.)

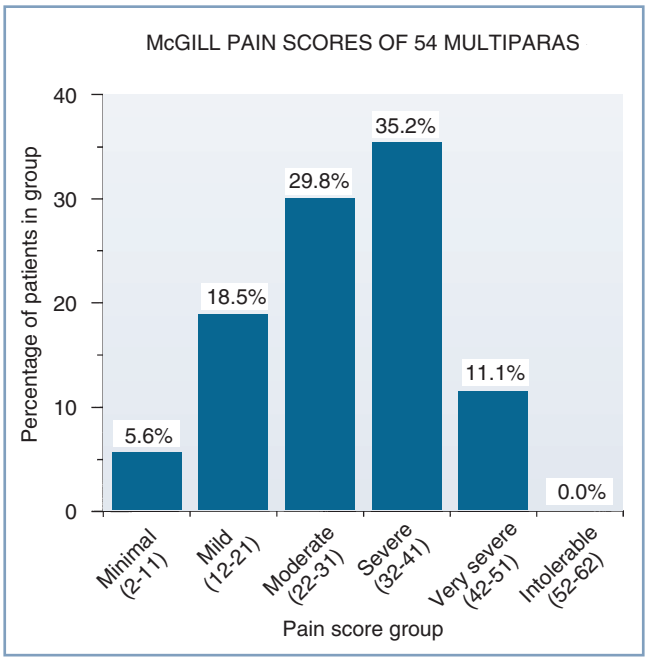

Fig. 21.2 The severity of pain during labor as assessed by the McGill Pain Questionnaire for 54 parous women. (Modified from Melzack R, Taezner P, Feldman P, Kinch RA. Labour is still painful after prepared childbirth training. *Can Med Assoc J.* 1981;125:357–363.)

analogue scales[5] to evaluate the maternal perception of pain during parturition. Melzack et al.[6,7] developed the McGill Pain Questionnaire to measure the intensity of labor pain for various conditions. They noted that labor pain is one of the most intense types of pain among those studied (see Fig. 20.2). Parous women had lower pain scores than nulliparous women, but responses varied widely (Figs. 21.1 and 21.2). Prepared childbirth training resulted in a modest decrease in the average pain score among nulliparous women, but it clearly did not eliminate pain in these women.[6,7]

CHILDBIRTH PREPARATION

History

The history of modern childbirth preparation began in the first half of the 20th century; however, it is important to review earlier changes in obstetric practice to understand the perceived need for a new approach. Before the mid-19th century, childbirth occurred at home in the company of family and friends. The specialty of obstetrics developed in an effort to decrease maternal mortality. Interventions initially developed for the management of complications became accepted and practiced as routine obstetric care. Physicians first administered anesthesia for childbirth during this period (see Chapter 1). The 1848 meeting of the American Medical Association included reports of the use of ether and chloroform in approximately 2000 obstetric cases.[8] The combination of morphine and scopolamine (i.e., twilight sleep) was introduced in the early 20th century. These techniques were widely used, and influential women demanded that they be made available to all parturients.[9] Together, these developments moved childbirth from the home and family unit to the hospital environment.[10] However, despite their desire for analgesia/anesthesia for labor and delivery, women began to resent the fact that they were not active participants in childbirth.

Beck et al.[11] wrote a detailed history of childbirth preparation. Dick-Read[12,13] reported the earliest method in his books, *Natural Childbirth* and *Childbirth Without Fear.* In his original publication, he asserted his belief that childbirth was not inherently painful. He opined that the pain of childbirth results from a "fear-tension-pain syndrome." He believed—and taught—that antepartum instruction about muscle relaxation and elimination of fear would prevent labor pain. Some readers incorrectly concluded that he advocated a return to primitive obstetrics, but this was not the case. Review of his practice reveals that he used the available obstetric techniques—including analgesia, anesthesia, episiotomy, forceps, and abdominal delivery—as appropriate for the individual patient. However, he cautioned against the routine use of these procedures, and he encouraged active participation of mothers in the delivery of their infants. Unfortunately, he did not use the scientific method to validate his beliefs.

Although Dick-Read was the earliest proponent of so-called "natural" childbirth, it was Fernand Lamaze[14] who introduced the Western world to psychoprophylaxis. His publications were based on techniques that he observed while traveling in Russia. Although his theories ostensibly were translations of teachings later published in the West by Velvovsky et al.,[15] they contained substantial differences and modifications. The "Lamaze method" became popular in the

United States after Marjorie Karmel[16] wrote about her childbirth experience under the care of Dr. Lamaze. Within 1 year of the publication of her book *Thank You, Dr. Lamaze: A Mother's Experiences in Painless Childbirth,* the American Society for Psychoprophylaxis in Obstetrics was born. Lamaze and Karmel published their experience at a time when organizations such as the International Childbirth Education Association and the La Leche League were formed.[17] These organizations actively and aggressively encouraged a renewed emphasis on family-centered maternity care, and society was ripe for the ideas and theories promoted by these organizations. Women were ready to actively participate in childbirth and to have input in decisions about obstetric and anesthetic interventions. Childbirth preparation methods were taught and used extensively, despite a lack of scientific validation of their efficacy.

In 1975, Leboyer[18] described a modification of natural childbirth in his book *Birth Without Violence.* He advocated childbirth in a dark, quiet room; gentle massage of the newborn without routine suctioning; and a warm bath soon after birth. He opined that these maneuvers result in a less shocking first-separation experience and a healthier, happier infancy and childhood. Although there are few controlled studies of this method, published observations do not support his claim of superiority.[19,20]

Physicians were the initial advocates of the various natural childbirth methods. Obstetricians had become increasingly aware that analgesic and anesthetic techniques were not harmless, and they supported the use of natural childbirth methods.[11] Subsequently, natural childbirth, like the methods of obstetric analgesia introduced earlier in the century, was actively promoted by lay groups rather than physicians.[21] Lay publications, national advocacy groups, and formal instruction of patients accounted for the greater interest in psychoprophylaxis and other techniques associated with natural childbirth.

Goals and Advantages

The major goals of childbirth education that were initially promoted by Dick-Read are taught with little modification in formal childbirth preparation classes today. Most current classes credit Lamaze with the major components of childbirth preparation, even though Dick-Read was the first to promote patient education, relaxation training, breathing exercises, and paternal participation.[11] Box 21.1 describes the goals of current childbirth preparation classes. In addition, some instructors and training manuals claim other benefits of childbirth preparation (Box 21.2),[22,23] although a 2015 review of two methods (Bradley method and HypnoBirthing) called for more rigorous study with transparent methods rather than self-reported outcomes.[24] A 2007 systematic review concluded that there is insufficient evidence to evaluate the efficacy of antenatal childbirth education on childbirth and parenting outcomes.[25] Existing studies are of poor quality and dated. Despite these shortcomings, childbirth preparation classes are widely available and attended.

Socioeconomic disparities exist in childbirth education class attendance.[26,27] In addition, the effect of childbirth education on attitude and childbirth experience depends in part on the social class to which the mother belongs. Most investigators have found that childbirth classes have a positive effect on the attitudes of both parents in all social classes, but this effect is more pronounced among "working class"[28] and indigent women[29]; this latter finding probably reflects the greater availability and use of other educational materials by middle- and upper-class women. Childbirth classes often are the only—or at least the primary—source of information for working class and indigent women.

Limitations

Limitations of the widespread application of psychoprophylaxis and other childbirth preparation methods remain. Proponents assume that these techniques are easily used during labor and delivery; however, Copstick et al.[30] concluded that this assumption is not valid. They found that patients were able to use the coping techniques in the early first stage of labor but that the successful use of the coping skills became less and less common as labor progressed. By the onset of the second stage, less than one-third of mothers were able to use any of the breathing or postural techniques taught during their childbirth classes.[30] The method of preparation influences the ability of the pregnant woman to use the breathing and relaxation techniques. Bernardini et al.[31] observed that self-taught pregnant women are less likely to practice the techniques during the prenatal period or to use the techniques during labor.

Childbirth preparation classes may create false expectations. If a woman does not enjoy the "normal" delivery discussed during classes, she may experience a sense of failure or inferiority. Both Stewart[32] and Guzman Sanchez et al.[33] have discussed the psychological reactions of women who were unable to use psychoprophylaxis successfully during labor

BOX 21.1 Goals of Childbirth Preparation

- Patient education about pregnancy, labor, and delivery
- Relaxation training
- Instruction in breathing techniques
- Participation of father/support person
- Early parental bonding

BOX 21.2 Purported Benefits of Childbirth Preparation

- Greater maternal control and cooperation
- Decreased maternal anxiety
- Reduced maternal pain
- Decreased maternal need for analgesia/anesthesia
- Shorter labor
- Diminished maternal morbidity
- Less fetal stress/distress
- Strengthened family relationships as a result of the shared birth experience

TABLE 21.1 Effects of Childbirth Preparation

and delivery. In addition, several women have written about their disappointment with the dogmatic approach of their childbirth instructors; these women described instructors who rigidly defined the "correct" way to have a "proper" birth experience.[34,35] There is, however, some evidence that antenatal childbirth education courses may help to ease fear of childbirth.[36]

Effects on Labor Pain and Use of Analgesics

Little scientific evidence supports the efficacy of childbirth preparation in mitigating labor pain. Psychology, nursing, obstetric, anesthesia, and lay journals provide extensive discussions of childbirth preparation, but most articles describe uncontrolled clinical experiences. Outcome studies often do not include a group of women who were randomly assigned to an untreated or a placebo-control group, and statistical analysis is often incomplete. Despite these shortcomings, supporters of childbirth preparation assume that it offers benefits for mother and child. Table 21.1 summarizes a few of the studies of Lamaze and other childbirth preparation techniques and their association with labor outcomes. The findings are not consistent. Some researchers have reported a *decreased* use of analgesics[37–39] or regional anesthesia,[37–41] shorter labor,[42] reduced performance of instrumental[37,38,41] and cesarean delivery,[41] and a lower incidence of nonreassuring fetal status,[41] whereas others have reported *no change* in the use of analgesics[41–45] or neuraxial analgesia,[43,44] length of labor,[38,39,41,43–46] performance of instrumental[43–45] and cesarean delivery,[38,43–45] or incidence of nonreassuring fetal status.[38,40,42,44] These diverse findings may reflect different patient populations, poor study design, or researcher bias.

To elucidate the effect of the coping techniques taught in childbirth classes, several investigators have attempted to quantify changes in pain threshold, pain perception, anxiety levels, and physiologic responses to standardized stimuli. Several studies have evaluated nonpregnant and nulliparous women in laboratory settings,[47–50] and another study evaluated pregnant women in the antepartum, intrapartum, and postpartum periods.[51] Conclusions varied according to the stimuli applied, the coping techniques studied, and the parameters analyzed. Together, these studies suggest that *practicing* these techniques facilitates their efficacy and that newer cognitive techniques (e.g., systematic desensitization, sensory transformation) may be more effective than traditional Lamaze techniques of varied breathing patterns and relaxation. Further studies may help refine childbirth preparation to maximize the positive psychophysiologic effects.

BOX 21.3 Nonpharmacologic Analgesic Techniques

Minimal Training/Equipment
- Emotional support
- Touch and massage
- Therapeutic use of heat and cold
- Hydrotherapy
- Vertical position

Specialized Training/Equipment
- Biofeedback
- Intradermal water injection
- Transcutaneous electrical nerve stimulation
- Acupuncture
- Hypnosis

NONPHARMACOLOGIC ANALGESIC TECHNIQUES

Nonpharmacologic analgesic techniques range from those that require minimal specialized equipment and training and are available to all patients to those that are offered only by institutions with the necessary equipment and personnel trained in their use (Box 21.3). Many studies have assessed nonpharmacologic methods of labor analgesia; however, most published studies have not fulfilled the requirements of the scientific method.[52–55] Several comprehensive reviews of alternative therapies for pain management during labor have been published,[52–54] providing a foundation for discussion with patients and obstetric providers. However, clinical evidence is insufficient to form the basis for an in-depth discussion of some of the more recent therapeutic suggestions, such as music therapy, aromatherapy, and chiropractic manipulation. These analgesic techniques may provide intangible benefits that are not easily documented by a rigorous scientific

method. Parturients may consider these benefits an integral and important part of their labor experience.

Continuous Labor Support

Some techniques that require minimum equipment and specialized training are taught as integral components of childbirth preparation classes. Continuous support during labor is essential to the process of a satisfying childbirth experience; typically, the parturient's husband or friend provides this support. This support appears most helpful for the parturient who lives in a stable family unit. At least one study noted that husband participation was associated with decreased maternal anxiety and medication requirements.[56] Others have found that emotional support provided by unfamiliar trained individuals (e.g., doulas) also has a positive effect.[57] Studies have evaluated the benefits of emotional support provided by doulas or other unrelated individuals on the mode of delivery, feelings about the birth experience, use of labor analgesia, oxytocin augmentation, length of labor, perineal trauma, breast-feeding outcomes, and Apgar scores, among other outcomes.[57] These studies all suggested that a patient's sense of isolation adversely affects her perception of labor. Further, the companionship of another woman who is not part of the medical establishment may reduce a parturient's anxiety more effectively than the companionship provided by her husband. In one study, women randomly assigned to receive intrapartum support from a friend or female relative (who was chosen by the parturient and trained as a doula) were more likely to have positive feelings about their delivery and had a higher rate of breast-feeding 6 to 8 weeks after delivery than women who were randomly assigned to receive usual care.[46]

A meta-analysis evaluated results from 26 studies that included 15,858 women who were randomly assigned to receive either continuous childbirth support or usual care (Table 21.2).[57] The pooled data suggested that women who received one-on-one support during labor were less likely to use any type of analgesia and report negative feelings about the childbirth experience, and were more likely to have a spontaneous vaginal delivery, although evidence was generally of low quality.[57] In addition, the mean duration of labor was slightly shorter (approximately 41 minutes) in the women who received continuous support during labor, and the likelihood of low 5-minute Apgar scores was less.

These results are fascinating and have important implications for obstetric care. The patient populations studied represent special situations, and the results may not be reproduced in all populations. For example, a large randomized, controlled trial in a North American hospital (in which intrapartum medical intervention is routine) found no differences in the rate of cesarean delivery or other labor outcomes between women randomly assigned to receive continuous labor support from a specially trained nurse and women who received usual care.[58] In general, results from trials in North America do not appear as striking as those from Europe or Africa.[52] The aforementioned systematic review of continuous labor support suggested that benefits were greater when the support person was present in a doula (trained labor companion) role.[57] Further studies should compare different models of continuous childbirth support and should include longer-term outcomes, including breast-feeding and postpartum depression.[57] Meanwhile, the preponderance of evidence suggests that all parturients should have access to emotional support, whether it is provided by the husband, a family member, a labor companion (e.g., doula), or professional hospital staff.

Touch and Massage

Various touch and massage techniques are discussed with women and their support persons during childbirth preparation classes. These techniques include effleurage, counterpressure to alleviate back discomfort, light stroking, and merely a reassuring pat.[52] There has been minimal scientific study of the effects of touch and massage on labor progress and outcome[59]; nonetheless, touch and massage provide a comfort that is appreciated by women during labor. These measures may be used by the parturient, her support person, or the professional staff members providing intrapartum care. The techniques are easily discontinued if the parturient desires. In some cases, touch and massage may reduce

TABLE 21.2 Systematic Review: Continuous Labor Support versus Usual Care

Outcome	Number of Trials	Number of Subjects	Relative Risk[a]	95% Confidence Interval
Use of neuraxial analgesia	9	11,444	0.93	0.88 to 0.99
Use of any analgesia	15	12,433	0.90	0.84 to 0.96
Spontaneous vaginal delivery	21	14,369	1.08	1.04 to 1.12
Instrumental vaginal delivery	19	14,118	0.90	0.85 to 0.96
Cesarean delivery	24	15,347	0.75	0.64 to 0.88
Negative feelings about childbirth experience	11	11,133	0.69	0.59 to 0.79
Labor length	13	5429	–0.69 h[b]	–1.04 to –0.34
Infant with a low 5-minute Apgar score	14	12,615	0.62	0.46 to 0.85

[b]Weighted mean difference.

discomfort. More often, touch and massage transmit a sense of caring, which fosters a sense of security and well-being.

Therapeutic Use of Heat and Cold

Another simple technique for alleviating labor pain is the therapeutic use of temperature (hot or cold) applied to various regions of the body. Warm compresses may be placed on localized areas, or a warm blanket may cover the entire body. Alternatively, ice packs may be placed on the low back or perineum to decrease pain perception. The therapeutic use of heat and cold during labor has not been studied in a rigorously scientific manner.[60,61] The use of superficial heat and cold for comfort is widespread (if not completely understood), and it has no discernible risk to the mother or the fetus.[52] Cold and heat should not be applied to anesthetized skin.

Aromatherapy

Aromatherapy is the use of essential oils, which are fragrant, volatile organic compounds obtained by distillation of plant material. The oils are commonly combined with a carrier oil and massaged into the skin, inhaled, or mixed in a bath.[62] Two commonly used oils are lavender and frankincense.[52] Studies evaluating the use of aromatherapy during labor are lacking.[62]

Hydrotherapy

Hydrotherapy may involve a simple shower or tub bath or may include the use of a whirlpool or large tub specially equipped for pregnant women. Purported benefits of hydrotherapy include decreased anxiety and pain and greater uterine contraction efficiency.[52] Results of randomized, controlled trials comparing water baths with usual care are inconsistent. For example, some studies have found no difference between groups in the use of pharmacologic analgesia,[63,64] whereas others have demonstrated a lower use in the water bath group.[65,66] A meta-analysis of 12 published trials involving 3243 women concluded that there was a reduction in the use of spinal/epidural/paracervical analgesia (risk ratio [RR], 0.90; 95% confidence interval [CI], 0.82 to 0.99) and duration of the first stage of labor (mean difference –32 minutes; 95% CI, –59 to –6 minutes) in women randomly assigned to water immersion compared with control subjects.[67] There were no differences in the rate of operative delivery or other maternal or neonatal outcomes, including maternal and neonatal infection. In summary, bathing, showering, and other hydrotherapy maneuvers are comfort measures with little risk to the mother and the infant, provided that appropriate monitoring continues during the immersion in water that is kept at body temperature.

Vertical Position

Several investigators have studied the effects of various positions on pain perception and labor outcome. These positions are broadly categorized as *vertical* (e.g., sitting, standing, walking, squatting) or *horizontal* (e.g., supine, lateral). A 2013 meta-analysis of 15 studies in 2503 women found that walking and the upright position during the first stage of labor were associated with shorter labor (mean difference –1.36 hours; 95% CI, –2.22 to –0.51) as well as a lower rate of cesarean delivery and epidural analgesia.[68] The authors noted study quality was variable, and there was a high degree of heterogeneity in the results; thus better quality trials are necessary to draw firm conclusions regarding the effect of position on labor outcomes.

Ambulation in the presence of neuraxial analgesia does not appear to influence the outcome of labor.[68–71] In a prospective, randomized study, Bloom et al.[69] noted that walking did not shorten the duration of the first stage of labor or reduce the requirement for oxytocin augmentation, the use of analgesia, or the requirement for operative delivery. They concluded that "walking neither enhanced nor impaired active labor and was not harmful to the mothers or their infants."[69] In a 2013 meta-analysis comparing outcomes in women with epidural analgesia randomized to upright and ambulant positions or recumbent positions,[68] there were no differences in any maternal or neonatal outcome, including mode of delivery.

A number of studies have assessed maternal position during the second stage of labor. There is renewed interest in the squatting or modified squatting position and its greater comfort for some women during childbirth. Most authorities have noted that Western women have insufficient muscular strength and stamina to maintain an unsupported squatting position for any length of time.[72–74] Squatting does not appear to alter pelvic dimensions.[75] Gardosi et al.[72] designed and studied a birth cushion that allows a modified, supported squat, which resulted in a higher incidence of spontaneous vaginal delivery and a lower incidence of perineal tears. Others have yet to substantiate the results of this trial.

Some studies have evaluated the use of a birth chair to facilitate delivery in the sitting position.[76–78] These studies noted no difference in length of the second stage of labor, mode of delivery, occurrence of perineal trauma, or Apgar scores in parturients who used a birth chair compared with those who did not. Of concern, two studies reported greater intrapartum blood loss and a higher incidence of postpartum hemorrhage in the birth-chair group.[77,78]

A 2017 systematic review of studies of maternal position in the second stage of labor in women without epidural analgesia concluded that currently published trials are generally of poor quality and the results should be interpreted with caution.[79] There may be a small reduction in duration of the second stage of labor and a lower rate of episiotomy and assisted deliveries, but a greater risk for postpartum hemorrhage.

A second 2017 systematic review assessed outcomes in women with epidural analgesia randomized to an upright or recumbent position for the second stage of labor.[80] The authors concluded that there are insufficient data to draw conclusions regarding the effects, if any, of parturient position in the second stage of labor in women with epidural analgesia. Although the authors of both systematic reviews[79,80] concluded that further study is required, many obstetricians and nurses believe that ambulation and the upright posture

result in a shorter labor that requires less analgesia. An alternative explanation for the observation that ambulatory parturients appear to have a less painful and shorter labor is that shorter, less painful labor is more likely to *allow* continued ambulation.

Other than the possibility of greater blood loss associated with the upright position during delivery, upright positions during most of labor are not associated with any harm to the mother or newborn and may aid maternal comfort. It is unclear whether birthing cushions or stools confer any benefit to the mother or the newborn.

Biofeedback

Biofeedback is a relaxation method that is used as an adjunct to the relaxation training taught in Lamaze classes and other childbirth education programs. Two biofeedback procedures may be applicable to the laboring woman: skin-conductance (autonomic) and electromyographic (voluntary muscle) relaxation. St James-Roberts et al.[81] demonstrated that electromyographic but not skin-conductance biofeedback techniques could be taught effectively in Lamaze classes. They noted no difference in length of the first stage of labor, use of epidural analgesia, incidence of instrumental delivery, or Apgar scores among electromyographic, skin-conductance, and control groups. In a small study, Duchene[82] reported reduced pain perception during labor and delivery, and a lower rate of epidural analgesia use (40% versus 70% for a control group) with electromyographic biofeedback; there was no difference between groups in Apgar scores. A 2011 systematic review assessing the effectiveness of biofeedback found that most studies had a high risk for bias, and although some studies demonstrated reduced use of analgesics with biofeedback, there was insufficient evidence to conclude that biofeedback is efficacious.[83] Biofeedback training does not appear to confer substantial benefit beyond that of traditional relaxation training taught in childbirth education classes.

Intradermal Water Injections

Intradermal or intracutaneous water injections are used to treat lower back pain, which is a common complaint during labor. The afferent nerve fibers that innervate the uterus and cervix, as well as the nerve fibers that innervate the lower back, all enter the spinal cord at the T10 to L1 spinal segments; therefore, a component of the pain may be referred pain. The technique consists of injecting 0.05 to 0.1 mL of sterile water, with an insulin or tuberculin syringe, at four sites on the lower back (i.e., over each posterior superior iliac spine, and at 1 cm medial and 3 cm caudad to the posterior superior iliac spine on both sides of the back, for a total of four injections) (Fig. 21.3). The injections themselves are acutely painful for 20 to 30 seconds, but as the injection pain fades, so does lower back pain. A 2012 systematic review assessing the effectiveness of water injections during labor concluded that the seven included studies were at high risk for bias and that there is little robust evidence that sterile water injections effectively reduce back pain or labor pain.[84]

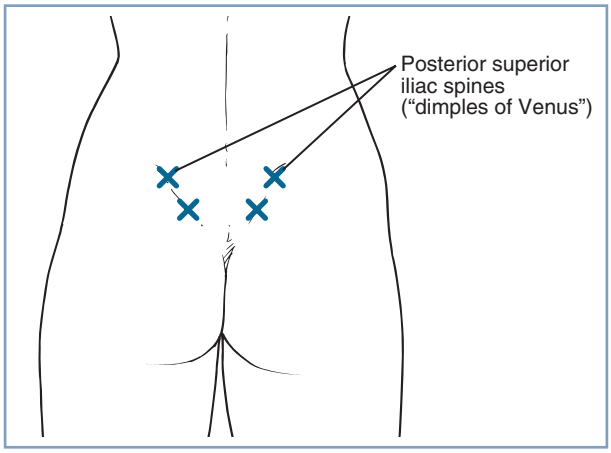

Fig. 21.3 Placement of intradermal water blocks *(x)*. Approximately 0.05 to 0.1 mL of sterile water is injected intradermally to form a small bleb over each posterior superior iliac spine and at 3 cm below and 1 cm medial to each spine on both sides of the back (i.e., for a total of four injections). The exact locations of the injections do not appear to be critical to the block success. (From Simkin P. Update on nonpharmacologic approaches to relieve labor pain and prevent suffering. *J Midwifery Womens Health*. 2004;49:489–504.)

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) involves the transmission of low-voltage electrical current to the skin via surface electrodes. Advantages of TENS are that it is easy to use and discontinue, is noninvasive, and has no demonstrable harmful effects on the fetus. The only stated disadvantage is the occasional interference with electronic fetal heart rate monitoring. It is most widely used for childbirth in Scandinavia and the United Kingdom.[52] Chao et al.[85] evaluated the use of TENS at specific acupuncture points and observed a reduction in pain perception more commonly in the study group than in the control group. However, a 2011 systematic review of nine trials in more than 1000 women concluded that TENS did not reduce labor pain and did not reduce the use of additional analgesic agents.[86] There also was no effect on the duration of labor or the incidence of instrumental delivery. Patients tend to rate the device as helpful despite the fact that it does not reduce the use of additional analgesics. Advocating widespread use of TENS does not seem warranted, although it may be offered to women if they desire to use it.

Acupuncture/Acupressure

Traditional Chinese medicine includes extensive use of acupuncture. Given that acupuncture can provide analgesia, there is interest in its use for intrapartum analgesia, although this is not a traditional use of the method. Early observational reports described conflicting results as to the efficacy of intrapartum acupuncture. Given the historic lack of use of acupuncture in obstetric patients, there is a lack of standardization of the acupuncture points to be stimulated.

Several randomized, controlled trials have compared "real" acupuncture to "false" or "minimal" acupuncture

using shallow insertion of needles in non-acupuncture points,[87–89] whereas other investigators have used a control group that did not receive acupuncture.[90,91] Four randomized trials found that pain scores were lower in women randomly assigned to receive acupuncture treatment, as was the rate of use of other modes of analgesia (e.g., epidural and systemic meperidine).[87,88,90,91] These results suggest that acupuncture may hold promise for the treatment of labor pain.[87,88,90,91] Hantoushzadeh et al.[88] and Asadi et al.[89] also observed a shorter duration of the active phase of labor. No adverse maternal or fetal effects were identified. Other randomized studies did not find reduced pain scores with acupuncture.[92,93]

A randomized, controlled trial of acupressure (treatment) compared with touch (control) at the SP6 acupoint found lower pain scores and a shorter duration of labor in the acupressure group.[94] A 2011 systematic review and meta-analysis of 13 acupuncture trials including 1986 women concluded that acupuncture may hold promise for labor analgesia; however, larger studies are required for definitive conclusions.[95] All of the randomized, controlled acupuncture studies were performed outside the United States, in countries (primarily Scandinavian) in which the use of neuraxial labor analgesia is less widespread than in the United States. Also, the use of acupuncture requires trained personnel. (Scandinavian midwives have been trained to administer acupuncture.) For these reasons, it is unlikely that either acupuncture or acupressure will gain widespread acceptance in the United States for intrapartum analgesia.

Hypnosis

The use of hypnosis for obstetric analgesia is not new.[96] Early proponents touted safety for the mother and the fetus, lower analgesic requirements, and shorter labor as the major advantages of intrapartum hypnosis. Whether hypnosis differs substantially from other childbirth preparation techniques is an unresolved controversy. Fee and Reilley[97] concluded that the breathing and relaxation exercises used in childbirth preparation do not represent a hypnotic trance; support for their conclusion is provided by the successful teaching of childbirth preparation exercises to women who are not susceptible to hypnosis. However, women susceptible to hypnosis may achieve a state much like a hypnotic trance when using the same exercises.

Instruction in the techniques of self-hypnosis occurs before the onset of labor and may entail visits to the hypnotist or involvement in a childbirth education program such as HypnoBirthing. Proponents previously suggested that successful hypnosis training should begin early in the third trimester. Rock et al.[98] found that hypnosis could be introduced to untrained, nonvolunteer patients during labor. A 2016 meta-analysis included nine randomized controlled trials of hypnosis; in eight trials the intervention was antenatal hypnosis training, and in one trial the intervention was during labor.[99] Women in the hypnosis group were less likely to use pharmacologic analgesia (RR 0.73; 95% CI, 0.57 to 0.94), but the evidence was judged to be of very low quality.[99] There were no differences in any other outcomes, including coping with labor and rate of spontaneous vaginal birth. The authors concluded that further high-quality, large trials are needed.

In summary, hypnosis has at least the following three limitations: (1) antepartum training sessions are required, (2) trained hypnotherapists must be available during labor, and (3) it offers no clear benefit. Therefore, hypnosis is unlikely to attain widespread use during childbirth.

IMPLICATIONS FOR ANESTHESIA PROVIDERS

Childbirth preparation classes and nonpharmacologic analgesic techniques are not comparable to neuraxial analgesia/anesthesia for the relief of labor pain. Thus, some might wonder whether it is important or useful for anesthesia providers to have knowledge of these techniques. If our only obligation to the obstetric patient is a technical one (i.e., to eliminate pain safely with the use of neuraxial analgesia), knowledge of these techniques is perhaps superfluous. However, the practice of obstetric anesthesia should not be limited to the performance of pain-relieving procedures; our contributions to the care of the obstetric patient and her family should extend beyond the administration of neuraxial analgesia.

Much has been written in professional and lay journals concerning the "proper" childbirth experience. Each patient's expectations of labor influence her childbirth experience. There is a growing movement toward patient-centered maternity care, and a definite need for widespread adoption of practices that support these shifts toward inclusion of women's values and beliefs in the birthing process.[100] Women currently view childbirth from the perspective of educated consumers; they expect to have choices and a level of control during childbirth. We may not always be comfortable with this situation, but it is a reality for modern obstetric practice. Our challenge is to provide safe, effective analgesia in a nonthreatening, "homelike" environment. We are not solely responsible for a patient's childbirth experience, but our interactions with the patient, her family, and her obstetrician will influence her perception of childbirth.[101] In a 2013 qualitative study from Montreal, Canada, 17 multidisciplinary health professionals and administrators, as well as 157 women with different levels of obstetric risk, parity, and type of delivery, were interviewed regarding barriers to—and facilitators of—provision of humanized obstetric care.[101] Major contributors to women's satisfaction during childbirth were related to the presence of a competent provider who provided a caring and humane presence during labor and delivery, while still providing medical interventions when necessary.

Anesthesia providers must become effective educators as well as health care providers. Patients should have realistic expectations about the pain of labor and the variability of individual labor patterns. They should be encouraged to define "success" as a positive childbirth experience regardless of the mode of delivery, use of analgesia and anesthesia, or

other arbitrary definitions. An obstetrician advised prospective mothers[102]:

> *If you do end up choosing some form of pain relief during labor, do not feel inadequate if a friend had her baby without assistance. Some labors are more intense than others. Ultimately, holding your baby in your arms is more important than the method you used to bring her into the world.*

Anesthesia providers may effectively provide similar advice. Unfortunately, anesthesia providers usually have little involvement in prenatal education classes. Our active participation in childbirth education classes may help patients receive more accurate information about the risks and benefits of analgesia/anesthesia for labor, vaginal delivery, and cesarean delivery. Anesthesia providers can encourage childbirth instructors to prepare patients for the unexpected and to acknowledge that the commonly described "typical" labor may, in fact, be atypical. Well-informed patients are more likely to accept the interventions that may become necessary during labor. Women with medical or obstetric diseases that may increase anesthetic risk should be encouraged to discuss these problems with an anesthesia provider before the onset of labor; thus, we must develop procedures to facilitate antepartum consultation. In a survey study, Beilin et al.[103] found that most women would prefer a prelabor visit with their anesthesiologist. In summary, the active participation of the anesthesia provider in childbirth education will lead women to perceive the anesthesia provider as an integral part of the obstetric care team.

Some nonpharmacologic analgesic techniques may have benefits other than decreased pain perception. For example, some obstetricians and nurses believe that ambulation and subsequent squatting (or use of a birth cushion) shortens labor and increases the rate of spontaneous vaginal delivery. Even if this belief proves not to be true, many women prefer to be mobile during labor and, at a minimum, to retain the ability to walk to the bathroom. We should attempt to develop and use analgesic techniques that take advantage of these relatively simple maneuvers. For example, the use of intrathecal opioids during early labor allows for continued ambulation and the use of showers and/or tubs. Some techniques of epidural analgesia allow sitting with support. Finally, epidural analgesia/anesthesia does not eliminate the beneficial effects of other comfort measures, such as massage, and continued emotional support from family and friends.

Whenever possible, anesthesia providers should provide safe anesthetic care that is compatible with reasonable patient expectations. Future studies on the efficacy of childbirth education, nonpharmacologic analgesic techniques, and neuraxial analgesic techniques should evaluate the patient's overall experience and satisfaction rather than limit assessment to the usual measures of obstetric outcome. In an editorial that accompanied a study of walking in labor,[69] Cefalo and Bowes[104] commented, "In the end, the nurses, midwives, and physicians who attend a woman with compassion, understanding, and professionalism are the most important factors in the management of any labor."

KEY POINTS

- Childbirth preparation does not eliminate the pain of labor or substantially reduce the use of analgesia/anesthesia, but it does decrease the anxiety associated with labor.
- Emotional support provided by doulas reduces the use of analgesics, the duration of labor, and the incidence of operative deliveries in selected patient populations.
- Biofeedback, transcutaneous electrical nerve stimulation, acupuncture, and hypnosis may provide mild analgesic benefits for some patients, but high-quality evidence is lacking.
- Intradermal water injections may provide treatment of low back pain during labor.
- Anesthesia providers should become active participants in childbirth education. We should encourage and facilitate the honest discussion of the risks and benefits of the analgesic/anesthetic techniques available at our hospitals.
- No nonpharmacologic technique consistently provides the quality of intrapartum pain relief that is provided by neuraxial analgesia.

Systemic Analgesia: Parenteral and Inhalational Agents

Thunga Setty, MBChB, FRCA, Roshan Fernando, MD, FRCA

CHAPTER OUTLINE

Systemic drugs have been used to decrease the pain of childbirth since 1847, when James Young Simpson used diethyl ether to anesthetize a parturient with a deformed pelvis. Since that time, the provision of labor analgesia has advanced significantly owing to a heightened awareness of the neonatal effects of heavy sedation or general anesthesia administered during vaginal delivery and a greater desire of women to actively participate in childbirth.

Neuraxial (i.e., epidural, spinal, combined spinal-epidural [CSE]) analgesic techniques have replaced systemic drug administration as the preferred method for intrapartum analgesia in the United States and Canada (Table 22.1).[1,2] By contrast, in the United Kingdom, fewer than one-third of parturients receive a neuraxial analgesic technique during labor and vaginal delivery.[3]

Despite the increased use of neuraxial analgesia for labor, the use of systemic analgesia remains a common practice in many institutions worldwide for several reasons. Many women labor and deliver in an environment where the provision of safe neuraxial analgesia is not available. Some parturients decline neuraxial analgesia or choose to receive systemic analgesia during early labor. Finally, some women may have a medical condition that contraindicates a neuraxial procedure (e.g., coagulopathy) or presents technical challenges (e.g., severe scoliosis, the presence of spinal hardware).

PARENTERAL OPIOID ANALGESIA

Opioids are the most widely used systemic medications for labor analgesia. These compounds are agonists at opioid receptors (Table 22.2). Their popularity lies in their low cost, ease of use, and the lack of need for specialized equipment and personnel. However, parturients commonly report dissociation from the reality of pain rather than complete analgesia. Although opioid use is associated with a high frequency of maternal side effects (e.g., nausea, vomiting, delayed gastric emptying, dysphoria, drowsiness, hypoventilation) and the potential for adverse neonatal effects, the availability of patient-controlled delivery systems has renewed interest in their administration during labor.

There is little scientific evidence to suggest that one opioid is superior to another; most often, drug selection is based on local policy or personal preference (Table 22.3). The efficacy

TABLE 22.3 Systemic Opioids for Labor Analgesia

Drug	Usual Dose (IV/IM)	Time to Peak Effect (IV/IM)	Duration of Action	Comments
Meperidine	25–50 mg IV 50–100 mg IM	5–10 min IV 45 min IM	2–3 h	Maximal neonatal depression 3–5 h after dose Has an active metabolite with a long half-life
Morphine	2–5 mg IV 5–10 mg IM	10 min IV 30 min IM	3–4 h	Possibly more neonatal respiratory depression than with meperidine Has an active metabolite
Diamorphine	5–10 mg IV 5–10 mg IM	2–5 min IV 5–10 min IM	90 min	Morphine prodrug More euphoria, less nausea than with morphine
Fentanyl	25–50 μg IV	2–4 min IV	30–60 min	Usually administered as an infusion or by PCA Accumulates during an infusion Less neonatal depression than with meperidine
Nalbuphine	10–20 mg IV 10–20 mg IM/SQ	2–3 min IV 15 min IM/SQ	3–6 h	Opioid agonist/antagonist Ceiling effect on respiratory depression Lower neonatal neurobehavioral scores than with meperidine
Butorphanol	1–2 mg IV 1–2 mg IM	5–10 min IV 30–60 min IM	4–6 h	Opioid agonist/antagonist Ceiling effect on respiratory depression
Meptazinol	50–100 mg IM	30 min IM	2–3 h	Partial opioid agonist Less sedation and respiratory depression than with other opioids
Pentazocine	30–60 mg IV 30–60 mg IM	2–3 min IV 20 min IM	3–4 h	Opioid agonist/antagonist Psychomimetic effects possible
Tramadol	50–100 mg IV 50–100 mg IM	10 min IM	2–4 h	Lower efficacy and more side effects than with meperidine

IM, Intramuscular; *IV,* intravenous; *PCA,* patient-controlled analgesia; *SQ,* subcutaneous.

of systemic opioid analgesia and the incidence of side effects are largely dose-dependent rather than drug-dependent.

As a result of their high lipid solubility and low molecular weight (< 500 Da), all opioids readily cross the placenta by diffusion and are associated with the risk for neonatal respiratory depression and neurobehavioral changes. Opioids may also affect the fetus *in utero.* The fetus and neonate are particularly susceptible to opioid-induced side effects for several reasons. The metabolism and elimination of these drugs are prolonged compared with adults, and the blood-brain barrier is less well developed, allowing for greater central effects. Opioids may result in decreased variability of the fetal heart

rate (FHR), although this change usually does not reflect a worsening of fetal oxygenation or acid-base status. The likelihood of neonatal respiratory depression depends on the dose and timing of opioid administration. Even in the absence of obvious neonatal depression at birth, there may be subtle changes in neonatal behavior for several days. In a meta-analysis, Reynolds et al.[4] concluded that lumbar epidural analgesia was associated with improved neonatal acid-base status at delivery compared with systemic opioid analgesia using meperidine, butorphanol, or fentanyl. Similarly, in a multicenter randomized trial, Halpern et al.[5] demonstrated an increased need for active neonatal resuscitation in a parenteral, patient-controlled analgesia (PCA) opioid group, compared with a patient-controlled epidural analgesia group using a local anesthetic combined with an opioid (52% versus 31%).

Opioids are commonly administered as intermittent boluses, but newer synthetic opioids are increasingly administered by PCA. Because the mode of delivery influences a drug's pharmacologic profile, the opioids will be discussed by route of administration.

INTERMITTENT BOLUS PARENTERAL OPIOID ANALGESIA

Opioids may be given intermittently by subcutaneous, intramuscular, or intravenous injection. The route and timing of administration influence maternal uptake and placental transfer to the fetus. Subcutaneous and intramuscular routes have the advantage of ease of administration but are painful. Absorption varies with the site of injection and depends on local and regional blood flow; consequently, the onset, quality, and duration of analgesia are highly variable.

Intravenous administration is generally preferred when available, as it offers several advantages. The onset of analgesia is fast, the timing and magnitude of the peak plasma concentration of drug are predictable, and titration to desired effect is possible.

Morphine

First isolated in 1806 and named morphium after *Morpheus,* the Greek god of dreams, morphine was introduced and soon abandoned as a labor pain medication because of neonatal depression. Its intrapartum use reappeared in the early 1900s as a component of "twilight sleep," a combination of morphine and scopolamine; the analgesia produced would often result in maternal sedation and neonatal depression.

Morphine has a high affinity for μ-opioid receptors and is a potent long-acting analgesic. Infrequently used during labor, morphine can be given every 4 hours intravenously (0.05 to 0.1 mg/kg) or intramuscularly (0.1 to 0.2 mg/kg), with a peak effect observed in 10 and 30 min, respectively. The duration of action when given intravenously or intramuscularly is 3 to 4 h.[6]

Morphine is principally metabolized by conjugation in the liver, with up to 70% being transformed into the largely inactive morphine-3-glucuronide. The remainder is transformed into the active metabolite morphine-6-glucuronide, an opioid agonist that is 13 times more potent than morphine and has significant analgesic properties.[6] Both metabolites are excreted in the urine and have elimination half-lives of up to 4.5 hours in the presence of normal renal function. Morphine rapidly crosses the placenta, and a fetal-to-maternal blood concentration ratio of 0.96 is observed at 5 minutes. The elimination half-life of morphine is longer in neonates than in adults.

Maternal side effects include respiratory depression and histamine release, which may result in rash and pruritus. Like many opioids, morphine is emetogenic and is associated with sedation and dysphoria with increasing doses.[6]

The greatest neonatal concern of morphine is that of respiratory depression, which has been attributed to an increased permeability of the neonatal brain. In a small study, Way et al.[7] observed that intramuscular morphine given to newborns seemed to cause greater respiratory depression than an equipotent dose of meperidine when response to carbon dioxide was measured.

Pregnancy alters the pharmacokinetics of morphine. Greater plasma clearance, shorter elimination half-life, and earlier peak metabolite levels occur in pregnant women than in nonpregnant women. In theory, these characteristics should reduce fetal exposure. One study observed no cases of neonatal depression after morphine administration during labor, prompting the researchers to suggest that morphine use in labor should be reevaluated.[8] Subsequently, Olofsson et al.[9] assessed the analgesic efficacy of intravenous morphine during labor (0.05 mg/kg every third contraction, to a maximum dose of 0.2 mg/kg) and observed clinically insignificant reductions in pain intensity. These investigators also compared intravenous morphine (up to 0.15 mg/kg) with intravenous meperidine (up to 1.5 mg/kg) and found that both groups had high pain scores despite high levels of maternal sedation.[10]

A randomized controlled trial comparing morphine (2 mg) to intravenous acetaminophen (1000 mg) for early labor analgesia observed no differences in visual analogue scale (VAS) pain scores before and at 15 minutes and 1 hour.[11] However, within 2 hours of administration, significantly more women receiving acetaminophen required rescue analgesia (52.9% versus 17.6%, $P < .01$).

Meperidine

In 1947, meperidine (pethidine) was the first synthetic opioid to be used for intrapartum analgesia and quickly displaced morphine as the most common opioid given for labor analgesia in the United Kingdom.[12] An agonist that binds to both μ and κ opioid receptors, meperidine is estimated to provide 10% of the analgesic potency of morphine. The usual dose is 50 to 100 mg intramuscularly, which can be repeated every 4 hours. The onset of analgesia occurs in 10 to 15 minutes, but 45 minutes may be required to reach peak effect. The duration of action is typically 2 to 3 hours.

Meperidine is highly lipid soluble, readily crosses the placenta, and equilibrates between the maternal and fetal

compartments within 6 minutes. Meperidine is metabolized in the liver to normeperidine, a pharmacologically active metabolite that may cause prolonged neonatal side effects.[13]

Maternal administration of meperidine may reduce fetal aortic blood flow, fetal muscle activity, and FHR variability.[13] Sosa et al.[14] demonstrated that intravenous meperidine 100 mg, given during the first stage of labor, resulted in an increased incidence of umbilical cord arterial acidemia at delivery compared with a placebo. The risk for neonatal respiratory depression is least with maternal administration of meperidine within 1 hour of delivery, and greatest when administered 3 to 5 hours before delivery.[13]

Normeperidine accumulation is associated with altered neonatal behavior, manifesting as reduced duration of wakefulness, attentiveness, and breast-feeding.[15] Meperidine administration is associated with lower Apgar scores and muscle tone in the neonate. Maternal side effects are of less clinical concern, although there is a high incidence of nausea, vomiting, and dysphoria.

The maternal half-life of meperidine is 2.5 to 3 hours, whereas that of normeperidine is 14 to 21 hours.[6] The half-life of both compounds is increased by up to three times in the neonate as a result of reduced clearance, resulting in adverse effects up to 72 hours after delivery.[6] The action of meperidine, but not normeperidine, is reversed by naloxone; consequently, antagonism with naloxone may exacerbate normeperidine-induced seizures owing to suppression of the anticonvulsant effect of meperidine.

The quality of labor analgesia produced by meperidine 50 mg is comparable to that of intravenous acetaminophen 1000 mg; a greater incidence of adverse effects has been observed (64% versus 0%).[16]

The effect of meperidine on the progress of labor is unclear. Historically, meperidine has been given to decrease the length of the first stage of labor in cases of dystocia. However in 407 parturients diagnosed with dystocia, Sosa et al.[14] found no differences in the duration of active labor or operative delivery rates, but significantly greater need for oxytocin augmentation (RR 2.24, 95% CI, 1.13 to 4.43), with the administration of intravenous meperidine 100 mg compared with saline-placebo.

Despite these concerns, meperidine is the most common opioid given for labor analgesia worldwide; this is most likely the result of its familiarity, ease of administration, availability, and low cost.

Diamorphine

Diamorphine (3,6-diacetylmorphine, heroin) is a synthetic morphine derivative used for labor analgesia in 34% of obstetric units in the United Kingdom.[12] Diamorphine is twice as potent as morphine. As a prodrug, diamorphine has no direct affinity for opioid receptors, but it is rapidly hydrolyzed by plasma esterases to active metabolites, which are responsible for its clinical effect.[6] The metabolite 6-monoacetylmorphine is responsible for a significant proportion of analgesic activity, and it is further metabolized to morphine.[17]

Although diamorphine 5 to 10 mg can be given intravenously, the same dose given intramuscularly results in approximately 90 minutes of labor analgesia. Both diamorphine and its active metabolite 6-monoacetylmorphine are more lipid soluble than morphine, resulting in a faster onset of analgesia with more euphoria but less nausea and vomiting. These pharmacokinetic properties may predispose to maternal respiratory depression. Because of rapid placental transfer, neonatal respiratory depression may also occur, although this is often associated with high doses of diamorphine.[18]

Rawal et al.[18] investigated the relationship between a single intramuscular dose of diamorphine 7.5 mg, the umbilical cord blood concentration of free morphine, and neonatal outcomes. A significant negative correlation between the dose-delivery interval and umbilical cord blood morphine levels was observed, with no correlation between higher free morphine concentrations and lower 1-minute Apgar scores (and the need for neonatal resuscitation). These findings suggest that infants born shortly after diamorphine administration are at greater risk for respiratory depression.

In 133 pregnant women randomized to receive intramuscular diamorphine 7.5 mg or meperidine 150 mg, Fairlie et al.[19] found significantly greater reports of poor or no pain relief at 60 minutes in the group receiving meperidine, although approximately 40% of women in both groups requested a second-line analgesic agent. The incidence of maternal sedation was comparable, but the diamorphine group had less vomiting and higher neonatal Apgar scores at 1 minute.

Wee et al.[20] conducted a two-center double-blinded randomized controlled trial of 484 women receiving intramuscular diamorphine 7.5 mg or intramuscular meperidine 150 mg for labor analgesia. The analgesia with diamorphine was modestly better, despite the average length of labor being 82 minutes longer (95% CI, 39 to 124). No differences in maternal sedation, nausea and vomiting, or primary neonatal outcomes were observed.

Fentanyl

Fentanyl is a synthetic opioid that is highly lipid-soluble, protein-bound, and selective for the μ-opioid receptor, with an analgesic potency 100 times that of morphine and 800 times that of meperidine. Its rapid onset (peak effect, 2 to 4 minutes), short duration of action (30 to 60 minutes), and lack of active metabolites make it attractive for labor analgesia. Although intramuscular and intranasal routes are available, fentanyl is most commonly administered via the intravenous route and titrated to effect, often with a patient-controlled device.

Small doses of fentanyl undergo rapid redistribution, but large or repeated doses may accumulate.[6] Importantly, clearance of fentanyl by elimination represents only 20% of that occurring by redistribution, resulting in a rapid increase in context-sensitive half-time with an increased duration of infusion.[6] Fentanyl has a longer elimination half-life than morphine, but it is metabolized to several inactive metabolites in the liver that are excreted in the urine.

Fentanyl readily crosses the placenta as it is lipophilic; however, the average umbilical vein/maternal vein ratio remains low, most likely owing to a significant degree of maternal protein binding and drug redistribution. In a chronically instrumented sheep model, Craft et al.[21] detected fentanyl in fetal plasma as early as 1 minute after maternal administration; however, maternal plasma levels were approximately 2.5 times greater than fetal plasma levels.

Rayburn et al.[22] compared women receiving intravenous fentanyl (50 to 100 μg every hour at maternal request) with those who did not receive analgesia. All patients receiving fentanyl (mean 140 μg; range 50 to 600 μg) experienced brief analgesia (mean 45 minutes), sedation, and a transient reduction in FHR variability (mean 30 minutes). There were no differences between groups in neonatal Apgar scores, respiratory status, or Neurologic and Adaptive Capacity Scores (NACS). In a similar comparison of intravenous fentanyl (50 to 100 μg every hour) with an equianalgesic dose of meperidine (25 to 50 mg every 2 to 3 hours), Rayburn et al.[22] observed less sedation, vomiting, and neonatal naloxone administration with fentanyl, but no difference in NACS. The two groups experienced similarly high pain scores, suggesting that both drugs have poor analgesic efficacy at the studied doses.

Rezk et al[23] randomized 80 parturients in active labor to receive intravenous fentanyl or intramuscular pethidine. A mild to moderate decrease in pain scores in both groups, but a return to baseline scores, was observed within 3 hours of fentanyl administration. Meperidine was associated with more maternal nausea and vomiting ($P < .05$), but less need for neonatal resuscitation and naloxone administration ($P < .05$).

A randomized controlled trial of 156 parturients investigated the efficacy of intranasal (i.n.) fentanyl, subcutaneous (s.c.) fentanyl, and intramuscular (i.m.) meperidine. Significant, similar reductions in pain scores were observed in all groups at 30 minutes; however, greater satisfaction (i.n. fentanyl 82.9%, s.c. fentanyl 80.6%, and i.m. meperidine 44%, $P < .05$) and less sedation (i.n. fentanyl 7.3%, s.c. fentanyl 2.9%, and i.m. meperidine 44%) were observed in the fentanyl groups. In a pilot study aimed at assessing the practicality and tolerability of patient-controlled analgesia with i.n. fentanyl (54 μg, lockout interval 3 min) for providing ongoing labor analgesia,[24] most women reported satisfactory analgesia (78.2%), with a mean fentanyl dose of 734 μg over 3.5 hours, and a willingness to use it again (84.4%). However, 12.5% of neonates ($n = 4$) required bag-and-mask ventilation at birth.

Nalbuphine

Nalbuphine is a mixed agonist-antagonist opioid analgesic with agonist activity at κ-opioid receptors, thereby producing analgesia, and partial agonist activity at μ-opioid receptors, thus resulting in less respiratory depression.[17] A partial agonist is a drug that has receptor affinity but produces a submaximal effect compared with a full agonist, even when given at very high doses.[6]

Nalbuphine can be administered by intramuscular, intravenous, or subcutaneous injection, with a usual dose of 10 to 20 mg every 4 to 6 hours. The onset of analgesia occurs within 2 to 3 minutes of intravenous administration and within 15 minutes of intramuscular or subcutaneous administration. The drug is metabolized in the liver to inactive compounds that are then secreted into bile and excreted in feces.[17]

Nalbuphine and morphine are of equal analgesic potency and result in sedation and respiratory depression at similar doses. However, because of its mixed receptor affinity, nalbuphine demonstrates a ceiling effect for respiratory depression at a dose of 0.5 mg/kg.[17] Nalbuphine causes less nausea, vomiting, and dysphoria than morphine. Concerns that it may have an antianalgesic effect, particularly in men, led to the withdrawal of nalbuphine in the United Kingdom in 2003.[17]

Wilson et al.[25] performed a randomized, double-blinded comparison of intramuscular nalbuphine 20 mg and meperidine 100 mg for labor analgesia. Nalbuphine was associated with less nausea and vomiting but more maternal sedation. Analgesia was comparable between the groups. Neonatal neurobehavioral scores were lower in the nalbuphine group at 2 to 4 hours, but there was no difference between groups at 24 hours. The umbilical vein-to-maternal vein concentration ratio was higher with nalbuphine (mean ± SEM, 0.78 ± 0.03) than with meperidine (0.61 ± 0.02). A subsequent study failed to demonstrate an analgesic advantage with either drug but again reported transient neonatal neurologic depression with nalbuphine.[26]

Amin et al.[27] compared the neonatal outcome for women who received either nalbuphine or saline-control before elective cesarean delivery. They found lower 1-minute Apgar scores and a significantly longer time to sustained respiration in the nalbuphine group. However, 5-minute Apgar scores and umbilical cord blood gas measurements were similar between groups.

Nicolle et al.[28] evaluated the transplacental transfer and neonatal pharmacokinetics of nalbuphine administered intramuscularly or intravenously in 28 laboring women. The investigators found a high umbilical vein-to-maternal vein concentration ratio of 0.74, which did not correlate with the administered dose. The estimated neonatal half-life was 4.1 hours, which is greater than the adult half-life and, more importantly, longer than the half-life of naloxone. There was a transient reduction in FHR variability in 54% of the fetuses, which was not associated with the plasma concentration of nalbuphine. Analgesia was rated as effective by 54% of parturients.

Giannina et al.[29] compared the effects of intravenous nalbuphine and meperidine on intrapartum FHR tracings. Nalbuphine significantly reduced both the number of FHR accelerations and FHR variability, whereas meperidine had little effect.

A prospective pilot study of 302 nulliparous parturients (57 women who received nalbuphine, and a control group of 245 women who received neither nalbuphine nor epidural analgesia) reported a marked reduction in duration of the

active phase of the first stage of labor in the nalbuphine group (75 minutes versus 160 minutes in the control group); this effect appeared to be independent of oxytocin use.[30] Additional investigations are needed to verify this finding.

Butorphanol

Butorphanol is a synthetic opioid with κ-opioid receptor agonist and μ-opioid receptor antagonist properties that resemble those of nalbuphine. It is five times more potent than morphine and 40 times more potent than meperidine.[31] The typical dose during labor is 1 to 2 mg intravenously or intramuscularly. Butorphanol is 95% metabolized in the liver to inactive metabolites. Excretion is primarily renal. A plateau effect for analgesia and respiratory depression is noted, where butorphanol 2 mg produces respiratory depression similar to that of morphine 10 mg or meperidine 70 mg. However, butorphanol 4 mg results in less respiratory depression than morphine 20 mg or meperidine 140 mg.[31] Higher doses do not provide any additional pain relief or respiratory depression but will increase the likelihood of other side effects.[32]

Maduska and Hajghassemali[33] compared intramuscular butorphanol (1 to 2 mg) with meperidine (40 to 80 mg) and found comparable labor analgesia; similar umbilical vein-to-maternal vein concentration ratios (0.84 and 0.89, respectively); and no differences in FHR tracings, Apgar scores, time to sustained respiration, or umbilical cord blood gas measurements at delivery. Conversely, in a double-blinded comparison of intravenous butorphanol (1 or 2 mg) and meperidine (40 or 80 mg) during labor, Quilligan et al.[34] noted lower pain scores at 30 minutes and 1 hour after the administration of butorphanol. There was no significant difference in Apgar scores between the two groups of infants; however, the mean FHR was noted to be higher among those fetuses whose mothers received butorphanol.

Nelson and Eisenach[35] investigated the possible synergistic effect of giving both intravenous butorphanol and meperidine. Women received intravenous butorphanol 1 mg, meperidine 50 mg, or butorphanol 0.5 mg with meperidine 25 mg. All three groups reported a similar reduction in pain intensity; however, only 29% of the women achieved clinically significant pain relief. There was no difference among groups in maternal side effects or neonatal Apgar scores. The investigators concluded that there was no therapeutic benefit to combining the two drugs.

Atkinson et al.[36] performed a double-blinded trial of intravenous butorphanol (1 to 2 mg) and fentanyl (50 to 100 μg) administered hourly on maternal request. They found that butorphanol provided better analgesia initially, with fewer requests for additional drug doses or progression to epidural analgesia. There was no difference in adverse maternal or neonatal effects between the two groups.

Meptazinol

Meptazinol is a partial opioid agonist specific to μ-opioid receptors with a rapid onset of action (15 minutes after intramuscular administration). The intramuscular dose (50 to 100 mg) and duration of action for labor analgesia are similar to those for meperidine, with an adult half-life of 2.2 hours, and a neonatal half-life of 3.4 hours. Its partial agonist activity is thought to result in less sedation, respiratory depression, and risk for dependence compared with other opioid agonists. Meptazinol is metabolized by glucuronidation in the liver and then excreted in the urine. This process is more mature in the neonate than is the metabolic pathway of meperidine.

Theoretically, this rapid elimination should confer a lower incidence of adverse neonatal effects than occurs with meperidine. In a single-blinded study, Jackson and Robson[37] compared the same dose (100 mg if maternal weight was ≤ 60 kg, 125 mg if 61 to 70 kg, and 150 mg if ≥ 70 kg) of intramuscular meptazinol or meperidine. Meptazinol provided significantly better analgesia than meperidine but resulted in a similar frequency of maternal side effects.

Nicholas and Robson[38] subsequently compared intramuscular meptazinol 100 mg with meperidine 100 mg in a randomized, double-blinded trial in 358 parturients. Meptazinol provided significantly better pain relief at 45 and 60 minutes, but the two drugs provided a similar duration of analgesia, and there was no significant difference between groups in maternal side effects. Neonatal outcomes were similar between groups, except significantly more infants whose mothers had received meptazinol had an Apgar score of 8 or higher at 1 minute.

Other investigators have reported little difference in analgesic efficacy, maternal side effects, or neonatal outcomes between meptazinol and meperidine. In a study of 1100 patients, Morrison et al.[39] found that neither drug given at equal doses (150 mg in patients weighing > 70 kg, 100 mg in those weighing ≤ 70 kg) was effective at relieving pain. Maternal drowsiness was significantly less pronounced with meptazinol, but the incidence of vomiting was higher. FHR changes and neonatal outcomes, including Apgar scores, need for resuscitation, and suckling ability, were comparable. The overall use of naloxone was similar in the two groups, but if the dose-delivery interval exceeded 180 minutes, significantly more neonates in the meperidine group required naloxone.

De Boer et al.[40] assessed neonatal blood gas and acid-base measurements after maternal intramuscular administration of meptazinol (1.5 mg/kg) or meperidine (1.5 mg/kg) during labor. Capillary blood gas measurements at 10 minutes of life showed a significantly lower pH and a higher $Paco_2$ in the meperidine group, although this difference resolved by 60 minutes. These findings suggest that meptazinol causes less neonatal respiratory depression.

Meptazinol may confer some benefits over meperidine in early neonatal outcome, but it is not widely used. A recent survey indicated that it is the intramuscular labor analgesic of choice in only 14% of obstetric units in the United Kingdom.[12] The cost of meptazinol is considerably higher than that of meperidine. Meptazinol is not available in the United States.

Pentazocine

Pentazocine is a selective κ-opioid receptor agonist with some weak antagonist activity at μ-opioid receptors.[17] It may be given orally or systemically by intramuscular or intravenous

injection. The typical parenteral adult dose is 30 to 60 mg, which is equivalent to morphine 10 mg. Onset of action occurs within 2 minutes when given intravenously and within 20 minutes if given by the intramuscular route. Metabolism occurs in the liver by oxidation and glucuronidation; metabolites are then excreted in the urine.

Pentazocine causes similar respiratory depression to that seen with equipotent doses of morphine and meperidine, but it exhibits a ceiling effect with doses in excess of 60 mg. Psychomimetic effects (e.g., dysphoria, hallucinations) may complicate its use, particularly with increasing doses.

In a double-blinded study of 94 laboring women who received intramuscular administration of pentazocine (up to 60 mg) and meperidine (up to 150 mg), Mowat and Garrey[41] observed equivalent and adequate analgesia for approximately 40% of women in each group. The incidence of sedation was comparable between groups, and fewer women in the pentazocine group complained of nausea and vomiting.

In a randomized study comparing intramuscular administration of pentazocine 30 mg with tramadol 100 mg in 100 laboring women, Kuti et al.[42] observed greater analgesia in the pentazocine group at 1 hour, with a longer time to subsequent request for additional analgesia (181 minutes versus 113 minutes, $P < .05$). The overall analgesic effect of both drugs was modest, with only 30% to 50% of women reporting satisfactory pain relief. More women in the pentazocine group were drowsy, but the result did not achieve statistical significance. There were no cases of maternal respiratory depression, and there was no difference between groups in neonatal outcomes. The investigators concluded that pentazocine provides better labor analgesia than tramadol.

Tramadol

Tramadol is an atypical, weak, synthetic opioid that has affinity for all opioid receptors, but particularly the μ-opioid subtype. A racemic mixture of two enantiomers, the analgesic properties of tramadol (+) are mediated via inhibition of the central neuronal reuptake of serotonin, while tramadol (−) inhibits norepinephrine reuptake.[43] Tramadol can be administered orally or by intramuscular or intravenous injection at a dose of 50 to 100 mg every 4 to 6 hours in adults.

The analgesic potency of tramadol is equal to that of meperidine and one-fifth to one-tenth that of morphine. In equianalgesic doses, tramadol causes less respiratory depression than morphine; at usual doses, no clinically significant respiratory depression occurs. The onset of analgesia is within 10 minutes of intramuscular administration, with an effective duration of 2 to 4 hours.

Tramadol is metabolized by demethylation and glucuronidation in the liver to several metabolites, one of which has independent analgesic activity (O-desmethyltramadol [M1]). The metabolites are almost entirely excreted in the urine. The elimination half-life is approximately 5 to 6 hours, whereas that of the active metabolite is 9 hours. Clinical experience in its use over 30 years is substantial. Since pregnant and breast-feeding women were excluded from randomized phase 1 to 3 clinical trials before marketing, research into its use in pregnancy and lactation is limited, and it is now difficult to conduct postmarketing clinical research in these populations.[43]

Tramadol and its active metabolite M1 readily cross the placenta, and an umbilical vein-to-maternal vein ratio of 0.94 has been observed at delivery.[44] Neonates possess complete hepatic capacity for metabolism of tramadol to its active metabolite M1. The elimination profile of M1 suggests a terminal half-life of 85 hours because of its requirement for renal elimination, which is an immature process in neonates. An observational study of women given intramuscular tramadol in doses up to 250 mg for labor analgesia[44] resulted in normal Apgar scores and NACS, with no correlation with tramadol or M1 concentrations. However, the single neonate who required naloxone had the highest plasma concentration of tramadol.

Tramadol for maternal pain relief in labor produces limited analgesic benefit. In a comparison of intramuscular tramadol 100 mg and meperidine 100 mg for labor analgesia, Keskin et al.[45] observed greater pain relief and a lower incidence of nausea and fatigue with meperidine. There was no significant difference between groups in neonatal outcome, but more infants in the tramadol group required supplemental oxygen for respiratory distress and hypoxemia. The investigators concluded that meperidine provided superior analgesia and was associated with a better side-effect profile.

By contrast, Viegas et al.[46] conducted a randomized, double-blinded trial to compare intramuscular administration of tramadol 50 mg, tramadol 100 mg, and meperidine 75 mg. Tramadol 100 mg and meperidine 75 mg provided similar labor analgesia; however, a higher incidence of maternal and neonatal adverse effects was observed with meperidine.

Khooshideh and Shahriari[47] evaluated the intramuscular administration of tramadol 100 mg or meperidine 50 mg on labor duration and analgesic efficacy in 160 parturients. The investigators observed that tramadol was associated with a reduced duration of both the first stage (140 versus 190 minutes, $P < .001$) and the second stage of labor (25 versus 33 minutes, $P = .001$). There was no difference in median and maximum pain scores between groups 1 hour after drug administration; however, lower pain scores were observed during the second stage of labor in the meperidine group. Nausea, vomiting, and drowsiness occurred less frequently in the tramadol group.

Shetty et al.[48] observed no difference with the intramuscular injection of tramadol 1 mg/kg compared with pentazocine 30 mg for labor analgesia; however, by the end of the first stage of labor, 55% and 60% of women rated their pain as severe and very severe, respectively. The mean injection to delivery interval was significantly shorter in the tramadol group compared with the pentazocine group.

PATIENT-CONTROLLED ANALGESIA

Patient-controlled analgesia has been used to control postoperative pain for several decades and for the provision of labor analgesia in more recent years. First described in women with

thrombocytopenia who were unable to undergo a neuraxial analgesia procedure, its use has grown in availability and popularity. A 2007 survey demonstrated that 49% of obstetric units in the United Kingdom offered PCA for labor analgesia.[49] Purported advantages of PCA include (1) superior pain relief with lower doses of drug, (2) less risk for maternal respiratory depression compared with bolus intravenous administration, (3) less placental transfer of drug, (4) less need for antiemetic agents, and (5) greater patient satisfaction.[50] The smaller, more frequent dosing used with this mode of analgesia may result in a more stable plasma drug concentration and a more consistent analgesic effect compared with that of intermittent bolus administration regimens.[50]

PCA represents an alternative method of labor analgesia when neuraxial analgesia is not requested or is unavailable, contraindicated, or unsuccessful. The parturient can tailor the administration of analgesia according to her individual needs, and with some regimens the bolus dose can be altered to allow further titration of analgesia as labor progresses.

However, PCA for labor is not without limitations. Despite the frequency of dose administration, the coordination of peak opioid concentrations with uterine contractions can be difficult and result in suboptimal analgesia. In addition, the relatively small doses of opioid may be less effective at controlling pain as labor progresses. Finally, a number of maternal and fetal side effects have been described (see later discussion). A variety of drugs, doses, and regimens have been studied, including comparisons of PCA with and without a continuous intravenous infusion (Table 22.4).

Meperidine

Meperidine was the first opioid to be used for PCA during labor. Isenor and Penny-MacGillivray[51] compared PCA meperidine (background infusion 60 mg/h with bolus doses of 25 mg, up to a maximum dose of 200 mg) with intermittent intramuscular meperidine (50 to 100 mg every 2 hours). Women in the PCA group reported lower pain scores than women in the intramuscular group, even when adjustment was made for the increased total amount of meperidine used.[51] There was no difference in maternal side effects, FHR abnormalities, or neonatal Apgar scores between groups.

When administered by PCA, meperidine appears to be less effective than shorter-acting opioids. Douma et al.[52] randomized parturients in labor to receive either meperidine (49.5-mg loading dose, 5-mg bolus dose with 10-min lockout, maximum total dose 200 mg), fentanyl (50-μg loading dose, 20-μg bolus dose with 5-min lockout, maximum dose 240 μg/h), or remifentanil (40-μg loading dose, 40-μg bolus dose with 2-min lockout, maximum dose 1200 μg/h). Meperidine provided the least effective analgesia, with no change in pain scores from baseline at 2 hours after administration and the highest rate of conversion to epidural analgesia.

Morphine and Diamorphine

Morphine and diamorphine are rarely administered by PCA for labor analgesia in parturients with a live fetus, but they are an option for women with intrauterine fetal demise.[49] The accumulation of the active metabolite morphine-6-glucuronide, which is a potent respiratory depressant, is a concern in mothers with a live fetus. No studies have compared the analgesic efficacy of morphine administered by PCA versus intermittent bolus administration during labor. In a single study of diamorphine, administered by either PCA or intermittent intramuscular bolus doses, less effective analgesia and lower satisfaction scores were observed in the PCA group.[53]

Fentanyl

The pharmacokinetic profile for fentanyl (i.e., rapid onset, high potency, short duration of action, absence of active metabolites) has resulted in its selection as one of the most commonly used opioids for PCA during labor and delivery. In the United Kingdom, it is used in 26% of the units that offer PCA during labor.[49]

Nikkola et al.[54] observed that fentanyl PCA (loading dose 50 μg, bolus 20 μg, lockout interval 5 min) provided a moderate reduction in labor pain in 50% of the parturients receiving this mode of analgesia; however, less overall pain relief was experienced when compared with a group that received epidural analgesia. The use of fentanyl was also associated with a higher incidence of maternal dizziness and sedation.

Rayburn et al.[55] compared fentanyl PCA (bolus 10 μg, lockout interval 12 min) with intermittent intravenous nurse-administered boluses (50 to 100 μg every hour, on demand). The degree of analgesia, adverse maternal effects, and neonatal outcomes (e.g., Apgar scores, naloxone requirement, neurobehavioral scores) were similar between the two groups. The two groups used a similar total amount of fentanyl, had comparable umbilical serum concentrations of fentanyl, and had incomplete analgesia during late labor.

Morley-Forster and Weberpals[56] observed a 44% incidence of moderate neonatal depression (1-minute Apgar score < 6) in a retrospective review of 32 neonates whose mothers had

TABLE 22.4 Opioids Used for Intravenous Patient-Controlled Analgesia in Labor

Drug	Bolus Dose	Lockout Interval (min)
Meperidine	5–15 mg	10–20
Nalbuphine	1–3 mg	6–10
Fentanyl	10–25 μg	5–12
Alfentanil	200 μg (+ 200 μg/h infusion)	5
Remifentanil (bolus only)	0.2–0.8 μg/kg (low dose initially, then titrated to effect)	2–3
Remifentanil (background infusion with bolus dose)	Infusion rate: 0.025–0.1 μg/kg/min Bolus dose: 0.25 μg/kg	2–3

received fentanyl PCA (at various initial doses, basal infusion rates, and lockout intervals) during labor. A total of 9.4% of the neonates required naloxone; the total dose of fentanyl was significantly higher in the mothers of neonates who required naloxone than in those who did not (mean ± SD, 770 ± 233 μg versus 298 ± 287 μg, respectively). By contrast, in a retrospective evaluation of fentanyl PCA (loading 50 μg, bolus 20 μg, lockout interval 5 min) compared with no analgesia during labor, Hosokawa et al.[57] observed lower mean umbilical arterial blood pH measurements, but comparable Apgar scores and no requirement for naloxone or bag-and-mask ventilation in the 129 neonates whose mothers received fentanyl.

Alfentanil

Alfentanil is a highly selective μ-opioid receptor agonist that is administered by the intravenous route only.[17] Although infrequently used during labor, it is typically administered by PCA. A fentanyl derivative, it is approximately 10 times less potent than fentanyl. It is less lipophilic and more protein bound than its parent compound, resulting in a smaller volume of distribution. Its low volume of distribution and low pK_a result in a rapid onset (within 1 minute), a short duration of action, and rapid clearance (elimination half-life of 90 minutes). Furthermore, its context-sensitive half-time is shorter than that of fentanyl. Metabolism of alfentanil occurs by demethylation in the liver to noralfentanil, which is then conjugated and excreted in the urine. Importantly, alfentanil is a potent respiratory depressant, and consequently there are concerns regarding potential adverse neonatal effects.

Morley-Forster et al.[58] compared alfentanil PCA (bolus 200 μg, lockout interval 5 min, background infusion 200 μg/h) with fentanyl PCA (bolus 20 μg, lockout interval 5 min, background infusion 20 μg/h). The two drugs appeared equally effective in early labor, up to a cervical dilation of 6 cm. Subsequently, fentanyl was associated with a greater reduction in pain scores compared with alfentanil. There were no significant differences in maternal side effects or neonatal outcomes.

Pentazocine

The use of pentazocine is uncommon in the western world, and there has been little evaluation of its use via PCA. One study in South Africa compared pentazocine PCA with meperidine PCA and reported acceptable maternal analgesia and neonatal outcomes with both, but a higher incidence of maternal nausea and sedation with meperidine.[59]

Tramadol

Tramadol is not commonly used via PCA. Long and Yue[60] compared tramadol PCA with CSE analgesia and found that both forms of pain relief resulted in a significant decrease in pain scores compared with a third group not receiving analgesia; however, the CSE technique provided the best analgesia. The tramadol group experienced a higher incidence of adverse maternal events (including one case of cardiovascular collapse) and neonatal depression.

Nalbuphine

Few studies have evaluated nalbuphine PCA in labor. In one study, maternal satisfaction was higher with nalbuphine PCA (bolus 1 mg, lockout interval 6 to 10 min) compared with intermittent intravenous administration (bolus 10 to 20 mg every 4 to 6 h).[61] Analgesia and Apgar scores were similar between groups, and no neonates required naloxone.

Frank et al.[62] concluded that nalbuphine PCA (bolus 3 mg, lockout interval 10 min) provided better analgesia in nulliparous women than meperidine PCA (bolus 15 mg, lockout interval 10 min). Maternal sedation scores were similar, and there was no difference in neonatal outcome as assessed by Apgar scores, time to sustained respiration, or neurobehavioral assessment at 6 to 10 hours after delivery.

Remifentanil

Remifentanil is a synthetic anilidopiperidine derivative with selective activity at the μ-opioid receptor, low lipid solubility, and a small volume of distribution (0.39 L/kg). Functional brain magnetic resonance imaging revealed an onset time of 20 to 30 seconds, peak concentration within 80 to 90 seconds at the cortical loci, and a blood-brain equilibration time of 1.2 to 1.4 minutes.[63] Remifentanil undergoes rapid hydrolysis by nonspecific plasma and tissue esterases to inactive metabolites, independent of organ metabolism, resulting in a short elimination half-life of approximately 9.5 minutes. The context-sensitive half-time is 3.5 minutes, irrespective of duration of infusion. The effective analgesic half-life is 6 minutes, thus allowing effective analgesia for consecutive uterine contractions. Plasma concentrations of remifentanil in pregnant patients are approximately one-half those found in nonpregnant patients.[64] This difference may be caused by the greater volume of distribution (increased blood volume and reduced protein binding), greater clearance (increased cardiac output and renal perfusion), and higher esterase activity during pregnancy.

Remifentanil is rapidly titratable, allowing for dose adjustments with labor progress or in response to side effects. Termination of a continuous remifentanil infusion results in a 50% recovery in minute ventilation within 5.4 minutes. Although remifentanil readily crosses the placenta, resulting in a fetal-to-maternal blood ratio of 0.88, the lower umbilical artery-to-vein concentration ratio of 0.29 demonstrates that the drug is extensively redistributed and/or metabolized by the fetus.[64] Kan et al.[64] found no adverse neonatal effects after a remifentanil infusion during cesarean delivery. The rapid onset and offset of remifentanil, with a peak effect-site concentration observed at 1 to 2 minutes, may not provide adequate or sustained analgesia for the desired or subsequent uterine contraction, respectively.

Comparison with Other Forms of Labor Analgesia

The efficacy of remifentanil patient-controlled intravenous analgesia (PCIA) has been compared with that of other labor analgesic agents and regimens (Table 22.5).

Remifentanil versus Meperidine. Thurlow et al.[65] conducted a randomized unblinded study in 36 women

comparing remifentanil PCA (bolus 20 μg, lockout interval 3 min) with intramuscular meperidine 100 mg. The remifentanil group experienced significantly lower pain scores (median maximum pain score 66.5/100 mm versus 82.5/100 mm, $P = .009$) within the first 2 hours of commencing analgesia. However, parturients in the remifentanil group also used nitrous oxide analgesia (56%) and experienced more sedation and episodes of oxygen saturation less than 94%. No significant difference in Apgar scores was found.

Ng et al.[66] conducted a randomized, double-blinded study in which 69 patients used a PCIA device containing either remifentanil (PCIA group) or 0.9% saline (meperidine group), and also received an intramuscular injection of either saline (PCIA group) or meperidine (meperidine group). The doses administered depended on patient weight; women weighing less than 60 kg or 60 kg or more were given a bolus dose of remifentanil of 25 μg or 30 μg, respectively. Similarly, the doses of meperidine were either 50 mg or 75 mg. The PCIA lockout interval was 3.75 to 4.5 minutes, and a background infusion was not used. Maternal analgesia was greater (particularly in the first 2 hours after initiation), the median time to first rescue analgesic request was longer (8.0 hours versus 4.9 hours), and maternal satisfaction scores were higher in the remifentanil PCIA group than in the meperidine group. There was no difference between groups in maternal sedation, nausea, or oxygen saturation. Neonatal outcomes were also similar.

Blair et al.[67] observed that the use of remifentanil PCIA (bolus 40 μg, lockout interval 2 min) resulted in higher maternal satisfaction scores and modest analgesic benefit compared with meperidine PCIA (bolus 15 mg, lockout

TABLE 22.5 Trials Comparing Remifentanil Patient-Controlled Analgesia with Alternative Labor Analgesia

Reference	Number of Subjects	Study Design	Groups; Drugs; Doses	Primary Data	Comments
Volikas et al.[117]	17	Double-blinded, randomized	$n = 8$; M PCA 10 mg b, 5 min l/o $n = 9$; R PCA 0.5 μg/kg b, 2 min l/o	VAPS hourly VAPS after delivery	Lower mean VAPS hourly in group R ($P = .0496$) Lower mean VAPS after delivery in group R ($P = .03$)

interval 10 min). Douma et al.[52] compared remifentanil PCIA (bolus 40 μg, lockout interval 2 min), fentanyl PCIA (bolus 20 μg, lockout interval 5 min), and meperidine PCIA (bolus 5 mg, lockout interval 10 min). The remifentanil group had the greatest analgesia, sedation, and pruritus, as well as overall satisfaction. The parturients receiving meperidine had the highest crossover rate to epidural analgesia. Despite similar labor analgesia in 98 women with PCIA fentanyl compared with PCIA remifentanil, Marwah et al.[68] reported a greater need for neonatal resuscitation in the fentanyl group.

In a systematic review of seven randomized controlled trials ($n = 349$), Leong et al.[69] evaluated the administration of remifentanil versus meperidine provided through a variety of drug delivery methods (e.g., PCA, continuous infusion, intramuscular) for labor analgesia. Remifentanil was noted to reduce the mean VAS pain score by 25 mm more than meperidine in the first hour. The conversion rate to epidural analgesia was less than 10% when using remifentanil. Schnabel et al.[70] reported similar conclusions from a meta-analysis comparing PCIA remifentanil, PCIA meperidine, and epidural analgesia. Women who received remifentanil PCIA had lower mean pain scores after 1 hour, a lower crossover rate to epidural analgesia, and a higher satisfaction scores than women who received meperidine.

Remifentanil versus Nitrous Oxide. Volmanen et al.[71] performed a double-blinded crossover trial comparing remifentanil (bolus 0.4 μg/kg, lockout interval 1 min) with 50% nitrous oxide during the first stage of labor. The 20 patients used both analgesics in a random order for 20 minutes, with an intervening washout period of 20 minutes. Pain relief (although modest), maternal sedation, and patient satisfaction were greater in the remifentanil group. No difference in the incidence of FHR changes was observed between the two groups.

Remifentanil versus Epidural Analgesia. In a randomized, double-blinded trial, Volmanen et al.[72] compared remifentanil PCIA (mean effective bolus 0.5 μg/kg [range 0.3 to 0.7 μg/kg], lockout interval 1 min) with lumbar epidural analgesia (20 mL of levobupivacaine 0.0625% with fentanyl 2 μg/mL). All patients received an epidural technique and a remifentanil or saline PCIA. Parturients receiving epidural analgesia had a more significant and rapid reduction in pain scores than those receiving remifentanil (10 minutes versus 40 minutes to reach the individual effective dose), but median "pain relief" scores were similar between the two groups. The investigators postulated that high maternal satisfaction with remifentanil PCIA may be the result of factors other than the degree of analgesia produced.

Two meta-analyses concluded that epidural analgesia provides superior labor analgesia (mean difference in effect size 3.0 cm/10 cm [95% CI, 0.7 to 5.2] at 2 hours) and satisfaction compared with remifentanil PCIA.[70,73] More recently, Stocki et al.[74] conducted an unblinded controlled noninferiority study in 39 healthy women randomized to receive remifentanil PCIA (titrated from 20 to 60 μg, lockout interval 1 to 2 min), or patient-controlled epidural analgesia (PCEA) (0.1% bupivacaine with 2 μg/mL fentanyl). Analgesia with remifentanil was inferior to the epidural technique at all time points, but maternal satisfaction was similar. All apnea events occurred in the women receiving remifentanil, who also had lower mean respiratory rates and oxygen saturation.

In a multicenter randomized controlled trial, Freeman et al.[75] randomized 1414 women to remifentanil PCIA or epidural analgesia. Satisfaction and analgesia were significantly higher in the women who received epidural analgesia. Remifentanil analgesia was most effective during the first few hours of use, after which pain scores returned to baseline preanalgesia levels.[70,73]

Efficacy and Optimal Regimen

Remifentanil can be given as a PCIA bolus, as a continuous infusion, or as a combination of the two. Although a number of studies have compared remifentanil with other opioids using fixed, non-titratable PCIA doses, Volmanen et al.[76] attempted to determine the minimum effective dose of remifentanil for labor analgesia during the first stage of labor. Using an initial bolus dose of 0.2 μg/kg, and dose increases of 0.2 μg/kg (lockout interval 1 min) over a 1-hour study period, the median effective bolus dose was observed to be 0.4 μg/kg (range, 0.2 to 0.8 μg/kg). However, frequent episodes of oxygen saturation less than 94% (10 of 17 subjects), maternal sedation, and reduced FHR variability were observed.

Balki et al.[77] compared the effect of a fixed remifentanil bolus dose with a titratable background infusion versus a fixed background infusion with a titratable bolus dose. Both groups started with a remifentanil bolus dose of 0.25 μg/kg (lockout interval 2 min) and a background infusion rate of 0.025 μg/kg/min. If analgesia was inadequate, either the background infusion or bolus dose was increased in a stepwise manner to a maximum of 0.1 μg/kg/min or 1 μg/kg, respectively. The mean pain scores, satisfaction scores, and cumulative remifentanil doses were similar in the two groups; only one patient eventually requested epidural analgesia. The incidence of maternal side effects was higher in the escalating bolus dose group, including drowsiness (100% versus 30%) and frequency of oxygen saturation less than 95% (60% versus 40%). There was no difference in the incidence of adverse neonatal effects. The investigators advocated the use of a titrated background infusion (range, 0.025 to 0.1 μg/kg/min) with a constant PCIA bolus dose (0.25 μg/kg, lockout interval 2 min).

D'Onofrio et al.[78] conducted an observational study of 205 parturients in whom a continuous infusion of remifentanil was titrated (initial to maximum dose range, 0.025 to 0.15 μg/kg/min) with a goal of achieving pain scores less than or equal to 4 during contractions. Adequate analgesia was achieved within 30 minutes but required a median remifentanil infusion dose of 0.075 μg/kg/min. The oxygen saturation remained above 95% in all patients without supplemental oxygen, and there were no reported neonatal side effects.

Together, these studies suggest that fixed-dose remifentanil PCA protocols are less effective than titratable regimens, with the potential for low doses resulting in poor analgesia, underdosing, and maternal dissatisfaction, and high doses resulting in adverse effects such as maternal sedation, respiratory

depression, and oxygen desaturation. Evidence is conflicting as to whether the use of a background infusion confers additional benefits, particularly given the greater risk for maternal sedation and respiratory depression.[67,77]

Rehberg et al.[79] sought to improve labor analgesia and reduce side effects by altering the timing of the remifentanil PCIA bolus. A handheld dynamometer was used to determine the peak effect of the next contraction; however, because of contraction variability, analgesia was not substantially improved. The analgesic benefit of remifentanil may be best optimized by training parturients to press the PCA button with the first perception of a contraction, given that the peak analgesic effect occurs within 1 to 3 minutes.[17]

Leong et al.[80] devised an automated closed interactive feedback system ("step-up–step-down" regimen) with the input of continuous monitoring devices (pulse oximeter and heart rate) to modulate drug delivery and improve labor analgesia and safety. The vital sign–controlled, patient-assisted intravenous analgesia (VPIA) prototype initially administered small boluses of remifentanil, with dosing alterations based on the presence or absence of patient demands over a predefined period. In the 29 parturients who used the device, despite all using supplemental oxygen, 52% experienced oxygen desaturation less than 95% for more than 60 seconds, and 24% experienced a heart rate less than 60 beats per min (bpm) for more than 60 seconds. The median dose of remifentanil was 0.07 μg/kg/min, and the system automatically reduced dosages and temporarily halted remifentanil administration when desaturation and bradycardia thresholds were achieved. Thirty-one percent required additional analgesia including Entonox or an epidural technique.

Side Effects

Remifentanil can cause respiratory depression through reductions in the ventilatory rate and tidal volume. Although the safety profile of remifentanil PCIA in labor has been specifically evaluated, the data are conflicting.[78,81] Volikas et al.[81] investigated the maternal and neonatal effects of remifentanil PCIA (bolus dose 0.5 μg/kg, lockout interval 2 min) in 50 women. Effective analgesia was reported in 86% of study participants, and 44% experienced slight drowsiness (but were rousable to voice and maintained oxygen saturation greater than 93%). Mild itching and FHR changes occurred in the first 20 minutes of remifentanil PCIA but did not require treatment. Umbilical cord blood gas measurements and neonatal Apgar scores and neurologic examinations were all within normal limits.

Even with the use of oxygen saturation and end-tidal CO_2 monitoring, Stocki et al[74] reported a moderate number of apneic events (respiratory arrest greater than 20 seconds), lower respiratory rates, and hypoxemic events in women receiving remifentanil PCIA, compared with none in women receiving epidural analgesia. These findings suggest that the analgesia onset from a bolus dose of remifentanil may occur after the cessation of uterine contractions (which have an average duration of 60 to 70 seconds). Although Thurlow et al.[65] encouraged parturients to activate a bolus dose at the very first detection of a contraction, or even between contractions, Volmanen et al[82] indicated that the onset of electroencephalographic depression and subsequent onset of peak respiratory depression does not happen until approximately 2.5 minutes after bolus injection. As a consequence, the bolus administration will frequently miss the uterine contraction.

Weiniger et al.[83] evaluated candidate variables (i.e., respiratory rate, end-tidal CO_2, pulse oximetry, heart rate, and integrated pulmonary index) to serve as early warning apnea alerts (defined as any variable value below a prespecified threshold for 15 seconds). A total of 331 immediate early warning alerts and 62 episodes of apnea (defined as maximal CO_2 less than 5 mm Hg for at least 30 consecutive seconds) occurred among 10 of 19 women (56.2%) who received remifentanil PCIA. Alerts for end-tidal CO_2, respiratory rate, and integrated pulmonary index detected most episodes of apnea, pulse oximetry alerts missed the majority of episodes of apnea, and all variables had a low positive predictive rate, indicating the limitations of respiratory monitors for early warning apnea surveillance in this setting.

Studies of remifentanil PCIA during labor have reported a wide range in the incidence of maternal sedation, dizziness, nausea, vomiting, and pruritus.[67,72,81,84] The wide incidence of nausea (0% to 60%)[77,78] may reflect an opioid-induced increase in vagal activity, which can decrease mean arterial pressure and heart rate; however, this has not been reported in laboring women receiving remifentanil PCIA, perhaps reflecting the doses administered and/or the high maternal sympathetic activity during labor. Pruritus occurs in approximately 16% of parturients.[52] In 140 parturients randomly assigned to either remifentanil PCIA or epidural analgesia, Douma et al.[85] observed fever (temperature > 38° C) in 10% of remifentanil PCIA patients compared with 37% in epidural analgesia patients.

Loss of heart rate variability, a potential indicator of fetal distress, and opioid-induced loss of heart rate variability may create diagnostic confusion in a labor setting.[86] Comparison studies have reported a lower incidence of FHR abnormalities with remifentanil than with meperidine.[67] However, similar to other opioids, available data suggest that remifentanil might induce fetal and neonatal acidosis. Marwah et al.[68] observed that the need for neonatal resuscitation was higher with fentanyl compared with remifentanil (OR 4.33, 95% CI, 1.75 to 10.76).

Many studies suggest that continuous patient monitoring is required with remifentanil use during labor. Van de Velde and Carvalho[87] suggested that monitoring for respiratory depression should ideally evaluate respiratory rate and sedation (one-to-one nursing or midwifery care), determine adequacy of ventilation (capnography, apnea monitors), and evaluate oxygenation (pulse oximetry). Routine use of supplemental oxygen may increase the duration of apnea and reduce the sensitivity of pulse oximetry for detecting hypoventilation. A method for assisting ventilation (e.g., self-inflating ventilating bag) should be immediately available.

A meta-analysis by Weibel et al.[88] assessed the effectiveness of remifentanil PCIA for labor analgesia compared with other parenteral and patient-controlled opioids, epidural analgesia,

continuous remifentanil infusion, or placebo. Remifentanil PCIA was found to be likely superior to the administration of other opioids (IV/IM, PCIA) but inferior to neuraxial analgesia.

To date, the studies of remifentanil administration for labor analgesia have included only healthy parturients with low-risk singleton pregnancies. In many centers, the inability to provide dedicated, one-to-one nursing care precludes the use of remifentanil PCIA in laboring women. Given the significant risk for maternal sedation, respiratory depression, and oxygen desaturation with remifentanil PCIA, the use of *continuous* pulse oximetry and *continuous* (or *near continuous*) one-to-one nursing care is critical for its safe use. An oxygen saturation less than 94% when breathing room air should prompt administration of supplemental oxygen. An anesthesia provider should be notified if excess sedation, a respiratory rate less than 8 breaths per minute, and/or oxygen saturation less than 94%, despite supplemental oxygen, occurs.[84]

OPIOID ANTAGONISTS

Naloxone is a pure opioid antagonist at the μ-, κ-, and δ-opioid receptors, although it has the greatest affinity for the μ-opioid receptor.[6,17] It is the drug of choice to treat adverse opioid effects in both the mother and the newborn, and it may be given intravenously, subcutaneously, or intramuscularly. The onset of action after an intravenous dose (1 to 4 μg/kg) is 2 minutes, with a duration of action of 30 to 40 minutes; this duration may be less than that of the opioid whose action it antagonizes, and repeated doses or an infusion may be necessary.

The administration of naloxone during labor or before delivery may reverse the quality of analgesia and confer only a limited reduction in maternal side effects; however, some neonatal benefit may be obtained. Hodgkinson et al.[89] reported significantly higher neurobehavioral scores in neonates born to mothers who had received an intrapartum combination of meperidine and naloxone compared with meperidine alone. However, this difference did not persist beyond 2 hours after birth. Clark et al.[90] reported minimal differences in the neurologic and acid-base status of neonates born to mothers who had received both meperidine and naloxone compared with no-analgesia controls, although there was some evidence that high-dose naloxone may have resulted in beneficial neonatal effects. When neonatal depression is anticipated secondary to maternal opioid administration, it is best to administer naloxone directly to the infant. Naloxone reverses neonatal respiratory depression by increasing both minute ventilation and the gradient of the CO_2 response curve.

Studies have evaluated prophylactic neonatal naloxone administration immediately after delivery of infants whose mothers received opioids during labor. Compared with saline administration, Wiener et al.[91] observed that intravenous naloxone resulted in a short-lived (30 minutes) improvement in neurobehavioral scores, whereas intramuscular naloxone resulted in similar improvements for the duration of the study period (48 hours).

The recommended neonatal dose of naloxone is 0.1 μg/kg (1 μg/mL solution). Administration of naloxone is not recommended during the primary steps of neonatal resuscitation; however, it may be given after positive-pressure ventilation has restored normal heart rate and oxygen saturation, if maternal opioid administration occurred during the 4 hours before delivery.[92] The preferred route of naloxone administration is intravenous; intramuscular administration is acceptable, although absorption may be delayed with this route. Endotracheal administration of naloxone is not recommended. Naloxone should not be given to the neonate of a mother who is opioid-dependent or on methadone maintenance therapy; this action may result in withdrawal activity and seizures.[92]

OPIOID ADJUNCTS AND SEDATIVES

Historically, many drugs have been used as adjuncts to parenteral opioid analgesia. Most of them cause maternal sedation and neonatal depression and are now used infrequently, particularly because neuraxial and opioid PCA techniques achieve satisfactory analgesia more safely.

Barbiturates are sedative agents with no analgesic effect. They are lipid soluble, rapidly cross the placenta, are detectable in fetal blood, and can result in neonatal depression, especially if combined with systemic opioid administration.

Phenothiazines (e.g., chlorpromazine, promethazine, propiomazine) are dopamine antagonists that have sedative, antiemetic, and antipsychotic properties. They rapidly cross the placenta and reduce FHR variability. Neurobehavioral outcomes after the maternal administration of these agents have not been studied carefully, but there is no evidence that they cause neonatal respiratory depression. Phenothiazines (particularly chlorpromazine) may cause hypotension from alpha-adrenergic receptor blockade, and they may produce unwanted extrapyramidal movements.[17] Parenterally administered promethazine (25 to 50 mg) has an onset of 15 minutes and a duration of action of up to 20 hours; it rapidly crosses the placenta, resulting in detectable fetal levels within 1 to 2 minutes of maternal intravenous administration.[17] Propiomazine is a mild respiratory depressant that may further depress maternal ventilation when co-administered with opioids. It has a faster onset and shorter duration of action than promethazine.

Metoclopramide is a procainamide derivative that can increase gastric motility and reduce nausea and vomiting. As an antagonist at central dopamine receptors, it can also cause drowsiness.[17] After meperidine administration for labor analgesia, Vella et al.[93] found metoclopramide as effective as promethazine for reducing the incidence of nausea and vomiting. Reduced pain scores and nitrous oxide use were observed in women who received metoclopramide compared with those who received promethazine or placebo; this may reflect either an antianalgesic effect of promethazine or a possible analgesic effect of metoclopramide.

Benzodiazepines (e.g., diazepam, lorazepam, midazolam) have been used for sedation in labor but are associated with significant side effects. **Diazepam** rapidly crosses the placenta and accumulates in the fetus at concentrations that may

exceed maternal concentrations. The elimination half-life of the parent drug is 24 to 48 hours, but active metabolites may persist for up to 120 hours. Diazepam may cause maternal and neonatal respiratory depression, as well as neonatal hypotonicity, impaired thermoregulation, and an abnormal stress response. These effects may be dose related. **Lorazepam** has a half-life of 12 hours and is metabolized to an inactive glucuronide. McAuley et al.[94] gave lorazepam 2 mg or placebo prior to the intramuscular administration of meperidine 100 mg for labor analgesia. Analgesia was better in the lorazepam group, but lorazepam administration was associated with a nonsignificant increase in neonatal respiratory depression. Neonatal neurobehavioral scores were similar in the two groups. Amnesia was common with lorazepam.

Midazolam has a rapid onset of action and an elimination half-life of 1 to 4 hours.[17] It is metabolized in the liver to one major and several minor pharmacologically active compounds, which may persist in patients with critical illnesses accompanied by hepatic and/or renal impairment. Midazolam readily crosses the placenta and when used at high doses (e.g., induction of general anesthesia) can result in neonatal hypotonia. Midazolam causes potent anterograde amnesia, a characteristic that may be undesirable for the childbirth experience.

Ketamine is a phencyclidine derivative that acts as a noncompetitive antagonist at the *N*-methyl-D-aspartate (NMDA) receptor and, at high doses, as an agonist at μ-opioid receptors. Most commonly given by intravenous or intramuscular injection, ketamine in small doses (0.2 to 0.5 mg/kg intravenously) can provide dissociative analgesia, whereas larger doses (1 to 2 mg/kg intravenously, 5 to 10 mg/kg intramuscularly) can be used to induce general anesthesia.

When given intravenously, ketamine has an onset within 30 seconds and a duration of action of 5 to 10 minutes; intramuscular administration has an onset of 2 to 8 minutes with a duration of 10 to 20 minutes.[17] Ketamine is hepatically metabolized to active metabolites, which are excreted in the urine.

Ketamine's sympathomimetic properties cause an increase in heart rate, systolic pressure, and cardiac output, which should be avoided in preeclamptic and hypertensive patients. Joselyn et al.[95] reported acceptable labor analgesia with an intravenous infusion of ketamine (bolus 0.1 mg/kg with an infusion of 0.2 mg/kg/h, titrated to effect). The average infusion rate was 0.17 mg/kg/h, yielding an average total dose of 57 mg (range, 18 to 160 mg). No unpleasant hallucinations were experienced; however, with the initial dose, emesis and transient lightheadedness and nystagmus occurred. All neonates had a 5-minute Apgar score of 9 or 10.

Ketamine may also provide effective analgesia just before vaginal delivery in parturients without neuraxial anesthesia, or it may be used as an adjunctive agent in parturients with unsatisfactory neuraxial analgesia/anesthesia. Using incremental doses of intravenous ketamine (0.2 to 0.4 mg/kg, up to a maximum dose of 100 mg) immediately before delivery, Akamatsu et al.[96] reported that 78 of 80 women experienced complete analgesia with no adverse maternal or neonatal effects. The occurrence of amnesia and a dreamlike state was high, but only one woman found this unpleasant.

Administration of small doses of ketamine (10- to 20-mg doses, repeated at intervals of 2 to 5 minutes, while not exceeding a total dose of 1 mg/kg during a 30-minute period) is associated with a low incidence of maternal hallucinations; however, amnesia is common. In these settings, the anesthesia provider must maintain continual verbal contact with the patient and must ensure that the patient remains sufficiently awake to maintain adequate ventilation and protect her airway.

INHALATIONAL ANALGESIA

The use of inhalational analgesia for labor varies by country. Although many of the anesthetic agents used in surgery have been administered for pain relief during childbirth, only nitrous oxide has achieved wide clinical use.

Nitrous Oxide

Globally, nitrous oxide is the most common inhalational agent used for labor analgesia.[97] Use of nitrous oxide during labor began in the late 1800s, and equipment for self-administration was introduced by Minnitt in England in 1934. Typically it is administered as 50% nitrous oxide in oxygen using a blender device (e.g., Nitronox in the United States) or premixed in a single cylinder (e.g., Entonox in the United Kingdom); when provided alone or in combination with other forms of analgesia, the incidence of its use during labor ranges from 1% (or less) in the United States to over 50% in many parts of Europe, Scandinavia, and the United Kingdom.

A tasteless and odorless gas that is nonirritating to the airway, nitrous oxide is a weak anesthetic agent with a minimum alveolar concentration more than 100% at 1 atmosphere.[98] The mechanism of action of nitrous oxide is not fully understood, although it is believed to enhance the release of endogenous opioid peptides in the midbrain and modulate descending spinal pain pathways.[99] Because of its low blood/gas solubility, nitrous oxide has a very rapid onset and offset, reaches peak brain concentrations within 60 seconds in laboring patients, and undergoes minimal metabolism.[100] To achieve optimal analgesia from nitrous oxide, inhalation should ideally begin in anticipation of the next contraction, although this is not always predictable.

Nitrous oxide does not interfere with uterine activity, but it readily crosses the placenta, and a fetal-to-maternal concentration ratio of 0.8 occurs within 15 minutes; however, no apparent detrimental effects on FHR, Apgar scores, or umbilical cord blood gas measurements have been reported.[99] Even when used immediately prior to delivery, there is no evidence that nitrous oxide causes neonatal respiratory depression or altered neurobehavioral scores. The neonate rapidly eliminates nitrous oxide by respiration, resulting in a half-life of less than 3 minutes.[99]

A systematic review of 12 randomized controlled trials concluded that nitrous oxide is not a potent labor analgesic, with

less effectiveness than epidural analgesia, but confers benefit and high levels of satisfaction for some women.[101] Similarly, Richardson et al.[102] observed that patients who received nitrous oxide alone for labor and vaginal delivery were as likely to express satisfaction with their anesthesia care as women who received neuraxial analgesia, even though they were less likely to report excellent analgesia. Further, among all laboring women who experienced poor analgesia effectiveness, those who used nitrous oxide alone were more likely to report high satisfaction than women who received epidural analgesia alone (OR 2.5; 95% CI, 1.4 to 4.5; $P = .002$). The authors concluded that analgesia quality is not the only contributor to maternal satisfaction.

Although a low incidence of serious adverse events (3 per 10,000 administrations of 50% nitrous oxide in oxygen) has been reported, suitable equipment must be available to ensure the safe administration of nitrous oxide. An apparatus that limits the concentration of nitrous oxide (e.g., a nitrous oxide/oxygen blender or a premixed 1 : 1 cylinder) is required and should be checked periodically for correct delivery concentrations. The constituent gases separate at approximately 7° C (19.4° F), which is not usually of practical concern.[17] Inhalation should occur through a mask or mouthpiece containing a one-way demand valve, which opens only when negative inspiratory pressure is applied. This is a safety feature that limits gas delivery in a drowsy patient, and it also helps limit pollution of the environment with unscavenged gases.

Environmental pollution from unscavenged gases may be significant, and it remains unclear whether regular occupational exposure to subanesthetic concentrations of nitrous oxide results in significant health risks for health care workers. Overall, epidemiologic data do not suggest the presence of higher reproductive risks in health care workers exposed to nitrous oxide in the work environment (see Chapter 17).

Nitrous oxide has limited cardiovascular effects and little direct effect on ventilatory drive; however, it can depress ventilation through a reduction in tidal volume; partial compensation of this ventilatory effect is achieved by an increase in respiratory rate. Hyperventilation with associated hypocapnia during uterine contractions, rather than diffusion hypoxemia, may be the cause of occasional oxygen desaturation.[103] It is unclear whether the incidence of intrapartum maternal hypoxemia differs among women who use nitrous oxide compared with women who receive no analgesia during labor. However, the risk for maternal hypoxemia with nitrous oxide may be more common with the concomitant administration of opioids or other sedatives; the entire obstetric care team should be aware of this possibility.

The most common maternal side effects of nitrous oxide are nausea and vomiting (occurring in up to 33% of parturients), drowsiness, dizziness, and the presence of paresthesias, which may be related to maternal hyperventilation during contractions.[99] In a large systematic review of 29 studies by Likis et al.,[101] nausea was reported to occur at rates up to 45% and dizziness up to 23%.

Significant adverse effects on the neonate have not been reported. Umbilical cord blood gas measurements and neonatal Apgar scores in mothers who used nitrous oxide were not different from those mothers who used other forms of labor pain relief or no analgesia.[101] However, neuroapoptosis in rodents exposed to large doses of nitrous oxide (and other anesthetic agents) at specific growth time points of the developing brain indicate the need for further clinical and research studies.[104]

Volatile Halogenated Agents

All volatile halogenated agents cause dose-dependent relaxation of uterine smooth muscle. Yoo et al.[105] observed that the minimum alveolar concentration (MAC) of volatile agents required to decrease the spontaneous myometrial contractility of isolated uterine muscle from pregnant women by 50% (ED_{50}) was similar for halothane, sevoflurane, and desflurane (1.72, 1.44, and 1.66 MAC, respectively). Other *in vitro* studies demonstrated that the ED_{50} for sevoflurane varied from 0.8 to 1.0 MAC and that the ED_{50} for desflurane varied from 0.9 to 1.4 MAC.[106,107] In contrast, Yoo et al.[105] observed that the ED_{50} of isoflurane was significantly higher (2.35 MAC) than that for sevoflurane, desflurane, and halothane; an additional unique feature observed with isoflurane was its ability to modulate K_{ATP} channels.[105] Whether these findings suggest that isoflurane is less likely to be associated with uterine atony in clinical practice requires further study. In general, when uterine tone is desirable (e.g., after delivery), volatile anesthetic concentrations higher than 0.5 MAC are not recommended and intravenous oxytocin should be administered concurrently.

A number of studies have examined the use of volatile agents for labor analgesia; most of these investigations used special breathing equipment and did not fully address the issue of unscavenged gases, which may limit their clinical application.

Enflurane

Abboud et al.[108] compared the analgesic effects of 0.25% to 1.25% enflurane with the administration of 30% to 60% nitrous oxide, both given in oxygen during the second stage of labor in 105 women. Satisfactory pain relief was reported in approximately 89% of women in the enflurane group and 76% of women in the nitrous oxide group; this outcome was achieved most frequently with the use of 0.5% enflurane and 40% nitrous oxide, respectively. Amnesia rates were less than 10% in both groups, and there were no differences observed in maternal blood loss, Apgar scores, or umbilical cord blood gas measurements. The mean umbilical cord concentrations of fluoride ions in the enflurane group were below that associated with nephrotoxicity. A subsequent study that compared administration of 1% enflurane in air to 50% nitrous oxide in oxygen during the first stage of labor observed lower pain scores, but higher levels of drowsiness, with enflurane.[109]

Isoflurane

McLeod et al.[110] observed improved labor analgesia with the self-administration of 0.75% isoflurane in oxygen compared with Entonox. Subsequent studies observed satisfactory pain relief with minimal levels of drowsiness with various concentrations of an isoflurane-Entonox mixture. Ross et al[111] evaluated the use of a 0.25% isoflurane-Entonox mixture in 221 parturients in whom Entonox alone provided inadequate analgesia. No mother experienced significant sedation or loss of consciousness, and there was no adverse effect on Apgar

scores, neonatal respiratory status, or maternal blood loss. The requirement for neonatal resuscitation was greater in mothers who had received systemic opioids within 5 hours of birth in addition to the inhaled mixture. The same investigators verified clinically acceptable performance and safety of premixed isoflurane-Entonox cylinders.[112]

Desflurane

Because of its low blood-gas partition coefficient, desflurane has a rapid onset and offset; however, it is also highly irritating to the airway, making it a less attractive option for inhalation analgesia. Abboud et al.[113] compared inhalation of 1% to 4.5% desflurane versus 30% to 60% nitrous oxide, both in oxygen, and found similar analgesia scores and neonatal outcomes between groups. The incidence of amnesia was significantly greater with desflurane than with nitrous oxide (23% versus 0%).

Sevoflurane

Sevoflurane is the volatile halogenated agent most commonly used for inhalational induction of general anesthesia. It has a short onset and offset of action, but it is less irritating and has a less unpleasant odor than the other volatile agents.

Toscano et al.[114] conducted a safety and feasibility pilot study of 50 parturients breathing 2% to 3% sevoflurane in an oxygen/air mixture via a compact anesthesia delivery system. They aimed for an end-tidal sevoflurane concentration of 1.2% to 1.4% (0.8 to 0.9 MAC during pregnancy) at the peak of uterine contractions. The mean (± SD) pain score was significantly lower during the times when parturients inhaled sevoflurane compared with times when they did not inhale sevoflurane (3.3 ± 1.5 versus 8.7 ± 1.0, respectively, on a scale of 0 to 10). Four women became drowsy, but there were no episodes of oxyhemoglobin desaturation or loss of consciousness, and there were no unexpected increases in blood loss. In addition, there were no reported adverse effects on FHR or neonatal Apgar scores.

In an escalating dose study, Yeo et al.[115] determined that 0.8% sevoflurane was the optimal concentration for labor analgesia, beyond which an increased level of sedation with no additional analgesic benefit was observed. Ng et al.[116] randomized 48 primigravid parturients to receive either 0.8% sevoflurane (via an inhaler attached to wall gas supply) or Entonox. No significant difference in median pain scores or adverse effects were observed.

Routine use of inhalational labor analgesia may be limited by the need for specialized equipment, concern for environmental pollution, and the potential for maternal amnesia and the loss of protective airway reflexes. Although sedation occurs during intermittent inhalation of volatile anesthetic agents, profound sedation to the extent that airway reflexes are jeopardized has not been reported. Further research and refinement of inhalational labor analgesia may allow the use of this technique for women in whom neuraxial anesthesia is contraindicated.

KEY POINTS

- Systemic analgesia is commonly used in laboring women worldwide.
- All opioid analgesic drugs rapidly cross the placenta and cause a transient reduction in fetal heart rate variability.
- Meperidine is most commonly administered as an intermittent bolus. Its active metabolite may have prolonged adverse effects on the neonate.
- There is little evidence that any individual opioid confers significant benefit over meperidine when administered as a bolus.
- Neonates whose mothers received systemic opioid analgesia are more likely to exhibit neonatal depression than those whose mothers who received no analgesia or epidural analgesia.
- Given the significant risk for maternal sedation, respiratory depression, and oxygen desaturation with remifentanil patient-controlled intravenous labor analgesia (PCIA), the use of *continuous* pulse oximetry and *continuous* (or *near continuous*) one-to-one nursing care is critical for its safe use. An oxygen saturation less than 94% when breathing room air should prompt administration of supplemental oxygen. An anesthesia provider should be notified if excessive maternal sedation, a respiratory rate less than 8 breaths per minute, and/or oxygen saturation less than 94%, despite supplemental oxygen administration, occurs.
- The optimal remifentanil PCIA regimen has not yet been determined, but titrated regimens likely confer an advantage as labor progresses. The use of a background infusion warrants extreme caution because of the significant risk for moderate to severe respiratory depression.
- Use of inhalation analgesia is less common in the United States than in other countries, but its use may increase with further study and advances in equipment and scavenging systems.
- Nitrous oxide may be used alone or with other systemic or inhaled agents. Inhalation of nitrous oxide provides variable analgesia, but high satisfaction in motivated patients. When used alone, it does not appear to be associated with adverse effects on the fetus or neonate.
- Intermittent inhalation of volatile anesthetic agents appears to provide good analgesia with few maternal or neonatal side effects, but larger studies are needed to assess the maternal and neonatal safety of these agents.

Epidural and Spinal Analgesia: Anesthesia for Labor and Vaginal Delivery

Cynthia A. Wong, MD

CHAPTER OUTLINE

Epidural analgesia and spinal analgesia are the most effective methods of intrapartum pain relief in contemporary clinical practice.[1,2] During the first stage of labor, pain results primarily from distention of the lower uterine segment and cervix (see Chapter 20). Painful impulses are transmitted by means of visceral afferent nerve fibers, which accompany sympathetic nerve fibers and enter the spinal cord at the 10th, 11th, and 12th thoracic and first lumbar spinal segments. As labor progresses and the fetus descends in the birth canal, distention of the vagina and perineum results in painful impulses that are transmitted via the pudendal nerve to the second, third, and fourth sacral spinal segments. Neuraxial analgesia is the only form of analgesia that provides complete analgesia for both stages of labor. During the first stage of labor, visceral pain impulses entering the spinal cord at T10 to L1 must be blocked. During the late first stage of labor and the second stage of labor, somatic impulses entering the spinal cord from S2 to S4 must also be blocked (see Chapter 20).

In a survey of 1000 consecutive women who chose a variety of analgesic techniques for labor and vaginal delivery (including nonpharmacologic methods, transcutaneous electrical nerve stimulation, intramuscular meperidine [pethidine], inhalation of nitrous oxide, epidural analgesia, and a combination of these techniques), pain relief and overall satisfaction with the birth experience were greater in patients who received epidural analgesia.[2] Similarly, randomized studies

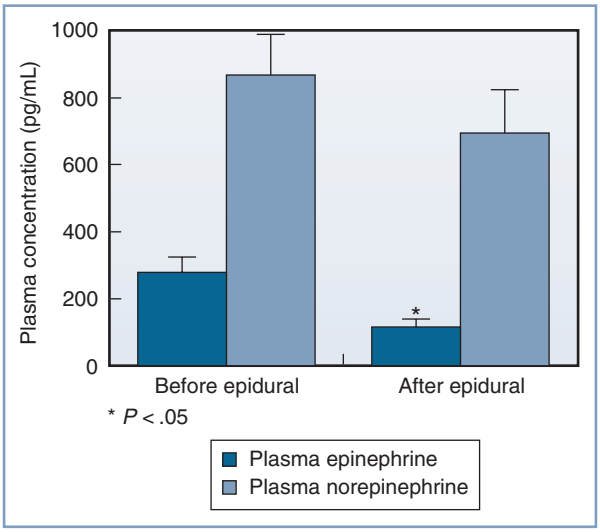

Fig. 23.1 Influence of epidural analgesia on maternal plasma concentrations of catecholamines during labor. *P < .05 compared with before initiation of epidural analgesia. (Modified from Shnider SM, Abboud TK, Artal R, et al. Maternal catecholamines decrease during labor after lumbar epidural anesthesia. *Am J Obstet Gynecol.* 1983;147:13–15.)

that have compared epidural analgesia with systemic opioids and/or inhalation analgesia (i.e., nitrous oxide) have shown that pain scores are lower and patients are more satisfied with neuraxial analgesia.[3]

The provision of analgesia for labor may result in other benefits. Effective epidural analgesia reduces maternal plasma concentrations of catecholamines (Fig. 23.1).[4] Decreased alpha- and beta-adrenergic receptor stimulation may result in better uteroplacental perfusion and more effective uterine activity.[5,6] Painful uterine contractions result in maternal hyperventilation. The hyperventilation, in turn, leads to maternal respiratory alkalosis, a leftward shift of the oxyhemoglobin dissociation curve, increased maternal hemoglobin affinity for oxygen, and reduced oxygen delivery to the fetus.[7] Hypocarbia also leads to hypoventilation between contractions, which may cause a decrease in maternal Pao_2. Effective epidural analgesia blunts this "hyperventilation-hypoventilation" cycle.[8] Additionally, one study showed that paternal anxiety levels were lower, and both paternal involvement in the childbirth process and paternal satisfaction were greater, in men whose partners received epidural analgesia than in those whose partners did not.[9] Finally, the presence of an epidural catheter and effective epidural *analgesia* facilitate the rapid initiation of epidural *anesthesia* for emergency cesarean delivery. Neuraxial anesthesia for cesarean delivery is associated with greater overall maternal safety than emergency administration of general anesthesia (see Chapter 26).[10]

Neuraxial analgesia is not used by all laboring women, although surveys of obstetric anesthesia practice in the United States have shown that the use of neuraxial analgesia has grown over the past four decades.[11] Data collected from the U.S. Standard Certificate of Live Birth in 27 states in 2008 indicated that 61% of women who had a singleton vaginal delivery received neuraxial analgesia.[12] The rate was higher among white women than in women of other races/ethnicities, and it was also higher in larger maternal units than in smaller units.[11,12] In a 2011 to 2013 survey of 2400 American women, 67% used spinal or epidural analgesia or anesthesia.[13] In France in 2016, over 80% of laboring women used neuraxial analgesia.[14]

The availability of skilled anesthesia providers influences the neuraxial analgesia rate.[11] Other factors include the information and advice provided to pregnant women by obstetricians, nurses, and childbirth education instructors. The personal and cultural expectations of a laboring woman,[15] as well as obstetric complications, also affect the childbirth experience and the use of neuraxial analgesia (see Chapters 20 and 21).

Ideally, the anesthesia provider should tailor the analgesic technique to meet the individual parturient's needs. Factors that should be considered in formulating an analgesic plan for individual parturients include the parturient's preferences for analgesia, coexisting maternal disease, the airway examination, fetal status, spontaneous versus induced labor, stage of labor, and anticipated risk for operative delivery. The risks and benefits of the various epidural and spinal analgesic techniques should be assessed for each parturient. Good technique requires thoughtful preparation and meticulous attention to detail to ensure maternal and fetal safety.

The ideal labor analgesic technique is safe for both the mother and the infant, does not interfere with the progress of labor and delivery, and provides flexibility in response to changing conditions. In addition, the ideal technique provides consistent pain relief, has a long duration of action, minimizes undesirable side effects (e.g., motor block), and minimizes ongoing demands on the anesthesia provider's time. No single technique or anesthetic agent is ideal for all parturients during labor. The American Society of Anesthesiologists (ASA) has published practice guidelines for obstetric anesthesia (see Appendix B),[16] as well as guidelines for neuraxial anesthesia in obstetric patients (see Appendix A). Guidelines promulgated by professional organizations in other countries also address obstetric anesthesia care. All obstetric anesthesia providers should review their country's respective guidelines. Specific neuraxial techniques for labor analgesia, including their advantages, disadvantages, side effects, and complications, are considered in this chapter.

PREPARATION FOR NEURAXIAL ANALGESIA

Indications and Contraindications

Epidural analgesia is indicated to treat the pain experienced by a woman in labor. In its 2017 Practice Bulletin, *Obstetric Analgesia and Anesthesia,* the American College of Obstetricians and Gynecologists (ACOG) reaffirmed an earlier opinion jointly published by the ASA and ACOG, which stated that "in the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor."[17] Furthermore, the ACOG[17] has stated that "decisions regarding analgesia should be closely

coordinated among the obstetrician-gynecologist or other obstetric care provider, the anesthesiologist, the patient, and skilled support personnel." Neuraxial analgesia is an appropriate treatment for the pain of labor, including early labor (defined as regular uterine contractions that cause progressive effacement and dilation of the uterine cervix). Randomized controlled trials[18-22] and a meta-analysis[23] have confirmed that initiation of neuraxial analgesia in early labor does not increase the risk for cesarean delivery (see later discussion).

Neuraxial analgesia may facilitate an atraumatic vaginal breech delivery, the vaginal delivery of twin infants, and vaginal delivery of a preterm infant (see Chapters 33 and 34). By providing effective pain relief, epidural analgesia facilitates blood pressure control in preeclamptic women (see Chapter 35). Epidural analgesia also blunts the hemodynamic effects of uterine contractions (e.g., sudden increase in cardiac preload) and the associated pain response (tachycardia, increased systemic vascular resistance, hypertension, hyperventilation) in patients with other medical complications (e.g., mitral stenosis, spinal cord injury, intracranial neurovascular disease, asthma; see Chapters 41, 48, and 52).

Box 23.1 lists the contraindications to administration of epidural or spinal analgesia. Some anesthesiologists have suggested that systemic maternal infection, preexisting neurologic disease, or severe stenotic heart lesions are relative contraindications to neuraxial analgesia. However, most cases of systemic infection (especially if properly treated), or neurologic or cardiac disease, do not contraindicate the administration of neuraxial analgesia (see Chapters 36, 41, and 48). It is also controversial whether mild or isolated abnormalities in tests of blood coagulation preclude the use of neuraxial analgesia. The dose and timing of administration of drugs administered for thromboprophylaxis must also be considered (see Chapter 44). The anesthesia provider should consider the risks and benefits of neuraxial analgesia for each patient individually.

Thorough preparation for neuraxial labor analgesia involves several steps (Box 23.2). These include (1) a review of the parturient's obstetric history; (2) a focused preanesthetic evaluation that includes maternal obstetric, anesthetic, and health history; and (3) a brief physical examination (i.e., vital signs, airway, heart, lungs, and back).[16] Routine measurement of the platelet count is not necessary; however, assessment of the platelet count and other laboratory measurements may be indicated in selected patients.[16] Similarly, routine intrapartum blood typing and screening or cross-matching is not necessary in healthy parturients, although consideration should be given to sending a blood sample to the blood bank (to facilitate the rapid availability of blood products in case of emergency need).[16] For parturients at increased risk for hemorrhage, intrapartum typing and screening or cross-matching should be performed. Fetal well-being should be assessed by a skilled provider, and equipment (including resuscitation equipment) should be checked by the anesthesia provider (see Box 12.1). Informed consent should be obtained (see Chapters 12 and 32). Early and ongoing communication among the obstetric and anesthesia providers, nursing staff, and other members of the multidisciplinary team is encouraged.

BOX 23.1 Contraindications to Epidural and Spinal Analgesia

- Patient refusal or inability to cooperate
- Increased intracranial pressure secondary to a mass lesion
- Skin or soft tissue infection at the site of needle placement
- Frank coagulopathy
- Recent pharmacologic anticoagulation[a]
- Uncorrected maternal hypovolemia (e.g., hemorrhage)
- Inadequate training in or experience with the technique
- Inadequate resources (e.g., staff, equipment) for monitoring and resuscitation

[a]Safety depends on specific drug and timing and dose of the most recent drug administration (see Chapters 38 and 44).

Types of Neuraxial Analgesia

The technical aspects of neuraxial analgesic/anesthetic techniques are discussed in detail in Chapter 12. These techniques include continuous epidural, combined spinal-epidural, and caudal analgesia and continuous and single-shot spinal analgesia. Continuous epidural and combined spinal-epidural analgesia are the most common techniques used for neuraxial labor analgesia. There are advantages and disadvantages to each technique (Table 23.1).

Epidural Analgesia

Continuous lumbar epidural analgesia has been the mainstay of neuraxial labor analgesia for several decades. Placement of an epidural catheter allows analgesia to be maintained until after delivery. No dural puncture is required. The presence of

BOX 23.2 Checklist: Preparation for Neuraxial Labor Analgesia

1. Communicate (early) with the obstetric provider.
   - Review parturient's obstetric history.
2. Perform focused preanesthetic evaluation.
   - Review maternal obstetric, anesthetic, and health history.
   - Perform targeted physical examination (vital signs, airway, heart, lungs, back).
3. Review relevant laboratory measurements and imaging studies.
4. Consider need for blood typing and screening or cross-matching.
5. Formulate analgesia plan.
6. Obtain informed consent.
7. Perform equipment check:
   - Check routine equipment.
   - Check emergency resuscitation equipment.
8. Obtain peripheral intravenous access.
9. Apply maternal monitors (blood pressure, heart rate, pulse oximetry).
10. Monitor fetal heart rate.
11. Perform a team time-out.

TABLE 23.1 Advantages and Disadvantages of Neuraxial Techniques in Labor

Neuraxial Technique	Advantages	Disadvantages
Continuous epidural	Continuous analgesia No dural puncture required Ability to extend analgesia to anesthesia for cesarean delivery	Slow onset of analgesia Larger drug doses required when compared with spinal techniques Greater risk for maternal local anesthetic systemic toxicity Greater fetal drug exposure
Combined spinal-epidural	Continuous analgesia Low doses of local anesthetic and opioid Rapid onset of analgesia Rapid onset of sacral analgesia Ability to extend analgesia to anesthesia for cesarean delivery Complete analgesia with opioid alone Decreased incidence of failed epidural analgesia	Increased incidence of pruritus Possible higher risk for fetal bradycardia
Continuous spinal	Continuous analgesia Low doses of local anesthetic and opioid Rapid onset of analgesia Ability to extend analgesia to anesthesia for cesarean delivery	Large dural puncture increases risk for post–dural puncture headache Possibility of overdose and total spinal anesthesia if the spinal catheter is mistaken for an epidural catheter
Continuous caudal	Continuous analgesia Avoids need to access neuraxial canal through lumbar interspace in patients with previous lumbar spine surgery	Requires large volumes/doses of drugs May be technically more difficult than other neuraxial techniques Possible higher risk for infection than with other neuraxial techniques Risk for inadvertent fetal injection
Single-shot spinal	Technically simple Rapid onset of analgesia Immediate sacral analgesia Low drug doses	Limited duration of analgesia

a catheter and effective analgesia allow the conversion to epidural anesthesia should cesarean delivery be necessary. Injection of a local anesthetic in the lumbar epidural space allows both cephalad and caudad spread of the anesthetic solution.

Analgesia is initiated by bolus injection of drug(s) through the epidural needle, catheter, or both. Analgesia is maintained with anesthesia provider-, patient-, or infusion pump–administered intermittent bolus injections or a continuous epidural infusion, or a combination of these techniques. The catheter is removed after delivery when there is no further need for analgesia or anesthesia.

Combined Spinal-Epidural Analgesia

Combined spinal-epidural (CSE) analgesia has become increasingly popular in the past 20 years. Onset of complete analgesia is significantly faster than with epidural techniques (2 to 5 minutes versus 10 to 15 minutes, respectively).[24] In a meta-analysis of the onset time of CSE compared with low-dose epidural analgesia,[24] the mean difference in onset was –5.4 minutes (95% confidence interval [CI], –7.3 to –3.6). More women with spinal analgesia than with epidural analgesia had effective analgesia at 10 minutes (relative risk [RR], 1.9; 95% CI, 1.5 to 2.5). In particular, the onset of sacral analgesia is significantly slower after the initiation of lumbar epidural analgesia than with spinal analgesia. It may take several hours of lumbar epidural infusion, or several bolus injections of local anesthetic into the lumbar epidural space, to achieve sacral analgesia. Rapid onset of sacral analgesia is advantageous in the parturient in whom analgesia is initiated late in the first stage of labor or in a parous parturient with rapid progress of labor. Spinal analgesia requires significantly lower drug doses to attain effective analgesia than does epidural analgesia; therefore, the risk for local anesthetic systemic toxicity is decreased. In addition, there is less systemic absorption of spinal anesthetic agents into the maternal circulation, so maternal and fetal plasma drug concentrations are lower with spinal than with epidural analgesia.

An additional advantage of spinal analgesia is that complete analgesia for early labor can be accomplished with the intrathecal injection of a lipid-soluble opioid without the addition of a local anesthetic. Thus, motor blockade is avoided and the risk for hypotension is lower.[25] This method is ideal for patients who wish to ambulate or for those with preload-dependent cardiac conditions such as stenotic heart lesions. Finally, use of the CSE technique may lower the incidence of failure of epidural analgesia (e.g., a nonfunctioning epidural catheter).[26,27] The likelihood of an epidural catheter placed for labor analgesia failing to provide satisfactory anesthesia for a

subsequent cesarean delivery was more than five times higher for catheters placed as part of an epidural technique than for catheters placed as part of a CSE technique.[28]

Several studies have described a modification of CSE analgesia in which a dural puncture is made with a small-gauge spinal needle but no drug is injected into the subarachnoid space (dural puncture epidural analgesia).[29–32] Results of studies are inconsistent, but two studies found that blockade of sacral dermatomes occurred more frequently after injection of epidural local anesthetic and opioid in parturients with a dural puncture than in those without.[30,32] Presumably, enhanced sacral analgesia occurs because of increased migration of anesthetic solution across the dural puncture site.

CSE analgesia has several possible undesirable side effects. Dural puncture is required to initiate CSE analgesia, although puncture with a small-gauge pencil-point needle does not appear to increase the risk for post–dural puncture headache.[24] A more serious concern, however, is that dural puncture during labor may be a risk factor for postpartum neuraxial infection, a rare but potentially life-threatening complication (see Chapter 31).

The incidence of pruritus is higher with intrathecal opioid administration than with epidural opioid administration.[24] Another purported disadvantage of the CSE technique is that the correct placement of the epidural catheter in the epidural space cannot be verified until spinal analgesia or anesthesia wanes. Therefore, it has been suggested that if a functioning epidural catheter is important to the safe care of the mother and fetus (e.g., in the setting of a suspected difficult airway or nonreassuring fetal status), an epidural rather than CSE technique is indicated. However, in a retrospective study that included 2395 neuraxial labor analgesia procedures, the CSE technique did not result in delayed recognition of epidural catheter failure, and the overall catheter failure rate was lower when the catheter was sited as part of CSE analgesia.[27]

The most common CSE technique for labor analgesia is the needle-through-needle technique in a midlumbar interspinous space (see Chapter 12). Analgesia is maintained via the epidural catheter, as with traditional epidural analgesia.

Continuous Spinal Analgesia

Continuous spinal analgesia is used occasionally for labor analgesia but is not practical for most parturients. Several spinal catheters are commercially available in the United States and Europe, but their use for continuous labor analgesia has not been well studied. Because the available catheters require dural puncture with a large-gauge needle, the technique may be associated with an unacceptably high incidence of post–dural puncture headache. However, continuous spinal analgesia is a management option in patients with unintentional dural puncture. Continuous spinal analgesia can readily be converted to surgical anesthesia if necessary.

Caudal Analgesia

Continuous caudal epidural analgesia is used infrequently in modern obstetric anesthesia practice. It is technically more difficult to place a caudal catheter than a lumbar epidural catheter. Large volumes of anesthetic solution are required to extend neuroblockade to the low thoracic spinal segments, resulting in higher maternal plasma concentrations of drug. There is a risk for needle/catheter misplacement and direct injection into the fetus. However, this technique is useful for parturients in whom access to the lumbar spinal canal is not possible (e.g., because of a fused lumbar spine).

Single-Shot Techniques

In general, single-shot techniques (spinal, lumbar epidural, or caudal) are not useful for most laboring women because of their limited duration of action. These techniques may be indicated for parturients who require analgesia or anesthesia shortly before anticipated vaginal delivery or in settings in which continuous neuraxial analgesia is not possible.[33] Intrathecal morphine has been combined with bupivacaine and sufentanil or fentanyl in an attempt to prolong analgesia. A 2016 meta-analysis of five randomized-controlled trials comparing single-shot spinal labor analgesia (bupivacaine and sufentanil or fentanyl) with and without morphine concluded that more adequately powered trials are necessary to determine the benefits and harms of the technique.[34]

Informed Consent

Informed consent is an important aspect of preparation for neuraxial labor analgesia (see Chapters 12 and 32). The preanesthetic evaluation and informed consent process allow the anesthesia provider to allay the parturient's concerns and to demonstrate a commitment to her care. Most laboring women understand the need for informed consent and appreciate the opportunity to participate in decisions about their care.

Equipment and Monitors

Resuscitation equipment, drugs, and supplies must be immediately available for the management of serious complications of neuraxial analgesia (e.g., hypotension, total spinal anesthesia, local anesthetic systemic toxicity) (see Box 12.1).[16] Emergency airway equipment should be checked before the administration of neuraxial analgesia.

During the initiation of neuraxial analgesia, the parturient's oxygen saturation is measured continuously and the blood pressure is assessed every 2 to 3 minutes for 15 to 20 minutes after the neuraxial anesthetic administration, or until the mother is hemodynamically stable (see Chapter 12). The fetal heart rate (FHR) should be monitored before and after the initiation of neuraxial analgesia; it may be difficult to monitor the FHR during the actual procedure.[16] During maintenance of neuraxial analgesia, maternal blood pressure is measured every 15 to 30 minutes, or more frequently if hypotension ensues. The sensory level of analgesia and the intensity of motor block (Box 23.3) are assessed after the administration of the test and therapeutic doses of local anesthetics. Subsequently, sensory level, motor block, and pain control are assessed at regular intervals.

BOX 23.3 Assessment of Motor Block

- Complete: patient unable to move feet or knees
- Almost complete: patient able to move feet only
- Partial: patient just able to move knees
- None: patient capable of full flexion of knees and feet

Modified from Bromage PR. *Epidural Analgesia*. Philadelphia, PA: WB Saunders; 1978:144.

Before the initiation of neuraxial analgesia, ultrasonographic imaging of the back may be helpful, especially in parturients whose landmarks are difficult to palpate.

Intravenous Hydration

Placement of an intravenous catheter (preferably 18-gauge or larger) and correction of hypovolemia with intravenous hydration are necessary before the initiation of neuraxial analgesia to mitigate hypotension that can result from sympathetic blockade. Data from small studies are conflicting as to whether a fluid bolus administered immediately before the initiation of analgesia decreases the risk for nonreassuring FHR patterns.[35–39] The ASA Task Force on Obstetric Anesthesia is silent on intravenous fluid management,[16] although many anesthesia providers administer approximately 500 mL of lactated Ringer's solution (without dextrose) immediately before or during the initiation of analgesia. Severe hypotension is less likely with the contemporary practice of administering a dilute solution of local anesthetic for epidural analgesia or an intrathecal opioid for spinal analgesia.

Studies of intravenous hydration and spinal anesthesia for cesarean delivery suggest that there is no advantage to administering the fluid before the initiation of anesthesia (preload) compared with administering the fluid at the time of initiation of anesthesia (co-load).[40] Rarely, hydration should be guided by serial assessment of intravascular fluid volume (e.g., central venous pressure, transthoracic echocardiography). Fluid administration should be judicious in parturients at risk for pulmonary edema (e.g., women with preeclampsia with severe features). Anesthesia and obstetric providers should avoid the bolus administration of dextrose-containing solutions in laboring women.

Maternal Positioning

Either the lateral decubitus or the sitting position can be used during initiation of neuraxial analgesia (see Chapter 12). Factors to consider when positioning the parturient for the procedure include patient comfort, avoidance of aortocaval compression, ability to monitor the FHR, provider comfort and experience, and optimal positioning of the spine and palpation of landmarks. Patient position relative to the baricity of the anesthetic solution should be considered during initiation of spinal analgesia/anesthesia. There is little evidence that patient position influences the extent of neuroblockade during initiation of epidural analgesia/anesthesia. After completion of the procedure, parturients should be assisted to the lateral position for the first 15 to 30 minutes after the neuraxial injection to alleviate aortocaval compression.

BOX 23.4 Suggested Procedure for Initiation of Epidural Labor Analgesia

1. Complete preparation for neuraxial analgesia checklist (see Box 23.2).
2. Position patient with the help of an assistant (lateral decubitus or sitting).
3. Initiate maternal blood pressure and pulse oximetry monitoring and fetal heart rate monitoring.
4. Initiate an intravenous fluid bolus (500 mL of lactated Ringer's solution).
5. Site epidural catheter in epidural space using sterile technique.
6. Administer an epidural test dose (see Table 12.2).
7. If the test dose is negative, secure epidural catheter and position patient in the lateral position.
8. Administer 5 to 15 mL of epidural local anesthetic, in 5-mL increments (usually low concentration of local anesthetic combined with a lipid-soluble opioid [see Table 23.2]).
9. Monitor maternal blood pressure every 2 to 3 minutes for 15 to 20 minutes, or until parturient is hemodynamically stable.
10. Assess pain score and extent of sensory blockade (cephalad and caudad).
11. Initiate maintenance epidural analgesia (see Table 23.5).

INITIATION OF EPIDURAL ANALGESIA

A procedure for initiating epidural labor analgesia is outlined in Box 23.4. Commonly, after siting the epidural catheter in the epidural space, a test dose is administered to rule out intrathecal or intravascular placement of the epidural catheter. After a negative test, epidural analgesia is established with the incremental injection of a local anesthetic, usually in combination with a lipid-soluble opioid. Maternal vital signs are monitored, and clinical analgesia is verified.

Epidural Test Dose

The purpose of the test dose is to help identify unintentional cannulation of a vein or the subarachnoid space. The test dose should contain a dose of local anesthetic and/or another marker sufficient to allow the recognition of intravenous or subarachnoid injection but not so large as to cause systemic toxicity or total spinal anesthesia. The most common *intravascular* test dose contains epinephrine (adrenaline) (see Chapter 12).

The use of the epinephrine test dose in obstetrics is not without detractors. Some anesthesia providers fear that intravenous injection of epinephrine may decrease uteroplacental perfusion and precipitate fetal compromise. However, there has been no report of adverse neonatal outcome after intravenous injection of an epinephrine-containing test dose. Another argument against routine use of a test dose is that aspiration of multi-orifice catheters is 98% sensitive in identifying their intravascular location.[41] (The sensitivity of aspiration is significantly lower for single-orifice catheters.) The epidural test dose contributes to undesirable motor

blockade.[42,43] Finally, because modern epidural labor analgesia involves the infusion of a low concentration of local anesthetic solution, unintentional intravascular or intrathecal administration is not likely to result in cardiovascular collapse or total spinal anesthesia.

Others argue that the test dose still has a role in obstetric anesthesia practice.[44] Large volumes of a concentrated local anesthetic solution are still routinely administered for emergency cesarean delivery. Although not a safety issue, it is easier for the parturient and anesthesia provider to identify a misplaced catheter at the time of initial placement and to replace the catheter at that time rather than identify the misplaced catheter after the sterile field has been breached and the parturient repositioned.

The epinephrine test dose is less specific in laboring women because cyclic changes in maternal heart rate complicate interpretation of its effects.[45] For this reason, if used, the test dose should be given immediately after a uterine contraction so there is less confusion as to whether tachycardia is caused by pain or intravenous epinephrine. Other methods of detecting intravascular injection are discussed in Chapter 12.

No matter whether a formal test dose is used or not, it is imperative that the anesthesia provider take the time to look for evidence of unintentional intrathecal or intravascular injection of local anesthetic. Finally, every anesthesia provider should remember that no single test dose regimen can exclude every case of unintentional intravenous or subarachnoid injection. Box 12.3 summarizes steps that may be taken to decrease the risk for unintentional intravenous or subarachnoid injection of local anesthetic.

Choice of Drugs

The ideal analgesic drug for labor would provide rapid onset of effective analgesia with minimal motor blockade, minimal risk for maternal toxicity, and negligible effect on uterine activity and uteroplacental perfusion. It would undergo limited transplacental transfer and thus have minimal direct effect on the fetus. Finally, this ideal agent would have a long duration of action. Although this perfect analgesic drug does not exist, the combination of a local anesthetic with an opioid allows us to approach this goal.

Traditionally, local anesthetics were administered to block both the visceral pain of labor (lower uterine segment distention and cervical dilation) and the somatic pain (descent of the fetus in the birth canal). More than 40 years ago, investigators identified dense concentrations of opioid receptors in the dorsal horn of the spinal cord.[46] The application of small doses of an opioid to these receptor sites generates a specific and profound opioid response.[46] The introduction of neuraxial opioids to the armamentarium of the obstetric anesthesia provider moved us closer to the prediction made by Benjamin Rush in 1805: "A medicine would be discovered which should suspend sensibility altogether and leave irritability or powers of motion unimpaired."[47] Intrathecal opioids effectively relieve the visceral pain of the early first stage of labor, although they must be combined with a local anesthetic to effectively relieve the somatic pain of the late first stage and the second stage of labor. The combination of a local anesthetic with a lipid-soluble opioid allows for the use of lower doses of each agent, thus minimizing undesirable side effects. For example, when used alone without an opioid, the local anesthetic dose required for effective epidural analgesia is associated with an unacceptably high incidence of motor blockade. Similarly, used alone, high doses of epidural opioid are required for satisfactory analgesia during early labor, and such doses are associated with significant systemic absorption and systemic side effects. The addition of an opioid to the local anesthetic also shortens latency,[48] an important aspect of labor analgesia, especially with the use of long-acting (and therefore, long-latency) local anesthetics. Thus, contemporary epidural labor analgesia practice most often incorporates low doses of a long-acting local anesthetic combined with a lipid-soluble opioid.

Local Anesthetics

Bupivacaine. Traditionally, the amide local anesthetic bupivacaine has been the most commonly used agent for epidural labor analgesia. Bupivacaine is highly protein-bound, a feature that limits transplacental transfer. The umbilical vein–to–maternal vein concentration ratio is approximately 0.3.[49] After epidural administration of bupivacaine (without opioid) during labor, the patient first perceives pain relief within 8 to 10 minutes,[50] but approximately 20 minutes are required to achieve the peak effect. Duration of analgesia is approximately 90 minutes. Bupivacaine 6.25 to 12.5 mg (e.g., 10 to 20 mL of a 0.0625% solution, or 5 to 10 mL of a 0.125% solution) combined with fentanyl or sufentanil is adequate to initiate labor analgesia in most parturients (Table 23.2).

The potency of local anesthetics for neuraxial labor analgesia is often assessed by determining the median effective concentration of local anesthetic solution when administered as a 20-mL epidural bolus (this concentration is sometimes referred to as the minimum local anesthetic concentration [MLAC]). It is lower for women in early labor than in late labor,[51] and it is also lower when the local anesthetic is combined with a lipid-soluble opioid.[52]

It is important to consider both the local anesthetic *dose* and *concentration* for initiation and maintenance of epidural analgesia. Christiaens et al.[53] randomly assigned parturients to receive epidural bupivacaine 20 mg diluted in 4 mL, 10 mL, or 20 mL (0.5%, 0.2%, and 0.1% solutions, respectively). Analgesia in the 10-mL and 20-mL groups was superior to that in the 4-mL group, and duration of analgesia was longest in the 20-mL group. Lyons et al.[54] compared the minimum local anesthetic volume (MLAV) and minimum local anesthetic dose (MLAD) for 0.125% and 0.25% bupivacaine for epidural labor analgesia. Bupivacaine 0.125% produced analgesia equivalent to that provided by bupivacaine 0.25%, with a 50% increase in required volume and a 25% reduction in dose (Table 23.3). Stated differently, a dose-sparing effect is achieved by administering a 0.125% solution of bupivacaine rather than a 0.25% solution. Ginosar et al.[55] randomized parturients to receive maintenance of analgesia

TABLE 23.2 Drugs Used for Initiation of Epidural and Spinal Labor Analgesia

Drug	Epidural Analgesia[a]	Spinal Analgesia
Local Anesthetics[b]		
Bupivacaine	0.0625%–0.125%	1.25–2.5 mg
Ropivacaine	0.08%–0.2%	2.0–3.5 mg
Levobupivacaine	0.0625%–0.125%	2.0–3.5 mg
Lidocaine[c]	0.75%–1.0%	NA
Opioids[b]		
Fentanyl	50–100 μg	15–25 μg[d]
Sufentanil	5–10 μg	1.5–5 μg[d]
Morphine[c]	NA	125–250 μg[d]
Meperidine[c]	NA	10–20 mg

Note: The suggested doses are based on clinical studies, potency ratios, and clinical experience.
NA, not applicable.
[a]The volume required to initiate epidural labor analgesia is 10 to 15 mL of local anesthetic solution.
[b]The local anesthetic dose/concentration and the fentanyl or sufentanil dose are reduced if the drugs are combined or if a local anesthetic-containing epidural test dose is administered before the initial therapeutic dose. The dose of opioid should be reduced or the opioid omitted if the parturient has recently received systemic opioid analgesia.
[c]Lidocaine, morphine, and meperidine are not commonly used for labor analgesia because of their short duration of action (lidocaine), long latency (morphine), and high incidence of nausea and vomiting (morphine and meperidine).
[d]Opioids may be administered without local anesthetics when spinal analgesia is induced in early labor. Women in active labor require a higher dose than women in latent labor.

TABLE 23.3 Comparison of Epidural Bupivacaine 0.125% and 0.25%: Median Effective Volume and Dose

	Bupivacaine 0.125%[c]	Bupivacaine 0.25%[c]
Median Effective Volume[a]		
Up-down analysis (mL)	13.6 (12.4–14.8)	9.2 (6.9–11.5)
Probit analysis (mL)	13.5 (11.4–15.9)	8.6 (7.2–10.3)
Median Effective Dose[b]		
Up-down analysis (mg)	17.0 (15.5–18.5)	23.1 (17.2–28.9)
Probit analysis (mg)	16.8 (14.2–19.9)	21.5 (17.9–25.7)

[a]Median effective volume at a fixed local anesthetic concentration.
[b]Median effective dose at a fixed local anesthetic concentration.
[c]95% confidence intervals shown in parentheses, which were calculated using up-down sequential and probit analysis.
Modified from Lyons GR, Kocarev MG, Wilson RC, Columb MO. A comparison of minimum local anesthetic volumes and doses of epidural bupivacaine (0.125% w/v and 0.25% w/v) for analgesia in labor. *Anesth Analg.* 2007;104:412–415.

with an epidural infusion of either bupivacaine 0.25% at 5 mL/h or bupivacaine 0.0625% at 20 mL/h (10 mg/h in both groups). The median bupivacaine dose was lower and patient satisfaction was greater with bupivacaine 0.0625% than with bupivacaine 0.25%. Together, these data suggest that epidural analgesia and safety are improved with the use of low concentration–high volume local anesthetic solutions.

Ropivacaine. Ropivacaine, a relatively newer amide local anesthetic, is similar to bupivacaine in structure and pharmacodynamics (see Chapter 13). It is a homologue of bupivacaine and mepivacaine, but unlike these other local anesthetics it is formulated as a single-levorotary enantiomer rather than a racemic mixture. Studies of pregnant sheep have demonstrated that clinically relevant plasma concentrations of ropivacaine do not adversely affect uterine blood flow.[56]

Studies *in vitro* and *in vivo* have shown that ropivacaine is less cardiodepressant and arrhythmogenic than bupivacaine when doses of equal *mass* are compared.[57,58] Ropivacaine is cleared more rapidly than bupivacaine after intravenous administration in both pregnant and nonpregnant sheep. Consequently, a larger dose of drug—but not a higher plasma concentration—is required to produce systemic toxicity.[59] These findings suggest that ropivacaine may have a greater margin of safety than bupivacaine if unintentional intravenous injection occurs in pregnant women. However, many early investigations assumed that ropivacaine and bupivacaine are equipotent; subsequent studies have demonstrated that ropivacaine is 25% to 40% less potent than bupivacaine.[60–62] In one study that characterized the full dose-response curves, the slope of the bupivacaine and ropivacaine curves were similar, suggesting that the nature of the drug-receptor interaction is not different between the two drugs.[62] When ropivacaine concentrations are adjusted for this difference in potency, there is a less clear advantage for ropivacaine in terms of the risk for systemic toxicity.[60] In reality, systemic toxicity is not a major concern with the contemporary administration of a dilute solution of local anesthetic for epidural labor analgesia.

Several studies that compared equal concentrations of ropivacaine and bupivacaine given by patient-controlled epidural analgesia (PCEA) have not found any significant difference in clinical efficacy between the two local anesthetics.[63–67] Other studies that adjusted for the potency difference and compared equipotent concentrations (e.g., 0.0625% bupivacaine versus 0.1% ropivacaine) also found no difference in clinical efficacy.[68,69] It is important to recognize that potency is an unchanging property of a drug, whereas clinical efficacy is influenced by multiple variables. For example, ropivacaine has a longer duration of analgesia than bupivacaine,[60] which may offset its lesser potency when it is administered by continuous epidural infusion.

Early clinical studies suggested that ropivacaine is associated with less motor block than bupivacaine[70,71]; avoidance of motor blockade is a desirable characteristic of neuraxial analgesia during labor. However, these studies also compared equal concentrations of ropivacaine and bupivacaine, and the observed lower degree of motor blockade may reflect the lesser potency of ropivacaine. A study of the relative motor-blocking potencies of epidural ropivacaine and bupivacaine showed that ropivacaine was less potent than bupivacaine in terms of motor blockade,[72] a finding that corresponded to the relative analgesic potencies of the two drugs.[60,61] The differences in potency of motor blockade may not be relevant

with the use of low concentrations of local anesthetic. Several clinical studies[63,65,73] and a well-conducted meta-analysis of studies that compared epidural ropivacaine and bupivacaine[74] did not demonstrate an advantage for ropivacaine in terms of outcome of labor (see later discussion), although the incidence of motor blockade was less in the ropivacaine groups.[65,73,74]

There is no clear evidence of greater patient safety, lower risk for instrumental vaginal delivery, or other improved outcomes when ropivacaine is used to provide epidural labor analgesia.[73,75] A 2010 review concluded that there is no advantage to the routine use of ropivacaine compared with bupivacaine for labor analgesia.[75] In contrast, ropivacaine offers greater patient safety in settings in which high concentrations and greater volumes of drugs are administered (e.g., brachial plexus blockade or epidural anesthesia for cesarean delivery).[76]

Like bupivacaine, ropivacaine is often combined with fentanyl or sufentanil for labor analgesia. Ropivacaine concentrations used to initiate epidural analgesia range from 0.08% to 0.2% (see Table 23.2). Higher concentrations are used if the drug is administered without an opioid.

Levobupivacaine. Levobupivacaine is the levorotary enantiomer of bupivacaine (which is a racemic mixture). It is not available in the United States. Both preclinical and clinical studies have suggested that, like ropivacaine, levobupivacaine has less potential for cardiotoxicity than bupivacaine when equal doses of the two drugs are compared.[77,78] One study found that levobupivacaine was essentially equipotent to bupivacaine with a potency ratio of 0.98; however, the 95% CI was wide (0.67 to 1.41).[79] Other studies have suggested that levobupivacaine and ropivacaine have similar potency.[80,81] In an MLAC study that compared the motor blocking potency of bupivacaine and levobupivacaine,[82] levobupivacaine was less potent than bupivacaine (potency ratio, 0.87; 95% CI, 0.77 to 0.98).[82] Beilin et al.[65] compared epidural bupivacaine, ropivacaine, and levobupivacaine (0.0625% with fentanyl 2 µg/mL*) for labor analgesia. There were no differences among groups in obstetric outcomes, although the incidence of motor blockade was lower in the ropivacaine and levobupivacaine groups. Therefore, although epidural bupivacaine is more potent than ropivacaine for both sensory and motor blockade during labor, and may be more potent than levobupivacaine, there do not appear to be any clinical advantages of one drug over the other two drugs for epidural labor analgesia.

Lidocaine. Lidocaine is an amide local anesthetic with a duration of action intermediate between those of bupivacaine and 2-chloroprocaine. During labor, the administration of a 0.75% to 1.0% solution of lidocaine typically provides satisfactory analgesia. However, lidocaine is not commonly used for initiation or maintenance of epidural labor analgesia, in part because of its shorter duration of action in comparison with bupivacaine, ropivacaine, and levobupivacaine. Lidocaine is less protein-bound than these other amide local anesthetics, and at delivery, the umbilical vein–to–maternal vein lidocaine concentration ratio is approximately twice that of bupivacaine.[83] Early studies discouraged the epidural administration of lidocaine in pregnant women because epidural lidocaine was associated with abnormal neonatal neurobehavioral findings.[84] Subsequently, larger, more carefully controlled studies have demonstrated that the epidural administration of lidocaine, bupivacaine, and 2-chloroprocaine have similar neonatal outcomes.[85,86] Although some investigators have observed subtle differences in neurobehavior between infants exposed to lidocaine and those exposed to other local anesthetics, these differences are within the inherent variability of the examinations and are not clinically significant. Other factors (e.g., mode of delivery) appear to be much more important determinants of neonatal condition.

2-Chloroprocaine. An ester local anesthetic, 2-chloroprocaine has a rapid onset of action. Epidural administration of 10 mL of 2% 2-chloroprocaine provides effective analgesia for approximately 40 minutes. The short duration of action limits its usefulness during labor. In addition, the epidural administration of 2-chloroprocaine may adversely affect the efficacy of subsequently administered epidural bupivacaine and opioids,[87,88] although it is unclear whether the mechanism is related to pharmacokinetic or pharmacodynamic properties of the drug.[89,90] In obstetric practice, 2-chloroprocaine is most commonly used for extension of epidural labor analgesia for instrumental vaginal delivery (see later discussion) or emergency cesarean delivery (see Chapter 26).

Opioids

Lipid-soluble opioids: fentanyl and sufentanil. Morphine was one of the first opioids to be studied for labor analgesia. However, because of its long latency, side effects, and inconsistent analgesia, morphine has largely been replaced by the lipid-soluble opioids fentanyl and sufentanil (see Chapter 13). The lipid-soluble agents have a rapid onset of action. Permeability (of the dura-arachnoid) is not a rate-limiting factor, and increasing the concentration gradient (by administration of a larger dose) facilitates faster entry into the spinal cord. The high lipid solubility of these agents also results in a shorter duration of action and greater systemic absorption than occurs with water-soluble drugs.

*The Institute of Safe Medicine Practices (ISMP) has recommended that health care providers never use µg as an abbreviation for micrograms, but rather they should use mcg (http://www.ismp.org/tools/errorproneabbreviations.pdf, accessed October 2017). The use of the symbol µg is frequently misinterpreted and involved in harmful medication errors. The abbreviation may be mistaken for mg (milligrams), which would result in a 1000-fold overdose. The symbol µg should never be used when communicating medical information, including pharmacy and prescriber computer order entry screens, computer-generated labels, labels for drug storage bins, and medication administration records. However, most scholarly publications have continued to use the abbreviation µg. The editors have chosen to retain the use of the abbreviation µg throughout this text. However, the editors recommend the use of the abbreviation mcg in clinical practice.

Some investigators have suggested that the improved analgesia results from a supraspinal action rather than a primary spinal action. However, several studies have refuted this theory, including studies of epidural opioid administration by bolus[91] and continuous infusion.[92] Vella et al.[91] observed that the initiation of epidural analgesia with 0.25% bupivacaine with *epidural* fentanyl 80 µg resulted in more rapid, complete, and prolonged analgesia than *intravenous* fentanyl 80 µg, even though plasma fentanyl concentrations were higher in the intravenous group. Similarly, D'Angelo et al.[92] demonstrated that a continuous epidural infusion but not an intravenous infusion of fentanyl reduced epidural bupivacaine requirements in laboring women. Polley et al.[93] determined that the MLAC of epidural bupivacaine administered as a 20-mL bolus in laboring women was reduced from 0.064% to 0.034% when epidural rather than intravenous fentanyl was co-administered with bupivacaine. Ginosar et al.[94] determined that the MLAC of bupivacaine administered by *continuous epidural infusion* during labor was lower by a factor of three when it was co-administered with an epidural (rather than intravenous) fentanyl infusion. Finally, in a volunteer study,[95] lumbar epidural administration of fentanyl resulted in tolerance to experimental pain at a lumbar but not a cranial dermatome, whereas intravenous fentanyl administration resulted in pain tolerance at both dermatomes. These studies strongly suggest that during labor, epidural fentanyl provides analgesia primarily through a spinal site of action.

Epidural fentanyl alone provides *moderate* analgesia in early labor,[48] but the dose needed to provide complete analgesia is accompanied by significant side effects (e.g., pruritus, nausea, maternal sedation, perhaps neonatal depression). In addition, epidural administration of an opioid alone provides inadequate analgesia during the late first stage as well as the second stage of labor. In a study comparing sufentanil alone, sufentanil with bupivacaine, and bupivacaine alone,[96] women randomly assigned to the sufentanil-alone (30 µg) group experienced satisfactory analgesia after the initial dose but not after subsequent doses. However, the initial dose was administered after an epidural test dose that contained lidocaine 60 mg. In clinical practice, epidural fentanyl and sufentanil are usually administered with a local anesthetic for the initiation of analgesia (at a minimum, with a local anesthetic–containing epidural test dose).

In clinical practice, either fentanyl or sufentanil is frequently combined with a low-concentration, long-acting amide local anesthetic to initiate epidural labor analgesia. Epidural opioid administration allows the anesthesia provider to use a more dilute solution of local anesthetic to provide epidural labor analgesia.[97] Epidural fentanyl and sufentanil decrease epidural bupivacaine requirements during labor in a dose-dependent fashion (Fig. 23.2).[52,98] The reduction in MLAC by the addition of fentanyl or sufentanil is observed with levobupivacaine,[99,100] ropivacaine,[100,101] and 2-chloroprocaine[102] as well as bupivacaine.

The addition of a lipid-soluble opioid to a local anesthetic for neuraxial labor analgesia decreases latency, prolongs the duration of analgesia, and improves the quality of analgesia.

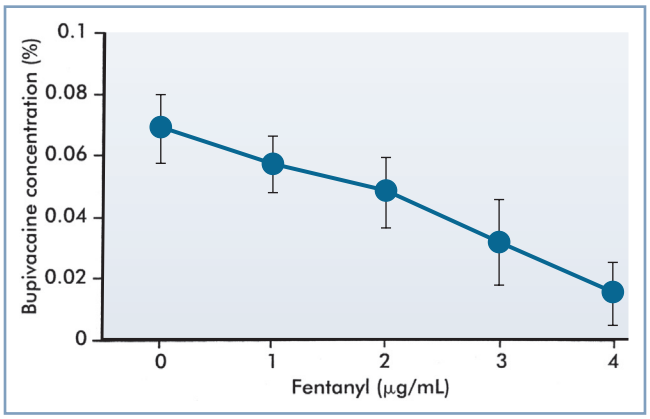

Fig. 23.2 The effect of epidural fentanyl on the minimum local anesthetic concentration (defined as the effective concentration in 50% of subjects [EC_{50}]) for epidural bupivacaine analgesia during labor. Data are expressed as median concentrations with 95% confidence intervals. (Data from Lyons G, Columb M, Hawthorne L, Dresner M. Extradural pain relief in labour: bupivacaine sparing by extradural fentanyl is dose dependent. *Br J Anaesth.* 1997;78:493–496.)

For example, Reynolds and O'Sullivan[103] showed that epidural bupivacaine 10 mg combined with fentanyl 100 µg was more effective for the treatment of breakthrough pain and had a faster onset and longer duration of action than either bupivacaine 25 mg or fentanyl 100 µg administered alone. Van Steenberge et al.[104] observed that the mean (± SD) onset of analgesia was 10.3 ± 3.8 minutes in women randomly assigned to receive bupivacaine 12.5 mg without sufentanil, whereas it was 8.7 ± 2.6 minutes in women who received bupivacaine combined with sufentanil 7.5 µg. Duration of analgesia was longer in the sufentanil group (131 minutes versus 86 minutes without sufentanil).[104] In another study,[105] the addition of fentanyl 100 µg to 0.125% bupivacaine prolonged the mean duration of analgesia from 55 minutes to 106 minutes.

The quality of analgesia is also better with the addition of an opioid to the local anesthetic. For example, 86% of women rated their analgesia as excellent after epidural analgesia was initiated with bupivacaine combined with sufentanil, compared with 50% of those who received bupivacaine without sufentanil.[104] The percentage of women who experienced no or short periods of pain during the first stage of labor was 94% in women who received sufentanil and 76% in women who did not.[106] After initiation of analgesia with 0.125% bupivacaine with epinephrine 1.25 µg/mL, 43% of women randomly assigned to receive epidural fentanyl 100 µg rated their analgesia as excellent, compared with 6% in a control group that did not receive fentanyl.[105]

The dose-sparing effects of fentanyl and sufentanil are also evident when the drugs are combined with a low-concentration solution of bupivacaine used for the maintenance of analgesia throughout labor. For example, the total bupivacaine dose (mean ± SD) was 34 ± 17 mg in laboring women who received 0.125% bupivacaine/epinephrine 1.25 µg/mL with sufentanil, compared with 42 ± 19 mg in those who received bupivacaine/epinephrine without

sufentanil.[106] Similarly, in women randomly assigned to receive bupivacaine/epinephrine with or without fentanyl 100 μg, the total bupivacaine dose was 55 mg or 110 mg, respectively.[105] Advantages of a lower total dose of local anesthetic include (1) decreased risk for local anesthetic systemic toxicity, (2) decreased risk for high or total spinal anesthesia, (3) decreased plasma concentrations of local anesthetic in the fetus and neonate, and (4) decreased intensity of motor blockade.

Several studies have directly compared the administration of epidural fentanyl or sufentanil combined with a local anesthetic for the initiation of labor analgesia. There were no differences in analgesia in women in early labor randomly assigned to receive either fentanyl 100 μg or sufentanil 20 μg immediately after a lidocaine 45-mg/epinephrine 15-μg test dose.[107] In contrast, a second study demonstrated slightly better analgesia 20 minutes after injection of 0.125% bupivacaine (15 mg) with sufentanil 15 μg than after the same dose of bupivacaine with fentanyl 75 μg.[108]

In the United States, fentanyl is more commonly used because historically it had a lower acquisition cost than sufentanil. Additionally, the concentration of the commercially available sufentanil preparation (50 μg/mL) may make drug errors more likely with sufentanil than with fentanyl because sufentanil doses significantly lower than 50 μg are used for initiation of epidural analgesia.

There are few rigorous *dose-response* studies of epidural fentanyl or sufentanil combined with bupivacaine for initiation of epidural labor analgesia. Herman et al.[109] randomly assigned 100 laboring women with a cervical dilation of 5 cm or less to receive 0.125% bupivacaine 10 mL, combined with fentanyl 0 to 100 μg (in 25-μg increments) or sufentanil 0 to 25 μg (in 5-μg increments), injected after a negative epidural test dose (bupivacaine 7.5 mg with epinephrine 15 μg). Using a probit dose-response analysis, these researchers calculated the effective dose in 95% of subjects (ED_{95}) to be 50 μg for fentanyl and 8 μg for sufentanil; these figures equate to a sufentanil-to-fentanyl potency ratio of 6.3:1. Capogna et al.[110] sought to determine the median effective analgesic dose (ED_{50}) of epidural fentanyl and sufentanil alone (no local anesthetic) for the initiation of epidural analgesia in nulliparous women with a cervical dilation between 2 and 4 cm. The ED_{50} of fentanyl was 124 μg (95% CI, 118 to 131), and the ED_{50} of sufentanil was 21 μg (95% CI, 20 to 22), with a potency ratio of 5.9:1. The potency ratio in volunteers subjected to an electrical stimulus was approximately 5:1.[111] Taken together, these data suggest that the potency ratio of sufentanil to fentanyl administered into the epidural space is approximately 6:1.

Several studies have compared bupivacaine combined with fentanyl 50 μg and 100 μg. No differences in the onset, duration, and quality of analgesia were noted in Asian women randomly assigned to receive 0.125% bupivacaine (10 mg) combined with either 50 or 100 μg of fentanyl.[112] In contrast, when 0.125% bupivacaine (15 mg) with epinephrine 15 μg was administered to laboring Italian women with either 50 or 100 μg of fentanyl, there was no difference in the onset or duration of analgesia, but more women in the 100-μg group had excellent analgesia.[105]

There were no differences in latency, duration of analgesia, and quality of analgesia when analgesia was induced with 0.125% bupivacaine (12.5 mg)/epinephrine 12.5 μg and either 7.5 or 15 μg of sufentanil.[104] Similarly, after injection of a lidocaine 60-mg/epinephrine 15-μg test dose, another study found no differences in latency and quality of analgesia among epidural sufentanil doses of 5, 10, 20, 30, 40, and 50 μg.[113] However, the duration of analgesia was longer after the higher doses of sufentanil.

The range of fentanyl and sufentanil doses used for the initiation of epidural labor analgesia is shown in Table 23.2. Pain and analgesic requirements vary depending on several factors, including parity, stage of labor, presence of ruptured membranes, oxytocin augmentation, and whether the opioid is administered in combination with a local anesthetic. One study reported that the ED_{50} of epidural sufentanil was higher in women undergoing prostaglandin induction of labor than in women with spontaneous labor.[114] Conell-Price et al.[115] developed a model of labor pain in nulliparous women and found that the use of oxytocin was associated with 48% more pain at the start of labor. Preliminary evidence suggests that pharmacogenetics may also play a role in dose requirements. Camorcia et al.[116] reported that nulliparous women who were heterozygous or homozygous for the single nucleotide polymorphism (SNP) A118G (substitution of guanine for adenine at position 118) of the gene encoding the μ-opioid receptor *(OPRM1)* had a lower ED_{50} for epidural sufentanil administered for labor analgesia.

Several early studies suggested that the duration of epidural and spinal analgesia may exhibit circadian rhythm (chronobiology), possibly secondary to human biologic rhythms.[117] However, in a secondary analysis of data from a large study, Scavone et al.[118] found no evidence of a circadian response to intrathecal fentanyl or intravenous opioid labor analgesia. In a detailed analysis of data from a study designed to test whether parturient response to intrathecal bupivacaine exhibited a circadian rhythm, Shafer et al.[119] demonstrated that external daily rhythms, such as nursing shifts, may contribute to the appearance of biologic rhythm. Thus, whether a circadian response to neuraxial local anesthetic or opioid exists, or is clinically significant, requires further study.

Current evidence supports the administration of epidural opioid doses at the lower end of the dose range for nulliparous women, for women in early labor, or when the opioid is coadministered with a local anesthetic. Higher doses are associated with a higher incidence of maternal side effects and the potential for neonatal depression (see later discussion). The major maternal side effect of epidural fentanyl and sufentanil for labor analgesia is pruritus. Neonatal outcomes do not appear to be adversely affected by the addition of fentanyl or sufentanil to a local anesthetic for epidural analgesia (see later discussion). In fact, the combination of drugs allows lower doses of both drugs to be administered, resulting in lower concentrations of both drugs in the neonate.

Two studies found that the diluent volume (2 to 20 mL) did not affect the onset and duration of epidural labor analgesia when fentanyl was injected into the epidural space after the injection of a local anesthetic solution.[120,121]

Other opioids. **Morphine** was one of the first opioids used for labor analgesia. Hughes et al.[122] compared analgesia using epidural administration of morphine (2.0, 5.0, and 7.5 mg) with that using epidural bupivacaine 0.5%. Morphine was effective in 7 of 11 parturients until the end of the first stage of labor, but all parturients required bupivacaine for adequate analgesia during the second stage of labor. Subsequently, investigators combined morphine with bupivacaine and observed a longer duration of analgesia compared with that for bupivacaine alone.[123] However, the inconsistent analgesia, long latency (30 to 60 minutes), and high incidence of side effects of morphine (which continued after delivery), along with the introduction of lipid-soluble opioids and epidural infusion pumps into clinical practice, have made the use of epidural morphine for labor analgesia largely obsolete.

Several studies described the use of **alfentanil** with bupivacaine for labor analgesia.[124,125] Alfentanil has lower lipid solubility than both fentanyl and sufentanil. Only a few small studies have compared alfentanil with other opioids for labor analgesia.

Several groups of investigators have reported the use of epidural **hydromorphone** for labor analgesia.[126–128] The lipid solubility of hydromorphone lies between those of morphine and fentanyl, but is closer to that of morphine.[129] In a large prospective observational study, effective labor analgesia was obtained by initiating analgesia with 0.25% bupivacaine (20 to 25 mg) with epinephrine (40 to 50 μg), followed by hydromorphone 100 μg.[126] However, Mhyre[128] observed that effective labor analgesia could not be provided by 0.035% bupivacaine (7 mg) with hydromorphone 100 to 110 μg. In another trial, parturients were randomly assigned to receive either epidural hydromorphone 300 μg or saline-control immediately after the initiation of analgesia with lidocaine 45 mg, epinephrine 15 μg, and fentanyl 100 μg.[127] Duration of analgesia and side effects were similar in the two groups. At the current time, further investigation is required before hydromorphone can be recommended for epidural labor analgesia.

Meperidine may be used effectively alone (without a local anesthetic), in part because it possesses local anesthetic properties.[130] When given during labor, epidural meperidine 100 mg provides analgesia similar to that provided by 0.25% bupivacaine, with less motor blockade. However, this dose of epidural meperidine produces more sedation, nausea, and pruritus than epidural bupivacaine. Handley and Perkins[131] observed that the addition of meperidine 25 mg to 0.125%, 0.187%, or 0.25% bupivacaine (10 mL) provided adequate analgesia for the first stage of labor. Epidural administration of meperidine effectively prevents or treats the shivering that often occurs during labor.[132] Investigators from Saudi Arabia randomly allocated women to receive 0.1% bupivacaine with either meperidine 1 mg/mL or fentanyl 2 μg/mL.[133] No differences were noted between groups in analgesic characteristics, except that women in the meperidine group had a higher incidence of nausea and vomiting. Currently there is no evidence that meperidine alone or in combination with bupivacaine has any advantages over a combination of a long-acting amide local anesthetic and a lipid-soluble opioid.

Butorphanol is a lipid-soluble opioid agonist-antagonist, with weak μ-receptor and strong κ-receptor activity. Because κ-opioid receptors appear to be involved in the modulation of visceral pain, κ-receptor agonists should be useful agents for the relief of labor pain, which has a significant visceral component (see Chapter 20).[123,134,135] Somnolence is the most prominent side effect of epidural butorphanol. The addition of butorphanol 1, 2, or 3 mg to 0.25% bupivacaine (25 mg) shortened latency and prolonged the duration of analgesia in comparison with epidural bupivacaine alone in one study.[134] The investigators concluded that the optimal dose of butorphanol was 2 mg. Of concern was the observation of a transient sinusoidal FHR pattern in the 3-mg group that was not unlike that seen after the intravenous administration of butorphanol.[135] However, there was no difference among groups in Apgar scores, umbilical cord blood gas and pH measurements, or neurobehavioral scores. Similarly, Abboud et al.[123] observed that the addition of butorphanol 1 or 2 mg to 0.25% bupivacaine resulted in better quality and longer duration of analgesia than the epidural administration of bupivacaine alone, without maternal or neonatal side effects. However, some anesthesia providers have noted that the epidural administration of butorphanol results in somnolence and occasional dysphoria, which are side effects of κ-receptor stimulation.

Diamorphine (heroin) is available for epidural analgesia in the United Kingdom. Using isobolographic analysis, McLeod et al.[136] concluded that the combination of diamorphine and levobupivacaine is additive when used for first-stage labor analgesia. Several studies from the United Kingdom have reported diamorphine doses between 250 and 500 μg/h (i.e., diamorphine 25 to 50 μg/mL combined with a low concentration of bupivacaine).[124,137] Whether diamorphine offers any advantages over fentanyl or sufentanil has not been studied. It is not available for clinical administration in the United States.

Adjuvants

Although the contemporary mainstay of epidural labor analgesia includes administration of a long-acting amide local anesthetic combined with a lipid-soluble opioid, other drugs may be added as adjuvants. Adjuvants may prolong the duration of analgesia or decrease the required anesthetic dose, thus reducing the risk for specific side effects.

Epinephrine. Some anesthesia providers add a low dose of epinephrine (1.25 to 5 μg/mL [1:800,000 to 1:200,000]) to the local anesthetic solution (Table 23.4). The addition of epinephrine shortens the latency and prolongs the duration of epidural bupivacaine analgesia.[50,138] The MLAC of bupivacaine with epinephrine (66 μg) is 29% lower than that of bupivacaine without epinephrine,[139] perhaps as a result of the stimulation of alpha-adrenergic receptors in the spinal cord.

TABLE 23.4 Adjuncts to Neuraxial Labor Analgesia

Adjunct Drug	Epidural Analgesia		Spinal Analgesia
	INITIATION BOLUS DOSE[a]	MAINTENANCE INFUSION DOSE[a]	INITIATION BOLUS DOSE
Epinephrine	25–75 μg[b]	25–50 μg/h[b]	2.25–200 μg
Clonidine	75–100 μg	10–30 μg/h[c]	15–30 μg
Neostigmine	500–750 μg	25–75 μg/h[d]	NR
Morphine	NA	NA	100–250 μg (0.1–0.25 mg)

NA, not applicable; *NR,* not recommended.
[a]Adjuncts are usually co-administered with a low-concentration local anesthetic solution (e.g., bupivacaine < 0.08%), often with a lipid-soluble opioid. There is extensive experience with epidural clonidine for labor analgesia in some European countries but less overall experience with epidural neostigmine.
[b]Usually administered in a 1 : 800,000 to 1 : 200,000 solution (1.25–5 μg/mL).
[c]Administered in a concentration of 0.75–1.5 μg/mL.
[d]Administered in a concentration of 4 μg/mL.

The addition of epinephrine to the local anesthetic has a variable effect on the systemic uptake of the local anesthetic in obstetric patients.[140–142] The systemic absorption of epinephrine may increase maternal heart rate and transiently decrease uterine activity as a result of beta-adrenergic receptor stimulation.[50,143,144] However, some studies have shown that the addition of epinephrine to bupivacaine, lidocaine, or levobupivacaine does not result in longer labor than the epidural administration of bupivacaine or lidocaine without epinephrine[143,145] or levobupivacaine-sufentanil without epinephrine.[146] Epidural administration of an epinephrine-containing local anesthetic solution does not adversely affect intervillous blood flow[147] or neonatal outcome.[138,140,146] One disadvantage of the use of epinephrine is that it increases the intensity of motor blockade.[145,146] The addition of epinephrine may improve the efficacy of epidural opioids,[148] but the enhanced effect is insufficient to make use of epidural opioids (without local anesthetic) an attractive regimen for the duration of labor. Finally, the addition of a third drug to the local anesthetic/opioid solution may increase the risk for drug error and contamination. For these reasons, at our institution my colleagues and I do not routinely administer epinephrine-containing local anesthetic solutions during labor. However, other anesthesia providers have a different view, and some consider epinephrine a useful adjuvant, especially when added to a very dilute solution of local anesthetic with an opioid.

Clonidine. Analgesia is enhanced by the direct stimulation of alpha$_2$-adrenergic receptors and the inhibition of neurotransmitter release in the dorsal horn of the spinal cord (see Chapter 20). Epidural administration of clonidine alone provides modest analgesia. Studies have evaluated the epidural administration of clonidine as an adjuvant to a local anesthetic alone,[149–152] to local anesthetic and opioid combinations,[153–157] to fentanyl,[158] and to neostigmine (see later discussion).[159,160] In an MLAC study,[161] clonidine 60 μg, but not 30 μg, decreased the MLAC of ropivacaine by approximately two-thirds. In another study,[151] clonidine 75 μg and sufentanil 5 μg both reduced the MLAC of ropivacaine by about two-thirds.[151] Unlike epinephrine, clonidine does not increase the motor blockade that results from the epidural administration of a local anesthetic, but it does potentiate both the quality and duration of analgesia.[153–157] However, in a "black box" warning on the package insert, the manufacturer of Duraclon (the epidural clonidine formulation approved by the U.S. Food and Drug Administration [FDA]) recommends against its use in obstetric patients because of the risk for hypotension[152–154,157,161] and bradycardia. Most studies, however, have found that the hypotension is readily amenable to treatment. An additional side effect is maternal sedation.[154,155,161] High doses (greater than 150 μg) may be associated with FHR changes,[153] although no adverse fetal effects have been observed with lower doses.

Clonidine is not often used for labor analgesia in North America, but it is more widely used in some European countries. It may be particularly useful in women in whom other epidural analgesics are contraindicated or in those who have breakthrough pain with standard local anesthetic/opioid solutions, despite a functioning epidural catheter. In this circumstance, additional local anesthetic will result in motor blockade but clonidine will not.

Neostigmine. Neostigmine inhibits the breakdown of acetylcholine within the spinal cord. Acetylcholine binds to muscarinic receptors, leading to a reduction in neurotransmitter release and subsequent analgesia. Roelants et al.[162] randomly assigned parturients to receive either epidural ropivacaine (20 mg) alone or epidural neostigmine (4 μg/kg) combined with ropivacaine 10 mg, with or without sufentanil 10 μg. The magnitude and duration of analgesia in the ropivacaine/neostigmine group were similar to that of the plain ropivacaine group but less than in the ropivacaine/sufentanil group. Neostigmine is hydrophilic, and the researchers hypothesized that only a small portion of the epidural dose penetrates the spinal cord.[162] In a subsequent study, the same researchers compared epidural sufentanil 20 μg with sufentanil 10 μg combined with neostigmine 250, 500, or 750 μg.[163] Neostigmine 250 μg with sufentanil was ineffective, but both 500 and 750 μg of neostigmine produced effective analgesia similar in duration to that obtained with sufentanil alone.

In another study, maintenance of epidural analgesia with a solution of neostigmine 4 μg/mL combined with bupivacaine 0.125% resulted in a 19% reduction in bupivacaine

consumption compared with administration of bupivacaine alone.[164] However, maternal sedation was noted in the neostigmine group in the first 5 to 20 minutes after initiation of epidural analgesia with bupivacaine and neostigmine 60 µg. Booth et al.[165] randomized laboring women to receive initiation and maintenance of epidural analgesia with 0.125% bupivacaine, combined with fentanyl 2 µg/mL or neostigmine 2, 4, or 8 µg/mL. The primary outcome, hourly bupivacaine consumption, did not differ among groups, nor did patient satisfaction. Pruritus was less common in the neostigmine groups, but other adverse effects did not differ, suggesting that there is no advantage to replacing the lipid-soluble opioid with neostigmine when combined with a local anesthetic.

Because animal studies suggest a synergistic antinociceptive effect of spinal alpha$_2$-adrenergic agonists and cholinesterase inhibitors,[166] researchers have also investigated epidural neostigmine combined with clonidine.[159,160,167] The combination of clonidine 75 µg with neostigmine 500 or 750 µg provided acceptable analgesia (visual analogue scale pain score less than 30/100 mm in 30 minutes) in approximately 80% of parturients. Epidural neostigmine 500 µg combined with clonidine 75 µg prolonged labor analgesia initiated with spinal ropivacaine and sufentanil.[160] In a follow-up study,[167] the same investigators initiated analgesia with spinal ropivacaine and sufentanil and maintained analgesia with ropivacaine/sufentanil PCEA. Study subjects were randomized to receive a 10-mL epidural bolus injection of a solution containing neostigmine 500 µg combined with clonidine 75 µg or placebo saline solution 15 minutes after the intrathecal injection. Hourly ropivacaine use and the incidence of breakthrough pain were less in the group that received the epidural neostigmine/clonidine bolus. Systolic blood pressures were lower in the treatment group, but the incidence of hypotension did not differ.

Taken together, the studies have not identified any significant adverse maternal or neonatal effects; however, the number of studies is small and further study is required to determine the role of epidural neostigmine for routine labor analgesia. Neostigmine is not approved for neuraxial injection in the United States.

Summary

Epidural labor analgesia is usually initiated with the bolus injection of a local anesthetic combined with a lipid-soluble opioid. The advantages of the addition of an opioid to an epidural solution of local anesthetic include (1) lower total dose of anesthetic, (2) decreased motor blockade, (3) reduced shivering, and (4) greater patient satisfaction. Some anesthesia providers contend that local anesthetic–opioid techniques result in a lower risk for hypotension, but this belief is unproven. There are no clinically significant differences among the three commonly used, long-acting amide local anesthetics (bupivacaine, ropivacaine, levobupivacaine), or between fentanyl and sufentanil. Other adjuvants (e.g., epinephrine, clonidine, neostigmine) may prove useful in selected patients. High-volume/low-concentration local anesthetic solutions compared with low-volume/high-concentration solutions are associated with lower dose requirements and better analgesia.

INITIATION OF SPINAL ANALGESIA

Initiation of neuraxial analgesia with the intrathecal injection of an opioid, or an opioid combined with a local anesthetic, usually performed as part of a CSE technique, results in a rapid onset of analgesia with a low dose of drug(s) (see Table 23.2). The onset of effective spinal analgesia occurs faster than epidural analgesia, and more women have effective analgesia at 10 minutes.[24] Intrathecal opioids can provide complete analgesia during early labor when the pain stimuli are primarily visceral. An intrathecal local anesthetic without an opioid is not commonly used for labor analgesia. Doses high enough to provide analgesia are associated with significant motor blockade, and lower doses either do not provide satisfactory analgesia or are associated with an unacceptably short duration of analgesia.[168,169] A lipid-soluble opioid is combined with a local anesthetic (bupivacaine, ropivacaine, or levobupivacaine) when sacral analgesia is necessary for complete analgesia (e.g., initiation of analgesia during the active first stage or the second stage of labor). The interaction between intrathecal local anesthetics and opioids is synergistic.[170] Like the combination of an epidural local anesthetic with an opioid, the combination of an intrathecal opioid with a local anesthetic results in better quality and longer duration of analgesia,[171,172] as well as a lower dose requirement for both drugs, compared with either drug used alone.[168,169,173]

Choice of Drugs

Opioids

Fentanyl and sufentanil. The two opioids most commonly used for initiation of spinal labor analgesia are fentanyl and sufentanil. When administered alone in early labor, intrathecal fentanyl and sufentanil provide complete analgesia without a sympathectomy or motor blockade. This is a particularly useful technique for patients in whom a sudden decrease in preload (secondary to neuraxial local anesthetic–induced sympathectomy) might not be well tolerated (e.g., patient with a stenotic heart lesion).

Studies suggest that the ED$_{50}$ of intrathecal fentanyl varies from 5.5 to 18 µg.[174–176] The wide range of published values may be explained by differences in patient population (e.g., parity), cervical dilation at initiation of analgesia, and definition of successful analgesia. Nelson et al.[177] hypothesized that acute mixing of fentanyl in cerebrospinal fluid (CSF) may explain the large interindividual variability observed after the injection of intrathecal opioid. In an elegant study, the investigators determined CSF fentanyl concentration at the site of the lumbar injection 60 seconds after the fentanyl injection. CSF fentanyl concentration did not correlate with onset, sensory level, or duration of analgesia. Instead, decreased diastolic and increased systolic blood pressure correlated with duration of analgesia. The authors hypothesized that hemodynamic characteristics may influence the distribution of drug in the CSF and, hence, block characteristics.

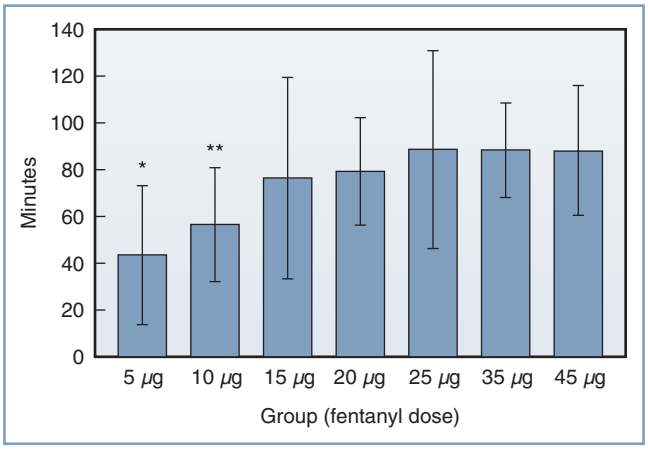

Fig. 23.3 Duration of intrathecal fentanyl analgesia (mean ± SD) among nulliparous women in active labor who received 5, 10, 15, 20, 25, 35, or 45 μg. Duration of analgesia (time from intrathecal dose to first request for additional analgesia) differed significantly among the groups (analysis of variance [ANOVA], $P < .005$). *$P < .05$ versus groups 15 to 45 μg; **$P < .05$ versus groups 25 to 45 μg. (From Palmer CM, Cork RC, Hays R, et al. The dose-response relationship of intrathecal fentanyl for labor analgesia. *Anesthesiology.* 1998;88: 355–361.)

Herman et al.[176] determined that the ED_{95} of intrathecal fentanyl for parturients of mixed parity in early labor (cervical dilation less than or equal to 5 cm) was 17.4 μg (95% CI, 13.8 to 27.1). The duration of analgesia is dose dependent but plateaus at 80 to 90 minutes after administration of 15 to 25 μg of fentanyl (Fig. 23.3).[174] There does not appear to be any reason to administer doses higher than 25 μg, because side effects (e.g., pruritus, respiratory depression) are also dose dependent.[168,174,176]

The reported ED_{50} of intrathecal sufentanil varies from 1.8 to 4.1 μg,[178–181] and the ED_{95} is 8 to 10 μg.[178,181] A comparison of the potencies of fentanyl and sufentanil using ED_{50} estimates from different studies is difficult because of differences in patient populations and the definition of efficacy. In a single-center study, the relative potency ratio of intrathecal sufentanil to fentanyl for labor analgesia was estimated to be 4.4:1.[175] When the drugs were administered at twice the ED_{50} (fentanyl 36 μg, sufentanil 8 μg), the duration of sufentanil analgesia was 25 minutes longer than that of fentanyl analgesia (104 versus 79 minutes), although the incidence of side effects was not different.[175]

Landau et al.[182] investigated the influence of genetic variability of the μ-opioid receptor *OPRM1* on the ED_{50} of intrathecal fentanyl for labor analgesia. Nulliparous women who were heterozygous or homozygous for A118G had a lower ED_{50} for intrathecal fentanyl (18 μg, 95% CI, 13 to 22) than women homozygous for the wild-type allele (A118) (27 μg, 95% CI, 23 to 31). Additionally, women in the group with the A118G allele requested analgesia at a more advanced cervical dilation. However, in two other studies assessing duration of intrathecal fentanyl labor analgesia,[183,184] there was no difference in the duration of analgesia in women with the A118G allele compared with women who were homozygous for the wild-type allele. Thus, the clinical implications of genetic polymorphisms of *OPRM1* on labor analgesia remain unclear.[185]

Typically, an intrathecal opioid injection for labor analgesia is administered as part of a CSE technique. Maintenance epidural analgesia is usually initiated soon after initiation of spinal analgesia. Therefore, the duration of intrathecal analgesia is relatively less important. Nelson et al.[175] concluded, and we concur, that the longer duration of sufentanil analgesia in comparison with fentanyl analgesia does not necessarily justify the former's use. Other factors, such as cost and the greater risk for a drug dose error with sufentanil (because of its greater potency), should be considered. In some European countries sufentanil is available in a dilute concentration (5 μg/mL), possibly making it easier and safer to use.

Intrathecal fentanyl (or sufentanil) is often co-administered with an amide local anesthetic (see later discussion), most commonly bupivacaine (see Table 23.2). The addition of a local anesthetic to intrathecal fentanyl or sufentanil markedly decreases the dose of opioid necessary to produce analgesia. Wong et al.[168] randomly assigned parous women to receive intrathecal bupivacaine 2.5 mg and intrathecal sufentanil 0, 2.5, 5, 7.5, or 10 μg, followed by a standard epidural test dose. There were no differences among the sufentanil groups in quality and duration of analgesia. These results suggest that a sufentanil dose as small as 2.5 μg is effective when combined with bupivacaine 2.5 mg. In current clinical practice, it is common to combine bupivacaine 2.5 mg with sufentanil 1.5 to 2 μg.[186] Stocks at al.[172] demonstrated that three different doses of intrathecal fentanyl (5, 15, and 25 μg) led to similar reductions in the ED_{50} of intrathecal bupivacaine, although both the duration of analgesia and the incidence of pruritus were dose dependent. As with sufentanil, the dose of intrathecal fentanyl is usually reduced when combined with bupivacaine.[169] Intrathecal fentanyl 10 to 15 μg, combined with bupivacaine 2.5 mg, provides effective analgesia for most parturients.

Other opioids. Early studies demonstrated that the intrathecal administration of 0.5 to 2 mg of **morphine** reliably produced analgesia during the first stage of labor, but the analgesia was less reliable during the second stage of labor and during instrumental vaginal delivery.[187,188] However, intrathecal administration of these relatively large doses of morphine resulted in a high incidence of side effects, including somnolence, nausea and vomiting, pruritus, and respiratory depression. In addition, the onset of analgesia is slower with intrathecal morphine than with lipid-soluble opioids, and the long duration of action may be a disadvantage (i.e., the parturient may deliver before the regression of side effects). Abouleish[189] reported a case of life-threatening respiratory depression 1 hour after delivery and 7 hours after the administration of 1 mg of hyperbaric intrathecal morphine.

In several studies,[190–192] *low-dose* morphine (0.1 to 0.25 mg) was successfully combined with intrathecal bupivacaine (2 to 2.5 mg) and fentanyl (12.5 to 25 μg); the combination resulted in short latency of onset and a prolonged duration of analgesia. In contrast, a single study from Sweden[193] found no

advantage to adding morphine 0.05 or 0.1 mg to bupivacaine 1.25 mg and sufentanil 5 µg. The addition of low-dose morphine to intrathecal bupivacaine and a lipid-soluble opioid may be useful in low-resource settings in which continuous epidural infusion techniques are impractical.[33] When used as part of a CSE technique, the addition of intrathecal morphine to bupivacaine and fentanyl has been shown to result in less breakthrough pain during labor[190–192] as well as decreased analgesic use in the first 24 hours postpartum, compared with intrathecal bupivacaine and fentanyl without morphine.[190,191] The incidence of intrapartum side effects was similar[190,192]; however, the morphine group had a higher incidence of postpartum nausea (17% versus 0% for no morphine).[190]

An alternative drug is **meperidine.** Meperidine is unique among the opioids in that it possesses weak local anesthetic properties,[130] and it has been used in large doses (e.g., 1 mg/kg) as the sole agent to provide spinal anesthesia for surgical procedures.[194] Intrathecal administration of meperidine (10 to 20 mg) results in effective labor analgesia within 2 to 12 minutes, with a duration of 1 to 3 hours. Honet et al.[195] compared the efficacy of intrathecal meperidine 10 mg, fentanyl 10 µg, and sufentanil 5 µg in 65 laboring women. The three drugs were similar in onset of analgesia (less than 5 minutes) and duration of effective analgesia (80 to 100 minutes). However, the meperidine group had significantly lower pain scores after cervical dilation had progressed beyond 6 cm. As labor advances, the nature of pain becomes increasingly somatic; only meperidine also functions as a local anesthetic. This fact helps explain why meperidine provided more effective analgesia during advanced labor, including the second stage. Booth et al.[196] observed that intrathecal meperidine was associated with a significantly higher incidence of nausea and vomiting than a combination of fentanyl and bupivacaine for labor analgesia. Therefore, intrathecal meperidine does not seem to offer any advantages over bupivacaine-fentanyl for routine intrathecal analgesia, although it may be useful for the rare patient with a contraindication to bupivacaine-fentanyl administration.

In the United Kingdom, some anesthesia providers have advocated the intrathecal administration of **diamorphine** (heroin) for labor analgesia, although it is not commonly used for this purpose. This drug is not available for clinical use in the United States. Kestin et al.[197] observed that the intrathecal administration of diamorphine (0.2 to 0.5 mg) provided good to excellent analgesia in 90% of laboring women. The mean duration of analgesia was approximately 100 minutes. However, 75% of patients had pruritus, nausea, and vomiting. In contrast, Vaughan et al.[198] randomly assigned parturients to receive intrathecal bupivacaine 2.5 mg with either fentanyl 25 µg or diamorphine 0.25 mg. Duration of analgesia was longer in the diamorphine group, but the incidence of side effects was low in both groups.

Local Anesthetics

In the late first stage and the second stage of labor, a local anesthetic must be added to the spinal opioid to block somatic stimuli from the vagina and perineum caused by descent of the fetus. The local anesthetic works synergistically with the opioid, so lower doses of both drugs can be used.[168–170,172,199] **Bupivacaine** is most commonly combined with fentanyl or sufentanil. The ED_{95} of bupivacaine was 3.3 mg when combined with sufentanil 1.5 µg[186] and 1.7 mg when combined with fentanyl 15 µg.[200] Intrathecal bupivacaine doses between 1.25 and 2.5 mg are commonly used (see Table 23.2). Levobupivacaine and ropivacaine are not usually used for intrathecal injection in the United States. They are less potent than bupivacaine for intrathecal labor analgesia (Fig. 23.4).[186,201] Spinal lidocaine has not been studied for use in labor analgesia, but it is unlikely to have any advantages compared with other, longer-acting amide local anesthetics. Common doses of spinal local anesthetics are shown in Table 23.2.

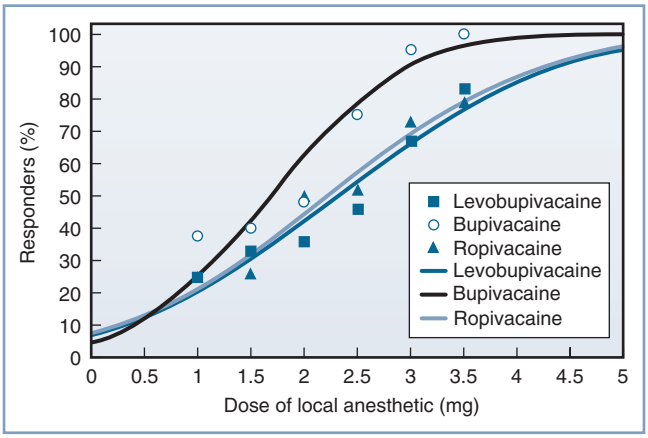

Fig. 23.4 Predicted *(lines)* and observed *(symbols)* dose-response of intrathecal bupivacaine, levobupivacaine, and ropivacaine combined with sufentanil 1.5 µg in 450 laboring women. The dose-response curves were constructed with the use of a probit regression model. The curves were compared with use of likelihood ratio tests. No difference was observed between ropivacaine and levobupivacaine. Significant differences were observed between bupivacaine and ropivacaine ($P = .003$) and bupivacaine and levobupivacaine ($P < .001$). (From Van de Velde M, Dreelinck R, Dubois J, et al. Determination of the full dose-response relation of intrathecal bupivacaine, levobupivacaine, and ropivacaine, combined with sufentanil, for labor analgesia. *Anesthesiology*. 2007;106:149–156.)

Controversy exists as to whether the lower incidence and degree of motor blockade associated with ropivacaine and levobupivacaine[65,201] are a result of their inherent difference in potency or of greater sensory-motor separation with the S(−)-enantiomer drugs.[186] Camorcia et al.[201] have suggested that, especially during intrathecal use, ropivacaine may be associated with less motor blockade than bupivacaine, even when equipotent doses (e.g., 3.6 mg ropivacaine and 2.4 mg bupivacaine) are administered. However, this difference, even if it exists, is unlikely to have any clinical significance during spinal labor analgesia because all local anesthetics administered for this purpose are administered in low doses that lead to minimal motor blockade.

Baricity of the intrathecal solution. The local anesthetic/opioid solutions commonly injected for intrathecal labor analgesia have lower specific gravity relative to that of CSF

and hence are hypobaric.[202] The extent of cephalad sensory blockade is higher for spinal analgesia initiated with the parturient in the sitting position than in the lateral position.[203] Adding dextrose to the solution (opioid alone or opioid with local anesthetic) to make the solution hyperbaric results in less extensive sensory blockade but also in inadequate analgesia.[204–206] It is probably necessary for the opioid to penetrate the spinal cord rather than just the nerve roots; therefore, injection of a hyperbaric solution of opioid and local anesthetic below the level of the spinal cord may lead to inadequate analgesia, even though the local anesthetic provides sensory blockade to the T10 dermatome.

Intrathecal Adjuvants

Several drugs have been investigated as adjuvants to local anesthetics, opioids, or combinations of local anesthetics and opioids for intrathecal labor analgesia (see Table 23.4). In one study, the addition of **clonidine** 30 µg to sufentanil (2.5 to 5 µg) prolonged the duration of analgesia from 104 to 145 minutes without motor block.[207] Other investigators have had similar results when clonidine was combined with sufentanil,[208] bupivacaine/ropivacaine and sufentanil,[209,210] and neostigmine.[211] Intrathecal clonidine alone also provides analgesia.[212] A disadvantage of clonidine is the high incidence of maternal hypotension and sedation as well as FHR abnormalities. The slightly longer duration of analgesia provided by the addition of clonidine to bupivacaine and sufentanil is not an advantage when maintenance analgesia is provided by a continuous epidural infusion. Therefore, at present, intrathecal clonidine cannot be recommended for routine spinal labor analgesia, although it might be considered in parturients with contraindications to the use of other drugs.[213]

Adding intrathecal **neostigmine** to sufentanil, bupivacaine/sufentanil, or clonidine has been found to potentiate the analgesia and prolong its duration.[211,214] However, intrathecal neostigmine was associated with a markedly higher incidence of severe nausea that was unresponsive to standard antiemetics.[211,214] Therefore, neostigmine cannot be recommended as an adjuvant for intrathecal labor analgesia.

Analgesia is prolonged by 15 to 40 minutes when **epinephrine** is added to intrathecal bupivacaine-opioid.[215–217] Even an epinephrine dose as low as 2.25 µg prolonged analgesia by 15 minutes.[216] However, epinephrine 200 µg combined with bupivacaine 2.5 mg and sufentanil 10 µg resulted in a significant incidence of motor blockade[215]; epinephrine doses between 12.5 and 100 µg prolonged analgesia without any difference in the quality of analgesia.[217]

In summary, no adjuvant studied to date prolongs the duration of fentanyl or sufentanil/bupivacaine analgesia long enough to avoid the use of maintenance epidural analgesia for most parturients, and no adjuvant reduces or eliminates the side effects associated with the analgesic drugs used clinically. Therefore, it makes little sense to routinely add adjuvant drugs, because they are associated with higher cost, higher rate or severity of side effects, and probably an increased risk for drug error.

MAINTENANCE OF ANALGESIA

Epidural Analgesia

Painful labor lasts several hours in most parturients; therefore, a single intrathecal or epidural injection of local anesthetic and/or opioid typically does not provide adequate analgesia for the duration of labor. Supplemental doses are needed to maintain analgesia in most women. Neuraxial analgesia is maintained with the intermittent or continuous administration of analgesics, usually a combination of a long-acting amide local anesthetic and a lipid-soluble opioid. By far the most common technique is administration of drugs via a catheter into the epidural space. It is occasionally advantageous to administer drugs via a catheter into the subarachnoid space.

Drugs for the Maintenance of Epidural Analgesia

In the past, epidural labor analgesia was maintained with the intermittent injection or continuous infusion of a neuraxial local anesthetic alone. Currently, most anesthesia providers maintain analgesia with a combination of a low-dose, long-acting amide local anesthetic and a lipid-soluble opioid (Table 23.5). In practice, neither lidocaine nor 2-chloroprocaine is used for maintenance of analgesia. Both have a short duration of action, and tachyphylaxis may develop more quickly with either of these local anesthetics than occurs with the longer-acting local anesthetics. Lidocaine crosses the placenta to a greater extent than bupivacaine, and there is less differentiation between the dose required for sensory and motor blockade.[218] There is no evidence that any one of the three long-acting local anesthetics (bupivacaine, ropivacaine, levobupivacaine) has any advantages in terms of clinical outcomes over the other two.[65,74,75] Fentanyl is more often detected in umbilical artery blood samples than sufentanil (see earlier discussion)[108]; however, neonatal outcomes are

TABLE 23.5 Anesthetic Solutions for Maintenance of Epidural Analgesia: Continuous Infusion or Patient-Controlled Epidural Analgesia[a]

Drug[b]	Concentration
Local Anesthetics	
Bupivacaine	0.05–0.125%
Ropivacaine	0.08–0.2%
Levobupivacaine	0.05–0.125%
Lidocaine[c]	0.5%–1.0%
Opioids	
Fentanyl	1.5–3 µg/mL
Sufentanil	0.2–0.4 µg/mL

[a]Local anesthetic is most often combined with an opioid.
[b]Continuous infusions are usually administered at a rate of 8–15 mL/h into the lumbar epidural space.
[c]Lidocaine is not usually used for maintenance of epidural analgesia because it crosses the placenta to a greater extent than the other amide local anesthetics and may be associated with greater tachyphylaxis.

good after maintenance of epidural analgesia with either drug.

As with the induction dose, the combination of a local anesthetic with a lipid-soluble opioid allows administration of a lower concentration and a smaller total dose of local anesthetic for maintenance of analgesia. This approach improves safety and leads to less motor blockade and greater patient satisfaction. Chestnut et al.[97] demonstrated that maintenance of epidural analgesia by a continuous infusion of 0.0625% bupivacaine with fentanyl 2 μg/mL resulted in comparable maternal and neonatal outcomes, with a lower incidence of motor blockade, compared with maintenance of analgesia by a continuous epidural infusion of 0.125% bupivacaine alone. When administered as intermittent epidural boluses for the maintenance of analgesia, the addition of sufentanil to bupivacaine resulted in better quality analgesia and decreased motor blockade at delivery.[104]

In contemporary clinical practice, the bupivacaine concentration of maintenance bupivacaine/opioid solutions ranges from 0.05% to 0.125%. Hess et al.[219] retrospectively analyzed the use of three solutions at their institution: bupivacaine 0.125% and bupivacaine 0.0625%, both with fentanyl 2 μg/mL, administered at 8 to 12 mL/h, and bupivacaine 0.04% with fentanyl 1.7 μg/mL and epinephrine 1.7 μg/mL, administered at 15 mL/h. There were more interventions for breakthrough pain in the two low-concentration groups and more interventions for hypotension and motor blockade in the high-concentration group. Beilin et al.[220] initiated analgesia with intrathecal bupivacaine/fentanyl and an epidural test dose, and then randomly assigned women to receive maintenance epidural analgesia with one of four solutions: bupivacaine 0.125%, bupivacaine 0.0625%, or bupivacaine 0.04% with epinephrine 1.7 μg/mL (all with fentanyl 2 μg/mL) or placebo (saline) at 10 mL/h. The time to request for supplemental analgesia was longest in the bupivacaine 0.125% group; however, this group also had a higher incidence of motor blockade than the other groups. Therefore, to avoid motor blockade, it would seem reasonable to use a bupivacaine concentration less than 0.125%, especially if it is administered via continuous epidural infusion (see later discussion).

The dose-response relationships for fentanyl and sufentanil combined with a local anesthetic for the maintenance of epidural analgesia have not been well studied. The concentration range of fentanyl used in clinical practice is 1.5 to 3 μg/mL, and that of sufentanil, 0.2 to 0.33 μg/mL. The optimal opioid concentration probably varies according to the local anesthetic concentration, the mode of drug delivery (i.e., bolus versus infusion), the presence of epinephrine, and the stage of labor, among other factors. Bader et al.[221] infused epidural bupivacaine 0.125% with fentanyl 2 μg/mL at 10 mL/h for 1 to 15 hours. Maternal and neonatal fentanyl concentrations, and their ratio, remained constant over the infusion period, and no adverse maternal or neonatal outcomes were noted. Porter et al.[222] compared neonatal outcomes in women randomly assigned to receive epidural bupivacaine with fentanyl 2.5 μg/mL or bupivacaine alone to maintain analgesia. There were no differences between groups in measures of neonatal well-being at birth or 24 hours after delivery.

Bernard et al.[223] combined sufentanil 0, 0.078, 0.156, 0.312, or 0.468 μg/mL with bupivacaine 0.125% and epinephrine 1.25 μg/mL. Each solution was administered as a 12-mL bolus via PCEA. Sufentanil concentrations lower than 0.156 μg/mL did not provide adequate analgesia for the second stage of labor, and higher doses were associated with an increased incidence of pruritus. Loftus et al.[108] compared bupivacaine with sufentanil 0.25 μg/mL or fentanyl 1.5 μg/mL as a continuous epidural infusion at 10 mL/h. Neonates in the fentanyl group had slightly lower 24-hour neuroadaptive capacity scores (NACS) than those in the sufentanil group.

Administration Techniques

Intermittent bolus. Before the introduction of infusion pumps, epidural analgesia was routinely maintained by the intermittent administration of an additional therapeutic bolus dose of local anesthetic when analgesia began to wane. When the patient began to experience recurrent pain, the anesthesia provider assessed the pain relative to the stage of labor and the extent of sensory blockade and then administered another epidural bolus of local anesthetic. Analgesia was usually reestablished with the bolus injection of 8 to 12 mL of a local anesthetic/opioid solution.

The spread and quality of analgesia may change with repeated lumbar epidural injections of local anesthetic. After several injections, blockade of the sacral segments, intense motor blockade, or both may develop.[145] The sensory level and the intensity of motor blockade should be assessed and recorded before and after each bolus injection of local anesthetic.

This intermittent bolus technique has several disadvantages, the most salient of which is that pain relief is constantly interrupted by the regression of analgesia. The patient must notify the labor nurse or midwife that she is again uncomfortable and request additional analgesia. In the United States, labor nurses are not allowed to administer additional epidural analgesic drugs[224]; therefore, the nurse must call the anesthesia provider, resulting in unavoidable delays in administration of additional analgesic drugs and additional pain for the patient.

Continuous infusion. Administration of a continuous epidural infusion of a dilute solution of local anesthetic combined with an opioid for the maintenance of epidural labor analgesia overcomes the disadvantages of intermittent boluses administered by an anesthesia provider or midwife. The potential benefits of a continuous epidural infusion include the maintenance of a stable level of analgesia and a less-frequent need for bolus doses of local anesthetic, which may reduce the risk for local anesthetic systemic toxicity. An additional advantage is a decreased workload for the anesthesia provider.

Published studies have suggested that the continuous epidural infusion and intermittent bolus injection techniques have a comparable safety record. Studies comparing intermittent bolus injections with continuous infusion were

performed before the era of neuraxial opioid administration; thus, the studies used concentrations of bupivacaine (0.125% to 0.25%) higher than those typically used in contemporary practice. In theory, maintenance of a constant level of anesthesia should promote maternal hemodynamic stability and improve fetal and neonatal outcomes. Only one published study has suggested a trend toward less frequent hypotension and a lower incidence of abnormal FHR patterns during the continuous epidural infusion of bupivacaine than with intermittent bolus injections of bupivacaine; however, neonatal outcomes were similar with the two techniques.[225]

Randomized trials of intrapartum epidural analgesia maintained by either intermittent bolus injection or continuous infusion of bupivacaine have demonstrated that women require fewer bolus injections administered by the anesthesia provider (i.e., fewer episodes of breakthrough pain) with the continuous infusion technique.[225–227] The continuous infusion technique lengthens the time between bolus injections and leads to greater patient satisfaction.[227,228]

Most studies suggest that the continuous epidural infusion technique leads to the administration of a larger total dose of bupivacaine,[226–229] but such a dose does not seem to result in higher maternal venous or umbilical venous bupivacaine concentrations at delivery.[227,229] The continuous epidural infusion of bupivacaine often achieves satisfactory perineal analgesia, obviating the need for a bolus dose of local anesthetic at delivery. Unfortunately, a prolonged epidural infusion of 0.125% bupivacaine at 10 to 14 mL/h may cause significant motor blockade.[85,225,226,228,229] Titrating the dose of bupivacaine to meet the individual needs of each patient (rather than administering the same dose to all patients), as well as reducing the total mass of bupivacaine by lowering the local anesthetic concentration and adding an opioid, helps minimize motor blockade while providing effective analgesia.

Migration of the epidural catheter into the subarachnoid, subdural, or intravenous space may occur with either the intermittent bolus injection or continuous infusion technique. If the epidural catheter should migrate into a vein during the continuous epidural infusion of a dilute solution of local anesthetic, it is unlikely that the patient will have symptoms of local anesthetic toxicity; rather, the level of anesthesia will regress. For this reason, the anesthesia provider should suspect the intravenous migration of an epidural catheter when a patient unexpectedly complains of pain during maintenance of analgesia during a continuous epidural infusion.

Migration of the epidural catheter into the subdural or subarachnoid space during an infusion should result in the slow ascent of the level of anesthesia and a greater density of motor blockade. These observations apply to the epidural infusion of a 0.125% solution of bupivacaine at a modest rate (e.g., 5 to 8 mL/h). The continuous infusion of a more concentrated solution or the use of a more rapid rate of infusion most likely narrows the margin of safety.

Patient-controlled epidural analgesia. The method of delivering the anesthetic solution into the epidural space influences the density of neuroblockade. Given the same concentration of local anesthetic, analgesia maintained by infusion results in greater drug use, a higher degree of motor blockade,[226,230] and a higher incidence of instrumental vaginal delivery than intermittent boluses.[229] However, intermittent manual bolus administration by the anesthesia provider results in more breakthrough pain, less patient satisfaction, and more work for the anesthesia provider. PCEA is a method of delivering anesthetic solution to the epidural space that overcomes these disadvantages. Since its first description in 1988 by Gambling et al.,[231] many studies have consistently found that the analgesia with PCEA is comparable to that with continuous infusion techniques.[232,233]

Van der Vyver et al.[233] reported a meta-analysis of nine randomized controlled trials (n = 640) comparing PCEA (without a background infusion) with continuous epidural infusion analgesia. There were fewer anesthetic interventions in the PCEA group, and the total bupivacaine dose was lower, as was the incidence of motor blockade (Fig. 23.5). There were no differences in pain scores, patient satisfaction, and maternal and neonatal outcomes between groups.

Data are conflicting as to whether PCEA should include a background infusion.[234–240] Most studies have reported background infusions of 3 to 4 mL/h. Bupivacaine consumption is higher in PCEA with a background infusion than in a pure PCEA technique without a background infusion.[233] A meta-analysis of five studies reported in the ASA Practice Guidelines for Obstetric Anesthesia[16] concluded that PCEA with a background infusion provides better analgesia than pure PCEA without a background infusion. Similarly, a 2015 meta-analysis that included seven studies identified a lower requirement for physician-administered rescue bolus doses in patients who receive a background infusion.[241] There is no evidence that the higher local anesthetic dose associated with a background infusion has adverse effects on obstetric outcome when low-concentration infusion solutions are used. A typical background infusion provides one-third to one-half of the total hourly dose.[232] Sng et al.[242] described a novel PCEA system in which they used a computer-integrated infusion pump to modify the background infusion rate based on the previous hour's requirement for patient-administered bolus doses. Future pump technology will likely incorporate machine learning to more closely tailor the administered anesthetic dose to patient need.

A wide variety of PCEA regimens have been described (Table 23.6). The anesthesia provider can manipulate the infusion solution (local anesthetic/opioid concentration), patient-controlled bolus volume, lockout interval, background infusion rate, and maximum allowable dose per hour. Patient-controlled bolus doses from 2 to 20 mL and lockout intervals from 5 to 30 minutes have been reported[238,239,243–248]; most studies have evaluated patient-controlled bolus doses of 5 to 12 mL. No study has found any differences in unscheduled provider interventions when investigators manipulated the patient-controlled bolus dose and lockout interval. There are no published reports of toxicity with larger bolus volumes, although the study populations were too small to allow

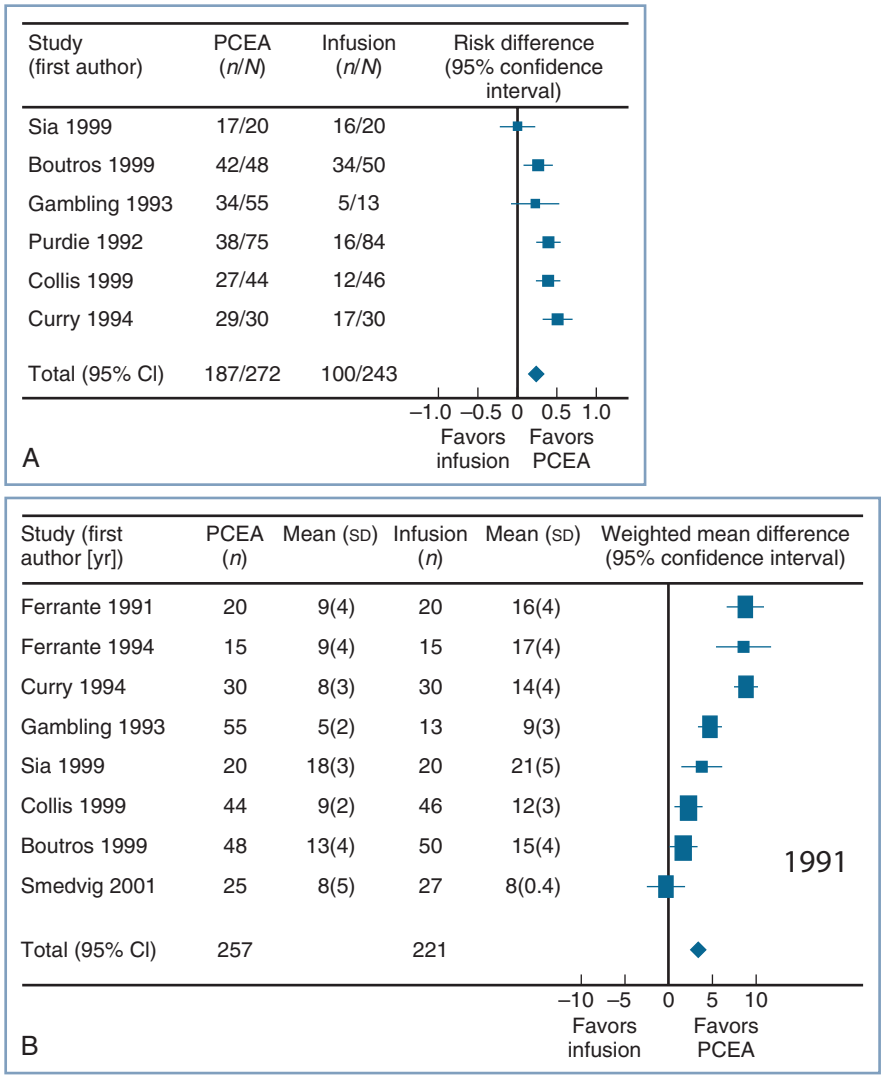

Fig. 23.5 Meta-analysis of patient-controlled epidural analgesia (PCEA) without background infusion compared with continuous epidural infusion for maintenance of analgesia. (A) The number of patients requiring no unscheduled interventions by the anesthesia provider was lower in the PCEA group (risk difference 27%; 95% confidence interval [CI], 18 to 36). (B) The dose of local anesthetic (mg/h) was lower in the PCEA group (weighted mean difference, –3.9 mg; 95% CI, –5.4 to –2.4). (From van der Vyver M, Halpern S, Joseph G. Patient-controlled epidural analgesia versus continuous infusion for labour analgesia: a meta-analysis. *Br J Anaesth.* 2002;89:459–465.)

TABLE 23.6 Examples of Patient-Controlled Epidural Analgesia (PCEA) Settings[a]

PCEA Technique	Basal Infusion Rate (mL/h)	Bolus Dose (mL)	Lockout Interval (min)
Without background infusion	0	8–12	10–20
With background infusion	4–8	5–8	10–15

[a]Anesthetic solutions are shown in Table 23.5.

determination of safety. Taken together, these studies suggest that there is no ideal bolus dose/volume or lockout interval for labor PCEA.

Various local anesthetic concentrations also have been studied. No studies have reported any differences in analgesia efficacy. Use of more-concentrated local anesthetic solutions results in higher local anesthetic consumption[249–251] and greater motor blockade than use of less-concentrated solutions.[173,238,250] Thus, as with continuous infusion epidural analgesia, administration of a dilute local anesthetic solution combined with an opioid results in less local anesthetic consumption and motor blockade without a reduction in analgesia efficacy.

In summary, solutions used for PCEA are identical to those used for continuous epidural infusion analgesia (see Table 23.5). It is suggested that larger bolus volumes be used if PCEA is administered without a background infusion. Early PCEA studies investigated higher-concentration local anesthetic solutions (i.e., 0.125% to 0.25% bupivacaine), smaller bolus volumes (less than or equal to 5 mL), and low background infusion rates (3 to 5 mL/h). Given the more recent data supporting the efficacy of epidural administration of higher volumes of more dilute solutions of local anesthetic, it appears reasonable to apply this principle to PCEA. The safety of large-volume boluses (greater than 10 mL) has not been determined.

Programmed intermittent epidural bolus injection. Bolus administration of a local anesthetic into the epidural space

results in better analgesia than continuous epidural infusion. Likewise, larger volumes of a less concentrated anesthetic solution provide better analgesia than smaller volumes of a more concentrated solution. Presumably, distribution of anesthetic solution in the epidural space is better when larger volumes are administered under high injection pressure.[252] However, both provider-administered bolus dosing and PCEA are associated with inconsistent analgesia as pain relief wanes and is then reestablished with a bolus dose. Several studies have demonstrated that programmed (automated) intermittent epidural boluses (PIEB) (5 to 10 mL every 30 to 60 minutes) administered via a programmable pump result in improved patient satisfaction, less drug use, longer duration of analgesia, and less breakthrough pain than a continuous infusion of the same mass of drug per unit of time.[253–259] For example, Wong et al.[253] randomly assigned patients to receive either a continuous epidural infusion of a dilute bupivacaine/fentanyl solution at 12 mL/h or 6 mL of the same solution delivered as a programmed bolus every 30 minutes. Similarly, Sia et al.[257] randomly assigned patients to receive either a continuous epidural infusion of a ropivacaine/fentanyl solution at 5 mL/h or 5 mL of the same solution delivered as a programmed bolus every hour. All patients in both studies were allowed PCEA for the treatment of breakthrough pain. The total dose of local anesthetic was smaller in the PIEB groups than in the continuous infusion groups.

Capogna et al.[258] compared motor block and mode of delivery in women randomized to receive PIEB with levobupivacaine 0.0625% with sufentanil 0.5 μg/mL (10 mL every 60 minutes) or the same solution as a continuous infusion (10 mL/h). Women were able to treat breakthrough pain with PCEA using levobupivacaine 0.125% (5-mL bolus). The incidence of motor block was greater in the continuous infusion group. Of interest, the rate of instrumental vaginal delivery was also higher in the continuous infusion group (7% versus 20%; risk ratio, 2.9; 95% CI, 1.1 to 7.9).

In a systematic review and meta-analysis of nine studies ($n = 344$), George et al.[260] concluded that the PIEB technique was associated with a small decrease in total anesthetic consumption and improved patient satisfaction. Although no difference was found in the need for anesthesia provider intervention and other outcomes, the confidence intervals were wide. The authors concluded that further study is needed to ascertain whether this technique impacts clinically significant anesthetic and obstetric outcomes. Infusion pumps with the ability to deliver this mode of analgesia are now commercially available. A schematic diagram demonstrating the use of PIEB is shown in Fig. 23.6, and examples of PIEB pump parameters are shown in Table 23.7.

TABLE 23.7 Examples of Programmed Intermittent Epidural Bolus (PIEB) Settings[a]

PIEB initial bolus time[b]	15–45 min
PIEB bolus volume	5–10 mL
PIEB bolus interval	30–60 min
PCEA bolus volume	5–10 mL
PCEA lockout interval	10–15 min

PCEA, patient-controlled epidural analgesia.
[a]Anesthetic solutions are shown in Table 23.5.
[b]Interval from initial neuraxial analgesia loading dose (spinal or epidural) to first programmed bolus dose.

Patient Monitoring during Maintenance Epidural Analgesia

The use of a continuous epidural infusion, PCEA, or PIEB technique does not abolish the need for frequent assessment of the patient by the anesthesia provider at regular intervals. Regular assessment may be particularly important for the PIEB technique in which unwitnessed bolus doses are administered independent of breakthrough pain. Indeed, a 2017 case report describes the migration of a properly-sited epidural catheter into the subarachnoid space after several hours of uneventful PIEB analgesia.[261] The patient became acutely hypotensive with new-onset nausea and dyspnea; CSF was easily aspirated from the neuraxial catheter.

Regular assessments should involve determining the quality of analgesia and progress of labor, recording the sensory level and intensity of motor block, and reviewing maternal vital signs and FHR tracings for the previous hour. An inappropriately high level of anesthesia signals the administration of an excessive dose of local anesthetic, or subdural or subarachnoid migration of the catheter. A low level of anesthesia may signal intravenous migration of the catheter, movement of the catheter outside the epidural space, or administration of an inadequate dose of local anesthetic.

Equipment

Anesthesia providers should consider the safety of their equipment when choosing a maintenance technique. The use of an infusion pump identical to that used for the intravenous administration of other drugs increases the chance that a nurse or physician will inject oxytocin, magnesium sulfate, or another drug into the epidural space unintentionally. Thus, the use of an infusion pump that is used exclusively for epidural analgesia and that differs from the pumps used for intravenous drug and fluid administration is recommended. The pump should be easy to use, reliable, adjustable, and sturdy. PCEA pumps should differ from patient-controlled *intravenous* analgesia (PCIA) pumps. The PCEA "buttons" should be labeled with instructions that only the patient (not medical providers or family members) should push the button. If possible, pumps should be preprogrammed with maximum safe limits to prevent errors in pump programming.

The anesthesia provider should use infusion tubing (which connects the pump to the epidural catheter) that is unique for the epidural administration of drugs. Some tubing is color-coded (yellow). Use of tubing that does not have an injection side-port is recommended. The epidural catheter and tubing should be clearly labeled with the word "epidural." Patient

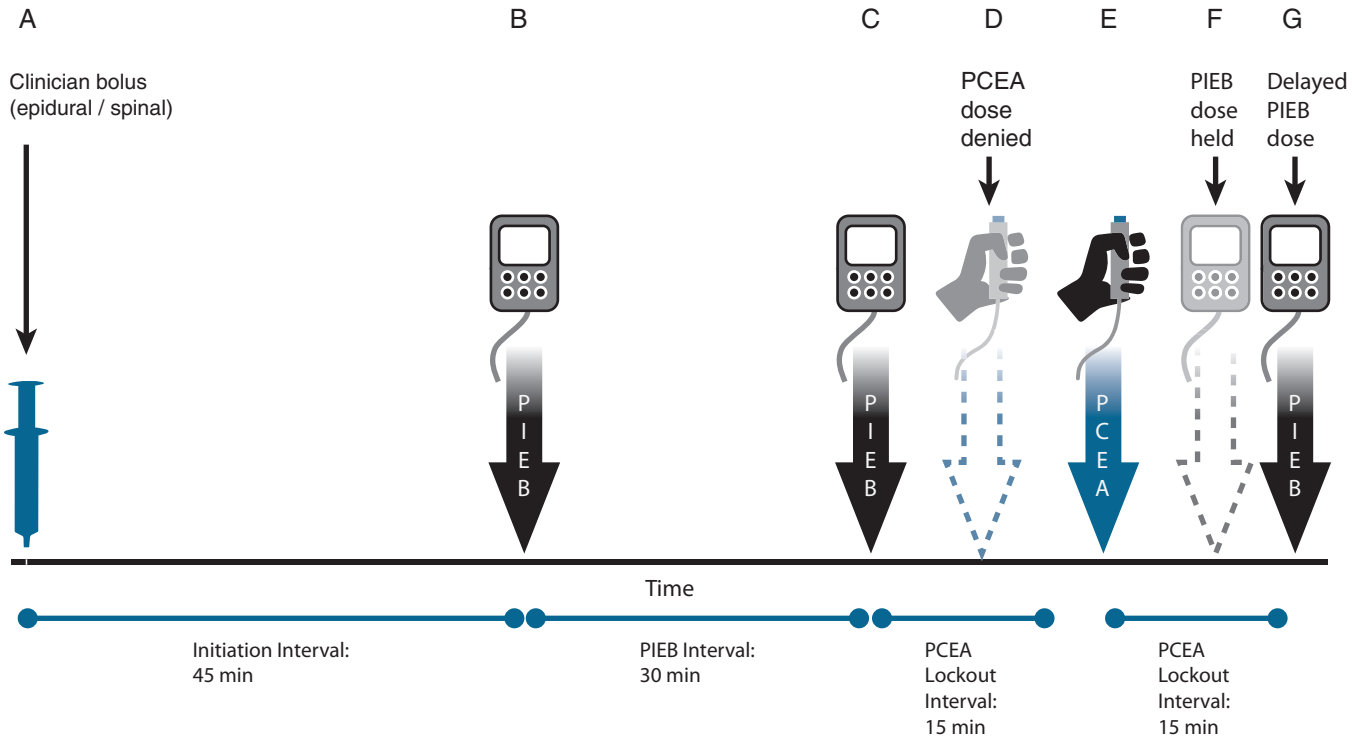

Fig. 23.6 Programmed intermittent epidural bolus (PIEB) schematic diagrams. The PIEB pump is programmed with the following parameters: initiation interval = 45 minutes (time from initial clinician-administered neuraxial analgesia loading dose to first PIEB dose), PIEB interval = 30 minutes (interval between each PIEB dose), patient-controlled epidural analgesia (PCEA) lockout interval = 15 minutes (interval after PIEB dose or PCEA dose during which a bolus request by the patient or a PIEB dose will not be administered by the pump). On figure time line, A: Clinician-administered initial neuraxial (epidural/spinal) analgesia loading dose, B: First PIEB dose administered, C: Second PIEB dose administered 30 minutes later, D: PCEA dose is requested, but the dose is not administered because it is within the 15-minute lockout interval of the PIEB dose at Time C, E: PCEA requested and administered, F: PIEB dose delayed because it was programmed to occur within the 15-minute lockout interval of the PCEA dose administered at Time E, G: Delayed PIEB dose is administered 15 minutes after the PCEA dose (Time E) at end of 15-minute lockout interval.

safety experts[262] and the UK National Patient Safety Agency (NPSA)[263] have recommended that syringes, needles, and catheters used for neuraxial injections be modified so that it is not possible to use this equipment for intravenous injections, thus making the possibility of drug administration error less likely.

Each labor unit must have a clear policy as to who may administer and adjust epidural infusion parameters. Anesthesia personnel should be responsible for changes in the content or rate of the infusion and the volume of bolus doses or develop protocols that allow nurses to make changes within the guidelines of the protocol or by order of the anesthesia provider. In the presence of maternal distress or fetal bradycardia, the nurse or obstetrician may discontinue the epidural infusion, but the anesthesia provider should be notified immediately.

Solutions for maintenance of neuraxial analgesia, consisting of dilute local anesthetic and opioid, require careful preparation. A hospital pharmacist or compounding pharmacy should prepare the solution in a clean or sterile environment. Preservative-free drugs and saline should be used to prepare the solutions. Solution contents should always be double-checked for content and expiration date by the anesthesia provider before analgesia is initiated.

Spinal Analgesia

Placement of a catheter in the subarachnoid space allows the anesthesia provider to administer continuous spinal analgesia by intermittent bolus injection or continuous infusion of a local anesthetic combined with an opioid. Continuous spinal analgesia is an option when unintentional dural puncture has occurred (see later discussion). The technique has also been described for use in patients in whom placement of an epidural catheter is difficult (e.g., in patients with morbid obesity or abnormal vertebral anatomy, such as kyphoscoliosis, or in patients with severe cardiac disease who require careful titration of analgesia).[264]

Reports of this technique usually describe the use of a standard epidural catheter placed through an 18- or 19-gauge epidural needle. Over 25 years ago, to reduce the incidence of post–dural puncture headache, very small (e.g., 28- to 32-gauge) catheters were developed for insertion through small (e.g., 22- to 26-gauge) spinal needles. Unfortunately, several cases of cauda equina syndrome (associated with

the use of spinal microcatheters during surgery in nonpregnant patients) prompted the U.S. FDA to remove these microcatheters from the market in 1992.[265] The etiology of these neurologic deficits is unclear. Some anesthesiologists have suggested that neurologic injury may result from the maldistribution of local anesthetic within the subarachnoid space.[266] The very slow rate of injection through a caudally directed microcatheter may lead to pooling of local anesthetic solution in the terminal part of the dural sac. If the local anesthetic solution is hyperbaric, the neighboring elements of the cauda equina experience prolonged exposure to a high concentration of local anesthetic and a hyperglycemic, hyperosmotic marinade (e.g., 550 to 800 mOsm/L). Permanent neural damage may occur from the combination of tissue dehydration and a toxic concentration of local anesthetic. It is unclear whether this complication is unique to the use of microcatheters.

Arkoosh et al.[267] reported a randomized multicenter study comparing continuous spinal labor analgesia (via a 28-gauge catheter) with continuous epidural analgesia. The incidence of neurologic complications was not different between the two groups, and patients in the spinal group had better early analgesia, less motor blockade, and better patient satisfaction. The incidence of post–dural puncture headache also was not different between the two groups (spinal 9%, epidural 4%; $P = .10$), although a type II statistical error is possible given the size of the study and the low incidence of this outcome. The spinal catheter was associated with a higher incidence of technical difficulties and catheter failures.

A 23-gauge, FDA-approved, spinal catheter is now available in the United States. The catheter is inserted using a "catheter-over-needle" technique. Initial observational study found that this catheter may have clinical utility[268]; however, similar to the Arkoosh et al. study,[267] the study was not large enough to assess the risk for complications. Further study is required to characterize ease of use and complications. Several commercial spinal catheters are available in Europe.

Continuous spinal analgesia can be initiated with the same drug combination and dose used to initiate CSE analgesia (see Table 23.2).[264] For maintenance of analgesia, my colleagues and I administer our standard epidural solution (0.06% bupivacaine with fentanyl 2 µg/mL) at an initial rate of 2 mL/h. The infusion is then titrated to patient needs. We prefer to use our standard PCEA pumps for the continuous infusion, with the PCEA function disabled. This approach allows the anesthesia provider to administer a small (1 to 3 mL) bolus from the infusion bag without disconnecting the spinal catheter from the infusion tubing. Alternatively, the infusion pump can be programmed to administer 1-mL patient-controlled bolus doses. The catheter and pump should be clearly labeled so that all care providers know that the catheter is a spinal, not an epidural, catheter.

Continuous spinal analgesia with opioids has also been described for patients with obstructive cardiac lesions.[269,270] If intrathecal local anesthetics are used for intrapartum analgesia, the sensory level and the intensity of motor blockade should be monitored. Moreover, the anesthesia provider must be prepared to treat hypotension and other complications associated with high spinal anesthesia.

Ambulatory "Walking" Neuraxial Analgesia

The term "walking" or "mobile" epidural analgesia was first coined to describe low-dose CSE opioid analgesia because motor function was maintained and the ability to walk was not impaired.[271] However, the term is more accurately applied to any neuraxial analgesic technique that allows safe ambulation. Initial studies using clinical testing to assess sensory and motor impairment and dorsal column function produced conflicting results. After initiation of epidural analgesia with 15 mL of 0.1% bupivacaine/fentanyl 2 µg/mL, Buggy et al.[272] demonstrated that 66% of women had altered proprioception and 38% had impaired vibration sense. In contrast, Parry et al.[273] found that dorsal column function was impaired in only 7% of laboring women who received low-dose epidural or CSE analgesia. The same group of investigators then used computerized dynamic posturography to assess balance in nonpregnant women, term pregnant women not in labor, and laboring women after initiation of CSE analgesia with bupivacaine 2.5 mg and fentanyl 5 µg.[274] Pregnancy significantly affected balance function, but initiation of CSE analgesia did not further impair function. However, further supplementation of analgesia with the epidural injection of 10 mL of 0.1% bupivacaine/fentanyl 2 µg/mL in a subgroup of patients resulted in impaired balance function. The investigators concluded that the results support the safety of allowing ambulation after low-dose CSE analgesia, but further studies are required to understand the relative contributions of dorsal column function, proprioception, and lower limb motor strength to overall balance and ability to ambulate.[274]

Several studies have shown that an epidural test dose containing lidocaine 45 mg and epinephrine 15 µg adversely affects the ability to ambulate after initiation of CSE or low-dose epidural analgesia.[42,43]

The concept of the "walking epidural" is popular in the lay press; however, many women, once comfortable, prefer to rest rather than ambulate. The ability to walk to the toilet or sit in a chair at the bedside, however, remains desirable to many laboring women.[275] In a small study, the ability to walk to the toilet to void resulted in lower postvoid residual volume than voiding on a bedpan.[276] Although ambulation *per se* has not been shown to affect the progress or outcome of labor positively or negatively, dense motor blockade may adversely affect the spontaneous vaginal delivery rate (see later discussion). Thus, the intent of the "walking epidural"—minimization of motor blockade—should be the goal of the anesthesia provider, whether or not the patient wishes to ambulate.[275]

Safe ambulation during labor requires several safeguards (Box 23.5). Before ambulation, orthostatic blood pressure and heart rate should be measured and motor function and balance must be assessed. The patient should not ambulate alone.

BOX 23.5 Criteria for Ambulation during Labor with Neuraxial Analgesia

- Reassuring fetal status
- Engagement of fetal presenting part
- Stable orthostatic vital signs (asymptomatic and within 10% of baseline)
- Ability to perform bilateral straight-leg raises in bed against resistance
- Ability to step up on a step stool with either leg taking the first step, without assistance
- Satisfactory trial of walking accompanied by a nurse or midwife
- Patient must be accompanied by a companion at all times
- Intermittent fetal heart rate monitoring (every 15 minutes)

BOX 23.6 Anesthesia for Vaginal Delivery

Lumbar Epidural Catheter

- Supplement existing analgesia with 5 to 10 mL of 1% or 2% lidocaine or with 5 to 10 mL of 2% or 3% 2-chloroprocaine.

Spinal Anesthesia

- Intrathecal injection of hyperbaric bupivacaine 6 to 8 mg or hyperbaric lidocaine 25 to 50 mg.
- Administer a larger dose for a "trial of forceps" in case cesarean delivery is necessary.

Combined Spinal-Epidural Anesthesia

- Intrathecal injection of bupivacaine 2.5 to 5 mg with fentanyl 15 to 25 µg.
- Follow with administration of additional drug(s) via epidural catheter if anesthesia is inadequate.

ANALGESIA/ANESTHESIA FOR VAGINAL DELIVERY

During the second stage of labor, pain results from distention of the pelvic floor, vagina, and perineum. Pain impulses are transmitted to the spinal cord by means of somatic nerve fibers that enter the cord at S2 to S4. These somatic nerve fibers are larger than the visceral afferent nerve fibers that transmit the pain of the first stage of labor. Blockade of these larger nerve fibers may require administration of a more concentrated solution and/or a greater volume of local anesthetic than is required during the first stage of labor[51]; this need often creates a dilemma for the anesthesia provider. Administration of a more concentrated solution of local anesthetic results in more intense motor blockade at a time when maternal expulsive efforts are helpful.

The continuous epidural infusion of bupivacaine often leads to the gradual development of sacral analgesia. Likewise, several lumbar epidural injections of local anesthetic (given every 60 to 90 minutes) may result in sacral analgesia.[145] If analgesia is not adequate for the second stage of labor and delivery, the anesthesia provider can give additional doses of local anesthetic to augment perineal analgesia (Box 23.6). Some anesthesia providers contend that the use of the sitting position helps facilitate the onset of perineal analgesia. Published studies suggest that maternal position does not consistently affect the spread of local anesthetic in the epidural space[277,278]; rather, the administration of a larger volume of local anesthetic solution facilitates the onset of sacral analgesia.[279] Unfortunately, the larger volume also results in a higher (i.e., more cephalad) sensory level of analgesia, so the patient should be observed for evidence of hemodynamic or respiratory compromise.

Dense anesthesia is often required for delivery, especially if the obstetrician performs an episiotomy or a forceps or vacuum-extraction delivery. After administration of a test dose (3 mL of the local anesthetic solution), at our institution my colleagues and I administer 5 to 10 mL of 1% to 2% lidocaine or 2% to 3% 2-chloroprocaine. We inject this "delivery dose" when the fetal head is visible on the perineum during pushing or when the obstetrician has decided to proceed with instrumental vaginal delivery. The anesthesia provider should monitor the maternal blood pressure carefully, especially if excessive blood loss occurs in a patient with extensive anesthesia.

Occasionally a parturient tolerates the pain of labor until late in the first stage (i.e., more than 8 cm cervical dilation) and then requests analgesia. Advanced labor does not preclude initiation of neuraxial analgesia, especially in a nulliparous woman, in whom the second stage of labor may last 2 to 3 hours. However, initiation of lumbar epidural analgesia in the late first stage of labor often results in inadequate sacral analgesia unless large volumes of a concentrated local anesthetic solution are administered. This leads to higher cephalad sensory blockade than necessary and dense motor blockade. Another option is to administer CSE analgesia. The advantages of this technique are that it provides a rapid onset of spinal analgesia with sacral coverage for advanced labor and that it includes the placement of an epidural catheter. Additional local anesthetic can be administered through the epidural catheter if the extent or duration of spinal analgesia is inadequate.

Single-shot spinal anesthesia for vaginal delivery may be indicated in a parturient who does not have epidural anesthesia and who requires perineal anesthesia. A so-called saddle block can be administered to achieve blockade of the sacral spinal segments; a small dose of a hyperbaric local anesthetic solution is adequate for this purpose. A saddle block may be advantageous in the patient with a preterm fetus or a vaginal breech presentation. In these cases, dense perineal relaxation may facilitate an atraumatic vaginal delivery. A saddle block performed with the patient in the sitting position with hyperbaric local anesthetic solution provides excellent anesthesia for an outlet/low forceps delivery. A higher level (T10) of anesthesia often is required for a mid-forceps delivery.

Clear communication between the obstetrician and anesthesia provider is essential. If the obstetrician is certain that the application of forceps (or vacuum extraction) will result

in a successful delivery, a saddle block will likely provide satisfactory anesthesia. However, in some cases, the obstetrician will perform a *trial* of forceps. If the trial fails, cesarean delivery must follow. We alter our technique when giving spinal anesthesia for a trial of forceps. In some cases, we give a dose of local anesthetic appropriate for cesarean delivery. Alternatively, a saddle block can be administered via the CSE technique. If spinal anesthesia is inadequate for the planned procedure, additional local anesthetic can be given through the epidural catheter.

SIDE EFFECTS OF NEURAXIAL ANALGESIA

Hypotension

Neuraxial anesthesia–induced sympathetic blockade leads to peripheral vasodilation and increased venous capacitance. Hypotension that occurs after extensive neuroblockade primarily reflects decreased systemic vascular resistance.[280] Hypotension is often defined as a 20% to 30% decrease in systolic blood pressure (compared with baseline) or a systolic blood pressure less than 100 mm Hg. Modest hypotension rarely has adverse consequences in young, nonpregnant patients. However, placental circulation has limited autoregulation; thus, maintenance of uteroplacental perfusion largely depends on maintenance of maternal blood pressure (see Chapter 3). Uncorrected hypotension results in decreased uteroplacental perfusion. If hypotension is severe and prolonged, hypoxia and acidosis will develop in the fetus. Blood pressure should be monitored frequently (every 2 to 3 minutes) after initiation of analgesia, until stable blood pressure is ascertained.

The incidence of hypotension after initiation of neuraxial analgesia *during labor* is approximately 14%.[24] Kinsella and Black[281] reported that maternal position and the position of the blood pressure cuff markedly influence the measured blood pressure. With laboring patients in the full lateral position, the mean difference in systolic blood pressure between the dependent and upper arm was 10 mm Hg; the mean difference in diastolic pressure was 14 mm Hg. Therefore, the incidence of hypotension may vary with the position of both the patient and the blood pressure cuff.

A meta-analysis of studies comparing low-dose epidural analgesia with CSE analgesia found no difference in the incidence of hypotension between the two techniques.[24]

The prevention of hypotension includes avoidance of aortocaval compression. Preston et al.[282] noted a higher incidence of severe FHR decelerations in women placed in the supine-lateral tilt position than in those in the full lateral position after initiation of epidural analgesia. In contrast, Beilin et al.[283] found no difference in maternal blood pressure and FHR decelerations between the two positions.

Traditionally, intravenous "preload" (also known as "prehydration") with 0.5 to 1.5 L of crystalloid solution was used to reduce the incidence and severity of hypotension after the initiation of neuraxial labor analgesia. However, several randomized controlled trials have shown that the incidence of hypotension after preload with 0.5 to 1.0 L of fluid is no lower than that after no preload.[35,39] In women undergoing spinal anesthesia for cesarean delivery, there is no difference in the incidence of hypotension when crystalloid is administered as a rapid bolus before the initiation of neuroblockade (preload) compared with administration concurrently with the initiation of anesthesia (co-load).[40] Data are inconsistent as to whether a fluid bolus decreases the risk for nonreassuring FHR changes associated with the initiation of neuraxial analgesia (see earlier discussion). Many anesthesia providers omit a fluid bolus. In our practice, my colleagues and I usually administer approximately 500 mL of intravenous crystalloid (co-load) at the time of initiation of neuraxial labor analgesia.

The hypotension associated with neuraxial analgesia is usually easily treated. Treatment includes the administration of additional intravenous crystalloid, placement of the mother in the full lateral and Trendelenburg position, and administration of an intravenous vasopressor. Traditionally, ephedrine 5 to 10 mg has been administered; however, studies in women undergoing spinal anesthesia for elective cesarean delivery have shown that phenylephrine is equally efficacious in restoring blood pressure and is associated with higher umbilical arterial blood pH measurements at birth.[284] No differences in neonatal outcome have been noted. Because there is no evidence that the choice of vasopressor influences maternal or neonatal outcome, the use of either drug is acceptable. The FHR should be monitored continuously, and treatment should be more aggressive if nonreassuring FHR patterns are noted or if the mother is symptomatic (e.g., presence of presyncope or nausea). Ephedrine crosses the placenta and may increase both FHR and FHR variability (e.g., saltatory FHR pattern).[285,286]

Data are conflicting as to whether there is a dose-response relationship between hypotension and intrathecal local anesthetics when these drugs are administered in low doses for labor analgesia. Palmer et al.[287] found no difference in blood pressure in women randomly assigned to receive intrathecal fentanyl combined with either 1.25 or 2.5 mg of bupivacaine. In contrast, Lee et al.[288] noted a greater decrease in blood pressure at 10 minutes in women who received bupivacaine 2.5 mg than in women who received 1.25 mg. Because 1.25 mg is less than the ED_{95} for bupivacaine (when combined with fentanyl)[200] and there is no apparent advantage to combining bupivacaine 1.25 mg with fentanyl over using fentanyl alone,[289] there is little reason to manipulate the dose of intrathecal bupivacaine with the goal of decreasing the incidence and severity of hypotension when low doses are used for labor analgesia.

Pruritus

Pruritus is the most common side effect of epidural or intrathecal opioid administration (see Chapter 13).[290] Intrathecal opioid administration is associated with a higher incidence and severity of pruritus than epidural opioid administration.[24] The incidence of pruritus after intrathecal opioid administration is close to 100% in some studies, although the need for treatment is much lower.[168] The incidence and

TABLE 23.8 Treatment of Neuraxial Opioid-Induced Pruritus

Drug	Dose
Naloxone	40–80 μg intravenous bolus
	1–2 μg/kg/h continuous intravenous infusion
Nalbuphine	2.5–5 mg intravenous bolus
Naltrexone	6 mg orally

severity of pruritus are dose dependent for both epidural[98] and spinal[168,176] opioid administration. The co-administration of local anesthetic decreases the incidence of pruritus,[199] whereas the co-administration of epinephrine may worsen pruritus.[291]

The cause of the neuraxial opioid-induced pruritus is poorly understood, but it appears to be unrelated to histamine release. The pruritus appears to be mediated through central μ-opioid receptors, given that μ-opioid receptor antagonists relieve itching.[292] The pruritus may be caused by a perturbation of sensory input that results from rostral spread of the opioid within the CSF to the level of the trigeminal nucleus in the medullary dorsal horn.[292] A disruption of sensory modulation is consistent with the observation that a similar pattern of pruritus is seen in medical conditions in which sensory modulation is disturbed (e.g., diabetic neuropathy, multiple sclerosis).[293]

Few studies have addressed the *treatment* of established pruritus (see Chapter 27). Most studies have addressed pruritus after intrathecal morphine, not lipid-soluble opioids such as fentanyl and sufentanil. The most effective treatment is a centrally acting μ-opioid antagonist (e.g., naloxone or naltrexone) or a partial agonist-antagonist such as nalbuphine (Table 23.8). However, the use of these agents in a bolus or continuous infusion may reverse the analgesia. Antihistamines (e.g., diphenhydramine), low-dose propofol, 5-HT_3 receptor antagonists (e.g., ondansetron), and pentazocine (a κ-opioid and partial μ-opioid receptor agonist) have been studied for the treatment of pruritus after spinal morphine, but not the lipid-soluble opioids fentanyl and sufentanil that are commonly used for neuraxial labor analgesia. Results of published studies are inconsistent.

A number of drugs have been investigated for *prophylaxis* against neuraxial opioid–induced pruritus, primarily coincident with neuraxial morphine administration. A 2016 meta-analysis included six randomized controlled trials of prophylactic ondansetron for prevention of intrathecal fentanyl or sufentanil-induced pruritus in both obstetric and nonobstetric patients.[294] Ondansetron 8 mg did not decrease the incidence of pruritus, although there was a trend for decreased need for rescue treatment. However, a single trial in obstetric patients who received ondansetron 4 mg or 8 mg before intrathecal fentanyl 25 μg found no benefit compared with placebo.[295]

We do not routinely administer prophylaxis for the pruritus associated with neuraxial administration of opioids for labor analgesia. The pruritus is typically self-limiting; the severity of pruritus usually diminishes markedly in the first hour after opioid administration, and most women do not require treatment. For moderate to severe pruritus that requires treatment, we usually administer **nalbuphine** 2.5 mg and repeat the dose in 10 to 15 minutes if no improvement is noted. The advantage of nalbuphine is that it is less likely to reverse the intrathecal or epidural opioid analgesia.[296]

Nausea and Vomiting

Nausea and vomiting occur frequently during labor. It is difficult to determine the incidence of nausea and vomiting directly related to epidural and intrathecal opioid administration. Nausea and vomiting may also be secondary to neuraxial analgesia–induced hypotension. Maternal blood pressure should be measured when the patient complains of nausea in the presence of neuroblockade. Other causes of nausea and vomiting during labor are pregnancy itself, pain, opioid-induced delay of gastric emptying (see later discussion), and systemic opioids, which are sometimes administered before intrathecal or epidural opioids. In one study, the incidences of nausea (7% versus 44%) and vomiting (2% versus 17%) were significantly lower in women randomly assigned to receive intrathecal fentanyl than in those assigned to receive systemic hydromorphone analgesia in early labor.[19]

The etiology of neuraxial opioid–associated nausea is unclear, but it may be caused by the modulation of afferent input at the area postrema (i.e., the chemoreceptor trigger zone) or at the nucleus of the tractus solitarius, which is a key relay station in the visceral sensory network (see Chapter 13).[297] Of interest, nausea is less common after epidural or intrathecal opioid administration during labor than after the administration of the same drugs for post–cesarean delivery analgesia. Norris et al.[298] noted that women who received epidural or intrathecal opioid analgesia during labor had an incidence of nausea of only 1.0% or 2.4%, respectively.

Although the incidence of nausea is low, treatment should be available. No studies, however, have specifically addressed the *treatment* of neuraxial analgesia–associated nausea and vomiting during labor. We do not routinely administer prophylactic antiemetics before the administration of neuraxial lipid-soluble opioids for labor analgesia.

Fever

Both observational and randomized controlled trials have consistently noted a gradual rise in core temperature over several hours in laboring women receiving epidural analgesia that was not observed in women receiving no analgesia, inhaled nitrous oxide, or parenteral opioids.[299] The mean increase in core temperature is typically small (less than 1.0° C); however, women with epidural analgesia are more likely to have clinical fever (usually defined as core temperature greater than or equal to 38° C) than those without epidural analgesia (risk ratio, 3.34; 95% CI, 2.63 to 4.23).[3] The incidence of clinical fever ranges from 20% to 30% in women randomized to receive epidural analgesia compared with 5% to 7% in women in the control groups.[299]

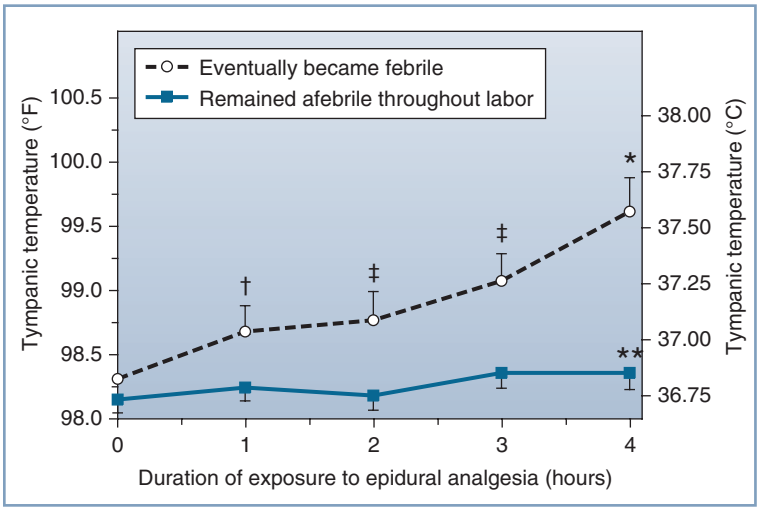

Fig. 23.7 Maternal tympanic temperature in the 4 hours immediately after initiation of epidural analgesia, stratified by ultimate intrapartum fever status (febrile ≥ 38.0° C or afebrile < 38° C). $*P < .001$; $^{\dagger}P < .05$; $^{\ddagger}P < .01$ (repeated measures analysis, febrile versus afebrile); $**P = .26$ (repeated measures analysis, afebrile group temperature change over time). (Modified from Goetzl L, Rivers J, Zighelboim I, et al. Intrapartum epidural analgesia and maternal temperature regulation. *Obstet Gynecol.* 2007;109:687–690.)

Newer evidence suggests that the slow increase in mean temperature observed in women with epidural analgesia may be an averaging artifact.[300] In a prospective observational study of women with epidural analgesia, Goetzl et al.[300] observed the incidence of fever was 22.2%. The mean temperature increase over 8 hours was 0.72° C, similar to that observed in earlier studies. However, the investigators noted that temperature increased in only a subset of women; the remaining cohort had no temperature increase (Fig. 23.7). In the small subset of women who eventually developed clinical fever, core temperature began to rise within 1 hour of initiation of epidural analgesia. The researchers concluded that most women do not become febrile after epidural analgesia, and therefore it is unlikely that a perturbation in thermoregulation induced by epidural analgesia is the cause of epidural analgesia–associated fever.

The mechanism of temperature elevation in some women who receive epidural labor analgesia is incompletely understood but likely reflects a noninfectious inflammatory process. Several lines of evidence support this mechanism.[299] Risk factors for intrapartum fever are similar to factors that are associated with the request for epidural analgesia, including nulliparity, prolonged rupture of membranes, and prolonged labor. Sharma et al.[301] randomized healthy nulliparous women requesting epidural analgesia to receive prophylactic antibiotics or placebo. Fever and placental inflammation were not reduced in women who received antibiotic prophylaxis. In an observational study in women who self-selected the type of analgesia, the histologic diagnosis of placental inflammation was more common in women with epidural analgesia.[302] However, the incidence of maternal fever was not different between women with and without epidural analgesia in the absence of placental inflammation. Additionally, Goetzl et al.[303] noted higher baseline maternal serum levels of interleukin-6 (IL-6), a marker of inflammation, in laboring women who eventually developed fever; final IL-6 levels were directly related to the duration of epidural analgesia.[303] In a subsequent study, women with epidural analgesia randomized to receive maternal methylprednisolone (100 mg) had a lower rate of fever than those who received placebo, again suggesting that a noninfectious inflammatory mechanism is involved.[304]

The technique used to initiate and maintain analgesia has not been shown to influence the risk for "epidural fever." The incidence of fever does not differ in women who receive epidural compared with CSE analgesia,[305] in early compared with late labor initiation of neuraxial analgesia,[19] bupivacaine epidural analgesia with and without fentanyl,[306] or with delayed initiation of the epidural infusion.[307]

The significance of the temperature changes during labor is unclear. Maternal fever is associated with mode of delivery; the rate of instrumental and cesarean delivery is higher in women with intrapartum fever.[308] Epidural analgesia during labor is associated with more neonatal sepsis evaluations but not with a higher incidence of neonatal sepsis.[309,310] This link likely exists because the diagnosis of intrapartum chorioamnionitis is based on the presence of fever and usually one or two additional criteria (i.e., maternal leukocytosis, maternal tachycardia, uterine tenderness, foul-smelling amniotic fluid).[311] Because maternal fever from any cause leads to maternal and fetal tachycardia, it may be difficult to differentiate women with actual infection (based on postpartum histologic placental examination) from women with fever associated with epidural analgesia. In the interests of maternal and fetal safety, intrapartum maternal fever typically prompts an intrapartum diagnosis of clinical chorioamnionitis. Revised 2010 guidelines from the U.S. Centers for Disease Control and Prevention stipulate that even well-appearing newborns whose mothers carry the diagnosis of suspected chorioamnionitis should undergo a limited evaluation (complete blood count [CBC] with differential cell count and blood culture) and antibiotic therapy pending the culture results.[312]

Of greater concern is the association between maternal or neonatal fever and serious adverse outcomes (i.e., neonatal seizures and encephalopathy, development of cerebral palsy).[299] Evidence suggests that the mechanism of neonatal brain injury is inflammatory rather than fever *per se*.[299,313]

Whether epidural analgesia plays any role in these outcomes requires further research. However, because of the growing evidence that maternal inflammation and infection, which manifest as fever, can be detrimental to the fetal brain, anesthesia providers should not dismiss this apparent physiologic effect as a mere curiosity. When maternal fever occurs, good clinical practice dictates that efforts be made to lower maternal temperature, and identify and treat a presumed maternal infection.

Shivering

Several factors, including hormonal factors, likely influence thermoregulatory response during labor and delivery. Shivering is frequently observed during labor and may occur more commonly after epidural analgesia.[314] Panzer et al.[315] performed an observational study of shivering during labor. Before delivery, 18% of women shivered, and 15% of these episodes were associated with normothermia and vasodilation, suggesting a nonthermoregulatory cause of the shivering. After delivery, shivering was observed in 16% of women, and in 28% of them, it was nonthermoregulatory. There was no difference in the incidence of shivering between women who chose epidural (bupivacaine/fentanyl) analgesia and those who chose systemic meperidine analgesia. The addition of an opioid to the local anesthetic solution may affect the shivering response.[132,316] At least one study has suggested that the epidural administration of epinephrine increases shivering[316]; the etiology of this response is unknown.

Urinary Retention

Urinary retention is a troublesome side effect of neuraxial anesthesia/analgesia. The bladder and urethral sphincters receive sympathetic innervation from the low thoracic/high lumbar sympathetic fibers and parasympathetic innervation from sacral fibers. Neuraxial local anesthetics cause urinary retention through blockade of sacral nerve roots. Efferent and afferent nerve traffic via the S2, S3, and S4 nerve roots controls the detrusor muscle (responsible for urine storage and micturition) and internal and external sphincter function. Intrathecal opioids cause dose-dependent suppression of detrusor muscle contractility and decreased urge sensation via inhibition of sacral parasympathetic nervous system outflow.[297,317] The onset of urinary retention appears to parallel the onset of analgesia.

It is difficult to determine the magnitude of this problem during labor, because parturients often require catheterization for other reasons. Postpartum bladder dysfunction was observed in 14% of women who had a normal spontaneous vaginal delivery and in 38% of women who underwent instrumental vaginal delivery, all without epidural analgesia.[318]

Several observational studies suggest that there is a higher risk for intrapartum and postpartum urinary retention in women who receive epidural labor analgesia than in those who receive nonepidural or no analgesia.[319,320] Similarly, a meta-analysis of three small randomized controlled trials comparing neuraxial with systemic opioid analgesia, in which urinary retention was reported as a secondary outcome, also identified this association.[3] Whether this higher risk reflects a cause-and-effect relationship or patient selection bias is not clear. Wilson et al.[321] found that women randomized to receive neuraxial labor analgesia with low-concentration bupivacaine with opioid more often retained the ability to void spontaneously than women who received epidural analgesia with 0.25% bupivacaine (approximately 31% versus 11%), which suggests a dose-response relationship.

Any difference in bladder function appears to be short-lived; differences between groups in one study had resolved by postpartum day 1.[319] In two studies, patients were randomly assigned to receive epidural analgesia with or without an opioid; there was no difference between groups in the incidence of intrapartum[322] or postpartum[320] urinary retention.

Parturients should be regularly observed during labor for evidence of bladder distention, especially if they complain of suprapubic pain during contractions. The differential diagnosis of breakthrough pain during neuraxial labor analgesia should include bladder distention. Personal observation suggests that many women can void in the presence of low-dose neuroblockade if placed on a bedpan or escorted to the toilet, even if they do not perceive a full bladder. Inability to void and bladder distention should prompt catheterization to empty the bladder.

Recrudescence of Herpes Simplex Virus

The common cold sore or fever blister is a manifestation of the reactivation of latent infection. Reactivation can occur after exposure to ultraviolet light, fever, immunosuppression, or trauma. Prospective randomized studies have demonstrated a higher incidence of postpartum *oral* herpes simplex virus (HSV) reactivation in women randomly assigned to receive neuraxial (epidural,[323,324] intrathecal[325]) morphine than among women assigned to receive systemic morphine for post–cesarean delivery analgesia. Case reports have associated intraspinal administration of meperidine and fentanyl with the subsequent recurrence of HSV infection.[326,327]

In a retrospective survey of data from the University of Washington, the seroprevalence of HSV type 1 among pregnant women in the years 2000 to 2010 was 65.5%; the seroprevalence of HSV type 2 was 16.3%.[328] HSV-1 is typically found in the trigeminal ganglia and causes orofacial lesions, whereas HSV-2 is more commonly found in the lumbosacral ganglia. However, either of these viruses can infect any region of the body.

To our knowledge, postcesarean reactivation of HSV infection after neuraxial opioid administration has not resulted in clinically significant maternal or neonatal complications.[329,330] In addition, we are unaware of any study that has investigated whether epidural or intrathecal opioid administration during labor increases the incidence of recurrent oral HSV infection after vaginal delivery. Therefore, we do not withhold neuraxial opioids during labor in women with a history of oral herpes.

Delayed Gastric Emptying

Labor may result in delayed gastric emptying, which may be exacerbated by opioid administration (see Chapter 28).[331,332]

TABLE 23.9 Characteristics of Neuraxial Analgesia Failures[a]

Characteristic	Rate According to Type of Analgesia (%) EPIDURAL (*N* = 7849)	COMBINED SPINAL-EPIDURAL (*N* = 4741)	TOTAL (*N* = 12,590)	*P* Value

Modified from Pan PH, Bogard TD, Owen MD. Incidence and characteristics of failures in obstetric neuraxial analgesia and anesthesia: a retrospective analysis of 19,259 deliveries. *Int J Obstet Anesth.* 2004;13:227–233.

Intravenous or intramuscular opioid administration results in delayed gastric emptying in laboring women. Studies suggest that epidural fentanyl combined with bupivacaine and administered as part of a continuous epidural infusion does not result in delayed gastric emptying compared with infusion of bupivacaine alone[333,334]; however, delayed gastric emptying may occur with epidural fentanyl administered as a bolus (50 to 100 µg)[335,336] or with a *prolonged* infusion.[333] In another study, intrathecal fentanyl 25 µg resulted in delayed gastric emptying compared with epidural fentanyl 50 µg plus bupivacaine or bupivacaine alone.[337] Delayed gastric emptying may predispose a patient to nausea and vomiting. In addition, it may result in a greater volume of gastric contents, which—in theory—might be problematic in patients who require induction of general anesthesia for emergency cesarean delivery.

COMPLICATIONS OF NEURAXIAL ANALGESIA

Inadequate Analgesia

The reported failure rate for neuraxial analgesia varies according to the definition of "failure."[338–340] In survey studies, the rate of epidural catheter replacement has ranged from 5% to 13%.[27,338–340] Successful location of the epidural space is not always possible, and satisfactory analgesia does not always occur, even when the epidural space has been identified correctly. Factors such as patient age and weight, the specific technique, the type of epidural catheter, and the skill of the anesthesia provider are associated with the rate of failure of neuraxial analgesia.[338,340] Failure to provide adequate analgesia not only results in a dissatisfying experience for the patient but also may lead to litigation.[341] The risk for failed anesthesia and the potential need to place a second epidural catheter should be discussed with the patient during the preanesthetic evaluation, before placement of the first epidural catheter.

Pan et al.[338] used quality assurance data to retrospectively assess the failure rate among more than 12,000 neuraxial procedures performed for labor analgesia over a 3-year period (Table 23.9). The overall failure rate of 12% included procedures that resulted in no or inadequate analgesia, unintentional dural puncture with an epidural needle or catheter, intravenous cannulation with the epidural catheter, or replacement of the catheter for any reason. The rate of failed analgesia was significantly lower after CSE than after epidural analgesia (10% versus 14%, respectively; $P < .001$). In a follow-up study from the same group of investigators,[27] the rate of epidural catheter failure was 6.6% after CSE analgesia and 11.6% after epidural analgesia ($P = .001$). Other studies have also found a higher epidural catheter failure rate when analgesia is initiated with a traditional epidural approach compared with a CSE technique.[340,342] Of note, these studies were performed in academic institutions where the neuraxial procedures were performed primarily by trainees. In a randomized trial comparing CSE to epidural analgesia in a large maternity hospital staffed by private practice anesthesiologists,[343] the epidural catheter replacement rate was lower and there was no difference between CSE and epidural analgesia (2% and 1.2% incidence, respectively; 95% CI of difference –3.3% to 1.8%).

Typically, failed analgesia after injection of intrathecal or epidural anesthetics results in no neuroblockade, unilateral blockade or missed segments, or inadequate density of neuroblockade. Patient complaints of pain should prompt timely evaluation and treatment (Box 23.7). The progress of labor should be assessed, and the patient should be queried as to the nature of the pain. Typically, pain becomes more intense as labor progresses; for example, an epidural block that was

BOX 23.7 Assessment and Management of Inadequate Neuraxial Analgesia

- Assess progress of labor.
  - Rule out other causes of pain (distended bladder, ruptured uterus).
- Perform an honest evaluation of the anesthetic.
  - Is the catheter really in the epidural space?
  - If in doubt, replace the catheter.
- If the catheter is in the epidural space, but the extent of neuroblockade is inadequate (does not extend from T10 to S4, as is required for late labor):
  - Inject a dilute solution of local anesthetic (5 to 15 mL), with or without an opioid.
  - Alter maintenance technique (e.g., increase volume, decrease concentration).
  - If this maneuver is unsuccessful, replace the catheter.
- If catheter is in the epidural space, but the block is asymmetric:
  - Inject a dilute solution of local anesthetic (5 to 15 mL), with or without an opioid.
  - Alter maintenance technique (e.g., increase volume, decrease concentration).
  - Place the less-blocked side in the dependent position.
  - If this maneuver is unsuccessful, replace the catheter.
- If the catheter is in the epidural space, but the patient has breakthrough pain despite adequate extent of neuroblockade:
  - Inject a more concentrated solution of local anesthetic, with or without an opioid.
  - Consider administration of epidural clonidine (75 μg)
  - Alter maintenance technique (e.g., increase concentration of local anesthetic).

adequate at 4-cm cervical dilation may not be adequate at 8-cm cervical dilation. Expectations and treatment may be different for women in latent versus active or second-stage labor. The bladder should be checked and emptied if distended. The position of the epidural catheter at the skin should be assessed to exclude the possibility of catheter migration out of the epidural space. Inadequate analgesia may also result from migration of the epidural catheter into a vein or movement of the catheter outside the epidural space. Before giving a bolus dose of local anesthetic, the anesthesia provider should give a test dose to exclude intravenous migration of the catheter.

The extent of neuroblockade should be assessed with a cold or sharp stimulus that starts over the lateral thighs (the dermatomal level at which the tip of the epidural catheter is sited) and moves both *cephalad* and *caudad* on both sides. Inexperienced anesthesia providers often fail to check for the presence of sacral blockade. In the case of no sensory blockade, the epidural catheter should be replaced. If the extent of neuroblockade is inadequate (in either the cephalad or caudad direction), or if there is unilateral blockade or missed segments, the injection of a large volume (10 to 15 mL) of a dilute local anesthetic solution (e.g., 0.0625% to 0.125% bupivacaine) may result in satisfactory analgesia. An advantage of using a more dilute solution of local anesthetic is the ability to increase the administered volume to ensure adequate spread of analgesia.

Some women appear to have adequate *extent* of sensory blockade but still complain of pain. These women may require more dense analgesia; a larger dose of local anesthetic (10- to 15-mL bolus of 0.125% bupivacaine or a 5- to 10-mL bolus of 0.25% bupivacaine) often successfully reestablishes analgesia. Alternatively, a lipid-soluble opioid (e.g., fentanyl 50 μg) may be added to the solution. The opioid is especially helpful if the parturient is experiencing back pain because the fetus is in the occiput posterior position. Epidural clonidine (75 μg) may be used to treat breakthrough pain that occurs during/after epidural administration of the standard local anesthetic-opioid solution.

Some anesthesia providers advocate pulling the epidural catheter 1 to 2 cm out of the epidural space before administering the bolus injection. Beilin et al.[344] investigated this practice by randomly assigning women with incomplete analgesia to one of two treatments: (1) immediate injection of 0.25% bupivacaine 5 mL or (2) withdrawal of the (multiorifice) epidural catheter 1 cm followed by injection of the same dose of bupivacaine. There was no difference in the ability to rescue analgesia between the two treatments (74% versus 77%, respectively).

Although available data are inconsistent, it appears that maternal position has little effect on the development of an asymmetric block after a *bolus* dose of anesthetic solution into the epidural space.[278,345–347] It is likely that the position of the epidural catheter in relation to other epidural space structures (e.g., connective tissue, fatty tissue, blood vessels) affects the spread and quality of analgesia to a greater extent than maternal position. Anatomic barriers (e.g., a longitudinal connective tissue band between the dura and ligamentum flavum) or placement of the catheter tip in the anterior epidural space or paravertebral space may explain some cases of single nerve root, unilateral, or asymmetric blockade.[348–351]

The response to the bolus dose should be assessed in a timely fashion, and the epidural catheter should be replaced (with the patient's consent) if satisfactory analgesia is not obtained.

Unintentional Dural Puncture

In a meta-analysis of 13 studies that involved more than 300,000 obstetric patients, Choi et al.[352] determined that the rate of unintentional dural puncture with an epidural needle or catheter was 1.5% (95% CI, 1.5% to 1.5%) (see Chapter 30). Dural puncture may be detected at the time of insertion of the epidural needle or after placement of the catheter. If dural puncture is detected with the epidural needle, the anesthesia provider has two primary options. He or she may elect to remove the needle and place an epidural catheter at another interspace; if CSE analgesia was planned, the intrathecal dose may be injected through the epidural needle before it is removed and re-sited at a different interspace. Alternatively, the anesthesia provider may place a catheter

in the subarachnoid space and administer continuous spinal analgesia for labor and delivery. This latter technique is particularly advantageous for patients at high risk for repeat dural puncture on a second attempt or in cases in which it may be difficult to enter either the epidural or subarachnoid space successfully at an alternative interspace (e.g., in obese women or in patients with abnormal anatomy of the lumbar spine). It is very important to append a label that clearly identifies the catheter as a spinal catheter to decrease the risk for injecting an epidural dose of local anesthetic into the subarachnoid space. The parturient and all providers on the labor and delivery unit, including nurses, midwives, and other anesthesia providers, must be made aware of the intrathecal catheter, and this information must be communicated during any hand-off of care to another provider. Particular care must be taken if the catheter is used to extend the block for cesarean delivery.

Re-siting the epidural catheter in a different interspace eliminates the problem of mistaking an intrathecal catheter for an epidural catheter. However, local anesthetic or opioid injected through the epidural catheter may pass through the dural puncture site and into the subarachnoid space, resulting in unexpectedly high neuroblockade.[353] This complication is more likely to occur with the bolus injection of local anesthetic than with an epidural infusion of local anesthetic.

If dural puncture is not recognized until CSF is aspirated from the catheter, or if administration of the test dose results in spinal anesthesia, the anesthesia provider has the following two options: (1) replace the epidural catheter at an alternative interspace or (2) provide continuous spinal analgesia through the existing catheter.

Respiratory Depression

The administration of opioids by any route entails risk for respiratory depression. Factors that affect the risk for respiratory depression after neuraxial opioid administration include the choice and dose of drug and its interaction with systemically administered opioids and other central nervous system depressants (see Chapter 13). The most important factor affecting the onset of respiratory depression is the lipid solubility of the drug.[297] In general, if respiratory depression is going to occur, it will do so within 2 hours of the injection of a lipid-soluble opioid such as fentanyl or sufentanil. When a lipid-soluble opioid gains access to the CSF, it is quickly absorbed by lipophilic body tissues. Subsequent clearance and elimination are similar to those associated with intravenous injection of the same drug. Thus, with spinal or epidural injection of a lipid-soluble opioid, the "time window" for respiratory depression is short. Conversely, with a hydrophilic drug such as morphine, the onset of respiratory depression is delayed. Once a hydrophilic drug such as morphine enters the CSF, it tends to stay in the CSF. Rostral migration and absorption into the respiratory centers occur over several hours, so respiratory depression may not occur until 6 to 12 hours after injection of the drug (see Fig. 13.13).

The dose of opioid is a major determinant of the risk for respiratory depression.[176] Herman et al.[176] observed an increase in end-tidal CO_2 concentration with intrathecal fentanyl doses of 15 µg or higher. The time of maximum end-tidal CO_2 was approximately 30 minutes after the intrathecal injection. A risk factor for respiratory depression is previous parenteral opioid administration. Several reports have implicated prior intravenous opioid administration as a contributing factor to the respiratory arrest that occurred after intrathecal sufentanil 10 µg administration in laboring women.[354,355] (This dose is higher than the currently recommended intrathecal dose range.) For this reason, we refrain from administering a bolus dose of epidural or spinal opioid to women who have recently received systemic opioid analgesia.

Intravascular Injection of Local Anesthetic

The incidence of fatal local anesthetic systemic toxicity (LAST) appears to have declined in the past quarter century.[10] In a prospective audit from the United Kingdom of more than 145,000 obstetric epidural procedures, the incidence of intravascular injection was 1 in 5000 (Table 23.10). Bupivacaine 0.75% is no longer used for epidural anesthesia in obstetric patients. In the United States, lidocaine or 2-chloroprocaine is most often used when a high-concentration local anesthetic is required for operative epidural anesthesia, but in other countries bupivacaine 0.5%, levobupivacaine 0.5% and ropivacaine 0.75% are often used; low concentrations of local anesthetic are now routinely used for labor analgesia. Nonetheless, LAST remains a serious potential complication during the administration of epidural anesthesia in obstetric patients.

Intravenous injection of a large dose of local anesthetic causes central nervous system symptoms (e.g., restlessness, dizziness, tinnitus, perioral paresthesia, difficulty speaking, seizures, loss of consciousness) (see Chapter 13). Cardiovascular effects may progress from increased blood pressure (as a result of sympathetic stimulation) to bradycardia, depressed ventricular function, and ventricular tachycardia and fibrillation. The extension of epidural labor analgesia to epidural

TABLE 23.10 Incidence of Unintentional Intravascular, Intrathecal, and Subdural Injections during Attempted Epidural Labor Analgesia[a]

Event	Incidence	Rate (%)[b]
Intravascular injection	1:5000	0.020 (0.014–0.029)
Intrathecal injection	1:2900	0.035 (0.027–0.046)
Subdural injection	1:4200	0.025 (0.017–0.033)
High/total spinal anesthesia	1:16,200	0.006 (0.003–0.012)

BOX 23.8 Management of Local Anesthetic Systemic Toxicity

- Stop injecting local anesthetic.
- Call for help.
- Position patient with left uterine displacement.
- Prepare for emergency delivery. Consider delivery of the infant if the mother is not resuscitated within several minutes because this may facilitate successful resuscitation of the mother.
- Consider 20% intravenous lipid emulsion administration at the first sign of LAST.[a]
  - Bolus dose: 1.5 mL/kg over 2-3 min (approximately 100 mL)
  - Infusion: 200-250 mL over 15-20 min
  - Repeat bolus dose once or twice for persistent cardiovascular collapse.
  - Recommended maximum dose: 12 mL/kg
- Administer 100% oxygen to maintain maternal oxygenation.
- Use positive-pressure ventilation if necessary. Tracheal intubation will facilitate support of ventilation and help protect the airway, but do not delay administration of oxygen to intubate the trachea.
- Stop the seizure with a benzodiazepine. Be aware that hypoxemia and acidosis develop rapidly during a seizure.
- Alert the nearest facility capable of cardiopulmonary bypass.
- Monitor maternal vital signs and fetal heart rate.
- Support maternal blood pressure with fluids and vasopressors.
- Initiate advanced cardiac life support if necessary, including modifications for pregnancy (see Chapter 54).
  - Avoid vasopressin, calcium entry-blocking agents, beta-adrenergic receptor antagonists, and local anesthetics.[a]
  - Reduce individual epinephrine doses to less than 1 µg/kg.[a]

LAST, Local anesthetic systemic toxicity.
[a]American Society of Regional Anesthesia and Pain Medicine. Checklist for treatment of local anesthetic systemic toxicity (LAST). Available from https://www.asra.com/content/documents/asra_last_checklist_2018.pdf. Accessed April 1, 2018.

anesthesia for intrapartum cesarean delivery may be a particularly vulnerable risk period for LAST.[356] Bupivacaine cardiotoxicity may be fatal in pregnant women.[357]

Steps for the management of the unintentional intravascular injection of local anesthetic are listed in Box 23.8. They include treatment of convulsions, supporting oxygenation and ventilation, and initiating advanced cardiac life support, if indicated. Lidocaine should not be administered for the treatment of life-threatening ventricular arrhythmias. Early delivery of the infant should be considered, because it may improve the likelihood of successful resuscitation.

In its 2015 Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, the American Heart Association suggested that it may be reasonable to administer lipid emulsion in cases of suspected LAST.[358] Both the American Society of Regional Anesthesia and Pain Medicine[359] and the Association of Anaesthetists of Great Britain and Ireland[360] have incorporated the administration of lipid emulsion into their guidelines for managing LAST. At least one case report described the successful use of lipid emulsion for resuscitation of a parturient who developed LAST after the epidural injection of bupivacaine.[361]

High Neuroblockade and Total Spinal Anesthesia

An unexpectedly high level of anesthesia may result in one of several situations. High (or total) spinal blockade may occur after the unintentional and unrecognized injection of local anesthetic (via a needle or catheter) into either the subarachnoid or subdural space during the planned initiation of epidural analgesia/anesthesia. Alternatively, the epidural catheter may migrate into the subarachnoid or subdural space during the course of labor and delivery. Finally, high spinal blockade may result from an overdose of local anesthetic in the epidural space. Crawford[353] reported 6 cases of high or total spinal anesthesia in a series of nearly 27,000 cases of lumbar epidural anesthesia administered during labor (an incidence of approximately 1 in 4500). Paech et al.[339] reported 8 cases of unexpectedly high neuroblockade in a series of 10,995 epidural blocks in obstetric patients (an incidence of approximately 1 in 1400). Two patients required tracheal intubation and mechanical ventilation. Jenkins[362] reported an incidence of 1 in 16,200 procedures (see Table 23.10). High spinal or epidural anesthesia contributed to 16% of anesthesia-related maternal deaths in the United States between 1997 and 2002.[10]

Aspiration alone, particularly through a single-orifice catheter, is a not completely reliable method of excluding subarachnoid placement of the catheter. Administration of an appropriate test dose and careful assessment of the patient's response to the test dose should minimize the chance of unintentional injection of a large dose of local anesthetic into the subarachnoid space.

High or total spinal anesthesia results in agitation, profound hypotension, dyspnea, the inability to speak, and loss of consciousness. Loss of consciousness usually results from hypoperfusion of the brain and brainstem, not from brain anesthesia. Evidence of spinal anesthesia may be apparent shortly after intrathecal injection of a local anesthetic, but the maximal spread may not be evident for several minutes. This delay underscores the need for the anesthesia provider to carefully assess the effects of both the test and therapeutic doses of local anesthetic. If total spinal anesthesia should occur, the anesthesia provider must be prepared to maintain oxygenation, ventilation, and circulation (Box 23.9). Immediate management consists of avoidance of aortocaval compression, ventilation with 100% oxygen, tracheal intubation, and administration of intravenous fluids and vasopressors to support the blood pressure as needed. The FHR should be monitored continuously.

Extensive neuroblockade may also result from subdural injection of a local anesthetic.[363–365] A subdural injection may be difficult to diagnose because onset is later than that with an intrathecal injection and more closely resembles that associated with epidural neuroblockade.

The subdural space is a potential space between the dura mater and the arachnoid mater. A retrospective review of 2182 lumbar epidural injections for pain management found

that clinical signs of subdural catheter placement occurred in approximately 0.82% of patients[363]; the true incidence is not known, but may be as high as 10%.[366] Subdural injection of local anesthetic typically results in unexpectedly high (but patchy) blockade with an onset time that is intermediate between that of spinal anesthesia and epidural anesthesia (i.e., 10 to 20 minutes) (Table 23.11).[366] Cranial spread is more extensive than caudal spread of the local anesthetic, so sacral analgesia typically is absent. The block may involve the cranial nerves. (The subdural space, unlike the epidural space, extends intracranially.) Thus, apnea and unconsciousness can occur during a subdural block. Horner's syndrome has been reported.[364] A subdural block usually results in less intense motor blockade than the blockade that occurs with high or total spinal anesthesia. This difference may reflect the limited spread of the local anesthetic within the subdural space, which helps spare the anterior motor fibers.[365] Subdural block results in less severe hypotension than that with high or total spinal anesthesia, most likely because subdural injection leads to less sympathetic blockade than spinal anesthesia. The unpredictable spread of local anesthetic, the slower onset of maximal spread (in comparison with spinal anesthesia), the patchy nature of the block, and the sacral sparing make it difficult to use a subdural catheter safely during labor and delivery. If it is suspected that a catheter is positioned within the subdural space, it should be replaced with an epidural catheter.

Unexpectedly high neuroblockade may result from the migration of an epidural catheter into the subdural or subarachnoid space.[365] The mechanism by which a soft epidural catheter penetrates the dura or dura-arachnoid is unclear. Disposable epidural needles are sharp, and insertion of the needle into the epidural space may result in an unrecognized nick in the dura, which may create a site for delayed migration of the catheter into the subdural or subarachnoid space. Subdural or subarachnoid injection of local anesthetic also may occur if a multi-orifice catheter is used, and one orifice is located within the epidural space while another is located within the subdural or subarachnoid space. In this situation, the force of injection determines the ultimate destination of the local anesthetic. Thus, each bolus injection of local anesthetic should serve as a test dose. During the continuous infusion of a local anesthetic, a gradual increase in the level of anesthesia and intensity of motor blockade may indicate the intrathecal infusion of the local anesthetic solution.

BOX 23.9 Management of High and Total Spinal Anesthesia

- High spinal anesthesia may occur several minutes after the unintentional intrathecal injection of local anesthetic or as a result of overdose of epidural local anesthetic. Communication with the patient is important. Agitation, dyspnea, difficulty speaking, and profound hypotension may herald the onset of total spinal anesthesia.
- Avoid aortocaval compression.
- Administer 100% oxygen.
- Provide positive-pressure ventilation, preferably through an endotracheal tube.
- Monitor maternal vital signs, electrocardiogram, and fetal heart rate.
- Support maternal circulation with intravenous fluids and vasopressors as needed. Do not hesitate to give epinephrine if needed.
- Maintain verbal communication with the mother, or administer a sedative-hypnotic (after treating any hypotension and hypoxemia) because total spinal anesthesia does not signal brain anesthesia. Patients may lose consciousness and stop breathing because of central nervous system hypoperfusion, not brain anesthesia.

Extensive Motor Blockade

Clinically significant motor block may occur after repeated bolus doses[145] or after many hours of a continuous infusion of local anesthetic into the epidural space.[367] The administration of bupivacaine with epinephrine may result in a greater likelihood of motor blockade than the administration of bupivacaine alone.[145] Extensive motor blockade is often bothersome for the patient, and it may impair maternal expulsive efforts during the second stage of labor and increase the likelihood of instrumental vaginal delivery (see later discussion). Some obstetricians argue that pelvic floor relaxation prevents rotation of the fetal head and increases the likelihood of an abnormal position of the vertex at delivery.

If intense motor blockade develops during the continuous epidural infusion of local anesthetic, the infusion can be

TABLE 23.11 Clinical Features of Epidural, Subdural, and Spinal Blocks

	Epidural Block	Subdural Block	Spinal Block
Onset Time	Slow	Intermediate	Rapid
Spread	As expected	Higher than expected; may extend intracranially, but sacral sparing is common	Higher than expected; may extend intracranially, and a sacral block is typically present
Nature of Block	Segmental	Patchy	Dense
Motor Block	Minimal	Minimal	Dense
Hypotension	Less than spinal, and dependent on the extent of the block	Intermediate between spinal and epidural, and dependent on the extent of the block	Likely

discontinued for a short period (e.g., 30 minutes). Subsequently, the infusion can be restarted at a reduced rate or with a more dilute solution of local anesthetic. Extensive motor blockade does not occur with administration of a very dilute solution of local anesthetic combined with an opioid.

Prolonged Neuroblockade

Rarely, the duration of neuraxial analgesia/anesthesia exceeds the time expected. Most cases of unexpectedly prolonged neuroblockade follow the epidural administration of a high concentration of local anesthetic with epinephrine.[368] Abnormal neurologic findings after the administration of neuraxial anesthesia should prompt the anesthesia provider to look for evidence of peripheral nerve injury or an epidural hematoma (see Chapter 31). Factors that argue against the presence of an epidural hematoma include (1) the absence of back pain, (2) a unilateral block, and (3) regression (rather than progression) of the symptoms. Peripheral nerve injuries typically result in a neurologic deficit in the distribution of a specific peripheral nerve. Neurologic or neurosurgical consultation and immediate imaging studies should be obtained if there is any question about the etiology of prolonged anesthesia. Avoiding the use of a high concentration of local anesthetic should help minimize the incidence of prolonged neuroblockade during and after labor and vaginal delivery.

Sensory Changes

In one of the early studies of intrathecal opioid administration during labor, Cohen et al.[290] observed sensory changes in women who received intrathecal sufentanil. Subsequent studies have demonstrated that these sensory changes do not result from a local anesthetic effect of sufentanil. Sensory changes do not predict the quality or duration of analgesia or the extent of hemodynamic change.[369] Further, intrathecal sufentanil does not cause a sympathectomy.[370] Wang et al.[371] have provided the best explanation for these sensory changes. They showed that intrathecal opioids block the afferent information from A-delta and C fibers to the spinal cord but that efferent nerve impulses are unaffected. These sensory changes can be clinically significant, especially when they extend to the cervical dermatomes. In such cases, patients may feel that they cannot breathe or swallow, a sensation that can be quite distressing. Fortunately, neither intrathecal sufentanil nor fentanyl affects the efferent limb of the nervous system and so does not impair motor function. Affected patients should be reassured that respiratory efforts are not compromised and that these symptoms will subside in 30 to 60 minutes.[372,373]

In addition to sensory changes, case reports have described mental status changes, aphasia, and automatisms after the intrathecal injection of fentanyl[374] and sufentanil.[375] These symptoms seem to be related to an opioid effect. In one case, the symptoms were partially reversed by naloxone.[374]

Back Pain

Approximately 50% of women complain of back pain during pregnancy and the puerperium.[376,377] The most significant risk factors for postpartum back pain are antepartum back pain and inability to reduce weight to prepregnancy levels.[376,378,379] Early retrospective studies identified an association between epidural anesthesia and an increased risk for postpartum back pain.[380,381] However, retrospective studies suffer not only from patient recall bias (i.e., patients with a problem are much more likely to complete and return the questionnaire) but also from selection bias in the epidural and nonepidural groups. Patients who select epidural analgesia for labor may have obstetric, orthopedic, social, or other unidentified factors that predispose them to postpartum back pain.

In an attempt to assess anesthetic factors that might contribute to postpartum backache (e.g., motor blockade), Russell et al.[379] randomly assigned laboring women requesting epidural analgesia to receive either bupivacaine alone or bupivacaine plus an opioid. Despite the expected differences in motor blockade, the incidence of backache did not differ between the two anesthetic groups (bupivacaine alone, 39%; bupivacaine plus an opioid, 30%). In addition, the incidence of backache in both epidural groups was similar to that found in a nonrandomized control group of women who labored without epidural analgesia (31%).

Prospective reports have not shown a significant relationship between the use of epidural analgesia and long-term backache. Breen et al.[378] observed no difference in the incidence of postpartum backache among women who delivered vaginally with or without epidural analgesia. A prospective Canadian study assessed the relationship between postpartum backache and patient-selected intrapartum analgesia.[382] The rate of low back pain was greater in the epidural group (53%) than in the nonepidural group (43%) on the first postpartum day, but the rates were similar on postpartum day 7 and at 6 weeks and 1 year.[382] These investigators suggested that the higher incidence of backache immediately after delivery may have resulted from tissue trauma during epidural needle placement. Finally, Loughnan et al.[383] enrolled 310 women in a randomized controlled trial that compared epidural bupivacaine with systemic meperidine analgesia. The primary outcome was back pain 6 months after delivery. There was no difference between the two groups in the incidence of backache (epidural 48%, meperidine 50%). Similarly, another randomized controlled trial of epidural versus nonepidural analgesia found no difference in the incidence of backache at 3 and 12 months[384] and several years[385] after delivery.

In summary, prospective studies have consistently shown that no causal relationship exists between epidural analgesia and the development of long-term postpartum backache. Short-term backache (several days) may be related to local tissue trauma at the site of skin puncture.

Pelvic Floor Injury

Several studies have evaluated the possible effects of epidural analgesia on postpartum pelvic floor function. Retrospective studies have not identified an association between epidural analgesia and risk for perineal lacerations[386] or pelvic floor dysfunction[387] For example, Loewenberg-Weisband et al.[386] identified severe perineal trauma in 0.3% of 61,308 women in

a retrospective cohort trial. Epidural analgesia was not associated with an increased odds of perineal trauma (OR, 0.95; 95% CI, 0.69 to 1.29) after correcting for parity. A meta-analysis of epidural labor analgesia compared with nonepidural or no analgesia did not identify a difference in the risk for perineal trauma requiring suturing.[3]

Any factor that increases the likelihood of instrumental vaginal delivery might be expected to increase the risk for pelvic floor injury and subsequent pelvic floor dysfunction (see later discussion). However, to our knowledge, there is no evidence that epidural analgesia *per se* predisposes to pelvic floor injury.

EFFECTS OF NEURAXIAL ANALGESIA ON THE PROGRESS OF LABOR

Neuraxial analgesia during labor is associated with a prolonged labor and operative delivery. (The term *operative delivery* refers to both cesarean delivery and instrumental vaginal delivery [i.e., forceps delivery or vacuum extraction]). Controversy exists as to whether there is a cause-and-effect relationship between the use of these analgesic techniques and prolonged labor or operative delivery. The understanding of this subject has been limited by the difficulty of performing controlled trials in which parturients are randomly assigned to neuraxial analgesia or a control group. Ideally, if one wants to study the effect of neuraxial analgesia on the progress and outcome of labor, the control group would receive no analgesia. However, such a study is not ethical, and even if it were and women volunteered to participate in it, the crossover rate would probably be high and the data consequently would not be interpretable. Therefore, controlled trials have randomly assigned parturients to receive neuraxial analgesia or an alternative form of pain relief, usually systemic opioid analgesia. However, even when the control group receives some type of analgesia, the crossover rate may be high because the quality of neuraxial analgesia is markedly superior to that of all other modes of labor analgesia.[388]

The difficulty in performing and interpreting the results of labor analgesia trials was aptly described by Noble et al.,[389] who assessed obstetric outcome in 245 patients randomly assigned to receive either epidural analgesia or "conventional" analgesia (i.e., meperidine, nitrous oxide, or no analgesia). The investigators made the following comments[389]:

> *Of 245 selected patients, 43 had to be removed from the trial after labour ensued.…Most of the patients removed from the non-epidural group were apparently experiencing severe pain; they were usually primigravidae whose baby presented in the occipito-posterior position.…The majority of patients removed from the epidural group were apparently normal and usually multigravidas; their labours were so rapid it was not possible to arrange for an epidural block.*

In other words, patients at low risk for operative delivery were excluded from the epidural group, and patients at high risk were excluded from the nonepidural group. The investigators' candid comments illustrate that, even when a prospective, randomized study is performed, it is difficult to maintain conditions that allow for the comparison of women at equal risk for abnormal labor and operative delivery.

Another concern is the external validity of these studies. Women who agree to participate in research trials may be inherently different from women who refuse to participate. Many women make a decision regarding labor analgesia well before the onset of labor and are unwilling to let chance randomization determine the type of labor analgesia. Thus, the study results may not be generalizable to the general obstetric population.

Ironically, the effect of systemic opioids on the progress and outcome of labor has not been well studied. Furthermore, there may be differences among the opioids.[390] Finally, neuraxial analgesia is not a generic procedure. Conclusions about the effect of one technique on the progress of labor may not be applicable to other techniques (see later discussion).

Additional factors prevent rigorous scientific study of this issue. Ideally, a randomized controlled trial should be double-blinded. This is not possible for studies that compare neuraxial analgesia with another mode of analgesia, because of the marked difference in the quality of analgesia. Therefore, the potential for bias on the part of the parturient, nurses, and anesthesia and obstetric providers is substantial. Additionally, a number of factors are known to affect or to be associated with the progress and outcome of labor, including parity, artificial rupture of membranes, use of oxytocin, and payer status; these factors should be controlled in well-conducted studies.

One factor known to markedly influence the outcome of labor is the obstetric provider. Neuhoff et al.[391] retrospectively reviewed the records of 607 nulliparous women at term gestation and compared the mode of delivery in "clinic" patients (whose care was given primarily by residents) and private patients (whose care was provided primarily by private obstetricians). Approximately 42% of patients received epidural analgesia during labor. Five percent of patients in the clinic group and 17% of patients in the private group underwent cesarean delivery ($P < .001$). More striking was the difference between groups in the incidence of cesarean delivery for dystocia (0.5% versus 13.7%, respectively; $P < .001$). Similarly, Guillemette and Fraser[392] observed marked obstetrician variation in cesarean delivery rates, despite similarities in the use of oxytocin and epidural analgesia.

Several groups of investigators have noted that the timing of cesarean delivery conforms to a "circadian" rhythm.[393,394] For example, investigators in Japan noted a delivery time rhythm in hospitals, but not birthing centers, suggesting that obstetric intervention, not biologic rhythm, partly determines the timing of delivery.[395]

Retrospective studies are difficult to interpret because they suffer from selection bias. In some cases, distinguishing between anesthesia administered for pain relief during labor and anesthesia administered in preparation for operative delivery is difficult. Moreover, women at higher risk for prolonged labor and operative delivery are more likely to

request and receive epidural analgesia during labor than women who have a rapid, uncomplicated labor.[396] Wuitchik et al.[396] observed a relationship between pain and cognitive activity during early labor and the subsequent progress of labor in 115 healthy nulliparous women. During the latent phase, higher levels of pain were predictive of longer latent and active phases of labor. Those women who reported "horrible" or "excruciating" pain during the latent phase were more than twice as likely to require instrumental delivery as women who only had "discomfort." In addition, women who reported "distress" rather than "coping" had a fivefold higher incidence of abnormal FHR patterns and a fourfold higher requirement for assistance from pediatricians during neonatal resuscitation.

Greater pain intensity during labor appears to be a risk factor for operative delivery. This fact will significantly bias observational studies of labor analgesia because women with greater pain intensity request analgesia, specifically neuraxial analgesia, at a higher rate than women with less intense pain. Alexander et al.[397] performed a secondary analysis of data from a randomized controlled trial in which one group of laboring women received patient-controlled intravenous meperidine analgesia. The rate of cesarean delivery for dystocia was 14% in women who self-administered 50 mg/h or more of meperidine, compared with 1.4% in women who self-administered less than 50 mg/h. In a retrospective study of factors that predict operative delivery in laboring women, Hess et al.[398] found that the cesarean delivery rate in women who had significant breakthrough pain during low-dose bupivacaine/fentanyl epidural analgesia was more than twice as high as the rate in women with less breakthrough pain (odds ratio, 2.62; 95% CI, 2.01 to 3.43).

Taken together, these studies suggest that the early onset of severe pain and the requirement of high doses of analgesic agents predict higher risks for abnormal labor, FHR abnormalities, and operative delivery. These findings may explain the observed association between neuraxial analgesia and operative delivery.

Cesarean Delivery Rate

Randomized Controlled Trials

A number of randomized controlled trials have studied the effect of neuraxial (primarily epidural) and systemic opioid (primarily meperidine) analgesia on the cesarean delivery rate.[384,388,399–423] These trials differ in a number of ways, including (1) the population studied (e.g., nulliparous women or women of mixed parity); (2) onset of labor (spontaneous labor alone or a mix of spontaneous and induced labors); (3) type of neuraxial analgesia; (4) density of neuraxial analgesia; (5) route of administration of systemic analgesia (although all studies included meperidine with or without an adjuvant); (6) the crossover rate; and (7) management of labor (e.g., active management of labor, including electronic FHR monitoring, artificial rupture of membranes, and oxytocin infusion). All but one of these studies found no difference in the rate of cesarean delivery between women randomly assigned to receive either neuraxial or systemic opioid analgesia.

Four prospective, randomized trials were performed at the University of Texas Southwestern Medical Center, Parkland Hospital, in Dallas.[388,404,418,419] This institution is unique among many others that have performed randomized trials, in that the population is composed largely of indigent women whose labor is managed by the same group of resident physicians and midwives, supervised by the same core group of attending obstetricians. In the first study, 1330 women of mixed parity were randomly assigned to receive either epidural bupivacaine/fentanyl or intravenous meperidine for labor analgesia.[388] Approximately one-third of the women did not receive the assigned treatment. The cesarean delivery rates were 9.0% in women who received epidural analgesia and 3.9% in women who received intravenous meperidine. However, the investigators did not report an intention-to-treat analysis of these data; thus, it was unclear whether there was a higher incidence of cesarean delivery in the women randomly assigned to the epidural analgesia group. Subsequently, the investigators published a re-analysis of the data that included an intention-to-treat analysis (Table 23.12).[424] The cesarean delivery rate in both groups was 6%. These analyses support the conclusion that women who choose epidural analgesia have an inherent risk factor(s) for cesarean delivery and that the administration of neuraxial analgesia *per se* does not alter this risk.

In an attempt to lower the rate of crossover by providing better analgesia to the control (meperidine) group, the Parkland Hospital investigators performed another study in which meperidine was administered by PCIA.[418] A significant number of women in both groups did not receive their assigned treatment, although the reason in all cases was rapid labor. Only 5 of 357 women randomly assigned to the

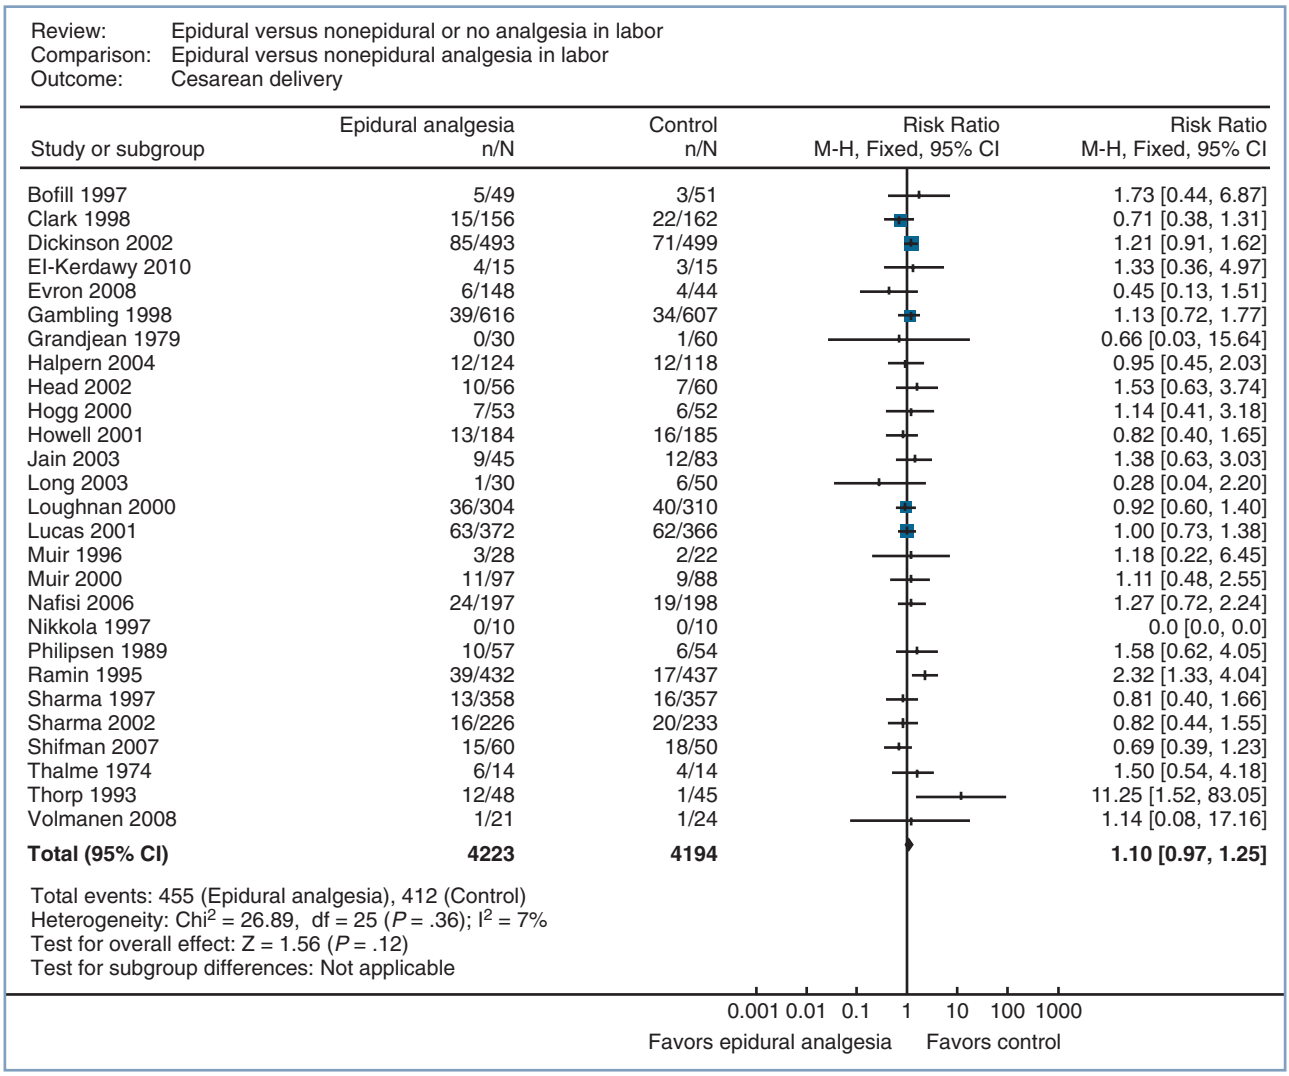

Fig. 23.8 Meta-analysis of cesarean delivery rate in women randomized to neuraxial or non-neuraxial labor analgesia. The number of women who had a cesarean delivery, the risk ratio, and 95% confidence interval (CI) of the risk ratio (fixed effect model) are shown for each study. For studies with no cesarean deliveries, the risk ratio could not be calculated. Control, nonepidural analgesia. *n,* number of events (cesarean delivery) in the neuraxial or non-neuraxial group; *N,* total number of subjects in the neuraxial or non-neuraxial group. The scale is logarithmic. (Modified from Anim-Somuah M, Smyth RM, Jones L. Epidural versus non-epidural or no analgesia in labour. *Cochrane Database Syst Rev.* 2011;CD000331.)

meperidine group crossed over to receive epidural analgesia. Using an intention-to-treat analysis, the investigators observed no difference between the groups in the incidence of cesarean delivery (4% in the epidural group and 5% in the PCIA group). There was no difference between the two groups in neonatal outcome, except that more neonates of women in the PCIA group received naloxone to reverse respiratory depression at birth.

Only one randomized trial has compared CSE and systemic opioid analgesia.[404] In this large study (n = 1223), patients of mixed parity were randomly assigned to receive CSE analgesia (intrathecal sufentanil 10 μg, followed by epidural bupivacaine with fentanyl at the second request for analgesia) or intravenous meperidine (50 mg every hour on request). Approximately 60% of patients complied with the protocol. An intention-to-treat analysis showed that there was no difference between groups in the rate of cesarean delivery (CSE 6%, systemic opioid 5.5%).

The studies comparing neuraxial with systemic opioid analgesia have been systematically reviewed in several meta-analyses.[3,425] The latest meta-analysis covered outcomes for 8417 women randomized to receive neuraxial or no neuraxial/no analgesia (control) from 27 trials (Fig. 23.8).[3] The risk ratio for cesarean delivery in women randomly assigned to receive neuraxial analgesia compared with those assigned to the control group was 1.10 (95% CI, 0.97 to 1.25).[3] In an individual patient meta-analysis of the studies performed at Parkland Hospital (n = 4465),[425] the odds ratio was 1.04 (95% CI, 0.81 to 1.34).

Mode and density of neuraxial analgesia and effect on cesarean delivery rate. If neuraxial analgesia adversely affects the outcome of labor, one would expect to observe a

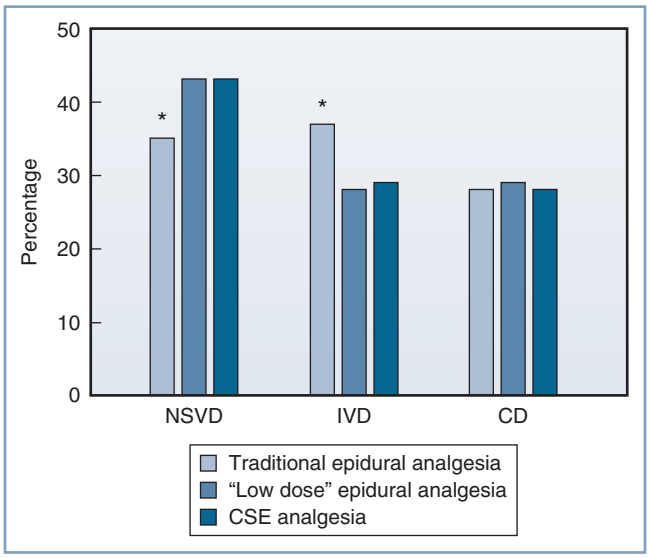

Fig. 23.9 Outcome of labor in the COMET study. Parturients were randomly assigned to traditional epidural analgesia or to one of two "low-dose" neuraxial techniques (see text). There was no difference among groups in the cesarean delivery (CD) rate. *Women who received traditional epidural analgesia had a higher rate of instrumental vaginal delivery (IVD) than those who received either "low-dose" technique ($P = .04$). *CSE,* combined spinal-epidural; *NSVD,* normal spontaneous vaginal delivery. (Data from Comparative Obstetric Mobile Epidural Trial Study Group UK. Effect of low-dose mobile versus traditional epidural techniques on mode of delivery: a randomised controlled trial. *Lancet.* 2001;358:19–23.)

dose-response effect. The COMET study randomly assigned more than 1000 parturients to one of three groups: (1) "high-dose" epidural analgesia (traditional epidural analgesia with bupivacaine 0.25%); (2) "low-dose" epidural analgesia (bupivacaine 0.1%/fentanyl 2 µg/mL bolus, followed by a continuous epidural infusion); and (3) "low-dose" CSE analgesia (intrathecal bupivacaine/fentanyl followed by intermittent boluses of epidural bupivacaine 0.1%/fentanyl 2 µg/mL).[426] There was no difference in cesarean delivery rates among groups (Fig. 23.9). Similarly, several other studies that compared traditional epidural analgesia (using bupivacaine 0.25%) and low-dose CSE techniques found no difference between groups in the cesarean delivery rate.[427–429] The results of these studies suggest that "high-dose" neuraxial analgesia does not entail a higher risk for cesarean delivery than "low-dose" techniques; in other words, no dose-response effect has been observed.

There is no evidence that CSE analgesia influences the mode of delivery, compared with epidural analgesia alone. A meta-analysis that compared CSE with low-dose epidural analgesia included 15 trials with 1960 women[24]; the risk ratio for cesarean delivery was 0.98 (95% CI, 0.82 to 1.16).

Impact Studies

Some physicians have questioned whether prospective, randomized studies provide an accurate representation of the effect of neuraxial analgesia on the mode of delivery in actual clinical practice. They have suggested the possibility that prospective studies may introduce a Hawthorne effect (which may be defined as the appearance or disappearance of a phenomenon on initiation of a study to confirm or exclude its existence). An alternative study design is to assess obstetric outcome immediately before and after a sentinel event, such as the introduction of an epidural analgesia service. The results of these studies may be generalizable to the general population because patients have not chosen to participate in a study. It also eliminates the problem of treatment group crossover because epidural analgesia was not available in the control period. One limitation of this study design is that it assumes that there were no other changes in obstetric management in the "after" period.

In 1999, Yancey et al.[430] published an impact study using data from the Tripler Army Medical Center in Hawaii. Because of relative homogeneity in socioeconomic status, universal access to health care, and the availability of dedicated health care providers in the population served by this hospital, its rate of cesarean delivery may not be subject to influences common to other hospitals. Before 1993, the rate of epidural analgesia was less than 1% at Tripler Army Medical Center. In 1993, a policy change within the U.S. Department of Defense mandated on-demand availability of neuraxial labor analgesia in military hospitals. In nulliparous women in spontaneous labor with a singleton infant with a vertex presentation, the rate of epidural labor analgesia rose from less than 1% to approximately 80% in a 1-year period.[431] The rate of cesarean delivery was unchanged during the same period (14.4% versus 12.1%, respectively; adjusted RR, 0.8; 95% CI, 0.6 to 1.2).

In another impact study, Impey et al.[432] compared obstetric outcome for the first 1000 nulliparous women (term gestation, singleton fetus, cephalic presentation, spontaneous labor) who delivered at the National Maternity Hospital in Dublin in 1987 with the outcome for a similar group of women who delivered in 1992 and 1994. The epidural analgesia rate rose from 10% in 1987 to 45% in 1992 and 57% in 1994. In each of these 3 years, 82% of women underwent spontaneous vaginal delivery. The cesarean delivery rate was 4% in 1987, 5% in 1992, and 4% in 1994 (P = NS) (Fig. 23.10). The investigators concluded that the consistency of the operative delivery rates in each of 3 years with very different epidural rates suggests that epidural analgesia does not increase the cesarean delivery rate.

Socol et al.[433] evaluated the impact of three initiatives to reduce the cesarean delivery rate in their hospital. First, they strongly encouraged a trial of labor and vaginal birth after cesarean delivery. Second, after the 1988 calendar year, they circulated data showing the cesarean delivery rate of every obstetrician to all obstetricians. Third, they recommended the active management of labor as the preferred method of labor management for term nulliparous women. The rates of total, primary, and repeat cesarean deliveries decreased from 27%, 18%, and 9% in 1986 to 17%, 11%, and 6%, respectively, in 1991 ($P < .001$ for all three comparisons). Meanwhile, the use of epidural analgesia rose from 28% in 1986 to 48% in 1991 ($P < .001$). There was no change in the incidence

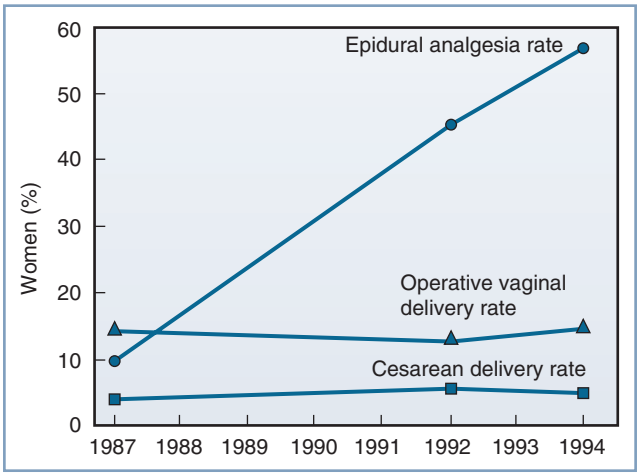

Fig. 23.10 Epidural analgesia and cesarean and instrumental vaginal delivery rates for 1000 consecutive nulliparous women in spontaneous labor at term during three different years at the National Maternity Hospital in Dublin, Ireland. (Modified from Impey L, MacQuillan K, Robson M. Epidural analgesia need not increase operative delivery rates. *Am J Obstet Gynecol.* 2000;182:358–363.)

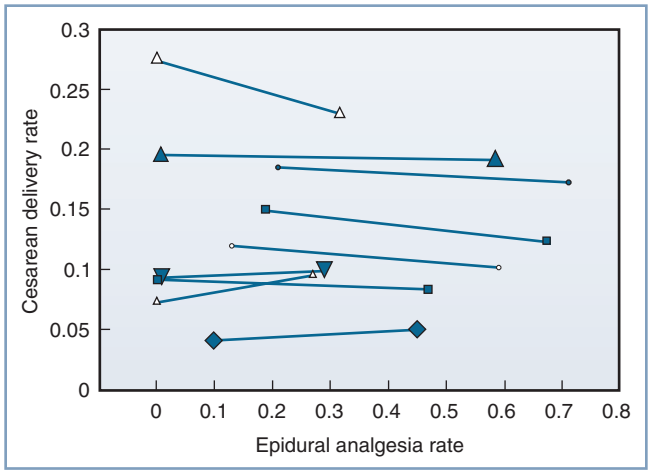

Fig. 23.11 Rates of cesarean delivery during periods of higher and lower availability of epidural analgesia in nine studies (n = 37,753) subjected to meta-analysis. Each pair of symbols shows data from one investigation (the *left symbol* is the epidural analgesia rate and cesarean delivery rate during the period of low epidural analgesia availability, and the *right symbol* is the epidural analgesia rate and cesarean delivery rate during the period of high epidural availability). The size of the plot symbol is proportional to the number of patients in the analysis. (Modified from Segal S, Su M, Gilbert P. The effect of a rapid change in availability of epidural analgesia on the cesarean delivery rate: a meta-analysis. *Am J Obstet Gynecol.* 2000; 183:974–978.)

of instrumental vaginal delivery (13% in 1986 versus 13% in 1991).

Wassen et al.[434] analyzed data from the Netherlands Perinatal Registry from 2000 to 2010. The final study population included more than 1.3 million women; among nulliparous women, the use of epidural analgesia tripled over the 10-year period, while the cesarean delivery rate increased by only 2.8% (the rate of instrumental vaginal delivery decreased by 3.3%). The authors concluded that epidural analgesia is not an important causal factor for operative deliveries.

In a meta-analysis, Segal et al.[435] identified nine impact studies involving a total of 37,753 patients. These researchers found no increase in the rate of cesarean delivery with the increase in availability of epidural analgesia (Fig. 23.11). Thus, the before-after impact studies support the results of randomized controlled trials—namely, that neuraxial analgesia does not cause an increase in the cesarean delivery rate.

Several studies have assessed whether there is a relationship between an individual obstetrician's cesarean delivery rate and the rate of epidural analgesia for his or her patients.[436,437] For example, Lagrew and Adashek[436] divided obstetricians into two groups according to whether their individual cesarean delivery rates were more than 15% (the control group) or less than 15% (the target group). Obstetricians in the target group used epidural analgesia more often than obstetricians in the control group. In other words, the target group of obstetricians was able to achieve a lower cesarean delivery rate despite their greater use of epidural analgesia.

Timing of Initiation of Neuraxial Analgesia

Review of observational data suggests an association between cesarean delivery and the initiation of neuraxial analgesia during early labor (often defined as a cervical dilation less than 4 to 5 cm).[422,428,438] For example, in a retrospective study of 1917 nulliparous women, the rate of cesarean delivery was twice as high in women who received neuraxial analgesia at a cervical dilation less than 4 cm than in those in whom neuraxial analgesia was initiated at a cervical dilation of 4 cm or more (18.9% versus 8.9%, respectively).[438] As a result of these data, for many years the ACOG suggested that women delay requesting epidural analgesia "when feasible, until the cervix is dilated to 4 to 5 cm."[439] However, as with the cause-and-effect question raised by the association of neuraxial labor analgesia and cesarean delivery, the question arises as to whether the early initiation of neuraxial labor analgesia *causes* a higher risk for cesarean delivery or whether the request for early labor analgesia is a marker for some other risk factor(s) for cesarean delivery.

A number of randomized controlled trials have addressed the question of whether initiation of neuraxial analgesia during early labor adversely affects the mode of delivery.[18–22,440–442] All except one small study[440] compared early labor neuraxial analgesia with systemic opioid analgesia, which was followed by neuraxial analgesia when cervical dilation reached 4 to 5 cm (the control group in the Luxman et al.[440] study received no analgesia).

Wong et al.[19] and Ohel et al.[20] reported randomized trials that compared early labor neuraxial analgesia with systemic opioid analgesia; the median cervical dilation at initiation of analgesia was 2 cm. There was no difference between the two groups in the rate of cesarean delivery or in the rate of instrumental vaginal delivery. The study protocols differed in that the treatment group in one study received *CSE* analgesia in early labor,[19] whereas the treatment group in the second study

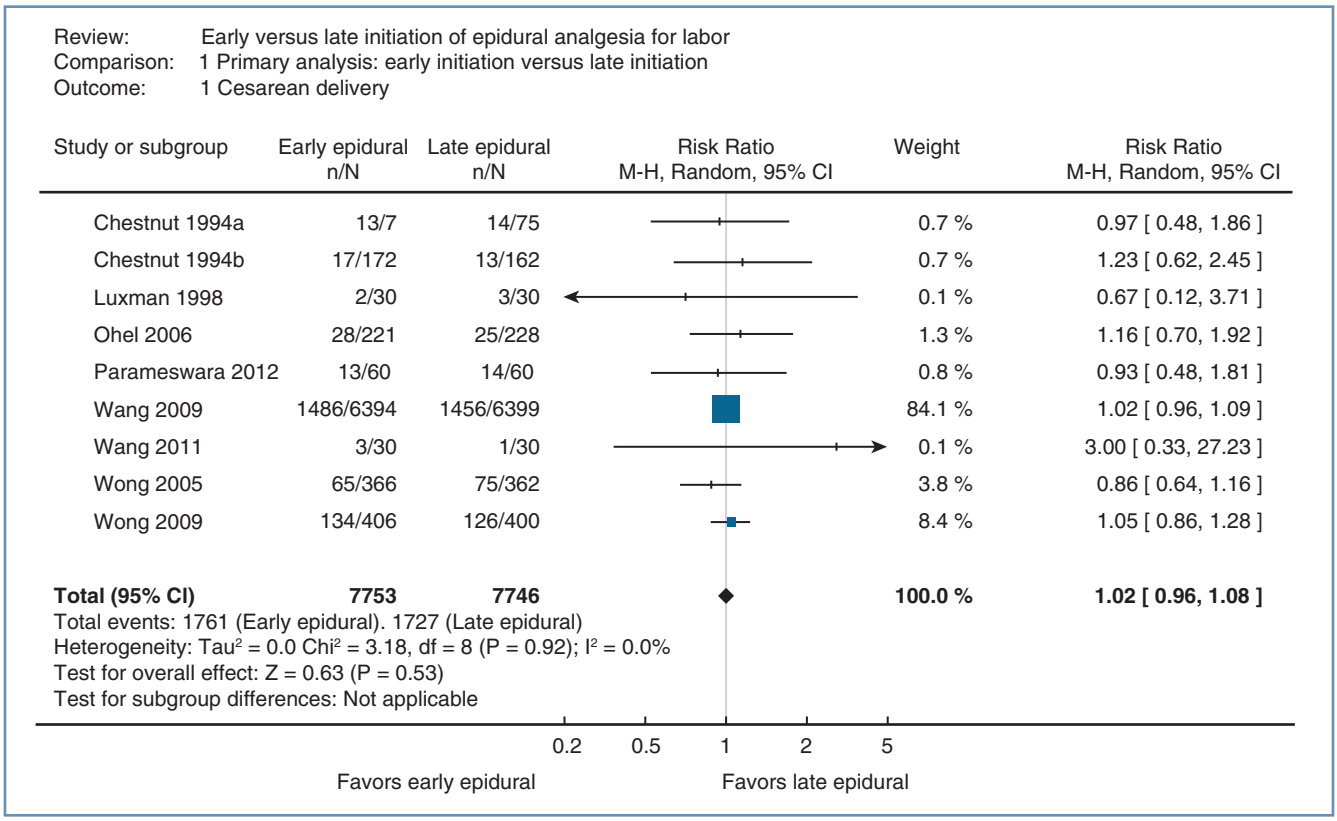

Fig. 23.12 Meta-analysis of cesarean delivery in women randomized to receive early labor initiation of neuraxial analgesia (cervical dilation < 4 to 5 cm) or late initiation (cervical dilation ≥ 4 to 5 cm). The size of the box at the point estimate for each study is proportional to the number of patients in the study. The diamond represents the point estimate of the pooled risk ratio, and the length of the diamond is proportional to the confidence interval. *n,* number of events (cesarean delivery) in the treatment (early) or control (late) group; *N,* total number of patients in the treatment or control group. received *epidural* analgesia alone.[20] The use of oxytocin augmentation was markedly different in the two studies (94%[19] and 29%[20]).

Subsequent to the publication of these studies, the ACOG[443] published an updated Committee Opinion entitled *Analgesia and Cesarean Delivery Rates.* This revised opinion included the following statement:

> *Neuraxial analgesia techniques are the most effective and least depressant treatments for labor pain. The American College of Obstetricians and Gynecologists previously recommended that practitioners delay initiating epidural analgesia in nulliparous women until the cervical dilation reached 4-5 cm. However, more recent studies have shown that epidural analgesia does not increase the risks of cesarean delivery. The choice of analgesic technique, agent, and dosage is based on many factors, including patient preference, medical status, and contraindications. The fear of unnecessary cesarean delivery should not influence the method of pain relief that women can choose during labor.*

Later randomized trials in nulliparous women in both spontaneous[22] and induced[441] labor, as well as a 2014 meta-analysis (nine randomized controlled trials; n = 15,752)[23] replicated these results. The researchers concluded that early initiation of neuraxial analgesia does not increase the rate of cesarean delivery (RR, 1.02; 95% CI, 0.96 to 1.08) (Fig. 23.12).[23]

Instrumental Vaginal Delivery Rate

Observational data associate neuraxial labor analgesia with a higher rate of instrumental (forceps or vacuum extraction) vaginal delivery. The effect of neuraxial analgesia on mode of vaginal delivery has not been assessed as a primary outcome in randomized controlled trials, although it has been assessed as a secondary outcome in multiple trials. Interpretation of these results is clouded by the fact that most studies have not assessed the quality of analgesia during the second stage of labor. Further, most investigators did not define the criteria for the performance of instrumental vaginal delivery. In clinical practice, and in study interpretation, it is often difficult to distinguish "indicated" instrumental deliveries from elective instrumental deliveries. Indeed, we have observed that indications for instrumental vaginal delivery vary markedly among obstetricians. An obstetrician is more likely to perform an elective instrumental delivery in a patient with satisfactory anesthesia than in a patient without analgesia. In addition, most randomized controlled trials are conducted in teaching institutions that have an obligation to teach obstetric residents

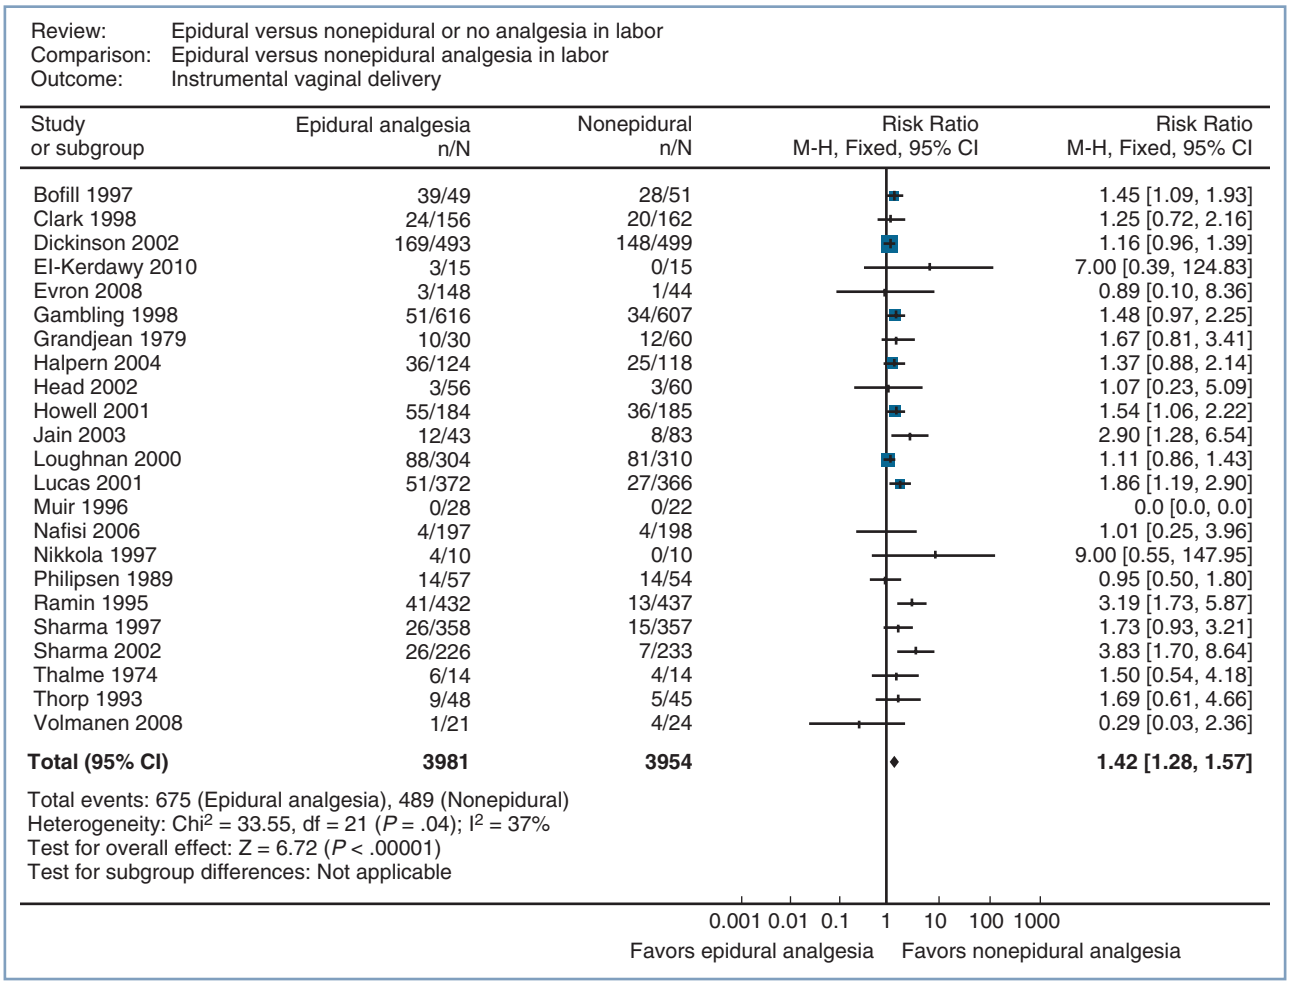

Fig. 23.13 Meta-analysis of instrumental vaginal delivery rate in women randomized to neuraxial or non-neuraxial labor analgesia. The number of women who had an instrumental vaginal delivery, the risk ratio, and 95% confidence interval (CI) of the risk ratio (fixed effect model) are shown for each study. For studies with no instrumental vaginal deliveries, the risk ratio could not be calculated. *n,* number of events (instrumental vaginal delivery) in the neuraxial or non-neuraxial group; *N,* total number of subjects in the neuraxial or non-neuraxial group. The scale is logarithmic. (Modified from Anim-Somuah M, Smyth RM, Jones L. Epidural versus non-epidural or no analgesia in labour. *Cochrane Database Syst Rev.* 2011;CD000331.)

how to perform instrumental vaginal delivery. Instrumental vaginal deliveries performed for the purpose of teaching are more likely to be done in women with adequate analgesia.

Multiple randomized, controlled studies comparing epidural analgesia with systemic opioid analgesia have assessed the rate of instrumental vaginal delivery as a secondary outcome variable.[a] Most systematic reviews have concluded that epidural analgesia is associated with a higher risk for instrumental vaginal delivery than systemic analgesia.[3,425] For example, in a 2011 meta-analysis of 23 studies ($n = 7935$),[3] the risk ratio for instrumental vaginal delivery in women randomly assigned to receive epidural analgesia or nonepidural/no analgesia was 1.42 (95% CI, 1.28 to 1.57) (Fig. 23.13). Similarly, in the individual patient meta-analysis reported by Sharma et al.,[425] the adjusted odds ratio was 1.86 (95% CI, 1.43 to 2.40).

In contrast to these studies, many of the impact studies observed no difference in the instrumental vaginal delivery rate between the control and study periods.[430–432,444] For example, despite a rise in the epidural analgesia rate from 1% to almost 80% at Tripler Army Medical Center, the rate of instrumental vaginal delivery did not change (11.1% versus 11.9%).[430] Similarly, despite a more than fivefold increase in the epidural analgesia rate at the National Maternity Hospital in Dublin (see earlier discussion), the instrumental vaginal delivery rate remained unchanged (see Fig. 23.10). A systematic review of seven impact studies[435] involving more than 28,000 patients did not identify a difference in instrumental vaginal delivery rates between periods of low and periods of high epidural analgesia rates (mean change, 0.76%; 95% CI, –1.2 to 2.8).

Studies of early versus late initiation of neuraxial labor analgesia have not identified an increased risk for instrumental vaginal delivery in the early analgesia group.[19,20,22,23,441]

[a]384,388,399–407,409,411–413,415–419,421–423

Obstetricians and anesthesiologists have suggested that multiple factors (e.g., station and position of the fetal vertex, maternal pain and the urge to bear down, and neuraxial analgesia–induced motor blockade) may contribute to the outcome of the second stage of labor. The contribution of these factors to the mode of vaginal delivery, and their interactions, are not well understood, and these factors have not been well controlled in many studies.

Several studies have specifically assessed the effect of maintenance of neuraxial analgesia until delivery with regard to the duration and outcome of the second stage of labor.[367,445–450] In a 2017 study from China,[450] 400 women receiving epidural infusion of 0.08% ropivacaine with sufentanil 0.4 μg/mL for labor analgesia were randomized to continue the same infusion or to receive saline-placebo at the onset of the second stage of labor. The primary outcome—mean (± SD) duration of the second stage of labor—did not differ between groups (epidural group, 52 ± 27 minutes; placebo-control 51 ± 25 minutes), nor did the rate of instrumental vaginal delivery. More women in the placebo-control group had low satisfaction scores.

The effect of neuraxial analgesia on the outcome of the second stage of labor may be influenced by the density of neuraxial analgesia. High concentrations of epidural local anesthetic may cause maternal motor blockade, leading to relaxation of pelvic floor musculature, which in turn may interfere with fetal rotation during descent. Abdominal muscle relaxation may decrease the effectiveness of maternal expulsive efforts. The effects of specific analgesic techniques, concentration of local anesthetic, total dose of local anesthetic, and degree of motor blockade on the risk for instrumental vaginal delivery are overlapping and difficult to study. For example, some studies suggest that administration of epidural analgesia using higher concentrations of bupivacaine is associated with a higher risk for instrumental vaginal delivery compared with use of lower concentrations.[426,428,429,451] In contrast, Collis et al.[427] observed no difference in mode of delivery between women randomly assigned to receive either a high-dose or a low-dose neuraxial technique. The COMET investigators reported a lower rate of instrumental vaginal delivery in the two groups of women randomly assigned to receive either the low-dose epidural or CSE technique than in the group that received 0.25% bupivacaine (see earlier discussion and Fig. 23.9).[426] However, the total bupivacaine dose in the traditional "high-dose" epidural group did not actually differ from that in the "low-dose" epidural group because the former was administered by intermittent injection and the latter by continuous infusion. In contrast, the total bupivacaine dose was significantly lower in the CSE group.

In a meta-analysis of 11 studies (n = 1145) comparing maintenance of epidural analgesia with high-concentration (defined as bupivacaine concentration greater than 0.1% or ropivacaine concentration greater than 0.17%) with low-concentration local anesthesia solutions,[452] the odds of instrumental vaginal delivery were lower in the low-concentration group (OR, 0.70; 95% CI, 0.56 to 0.86), as was the duration of the second stage of labor. The odds of cesarean delivery did not differ. A 2017 meta-analysis[453] compared parturients randomized to low-concentration epidural analgesia with nonepidural or no analgesia (earlier meta-analyses included studies using both high- and low-concentration solutions[3]). There was no difference in the duration of the second stage of labor (mean difference, 5.7 minutes; 95% CI, –6.1 to 17.8) or the rate of instrumental vaginal delivery (RR, 1.52; 95% CI, 0.97 to 2.4), although the confidence intervals are wide. Finally, in a meta-analysis of studies that compared CSE and epidural analgesia,[24] the instrumental vaginal delivery rate was lower in the CSE group than the traditional "high-dose" epidural analgesia group, but there was no difference between "low-dose" epidural and CSE analgesia. Taken together, these data suggest that the specific analgesia technique may influence the risk for instrumental vaginal delivery.

In general, the dose of bupivacaine is significantly lower if epidural analgesia is maintained with an intermittent bolus technique rather than a continuous infusion technique (see earlier discussion). Most investigators have noted a difference in motor blockade between the two techniques; higher total bupivacaine doses (i.e., continuous infusion techniques) are associated with a greater degree of motor blockade. However, the relationship between motor blockade and instrumental vaginal delivery is inconsistent. Smedstad and Morison[229] reported a higher incidence of instrumental vaginal delivery when bupivacaine 0.25% was administered as a continuous epidural infusion than as intermittent bolus injections. In contrast, the COMET investigators observed no difference in the instrumental vaginal delivery rate in the two groups who received "low-dose" bupivacaine/fentanyl, one by infusion and the other by intermittent bolus.[426] Similarly, in a meta-analysis of PCEA (without background infusion) compared with continuous epidural infusion analgesia,[233] the dose of bupivacaine and degree of motor blockade were significantly lower in the PCEA group, but the rates of instrumental vaginal delivery did not differ.

It is possible that the inconsistent results can be explained by the actual absolute differences in bupivacaine dose and motor blockade. For example, the differences in dose and motor blockade may have clinically significant adverse effects on the outcome of the second stage of labor if bupivacaine 0.25% is compared with bupivacaine 0.125% but not if bupivacaine 0.125% is compared with bupivacaine 0.0625%. Many of the randomized controlled trials included in the meta-analysis that compared epidural with systemic opioid analgesia used concentrated solutions of bupivacaine for both the loading and infusion doses (e.g., bupivacaine 0.25% for the loading dose, bupivacaine 0.125% by continuous infusion for maintenance of analgesia).[3]

Motor blockade may increase the risk for malrotation of the fetal vertex. Robinson et al.[454] and Le Ray et al.[455] observed a higher incidence of occiput malposition at delivery in patients who received epidural analgesia before engagement of the fetal head. In contrast, Yancey et al.[456] and Sheiner et al.[457] noted that the administration of on-demand epidural analgesia did not increase the frequency of malposition of the fetal head at delivery; the incidence of instrumental vaginal

delivery was not related to fetal station at initiation of analgesia. In a prospective cohort study using ultrasonography, Lieberman et al.[458] reported that fetal position changed frequently during labor but that epidural analgesia was associated with a higher incidence of occiput posterior position at delivery (13% versus 3%, $P < .002$). However, these results should be interpreted with caution as women were not randomly assigned to the treatment group. Factors that cause women to request analgesia when the fetal head is high may also be independent risk factors for instrumental vaginal delivery. A study from Italy[459] in which ultrasonography was used to assess fetal head position found no association between use of early labor neuraxial analgesia and fetal head position at delivery.

In an editorial, Chestnut[460] concluded that *effective* second-stage analgesia increases the risk for instrumental vaginal delivery. However, effective analgesia is a spectrum that ranges from complete absence of sensory input (dense analgesia) to perception of uterine contraction "pressure" without pain (less dense analgesia). Minimizing the risk for instrumental vaginal delivery while maximizing analgesia is both an art and a science and requires the attention of the anesthesia provider to the individual needs of the patient. A single analgesic technique or single dose/concentration of drug(s) is not likely to have optimal results for everyone. We believe the best technique for maintenance of analgesia incorporates a low-rate continuous infusion (4 to 8 mL/h) or PIEB, using a dilute solution of local anesthetic and opioid, with PCEA. Use of a dilute local anesthetic solution without PCEA leads to inadequate analgesia for many women. Increasing the infusion dose improves analgesia and reduces the workload for the anesthesia provider but will result in overly dense analgesia for some patients, thus potentially increasing the risk for instrumental vaginal delivery. In the future, new pump technology may allow closed-loop feedback anesthetic administration that will better tailor anesthetic dose to patient need.

Why should anesthesia providers give attention to the effects of analgesia on the method of vaginal delivery? Lack of effective maternal effort associated with inadequate progress of labor (descent of the fetus) is an indication for operative vaginal delivery.[461] Studies suggest that vacuum extraction may be associated with a higher neonatal risk for cephalohematoma, subgaleal hemorrhage, and intraventricular hemorrhage than spontaneous vaginal, forceps, or cesarean delivery, whereas forceps delivery is associated with an increased risk for facial trauma.[462] However, there is some evidence that these injuries may be attributed to the indication for delivery, rather than the specific delivery technique.[461] There is no evidence of adverse long-term neonatal outcome with operative vaginal compared with spontaneous vaginal or cesarean delivery.[461,462]

The risk for maternal trauma is also greater with operative vaginal delivery (e.g., third- and fourth-degree vaginal lacerations). Robinson et al.[463] observed that epidural analgesia was associated with an increased rate of severe perineal trauma because of the more frequent use of instrumental vaginal delivery and episiotomy in nulliparous women who received epidural analgesia. In contrast, several large observational studies suggest that epidural analgesia is associated with a decreased risk for anal sphincter laceration in nulliparous women.[464,465] Regardless of the presence or magnitude of the risks for maternal or neonatal injury, many women want to minimize the likelihood of operative delivery, and they perceive that a higher risk for instrumental vaginal delivery is undesirable. Of concern is a decline in the number of obstetricians skilled at operative vaginal delivery.[462] The concern is that loss of these skills will lead to an increase in second-stage cesarean delivery rates.

Duration of Labor

First Stage of Labor

The effect of neuraxial labor analgesia on the duration of the first stage of labor was addressed as a secondary outcome variable in many of the randomized controlled trials. A 2011 meta-analysis[3] of 11 studies found no difference in the duration of the first stage of labor between women who were randomly assigned to receive epidural analgesia and those assigned to receive systemic opioid analgesia, although the confidence interval was wide, indicating significant heterogeneity among studies (Table 23.13). There was significant heterogeneity in the outcome because of the mixed parity of the patient populations and differences among studies in the definition of the duration of the first stage of labor. In contrast,

Labor analgesia and cesarean delivery: an individual meta-analysis of nulliparous women. *Anesthesiology.* 2004;100:142–148.

the individual meta-analysis of the Parkland Hospital data showed a significant prolongation of the first stage of labor (approximately 30 minutes) in nulliparous women who were randomly assigned to receive epidural analgesia.[425]

Wong et al.[19] and Ohel et al.[20] assessed duration of labor as a secondary outcome in their randomized controlled trials of the initiation of neuraxial analgesia during early labor. Both groups of investigators determined that the duration of the first stage of labor, and thus consequently the overall duration of labor, were significantly shorter in women randomly assigned to receive early labor neuraxial analgesia than in those assigned to receive systemic opioid analgesia. In the Wong et al. study,[19] the median difference in the overall duration of labor between the early and late neuraxial analgesia groups was 81 minutes (95% CI, 28 to 123).

Determining the duration of labor requires that investigators document start and end times. The definition of the start time varies among studies but is usually consistent between groups within a study. The end of the first stage of labor is defined as the time of full (10 cm) cervical dilation. This point can be determined only with manual cervical examination. Most studies do not mandate regular cervical examinations by study protocol, or if they do, the intervals are fairly long (e.g., 1 to 2 hours). Clinically, full cervical dilation is diagnosed when a cervical examination is performed because the patient complains of rectal pressure. It is likely that women with effective epidural analgesia will complain of rectal pressure at a later time (and lower fetal station) than women with systemic opioid analgesia. In other words, the patient may be fully dilated for a significant time before cervical examination verifies full cervical dilation. This difference serves to artificially prolong the duration of the first stage of labor in the epidural group, although it shortens the apparent duration of the second stage of labor.

Other factors may also influence the duration of the first stage of labor. Some clinicians have noted enhanced uterine activity in some patients for approximately 30 minutes after the initiation of neuraxial analgesia, whereas uterine activity appears to be reduced in other patients. Schellenberg[466] suggested that aortocaval compression is responsible for the transient decrease in uterine activity that occurs after the administration of epidural analgesia in some patients. Cheek et al.[467] noted that uterine activity decreased after the intravenous infusion of 1 L of crystalloid solution, but not after infusion of 0.5 L or maintenance fluid alone. Miller et al.[468] hypothesized that a fluid bolus might inhibit antidiuretic hormone (vasopressin) release from the posterior pituitary gland. Because this organ also releases oxytocin, the production of that hormone might also be transiently suppressed; this possible decrease in oxytocin release may partially explain the transient changes in uterine contractility observed in association with epidural analgesia.

In a prospective but nonrandomized study, Rahm et al.[469] observed that epidural analgesia (bupivacaine with sufentanil) was associated with lower plasma oxytocin levels at 60 minutes after initiation of analgesia than in healthy controls who did not receive epidural analgesia. Behrens et al.[470] noted that epidural analgesia during the first stage of labor significantly reduced the release of prostaglandin $F_{2\alpha}$ and "impede[d] the normal progressive increase in uterine activity." In contrast, Nielsen et al.[471] measured upper and lower uterine segment intrauterine pressures for 50 minutes before and after the administration of epidural bupivacaine analgesia in 11 nulliparous women during spontaneous labor. No significant difference in the number of contractions before and after epidural analgesia was observed. There was greater intrauterine pressure in the upper uterine segment than in the lower segment (consistent with fundal dominance) both before and after initiation of epidural analgesia. Further, fundal dominance was higher after epidural analgesia than in the preanalgesia period.

Increased uterine activity after the initiation of neuraxial analgesia has been hypothesized to be an indirect effect of neuraxial analgesia (see later discussion).[472] Initiation of neuraxial analgesia is associated with an acute decrease in the maternal plasma concentration of circulating epinephrine.[4] Epinephrine is a tocolytic, and the acute decrease in maternal concentration may result in greater uterine activity. This may be an explanation for the salutary effect on the progress of labor that is observed in some women with dysfunctional labor after the initiation of neuraxial analgesia[473] or in women who are extremely anxious.[474]

The epidural administration of a local anesthetic with epinephrine is followed by systemic absorption of both drugs. Some physicians have expressed concern that the epinephrine may exert a systemic beta-adrenergic tocolytic effect and slow labor. Early studies, which used large doses of epinephrine, suggested that the caudal epidural administration of local anesthetic with epinephrine prolonged the first stage of labor and increased the number of patients who required oxytocin augmentation of labor.[475] Subsequently, most studies have suggested that the addition of epinephrine 1.25 to 5 µg/mL (1 : 800,000 to 1 : 200,000) to the local anesthetic solution does not affect the progress of labor or method of delivery.[b]

There is no evidence that the specific local anesthetic or opioid used for neuraxial analgesia directly or indirectly affects the duration of labor.[85,477] In a randomized controlled trial, Tsen et al.[478] observed a higher rate of cervical dilation in women who received CSE analgesia than in those who received epidural analgesia. However, randomized controlled trials that compared CSE and epidural analgesia have not found a difference in the duration of labor between the two techniques.[343,426–428,479]

Evidence suggests that genetic polymorphism in the oxytocin receptor *(OTXR),* catechol-O-methyltransferase *(COMT),* and beta$_2$-adrenergic receptor *(ADRB2)* genes affect the progress of labor.[480,481] Whether these genotypes interact with neuraxial analgesia to affect the progress of labor requires further study with large numbers of parturients.

In summary, neuraxial analgesia appears to have a variable effect on the duration of the first stage of labor. It may shorten labor in some women and lengthen it in others. However, analgesia-related prolongation of the first stage of labor, if it

[b] 50,87,138,140,143,476

occurs, is short, has not been shown to have adverse maternal or neonatal effects, and is probably of minimal clinical significance.

Second Stage of Labor

There is little doubt that effective neuraxial analgesia prolongs the second stage of labor. Meta-analyses of randomized controlled trials that compared neuraxial with systemic opioid analgesia support this clinical observation (see Table 23.13).[3,425] The mean duration of the second stage was 15 to 20 minutes longer in women randomly assigned to receive neuraxial analgesia than in women assigned to receive systemic opioid analgesia.[3,425] In a retrospective cohort single-institution study of 42,268 women who delivered vaginally between 1979 and 2008, the 95th percentile length of the second stage of labor was 197 minutes (3.2 hours) in nulliparous women without epidural analgesia and 336 minutes (5.6 hours) in nulliparous women with epidural analgesia.[482]

Historically, the ACOG has defined a prolonged second stage in nulliparous women as lasting more than 3 hours with neuraxial analgesia and more than 2 hours without neuraxial analgesia; for parous women, it is more than 2 hours in those with neuraxial analgesia and more than 1 hour in those without neuraxial analgesia.[483] Zhang et al.[484] performed a secondary analysis of data from the Consortium on Safe Labor, a large, multicenter study from 19 hospitals across the United States, to characterize the duration of labor in a contemporary cohort of American women. Data were abstracted for term parturients in spontaneous labor with a singleton gestation in the vertex presentation and with normal perinatal outcome. The 95th percentiles for duration of the second stage of labor were 3.6 and 2.8 hours for nulliparous women with and without epidural analgesia, respectively (Table 23.14). These data and other contemporary data[482] suggest that a significant proportion of women will have a "prolonged" second stage, as defined by the ACOG criteria.

Rouse et al.[485] studied the relationship between second-stage duration and maternal and neonatal outcomes in nulliparous women by performing a secondary analysis of data collected as part of a multicenter study between 2002 and 2005. The rate of spontaneous vaginal delivery declined as the duration of the second stage of labor increased; however, more than 55% of women whose second-stage duration was 3 hours or longer still went on to deliver vaginally.[485] The risk for chorioamnionitis, third- or fourth-degree perineal laceration, and uterine atony was greater in women with a prolonged second-stage duration; however, after adjusting for mode of delivery, adverse neonatal outcomes did not differ in women whose second-stage duration was 3 hours or longer, compared with those women with a shorter second-stage labor duration. The authors concluded that the second stage of labor does not need to be terminated based on duration alone. Extending the duration of the second stage will allow a significant number of women to deliver vaginally.

Other studies have confirmed that a delay in delivery is not harmful to the infant or mother provided that (1) electronic FHR monitoring confirms the absence of nonreassuring fetal status, (2) the mother is well hydrated and has adequate analgesia, and (3) there is ongoing progress in the descent of the fetal head.[486] In a small study, Gimovsky et al.[487] randomized 78 nulliparous women to an extended care group (allowed at least 3 hours of second stage before facilitating delivery) or usual care group (allowed 2 hours of second stage before expediting delivery). All women received epidural analgesia. The cesarean delivery rate was 19.5% in the extended care group and 43.2% in the usual care group (RR, 0.45; 95% CI, 0.22 to 0.93). The operative vaginal delivery rate did not differ between groups.

A 2012 workshop was convened by the National Institute of Child Health and Human Development, the Society for Maternal-Fetal Medicine, and the ACOG, with the goal of recommending practices that prevent primary cesarean delivery. The group concluded that a cesarean delivery for second-stage arrest in nulliparous women with epidural analgesia should not be considered unless there is no progress (descent or rotation) for more than 4 hours (Box 23.10).[483] Thus, the decision as to whether to perform an operative delivery in the second stage or allow continued observation should be made on the basis of clinical assessment of the woman and the fetus, and the skill and training of the obstetrician.

TABLE 23.14 Duration of Second Stage of Labor by Parity

	Parity 0 ($n = 25,624$)	Parity 1 ($n = 16,755$)	Parity ≥ 2 ($n = 16,219$)
Epidural analgesia (h)	1.1 (3.6)	0.4 (2.0)	0.3 (1.6)
No epidural analgesia (h)	0.6 (2.8)	0.2 (1.3)	0.1 (1.1)

Data are median (95th percentile) duration of the second stage of labor in spontaneous laboring women.

BOX 23.10 Definition of Second-Stage Arrest

No progress (descent or rotation) for:
- Four hours or more in nulliparous women with epidural analgesia
- Three hours or more in nulliparous women without epidural analgesia
- Three hours or more in parous women with epidural analgesia
- Two hours or more in parous women without epidural analgesia

Definitions from Spong CY, Berghella V, Wenstrom KD, et al. Preventing the first cesarean delivery. Summary of a joint Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal-Fetal Medicine, and American College of Obstetricians and Gynecologists Workshop. *Obstet Gynecol.* 2012;120:1181–1193.

Second-stage management: immediate versus "delayed" pushing. Many women are asked to begin "pushing" as soon as full cervical dilation has been confirmed, regardless of the fetal station. Some practitioners have suggested that "delayed" pushing might result in less maternal exhaustion and better maternal and fetal outcomes. Several randomized studies have sought to determine whether immediate or delayed pushing for women with epidural analgesia during the second stage of labor affects labor duration and outcome.[488–499] Data are conflicting. In a 2017 meta-analysis including 13 studies that compared early and delayed pushing in women with epidural analgesia, the authors judged that the evidence ranged from moderate to very low quality.[500] Delayed pushing resulted in an increase in the rate of spontaneous vaginal delivery (RR, 1.07; 95% CI, 1.03 to 1.12; Fig. 23.14), and shorter duration of pushing at the expense of an increase in the total duration of the second stage of labor (mean difference 56 minutes). There was no difference in perineal trauma, neonatal intensive care unit admissions, or 5-minute Apgar scores. The authors concluded that the current evidence is insufficient and inconclusive to support any specific timing and type of pushing; further high-quality studies are necessary.

Although there do not appear to be any major advantages to delayed pushing, it does not seem reasonable to ask the mother to push from a high fetal station. It is common for anesthesia providers to be asked to decrease or discontinue neuraxial analgesia because the mother does not feel the urge to push when she is fully dilated. However, women with effective neuraxial analgesia do not feel the urge to push at a high fetal station. The density of neuraxial analgesia should not be decreased until the fetus has descended. If evaluation at this point determines that the mother still does not feel the urge to push, the maintenance dose may be reduced. Discontinuing the maintenance of analgesia is rarely indicated because analgesia/anesthesia may be difficult to reestablish if the need for operative delivery arises.

Third Stage

Rosaeg et al.[501] retrospectively reviewed the outcomes of 7468 women who underwent vaginal delivery at their hospital between 1996 and 1999. Epidural analgesia was not associated with a prolonged third stage of labor. The duration of the third stage of labor was shorter in women who received epidural analgesia and subsequently required manual removal of the placenta. The researchers suggested that epidural analgesia

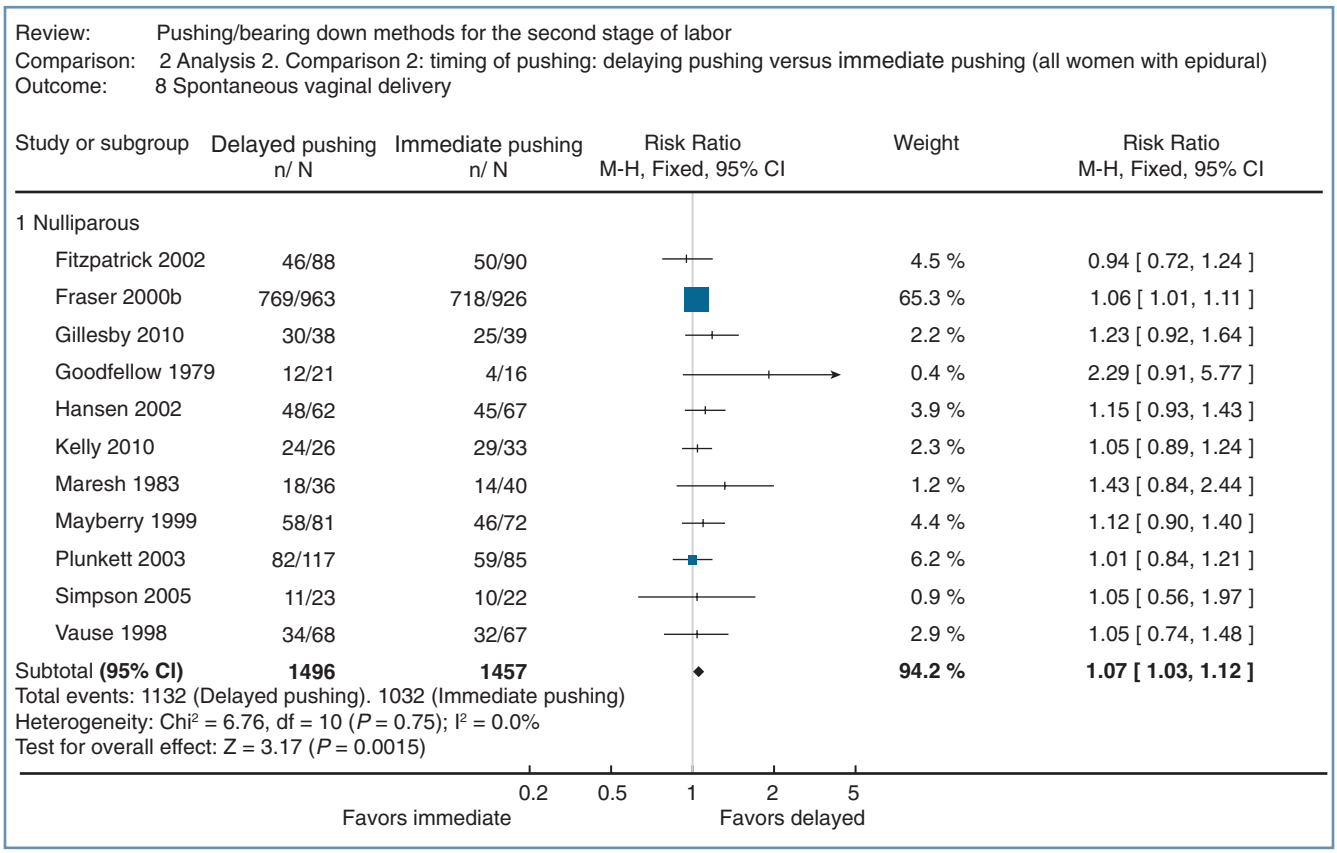

Fig. 23.14 Meta-analysis of delayed versus immediate pushing on the rate of spontaneous vaginal delivery in women with epidural analgesia. The size of the box at the point estimate for each study is proportional to the number of patients in the study. The *diamond* represents the point estimate of the pooled risk ratio, and the length of the diamond is proportional to the confidence interval. *n,* number of events in the treatment (delayed pushing) or control (immediate pushing) group; *N,* total number of patients in the treatment or control group. *RR,* risk ratio; *CI,* confidence interval. (Modified from Lemos A, Amorim MMR, Dornelas de Andrade A, et al. Pushing/bearing down methods for second stage labor. *Cochrane Database Syst Rev.* 2017;CD009124.)

"provided a 'permissive' role"—in other words, epidural analgesia likely facilitated and/or encouraged earlier intervention by the obstetrician.

Other Factors and Progress of Labor

Oxytocin

Active management of labor is a concept that consists of a disciplined, standardized labor management protocol that includes early amniotomy and oxytocin augmentation if the cervix fails to dilate at a minimum rate (usually 1 cm/hour in nulliparous women). Early studies suggested that this type of labor management decreased the rate of cesarean delivery.[502] More recently, a 2013 meta-analysis that included 14 randomized controlled trials suggests that active management of labor may have little effect on the cesarean delivery rate.[503] Although randomized trials of neuraxial compared with systemic opioid analgesia have consistently found that neuraxial analgesia does not cause an increase in the rate of cesarean delivery (see earlier discussion), Kotaska et al.[504] questioned the external validity of these trials because of oxytocin management. In a search of the medical literature, they identified 16 randomized controlled trials; 8 of the 16 trials included descriptions of labor management, and these trials were included in the analysis. Seven of the eight trials described active management of labor and found no difference in the mode of delivery between groups. Only one of eight trials described the use of low-dose oxytocin and reported a markedly higher rate of cesarean delivery in the neuraxial analgesia group. Kotaska et al.[504] concluded that epidural analgesia in the setting of low-dose oxytocin probably increases the rate of cesarean delivery. The researchers were correct in stating that the role of oxytocin in neuraxial analgesia outcome studies has not been well controlled. However, their conclusion that epidural analgesia in the setting of low-dose oxytocin probably causes an increase in the rate of cesarean delivery is highly flawed because, in their analysis, the researchers did not include the eight studies that did not describe the management of labor. In all probability, the management of labor in these studies was not active (i.e., did not include high-dose oxytocin administration), or this would have been described.

In randomized controlled trials that compared the effects of neuraxial and systemic opioid analgesia on the outcome of labor, women who received neuraxial opioids had a higher rate of oxytocin augmentation.[3,425] In a meta-analysis that included 13 randomized trials, the risk ratio was 1.19 (95% CI, 1.03 to 1.39).[3] The reason(s) for this observation are not clear.

Randomized controlled trials that compared early and late initiation of neuraxial analgesia have used markedly different oxytocin protocols, yet all have concluded that early initiation of neuraxial analgesia does not have an adverse effect on the outcome of labor. In the study of early CSE analgesia by Wong et al.,[19] the rate of oxytocin use was high in both groups (approximately 93%). However, the maximum oxytocin infusion rate in the control (early systemic opioid) group was significantly higher than that in the early CSE group even though the median duration of labor was 81 minutes shorter in the CSE group. In the study of early epidural analgesia by Ohel et al.,[20] the rate of oxytocin use in both groups was much lower (approximately 29%); however, as in the study by Wong et al.,[19] the duration of labor was significantly shorter in the early neuraxial analgesia group. Taken together, the results of these studies do not support the hypothesis that oxytocin played a major role in the outcomes.

Ambulation

Observational studies suggest that ambulation may be associated with less pain and a shorter duration of labor.[505] However, randomized controlled trials that compared ambulation and bed rest during the first stage of labor in women with neuraxial analgesia have not demonstrated any advantages of ambulation with regard to the progress or outcome of labor. Nageotte et al.[428] randomly assigned 505 nulliparous women to receive CSE analgesia either with or without ambulation. There was no difference between groups in the mode of delivery or duration of labor. These results agree with those of a meta-analysis of five randomized controlled trials involving 1161 women.[506] In addition, there were no differences between groups in the use of oxytocin augmentation, satisfaction with analgesia, or Apgar scores. No adverse effects were reported. These results are similar to those of trials that compared ambulation and bed rest in women without neuraxial analgesia.[507]

EFFECTS OF NEURAXIAL ANALGESIA ON THE FETUS AND NEONATE

Neuraxial analgesia may affect the fetus directly, indirectly, or both. First, systemic absorption of the anesthetic agents may be followed by transplacental transfer of the drug, which has a direct effect on the fetus. Second, the effects of neuraxial blockade on the mother may affect the fetus indirectly. Effects of local anesthetics and opioids on the fetus and neonate are discussed in detail in Chapter 13.

Direct Effects

Direct fetal effects include intrapartum drug effects on the FHR as well as possible respiratory depression after delivery. The determinants of maternal plasma drug concentration, transfer across the placenta, and effects on the neonate are discussed in Chapters 4 and 13. Determinants of maternal plasma drug concentration include dose, site of administration, metabolism and excretion of the drug, and the presence of adjuvants (e.g., epinephrine). Factors that influence placental transfer include maternal and fetal placental perfusion, the physicochemical characteristics of the drug, concentration of the free drug in maternal plasma, and permeability of the placenta. Most anesthetic and analgesic drugs, including local anesthetics and opioids, readily cross the placenta.

Fetal Heart Rate

Effects of local anesthetics and opioids on FHR may be direct and indirect (see earlier discussion)[472,477]; however, there is little evidence for a direct effect when these drugs are administered as components of neuraxial analgesia. Transient changes in FHR variability and periodic decelerations

have been observed during epidural labor analgesia with bupivacaine and other local anesthetics.[477,508,509] These FHR decelerations were not associated with maternal hypotension. However, Loftus et al.[510] did not observe FHR decelerations in women who received epidural bupivacaine for elective cesarean delivery, despite the use of larger doses of bupivacaine and the occurrence of more extensive sympathetic blockade in comparison with epidural labor analgesia. Of interest, one study noted that the administration of either epidural bupivacaine or intrathecal sufentanil was followed by a similar incidence of FHR decelerations (23% and 22%, respectively) in laboring women.[511] Other studies have not observed a higher incidence of FHR decelerations associated with epidural administration of bupivacaine during labor.[512] Further, the reports of FHR decelerations after bupivacaine did not demonstrate adverse neonatal outcome; thus, the significance of these decelerations is unclear. There are no published data on the relationship between the concentration of bupivacaine used for intrapartum epidural analgesia and the incidence of FHR decelerations. Altogether, these data suggest that epidural local anesthetics have minimal, if any, direct effect on FHR.

Similarly, neuraxial opioid administration has little direct effect on the FHR.[108,513,514] In contrast, systemic meperidine analgesia was associated with a greater reduction of FHR variability and fewer FHR accelerations than epidural bupivacaine analgesia.[515] Spinal administration of local anesthetics and opioids results in lower maternal plasma concentrations of drug(s) than epidural administration and is therefore even less likely to cause a direct fetal effect.

Neonatal Depression

Systemic absorption of local anesthetic or opioid may have neonatal effects. This occurs more often after the systemic administration of opioid for labor analgesia.[19,516] The neonatal depressant effects of drugs administered to the mother in the intrapartum period are usually assessed with neurobehavioral testing. Unfortunately, these tests are quite subjective and lack specificity. Additionally, scientifically rigorous studies are lacking, and most of the local anesthetic studies were performed in the era when high-dose epidural analgesia was common; these observational studies found that local anesthetics administered as components of epidural analgesia were sometimes associated with minor, transient effects on neonatal behavior.[85,477,517]

When given by continuous epidural infusion, epidural opioid administration rarely results in accumulation of the drug and subsequent neonatal respiratory depression.[c] Bader et al.[221] noted that a continuous epidural infusion of 0.125% bupivacaine with fentanyl 2 μg/mL over a period of 1 to 15 hours did not result in significant fetal drug accumulation or adverse neonatal effects (in this study, the maximal cumulative dose of fentanyl was 300 μg). Porter et al.[222] reported no adverse effect of fentanyl on neurobehavioral scores or other indices of fetal welfare when patients received an epidural infusion of 0.0625% bupivacaine with or without fentanyl 2.5 μg/mL. The mean ± SD maternal dose of fentanyl was 183 ± 75 μg (range, 53 to 400 μg). Loftus et al.[108] observed only a modest reduction in neuroadaptive capacity scores (NACS) at 24 hours in neonates whose mothers had received epidural fentanyl during labor; neonates exposed to sufentanil during labor had a somewhat higher NACS at 24 hours, and sufentanil was detected in the umbilical arterial blood in only one of nine samples. Vertommen et al.[106] observed no difference in Apgar scores or NACS in neonates whose mothers were randomly assigned to receive epidural sufentanil (up to 30 μg) during the course of labor and a control group that did not receive sufentanil.[106] Maternal sufentanil levels were below the sensitivity of the assay (0.1 ng/mL) after an epidural bolus of 10 μg.[113]

Intrathecal administration of an opioid during labor would be expected to have even fewer direct effects on the fetus than epidural administration. Smaller doses of opioid are administered, and less drug is absorbed systemically.

Indirect Effects

The indirect fetal effects of epidural and intrathecal opioids may be more significant than the direct effects. Obviously, if the mother has severe respiratory depression and hypoxemia, fetal hypoxemia and hypoxia will follow. More common is the occurrence of fetal bradycardia after initiation of neuraxial analgesia. The presumed cause is that the rapid onset of analgesia results in decreased plasma concentrations of catecholamines.[472] Epinephrine causes uterine relaxation by stimulating beta$_2$-adrenergic uterine receptors. A reduced circulating concentration of epinephrine may result in increased uterine tone. Because uteroplacental perfusion occurs during periods of uterine diastole (i.e., uterine relaxation), uterine tachysystole may result in decreased uteroplacental perfusion and fetal hypoxia.

Published observations suggest that uterine tachysystole and fetal bradycardia may follow the administration of either intrathecal or epidural analgesia during labor. Abrão et al.[519] randomized 72 laboring women to receive either CSE or epidural analgesia, and they observed the incidence of FHR abnormalities (prolonged deceleration or bradycardia) and an elevation in uterine tone (defined as an increase of 10 mm Hg or more in basal uterine pressure). The incidences of FHR abnormalities (32% versus 6%), and FHR abnormalities combined with an increase in uterine pressure (27% versus 3%), were significantly higher in the CSE group than in the epidural group. However, a significant limitation of this study is that the outcomes were assessed for only 15 minutes after the initiation of analgesia and the analgesic techniques were not equipotent.[520] The overall high incidence of FHR abnormalities noted in the study may have been caused by the initiation of analgesia in women in advanced labor.

Fortunately, fetal bradycardia after labor analgesia does not appear to increase the overall risk for adverse outcome. Albright and Forster[521] retrospectively reviewed outcomes for 2560 women who delivered at their hospital between March

[c]106,108,113,221,222,518

1995 and April 1996. Approximately one-half of the patients received CSE analgesia (10 to 15 μg of intrathecal sufentanil), and the other half received either systemic opioids or no medication. There was no difference between the two groups in the incidence of emergency cesarean delivery (1.3% versus 1.4%, respectively).

Mardirosoff et al.[522] performed a systematic review of reports of randomized comparisons of intrathecal opioid analgesia with any nonintrathecal opioid regimen in laboring women. The investigators noted that intrathecal opioid analgesia was associated with a significant increase in the risk for fetal bradycardia (OR, 1.8; 95% CI, 1.0 to 3.1). However, the risk for cesarean delivery for FHR abnormalities was similar in the two groups (6.0% versus 7.8%, respectively). Data are conflicting regarding an opioid dose-response for fetal bradycardia. Van de Velde et al.[523] randomly assigned laboring women to one of the following three treatment regimens: intrathecal sufentanil 7.5 μg, intrathecal sufentanil 1.5 μg/bupivacaine 2.5 mg/epinephrine 2.5 μg, or epidural bupivacaine 12.5 mg/sufentanil 7.5 μg/epinephrine 12.5 μg. Although the incidence of FHR abnormalities was higher in the high-dose intrathecal sufentanil group, there was no difference among groups in the need for emergency cesarean delivery. Wong et al.,[168,169] in two separate studies, randomized multiparous women to receive intrathecal fentanyl 0, 5, 10, 15, 20, or 25 μg, or sufentanil 0, 2.5, 5, 7.5 or 10 μg, combined with bupivacaine 2.5 mg. There was no difference in the incidence of fetal bradycardia among groups. Abrão et al.[519] and Cheng et al.[524] noted an association with the extent of decrease in pain scores after the initiation of analgesia and the incidence of fetal bradycardia. These data suggest that the incidence of bradycardia is associated with the rate of onset of analgesia; faster onset of analgesia is associated with the CSE technique and may be related to the dose/potency of the neuraxial drugs.

In a randomized controlled study, Gambling et al.[525] tested the hypothesis that prophylactic administration of ephedrine (via its beta$_2$-adrenergic effects) would decrease the incidence of fetal bradycardia. They found no difference between groups in the incidence of fetal bradycardia or uterine tachysystole, or need for urgent delivery.

Given the risk for fetal bradycardia with neuraxial analgesia in laboring women, the FHR should be monitored during and after the administration of either epidural or intrathecal analgesia. Treatment of fetal bradycardia includes (1) relief of aortocaval compression; (2) discontinuation of intravenous oxytocin; (3) treatment of maternal hypotension, if present; and (4) fetal scalp stimulation. Persistent uterine tachysystole should also prompt the administration of a tocolytic drug (e.g., terbutaline or nitroglycerin).

CONCLUSIONS AND RECOMMENDATIONS

Philosophy of Labor Analgesia

An unacceptably high number of women involuntarily experience severe pain during labor. As noted by the ACOG, "There is no other circumstance where it is considered acceptable for a person to experience severe pain, amenable to safe intervention, while under a physician's care."[17] Unfortunately, labor represents one of the few circumstances in which the provision of effective analgesia is alleged to interfere with the parturient's and obstetrician's goal (e.g., spontaneous vaginal delivery). Dense neuraxial anesthesia may adversely affect the progress of labor in some patients. Indeed, given the complicated neurohumoral and mechanical processes involved in childbirth, it would be unreasonable to expect that neuroblockade of the lower half of the body would *not* have an effect on this process, whether positive or negative. However, maternal-fetal factors and obstetric management—not the use of neuraxial analgesia—are the most important determinants of the outcome of labor. Anesthesia providers should identify those methods of analgesia that provide the most effective pain relief without unduly increasing the risk for obstetric intervention.[526] Operative delivery increases the risk for maternal morbidity and mortality and is more expensive than spontaneous vaginal delivery. Randomized trials suggest that the use of neuraxial analgesia does not increase the cesarean delivery rate but may adversely influence the instrumental vaginal delivery rate.[3] Further, neuraxial analgesia may occasionally, either directly or indirectly, have adverse—usually temporary—effects on the fetus.

Despite these risks, many women opt for neuraxial analgesia because no other method of labor analgesia provides its benefits (almost complete analgesia), and the risks are acceptably low. Even no analgesia may be more hazardous to some women than neuraxial analgesia (e.g., patients with an anticipated difficult airway or those at high risk for emergency cesarean delivery). Therefore, it is the duty of the anesthesia provider to provide appropriate (albeit not always total) pain relief during the first and second stages of labor. Analgesia should be tailored to the individual patient's labor, medical condition, preferences, and goals. Most women strongly dislike dense motor blockade, and many prefer to maintain some sensation of uterine contractions and perineal pressure, especially during the second stage of labor. However, a few women may accept the probable increase in risk for instrumental vaginal delivery in exchange for dense analgesia.

A Practical Guide to Neuraxial Labor Analgesia

Initiation of Analgesia

Neuraxial labor analgesia may be initiated with either the intrathecal (CSE) or the epidural injection of analgesic/anesthetic agents. The decision regarding the specific technique and choice of drugs and doses is individualized for each parturient. Parity, stage and phase of labor, use of intravenous oxytocin, and the presence of any coexisting disease(s), as well as the status of the fetus, are all considered in the decision.

In healthy *nulliparous* women in *early* labor (less than 4 to 5 cm cervical dilation), my colleagues and I often initiate CSE analgesia with an intrathecal opioid alone (e.g., fentanyl 25 μg or sufentanil 5 μg), followed by placement of an epidural catheter and administration of a standard

lidocaine 45 mg/epinephrine 15 μg epidural test dose. Some anesthesia providers initiate intrathecal analgesia with both an opioid and a local anesthetic. The addition of a local anesthetic is unnecessary for achieving complete spinal analgesia during early labor; it may increase the risk for hypotension and result in motor blockade in some patients, particularly if it is followed by injection of an epidural test dose that contains a local anesthetic. However, the intrathecal administration of both an opioid and a local anesthetic achieves a longer duration of analgesia and lower incidence and severity of pruritus than intrathecal injection of an opioid alone.

Alternatively, epidural analgesia can be initiated with injection of a low-concentration local anesthetic solution (bupivacaine 0.0625% to 0.125%) combined with an opioid (fentanyl 50 to 100 μg). The epidural catheter is sited and a standard epidural test dose is injected, followed by administration of 5 to 15 mL of the local anesthetic/opioid solution, injected in 5-mL increments. Ten to 15 mL provides satisfactory analgesia for most nulliparous women in early labor; injection of 20 mL may be necessary if a dilute solution (e.g., 0.0625% bupivacaine) is used. A smaller dose is necessary if administered after a standard test dose.

We typically give an epinephrine-containing test dose before initiation of epidural analgesia in laboring women. Some anesthesia providers elect to omit the epidural test dose when initiating epidural labor analgesia, particularly if a woman wishes to ambulate in early labor. The omission of the epidural test dose requires that the therapeutic dose of local anesthetic be injected slowly, incrementally, and cautiously, because the therapeutic dose functions as the test dose. These precautions should be followed with all bolus injections of local anesthetic through an epidural catheter.

For *nulliparous* women in the active phase of the first stage of labor, CSE analgesia is usually initiated with the intrathecal injection of an opioid combined with a local anesthetic (fentanyl 15 μg and bupivacaine 2.5 mg). Alternatively, epidural analgesia can be initiated with a local anesthetic (bupivacaine 0.125%) combined with an opioid (fentanyl 100 μg). Women in active labor may require a higher total volume of epidural local anesthetic solution (15 to 20 mL) than women in early labor (10 to 15 mL) as well as a higher local anesthetic concentration (e.g., 0.125% rather than 0.0625% bupivacaine).

Labor typically progresses at a faster rate in *parous* women, who often require a more rapid onset of analgesia and more extensive neuroblockade than nulliparous women when neuraxial analgesia is initiated at the same cervical dilation. Therefore, in healthy parous women CSE analgesia is usually initiated with an intrathecal opioid combined with a local anesthetic, regardless of the stage and phase of labor. Alternatively, epidural analgesia is initiated with bupivacaine 0.125% combined with fentanyl 100 μg.

CSE analgesia with both a local anesthetic and an opioid is particularly advantageous for parous women in the late active phase of the first stage of labor and in all women in whom neuraxial analgesia is initiated in the second stage of labor. Sacral neuroblockade is required for complete analgesia during the second stage of labor; this neuroblockade is difficult to accomplish in a timely fashion with an initial *(de novo)* lumbar epidural injection of analgesic/anesthetic agents. (For initiation of lumbar epidural anesthesia in late labor, the injection of a large volume [greater than or equal to 20 mL] of local anesthetic solution may be required to achieve sacral analgesia, and this injection often results in a mid- or high-thoracic neuroblockade that is more extensive than desired. Therefore, when initiating neuraxial analgesia in late labor, a CSE technique is preferred).

Maintenance epidural analgesia is typically initiated soon after the initiation of analgesia (within 15 to 30 minutes) rather than waiting for the neuroblockade to regress. There are several advantages to this technique. Most women experience seamless analgesia (i.e., there is no window of pain as the initial block regresses). The workload for the anesthesia provider is lessened, because he or she can set up and initiate the epidural infusion while monitoring the patient for hypotension after initiation of neuroblockade. Finally, an epidural bolus of local anesthetic is not required to reestablish or extend neuroblockade, possibly enhancing safety.

Analgesia is typically maintained with a dilute solution of an amide local anesthetic and an opioid, administered by continuous infusion or PIEB, combined with PCEA. My colleagues and I use PCEA because it allows patient titration of neuroblockade and entails less risk for breakthrough pain. Patient satisfaction is better, and the workload for the anesthesia provider is decreased. At our institution, the PCEA infusion pump parameters are the same for all laboring women, so there are fewer errors in pump setup. However, when a continuous infusion is used without PCEA to maintain analgesia, it may be necessary to titrate the continuous infusion rate to individual patient needs. For example, women in early labor require less drug to maintain analgesia (6 to 10 mL/h), whereas women in more advanced labor may require a higher infusion rate (8 to 15 mL/h). Similarly, a parous patient may require a higher infusion rate than a nulliparous patient, even though analgesia is initiated at the same stage of labor.

Some parturients experience breakthrough pain. After evaluating the nature of the pain, the extent of neuroblockade, and the progress of labor, we usually treat breakthrough pain with a bolus epidural injection of bupivacaine 0.125%, 10 to 15 mL, administered in 5-mL increments. The patient may benefit from additional instruction about the optimal use of PCEA. Occasionally, we may elect to use a more concentrated local anesthetic solution (e.g., bupivacaine 0.25%), particularly in the presence of an abnormal fetal position or dysfunctional labor. In this case, the concentration of the maintenance solution may also need to be increased.

This maintenance technique usually results in satisfactory perineal analgesia for delivery. Occasionally, women with epidural analgesia require additional (more dense) analgesia for delivery, particularly if an instrumental vaginal delivery is planned. In this case, we often administer 5 to 12 mL of 1% to

2% lidocaine or 2% to 3% 2-chloroprocaine. This usually results in satisfactory sacral anesthesia in a patient with preexisting epidural labor analgesia.

There is no single correct way to provide neuraxial labor analgesia, although for particular patients and specific clinical conditions some methods may have advantages over others. Frequent communication among members of the anesthesia, obstetric, and nursing teams is essential to the safe and satisfactory provision of neuraxial labor analgesia. In addition, within each labor and delivery unit, consistency among anesthesia providers in their choice of techniques, specific drugs, and drug doses/concentrations is likely to result in fewer errors and higher satisfaction among other caregivers and patients.

KEY POINTS

- Neuraxial analgesia is the most effective form of intrapartum analgesia currently available.
- In most cases, maternal request for pain relief represents a sufficient indication for the administration of neuraxial analgesia.
- The safe administration of neuraxial analgesia requires a thorough (albeit directed) preanesthetic evaluation and the immediate availability of appropriate resuscitation equipment.
- Neuraxial labor analgesia is not a generic procedure. The procedure should be tailored to individual patient needs.
- The administration of the epidural test dose should allow the anesthesia provider to recognize most cases of unintentional intravascular or intrathecal placement of the epidural catheter. All therapeutic doses of local anesthetic should be administered incrementally.
- Bupivacaine is the local anesthetic most often used for epidural analgesia during labor in the United States. Ropivacaine and levobupivacaine are satisfactory alternatives. Most anesthesia providers reserve 2-chloroprocaine and lidocaine for cases that require the rapid extension of epidural anesthesia for vaginal or cesarean delivery.
- The addition of a lipid-soluble opioid to a neuraxial local anesthetic allows the anesthesia provider to provide excellent analgesia while reducing the total dose of local anesthetic and minimizing the side effects of each agent. Perhaps the major advantage of this technique is that the severity of motor block can be minimized during labor.
- Intrathecal opioids alone may provide complete analgesia during the early first stage of labor. Epidural opioids without local anesthetic do not provide complete analgesia during labor.
- Administration of a local anesthetic (with or without an opioid) is necessary to provide complete neuraxial analgesia for the late first stage and the second stage of labor. Although a neuraxial local anesthetic alone can provide complete analgesia, the required dose is often associated with an undesirably dense degree of motor blockade.
- Hypotension is a common side effect of neuraxial analgesia. Prophylaxis and treatment involve the avoidance of aortocaval compression and the administration of a vasopressor as needed. The administration of an intravenous fluid "preload" does not significantly decrease the incidence of hypotension in euvolemic patients.
- Other potential side effects of neuraxial analgesia include pruritus, shivering, urinary retention, delayed gastric emptying, maternal fever, and fetal heart rate changes.
- Complications of neuraxial analgesia include inadequate analgesia, unintentional dural puncture, respiratory depression, unintentional intravenous injection, and extensive or total spinal anesthesia.
- The presence of severe pain during early labor—and/or an increase in local anesthetic/opioid dose requirement—may signal a higher risk for prolonged labor and operative delivery.
- Neuraxial labor analgesia does not result in a higher rate of cesarean delivery than systemic opioid analgesia.
- Initiation of neuraxial analgesia in early labor (cervical dilation less than 4 to 5 cm) does not increase the rate of cesarean delivery or prolong the duration of labor.
- Effective neuraxial analgesia likely results in a modest prolongation of the second stage of labor.
- Controversy exists as to whether there is a cause-and-effect relationship between neuraxial labor analgesia and risk for instrumental vaginal delivery. Dense neuroblockade (e.g., presence of significant motor blockade) and complete analgesia during the second stage of labor probably increase the rate of instrumental vaginal delivery. Use of a dilute solution of local anesthetic and opioid is less likely to adversely affect the progress of labor.
- Maternal-fetal factors and obstetric management—not the use of neuraxial analgesia—are the most important determinants of the cesarean delivery rate.

Alternative Regional Analgesic Techniques for Labor and Vaginal Delivery

David H. Chestnut, MD

CHAPTER OUTLINE

Neuraxial analgesic techniques are the most flexible analgesic techniques available for obstetric patients. The anesthesia provider may use an epidural or spinal technique to provide effective analgesia during the first and/or second stage of labor. Subsequently, the epidural or spinal technique may be used to achieve anesthesia for either vaginal or cesarean delivery. Unfortunately, some maternal conditions (e.g., coagulopathy, severe thrombocytopenia) contraindicate the administration of neuraxial analgesia. Many parturients do not have access to neuraxial analgesia, and others do not want it. The purpose of this chapter is to discuss alternative regional analgesic techniques for labor and vaginal delivery.

PARACERVICAL BLOCK

During the first stage of labor, pain results primarily from dilation of the cervix and distention of the lower uterine segment and upper vagina. Pain impulses are transmitted from the upper vagina, cervix, and lower uterine segment by visceral afferent nerve fibers that join the sympathetic chain at L2 to L3 and enter the spinal cord at T10 to L1. Obstetricians may perform a paracervical block to provide analgesia during the first stage of labor, although the block is not discussed in the updated 2017 American College of Obstetricians and Gynecologists Practice Bulletin on Obstetric Analgesia and Anesthesia.[1] The goal is to block transmission through the paracervical ganglion—also known as *Frankenhäuser's ganglion*—which lies immediately lateral and posterior to the cervicouterine junction.

Paracervical block does not adversely affect the progress of labor. Further, it provides analgesia without the annoying sensory and motor blockade that may result from neuraxial analgesia. The paracervical technique does not block somatic sensory fibers from the lower vagina, vulva, and perineum. Thus, it does not relieve the pain caused by distention of these structures during the late first stage and second stage of labor. Experience suggests that paracervical block results in satisfactory analgesia during the first stage of labor in 50% to 75% of parturients. One study noted that paracervical block provided better analgesia in nulliparous women than in parous women, probably because paracervical block does not provide effective analgesia for the sudden and rapid descent of the presenting part that often occurs in parous women.[2]

In 2011, 2% to 7% of parturients in the United States received paracervical block during labor.[3] The decline in the popularity of paracervical block has resulted from both fear of fetal complications and the greater popularity and flexibility of neuraxial analgesic techniques.

Jensen et al.[4] randomly assigned 117 nulliparous women to receive either bupivacaine paracervical block or intramuscular meperidine 75 mg. Women in the paracervical block group had significantly better analgesia than women in the meperidine group at 20, 40, and 60 minutes. During the first 60 minutes, pain relief was complete or acceptable in 78% of

the women in the paracervical block group but in only 31% of the women in the meperidine group. Two fetuses in the paracervical block group and one in the meperidine group had transient bradycardia. A total of 6 infants in the paracervical block group and 16 infants in the meperidine group ($P < .05$) had fetal/neonatal depression, which the investigators defined as an umbilical arterial blood pH of 7.15 or less and/or a 1-minute Apgar score of 7 or less.[4] A 2012 Cochrane Review cited this study as evidence that paracervical block provides more effective analgesia during labor than intramuscular meperidine.[5]

In a 2009 study, Junttila et al.[6] randomly assigned 122 parous women to receive either bupivacaine paracervical block or single-shot spinal bupivacaine with sufentanil. Single-injection spinal analgesia was superior to that provided by paracervical block (Fig. 24.1), although paracervical block resulted in a pain score of 3 or less in 43% of the study subjects, and 51% of the women in the paracervical block group indicated that they would be happy to receive this method of analgesia during labor in a future pregnancy. There was no difference between the two groups in the incidence of fetal heart rate (FHR) abnormalities, and there were no cases of fetal bradycardia in either group.[6]

Kangas-Saarela et al.[7] compared neonatal neurobehavioral responses in 10 infants whose mothers received bupivacaine paracervical block with those in 12 infants whose mothers received no analgesia. The investigators performed paracervical block while each patient lay in a left lateral position, and they limited the depth of the injection into the vaginal mucosa to 3 mm or less. They observed no significant differences between groups in neurobehavioral responses at 3 hours, 1 day, 2 days, or 4 to 5 days after delivery. These investigators concluded that properly performed paracervical block does not adversely affect newborn infant behavior or neurologic function.[7]

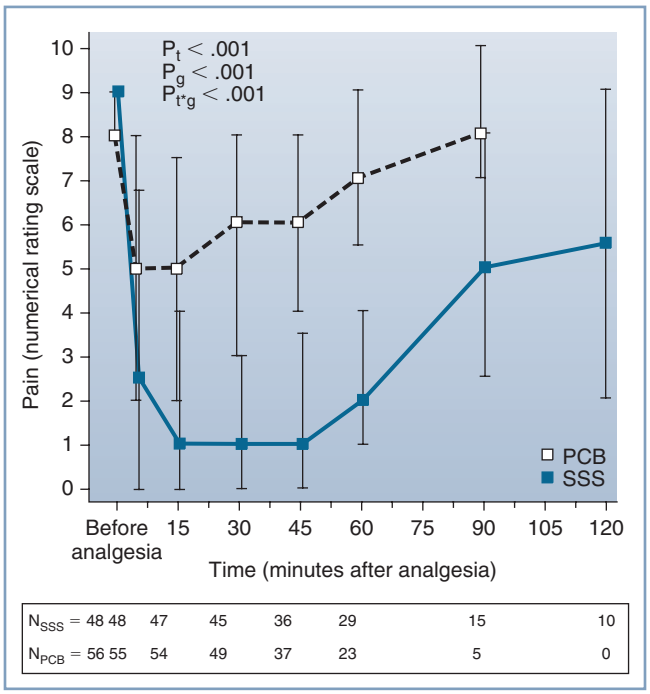

Fig. 24.1 Pain scores over time before and after paracervical block (10 mL of 0.25% bupivacaine) or single-shot spinal (intrathecal) injection of bupivacaine 2.5 mg and sufentanil 2.5 µg. Data are median pain scores with the 25th and 75th percentiles. *PCB,* paracervical block; *SSS,* single-shot spinal analgesia; P_t, P-time; P_g, P-groups; P_{t*g}, P-time*group. *N,* number of parturients at the measurement time points. (From Junttilla EK, Karjalainen PK, Ohtonen PP, et al. A comparison of paracervical block with single-shot spinal for labour analgesia in multiparous women: a randomized controlled trial. *Int J Obstet Anesth.* 2009;18:15–21.)

Technique

Paracervical block is performed with the patient in a modified lithotomy position. The uterus should be displaced leftward during performance of the block; this displacement may be accomplished by placing a folded pillow beneath the patient's right buttock. The physician uses a needle guide to define and limit the depth of the injection and to reduce the risk for vaginal or fetal injury. The physician introduces the needle and needle guide into the vagina with the left hand for the left side of the pelvis and with the right hand for the right side (Fig. 24.2). The needle and needle guide are introduced into the left or right lateral vaginal fornix, near the cervix, at the 4-o'clock or the 8-o'clock position. The needle is advanced through the vaginal mucosa to a depth of 2 to 3 mm.[8] The physician should aspirate before each injection of local anesthetic. A total of 5 to 10 mL of local anesthetic, without epinephrine, is injected on each side.[9] Some obstetricians recommend giving incremental doses of local anesthetic on each side (e.g., 2.5 to 5 mL of local

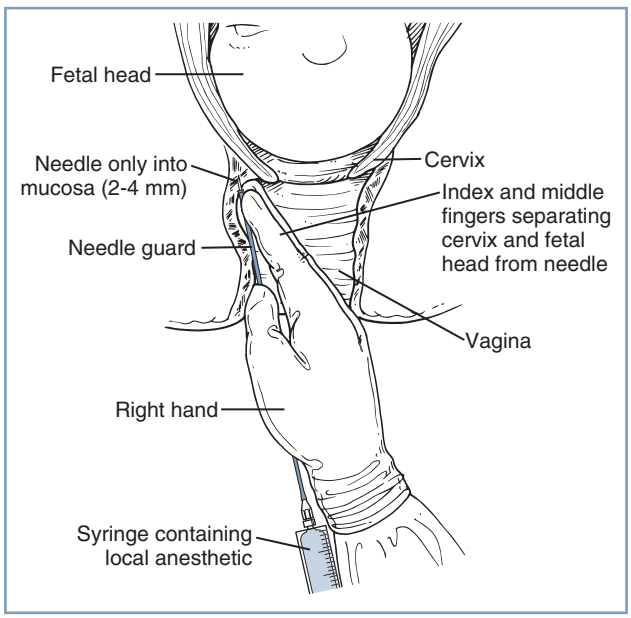

Fig. 24.2 Technique of paracervical block. Notice the position of the hand and fingers in relation to the cervix and fetal head. No undue pressure is applied at the vaginal fornix by the fingers or the needle guide, and the needle is inserted to a shallow depth. (Redrawn from Abouleish E. *Pain Control in Obstetrics.* New York, NY: JB Lippincott; 1977:344.)

anesthetic between the 3-o'clock and 4-o'clock positions, followed by 2.5 to 5 mL between the 4-o'clock and 5-o'clock positions).[8,10,11]

After injecting the local anesthetic in either the left or right lateral vaginal fornix, the physician should wait 5 to 10 minutes and observe the FHR before injecting the local anesthetic on the other side.[11] Some obstetricians do not endorse this recommendation. Van Dorsten et al.[12] randomly assigned 42 healthy parturients at term to either of two methods of paracervical block. The study group experienced a 10-minute interval between injections of local anesthetic on the left and right sides of the vagina. The control group had almost simultaneous injections on the left and right sides. No cases of fetal bradycardia occurred in either group. The investigators concluded that patient selection and lateral positioning after the block have a more important role in the prevention of post-paracervical block fetal bradycardia than spacing the injections of local anesthetic. However, because they studied only 42 patients and had no cases of fetal bradycardia in either group, they could not exclude the possibility that incremental injection might result in a lower incidence of fetal bradycardia in a larger series of patients.

Choice of Local Anesthetic

The physician should administer small volumes of a dilute solution of local anesthetic. There is no reason to inject more than 10 mL of local anesthetic on each side. Further, there is no indication for the use of concentrated solutions, such as 2% lidocaine, 0.5% bupivacaine, or 3% 2-chloroprocaine. Nieminen and Puolakka[13] observed that paracervical block with 10 mL of 0.125% bupivacaine (5 mL on each side) provided analgesia similar to that provided by 10 mL of 0.25% bupivacaine.

The choice of local anesthetic is controversial. The North American manufacturers of bupivacaine have stated that bupivacaine is contraindicated for the performance of paracervical block. In contrast, Scandinavian obstetricians have used bupivacaine for this procedure. Bupivacaine has greater cardiotoxicity than other local anesthetic agents, and some investigators have suggested that its use leads to a higher incidence of fetal bradycardia or adverse outcome than use of other local anesthetics for paracervical block. In a review of 50 cases of perinatal death associated with paracervical block, Teramo[14] found that the local anesthetic was bupivacaine in at least 29 of the 50 cases.

Palomäki et al.[15] hypothesized that levobupivacaine might result in a lower incidence of post-paracervical block fetal bradycardia than racemic bupivacaine. In a randomized double-blind study of 397 laboring women, paracervical block was performed with 10 mL of either 0.25% levobupivacaine or 0.25% racemic bupivacaine. The incidence of transient FHR abnormalities was 10.4% in the levobupivacaine group and 12.8% in the racemic bupivacaine group, and that of fetal bradycardia was 2.6% in the levobupivacaine group and 3.8% in the racemic bupivacaine group (P = NS).

Some physicians have suggested that 2-chloroprocaine is the local anesthetic of choice for paracervical block. Published studies suggest but do not prove that post-paracervical block fetal bradycardia occurs less frequently with 2-chloroprocaine than with amide local anesthetics.[10,16–18] Weiss et al.[16] performed a double-blind study in which 60 patients were randomly assigned to receive 20 mL of either 2% 2-chloroprocaine or 1% lidocaine for paracervical block. Bradycardia occurred in 1 of the 29 fetuses in the 2-chloroprocaine group, compared with 5 of 31 fetuses in the lidocaine group (P = .14). LeFevre[18] retrospectively observed that fetal bradycardia occurred after 2 (6%) of 33 paracervical blocks performed with 2-chloroprocaine versus 44 (12%) of 361 paracervical blocks performed with mepivacaine (P = .29).

2-Chloroprocaine undergoes rapid enzymatic hydrolysis. Thus it has the shortest intravascular half-life among the local anesthetics used clinically. This rapid metabolism seems advantageous in the event of unintentional intravascular or fetal injection. Philipson et al.[17] performed paracervical block with 10 mL of 1% 2-chloroprocaine in 16 healthy parturients. At delivery, only trace concentrations of 2-chloroprocaine were detected in one (6%) of the maternal blood samples and four (25%) of the umbilical cord venous blood samples. The investigators concluded[17]:

> *In all of the studies of paracervical block with 2-chloroprocaine, there were no cases in which the abnormal fetal heart rate patterns were associated with depressed neonates. This is in contrast to the studies with amide local anesthetics and may be explained by the rapid enzymatic inactivation of 2-chloroprocaine.*

Some obstetricians dislike 2-chloroprocaine because of its relatively short duration of action. However, in one study the mean duration of analgesia was 40 minutes after paracervical administration of either 2-chloroprocaine or lidocaine.[16] A 2012 Cochrane Review concluded that the choice of local anesthetic agent did not affect maternal satisfaction with pain relief after paracervical block.[5]

Maternal Complications

Maternal complications of paracervical block are uncommon but may be serious (Box 24.1).[19–22] Local anesthetic systemic toxicity may result from direct intravascular injection or rapid systemic absorption of the local anesthetic. Postpartum neuropathy may follow direct sacral plexus trauma, or it may result from hematoma formation. Retropsoal and subgluteal abscesses are rare but may result in maternal morbidity or mortality.[21,22]

BOX 24.1 Maternal Complications of Paracervical Block

- Vasovagal syncope
- Laceration of the vaginal mucosa
- Local anesthetic systemic toxicity
- Parametrial hematoma
- Postpartum neuropathy
- Paracervical, retropsoal, or subgluteal abscess

Fetal Complications

In some cases, fetal injury results from direct injection of local anesthetic into the fetal scalp during paracervical block.[23] Fetal scalp injection of 10 or 20 mL of local anesthetic undoubtedly causes local anesthetic systemic toxicity, which may result in fetal death. Fetal scalp injection seems more likely to occur when the obstetrician performs paracervical block in the presence of advanced (i.e., > 8 cm) cervical dilation.

Bradycardia is the most common fetal complication. Fetal bradycardia typically develops within 2 to 10 minutes after the injection of local anesthetic. Most cases resolve within 5 to 10 minutes, but some cases of bradycardia persist for as long as 30 minutes. Published studies have noted an incidence of bradycardia that varies between 0% and 70%.[4,11,18,24–31] These figures represent extremes on either side of the true incidence of this complication. Some studies have overstated the problem by defining bradycardia as a baseline FHR of less than 120 bpm. (A baseline FHR of 110 bpm does not necessarily indicate fetal compromise.) Experienced obstetricians clearly do not encounter clinically significant fetal bradycardia after 70% of their paracervical blocks. It is equally clear that the incidence of clinically significant fetal bradycardia is not zero, and it is difficult to teach this technique without placing some fetuses at risk.

Shnider et al.[26] reported that fetal bradycardia occurred after 24% of 845 paracervical blocks administered to 705 patients with either 1% mepivacaine, 1% lidocaine, or 1% propitocaine (prilocaine). Neonatal depression occurred significantly more often in infants who had FHR changes after paracervical block than in a control group or in a group of infants with no FHR changes after paracervical block. In contrast, Carlsson et al.[27] performed 523 paracervical blocks with 0.125% or 0.25% bupivacaine in 469 women. Of the total, nine (1.9%) fetuses had bradycardia, but at delivery all nine of the newborns had a 5-minute Apgar score of 9 or 10.

Goins[28] observed fetal bradycardia in 24 (13%) of 182 patients who received paracervical block with 20 mL of 1% mepivacaine. He compared neonatal outcome for these patients with neonatal outcome for 343 patients who received other analgesic/anesthetic techniques. There was a slightly higher incidence of low Apgar scores at 1 minute and 5 minutes in the paracervical block group, but the difference was not statistically significant. LeFevre[18] observed fetal bradycardia after 46 (11%) of 408 paracervical blocks. Fetal bradycardia was more common in those patients with a nonreassuring FHR tracing before the performance of paracervical block.

In a review of four randomized controlled trials published between 1975 and 2000, Rosen[30] estimated that the incidence of post-paracervical block fetal bradycardia is 15%. More recently, Volmanen et al.[31] reviewed four studies of paracervical block that had adequate sample size ($n > 200$), used the superficial injection technique, and administered 0.125% or 0.25% bupivacaine. Among the 1361 patients in these four studies, the incidence of fetal bradycardia was 2.2%. The observed episodes of fetal bradycardia were transient and did not require emergency cesarean delivery.[31]

Etiology of Fetal Bradycardia

The etiology of fetal bradycardia after paracervical block is unclear. Investigators have offered at least four theories that might explain the etiology of fetal bradycardia, as discussed here.

Reflex bradycardia. Manipulation of the fetal head, the uterus, or the uterine blood vessels during performance of the block may cause reflex fetal bradycardia.[25]

Direct fetal central nervous system and myocardial depression. The performance of paracervical block results in the injection of large volumes of local anesthetic close to the uteroplacental circulation. Local anesthetic rapidly crosses the placenta[32] and may cause fetal central nervous system (CNS) depression, myocardial depression, and/or umbilical vasoconstriction. Puolakka et al.[33] observed that the most common abnormality after paracervical block was the disappearance of FHR accelerations. They speculated that FHR changes result from rapid transplacental passage of local anesthetic into the fetal circulation, followed by a direct toxic effect of the local anesthetic on the FHR regulatory centers.

Some investigators have suggested that fetal bradycardia results from a direct toxic effect of the local anesthetic on the fetal heart.[34,35] Shnider et al.[34] reported that in four cases of fetal bradycardia, mepivacaine concentrations in fetal scalp blood were higher than peak concentrations in maternal arterial blood. Asling et al.[35] made similar observations in six of seven cases of fetal bradycardia. They suggested that local anesthetic reaches the fetus by a more direct route than maternal systemic absorption, and they speculated that high fetal concentrations of local anesthetic result from local anesthetic diffusion across the uterine arteries. This would lead to local anesthetic concentrations in intervillous blood that are higher than concentrations in maternal brachial arterial blood. High fetal concentrations would then occur from the passive diffusion of local anesthetic across the placenta.

High fetal concentrations of local anesthetic also may result from fetal acidosis and ion trapping.[36,37] Local anesthetics are weak bases, and if acidosis develops in a fetus, increasing amounts of local anesthetic will be trapped in the fetal circulation. It is also possible that the obstetrician may directly inject local anesthetic into uterine blood vessels.

Most studies have noted that local anesthetic concentrations in the fetus are consistently lower than those in the mother after paracervical block.[9] Further, fetal bradycardia has not consistently occurred in documented cases of fetal local anesthetic toxicity. Freeman et al.[38] injected 300 mg of mepivacaine directly into the scalp of two anencephalic fetuses. The QRS complex widened, the PR interval lengthened, and both fetuses died, but fetal bradycardia did not occur before fetal death. In contrast, the investigators observed no widening of the QRS complex or lengthening of the PR interval in normal fetuses demonstrating bradycardia after paracervical block. Rather, the fetal electrocardiogram (ECG)

changes were consistent with sinoatrial node suppression with a wandering atrial pacemaker. The investigators concluded that a mechanism other than direct fetal myocardial depression is responsible for fetal bradycardia after paracervical block.

Increased uterine activity. Increased uterine activity results in decreased uteroplacental perfusion. Fishburne et al.[39] noted that direct uterine arterial injection of bupivacaine consistently caused a significant increase in uterine tone in gravid ewes. Uterine arterial injection of 2-chloroprocaine did not affect myometrial tone, whereas injection of lidocaine had an intermediate effect.

Myometrial injection of a local anesthetic also may cause greater uterine activity. Morishima et al.[40] performed paracervical block with either lidocaine or 2-chloroprocaine in pregnant baboons with normal and acidotic fetuses. A transient increase in uterine activity and a significant reduction in uterine blood flow occurred after paracervical block in 73% of the mothers. Approximately 33% of the normal fetuses and all of the acidotic fetuses had bradycardia after paracervical block. The acidotic fetuses had more severe bradycardia, greater hypoxemia, and slower recovery of oxygenation compared with fetuses that were well oxygenated before paracervical block. The researchers concluded that post-paracervical block fetal bradycardia is in part a result of greater uterine activity, diminished uteroplacental perfusion, and decreased oxygen delivery to the fetus. They also concluded that paracervical block should be avoided in the presence of fetal compromise.

Uterine and/or umbilical artery vasoconstriction. The deposition of local anesthetic in close proximity to the uterine arteries may cause uterine artery vasoconstriction, with a subsequent drop in uteroplacental perfusion. At least two studies noted that lidocaine and mepivacaine caused vasoconstriction of human uterine arteries *in vitro*.[41,42] (These studies were performed before recognition of the importance of intact endothelium during investigation of vascular smooth muscle response.) Similarly, Norén et al.[43,44] noted that bupivacaine caused concentration-dependent contraction of uterine arterial smooth muscle from rats and pregnant women. The calcium entry-blocking drugs verapamil and nifedipine decreased the vascular smooth muscle contraction caused by bupivacaine. The researchers concluded that the use of bupivacaine for paracervical block may cause uterine artery vasoconstriction, especially when the bupivacaine is injected close to the uterine arteries. Further, they suggested that the administration of a calcium entry-blocking drug may successfully eliminate this vasoconstrictive effect of bupivacaine. (The researchers did not mention whether they preserved, removed, or even observed the presence of the vascular endothelium. The presence of vascular endothelium may alter the response of vascular smooth muscle to local anesthetics.[45])

Greiss et al.[46] observed that intra-aortic injection of lidocaine or mepivacaine led to decreased uterine blood flow in gravid ewes. Similarly, Fishburne et al.[39] noted that direct uterine arterial injection of lidocaine, bupivacaine, or 2-chloroprocaine reduced uterine blood flow in gravid ewes. They concluded that only paracervical block "would be expected to produce the high, sustained uterine arterial concentrations of anesthetic drugs that cause the significant reductions in uterine blood flow which we now feel are the etiology of fetal bradycardia."[39] In a later study, Manninen et al.[47] observed that paracervical injection of 10 mL of 0.25% bupivacaine led to an increase in the uterine artery pulsatility index—an estimate of uterine vascular resistance—in healthy nulliparous women, suggesting that paracervical block may result in uterine artery vasoconstriction.

In contrast, Puolakka et al.[33] used ^{133}Xe to measure intervillous blood flow before and after the performance of paracervical block with 10 mL of 0.25% bupivacaine in 10 parturients. They observed no decrease in mean intervillous blood flow in these patients. Further, they noted minimal change in intervillous blood flow in the three patients who had fetal bradycardia after paracervical block. Using Doppler ultrasonography, Räsänen and Jouppila[48] observed no significant change in either uterine or umbilical artery pulsatility index after the performance of paracervical block with 10 mL of 0.25% bupivacaine in 12 healthy parturients. However, fetal bradycardia occurred in two patients, and in those two cases, a marked increase in umbilical artery pulsatility index occurred.

Baxi et al.[49] performed paracervical block with 20 mL of 1% lidocaine in 10 pregnant women. They observed a decrease in fetal transcutaneous Po_2 5 minutes after injecting lidocaine in each of the 10 patients. There was a maximum decline in transcutaneous Po_2 at 11.5 minutes, and transcutaneous Po_2 returned to baseline by approximately 31 minutes. Some of the patients had increased uterine activity after paracervical block. In contrast, Jacobs et al.[50] observed a consistent, sustained decrease in fetal transcutaneous Po_2 after only 1 of 10 paracervical blocks performed with 10 mL of 0.25% bupivacaine. These investigators attributed their good results to the following precautions: (1) performance of paracervical block only in healthy mothers with normal pregnancies; (2) administration of a small dose of bupivacaine; (3) a limited depth of injection; (4) administration of bupivacaine in four incremental injections (i.e., two injections on each side); and (5) use of the left lateral position immediately after performance of the block. In a later study, Kaita et al.[51] observed that paracervical injection of 10 mL of 0.25% bupivacaine in 10 healthy parturients resulted in a slight (clinically insignificant) increase in fetal Sao_2 as measured by fetal pulse oximetry.

Summary

Most observers currently believe that post-paracervical block bradycardia results from reduced uteroplacental and/or fetoplacental perfusion. Reduction in uteroplacental perfusion may occur because of increased uterine activity and/or a direct vasoconstrictive effect of the local anesthetic. Likewise, decreased umbilical cord blood flow may result from increased uterine activity and/or umbilical cord vasoconstriction. Regardless of the etiology, the severity and duration of

fetal bradycardia correlate with the incidence of fetal acidosis and subsequent neonatal depression. Freeman et al.[38] reported a significant drop in pH and a rise in base deficit only in fetuses with bradycardia of longer than 10 minutes' duration. In an observational study of paracervical block and nalbuphine analgesia during labor, Levy et al.[52] observed no association between paracervical block and low umbilical arterial blood pH at delivery.

Physician Complications

The performance of paracervical block requires the physician to make several blind needle punctures within the vagina. The needle guide does not consistently protect the physician from a needle-stick injury. Thus, the performance of paracervical block may entail the risk for physician exposure to hepatitis C virus (HCV), human immunodeficiency virus (HIV), or another infectious agent.

Recommendations

It is difficult for us to offer enthusiasm for the performance of paracervical block in contemporary obstetric practice. Nonetheless, paracervical block may be an appropriate technique in circumstances in which neuraxial analgesia is contraindicated or unavailable. The following recommendations seem reasonable:

1. Perform paracervical block only in healthy parturients at term who have no evidence of uteroplacental insufficiency or fetal compromise.
2. Continuously monitor the FHR and uterine activity before, during, and after performance of paracervical block. Perform paracervical block only in patients with a reassuring FHR tracing. An obvious exception would be a patient whose fetus has an anomaly incompatible with life (e.g., anencephaly).
3. Do not perform paracervical block when the cervix is dilated 8 cm or more.
4. Establish intravenous access before performing paracervical block.
5. Maintain left uterine displacement during and after performance of the block.
6. Limit the depth of injection to approximately 3 mm.
7. Aspirate before each injection of local anesthetic.
8. After injecting the local anesthetic on one side, wait 5 to 10 minutes and observe the FHR before injecting the local anesthetic on the other side.
9. Administer small volumes of a dilute solution of local anesthetic; 2-chloroprocaine is the agent of choice.
10. Avoid the administration of epinephrine-containing local anesthetic solutions.
11. Monitor the mother's blood pressure and watch for signs of local anesthetic systemic toxicity after performance of the block. Maintain normal maternal blood pressure.
12. If fetal bradycardia should occur, try to achieve fetal resuscitation *in utero.* Discontinue oxytocin, administer supplemental oxygen, and ensure that the patient is on her left side. Perform operative delivery if the fetal bradycardia persists beyond 10 minutes.

LUMBAR SYMPATHETIC BLOCK

In 1933, Cleland[53] demonstrated that lower uterine and cervical visceral afferent sensory fibers join the sympathetic chain at L2 to L3. Subsequently, lumbar sympathetic block was used as an effective—if not popular—method of first-stage analgesia in some hospitals.[54–57] Like paracervical block, paravertebral lumbar sympathetic block interrupts the transmission of pain impulses from the cervix and lower uterine segment to the spinal cord. Lumbar sympathetic block provides analgesia during the first stage of labor but does not relieve pain during the second stage. It provides analgesia comparable to that provided by paracervical block but with less risk for fetal bradycardia.

Lumbar sympathetic block may have a favorable effect on the progress of labor. Hunter[58] reported that lumbar sympathetic block accelerated labor in 20 of 39 patients with a normal uterine contractile pattern before performance of the block. (Indeed, some of the patients in that study had a 5- to 15-minute period of uterine tachysystole after the block.) Further, he observed that lumbar sympathetic block converted an abnormal uterine contractile pattern to a normal pattern in 14 of 19 patients. He concluded that lumbar sympathetic block represents "one of the most reliable methods reported to actively convert an abnormal labor pattern to a normal pattern."[58] In a later study, Leighton et al.[59] randomly assigned 39 healthy nulliparous women at term to receive either epidural analgesia or lumbar sympathetic block. The women who received lumbar sympathetic block had a more rapid rate of cervical dilation during the first 2 hours of analgesia, a shorter second stage of labor, and a nonsignificant trend toward a lower incidence of cesarean delivery for dystocia. However, there was no difference between the groups in the rate of cervical dilation during the active phase of the first stage of labor.

Anesthesiologists may successfully perform lumbar sympathetic block when a history of previous back surgery precludes the successful administration of epidural analgesia.[60] Some anesthesiologists offer lumbar sympathetic block to prepared childbirth enthusiasts who desire first-stage analgesia without any motor block or loss of perineal sensation. Meguiar and Wheeler[61] stated that the primary usefulness of lumbar sympathetic block is "in cases where continuous lumbar epidural analgesia is refused or contraindicated." They administered 20 mL of 0.5% bupivacaine with 1:200,000 epinephrine to 40 nulliparous women. Among these women, 38 experienced good analgesia, and 28 delivered before resolution of the block. Pain recurred before delivery in the remaining 12 women; the mean ± SD duration of analgesia was 283 ± 103 minutes among these patients.[61] Leighton et al.[59] administered the same dose of bupivacaine, but they observed a shorter duration of analgesia than that observed by Meguiar and Wheeler.[61]

During the past three decades, lumbar sympathetic block has all but disappeared from obstetric anesthesia practice in the United States, for several reasons. Most anesthesiologists minimize motor block during epidural analgesia by

giving a dilute solution of local anesthetic, with or without an opioid. For those few patients who want to retain full perineal sensation, anesthesiologists may give an opioid alone, either intrathecally or epidurally. Thus, there are few patients for whom lumbar sympathetic block holds unique advantages. Further, the procedure often is painful, and few anesthesiologists have acquired and maintained proficiency in performing lumbar sympathetic block in obstetric patients.

Lumbar sympathetic block remains an attractive technique in a small number of patients.[60] Alternatively, two reports have described the performance of bilateral lower thoracic paravertebral block in five laboring women in whom epidural analgesia was contraindicated.[62,63] As anesthesiologists gain greater proficiency with thoracic paravertebral block for patients undergoing breast surgery, perhaps this technique will be used more often in parturients for whom neuraxial analgesia is contraindicated.

Technique

With the patient in the sitting position, a 10-cm, 22-gauge needle is used to identify the transverse process on one side of the second lumbar vertebra. The needle is then withdrawn, redirected, and advanced another 5 cm so that the tip of the needle is at the anterolateral surface of the vertebral column, just anterior to the medial attachment of the psoas muscle (Fig. 24.3). It is possible to place the needle within a blood vessel or the subarachnoid space; thus, the anesthesiologist must aspirate before injecting the local anesthetic. Two 5-mL increments of a dilute solution of local anesthetic (with or without epinephrine) are then injected, and the procedure is repeated on the opposite side of the vertebral column.

Complications

Modest hypotension occurs in 5% to 15% of patients.[58,59,61] The risk for hypotension may be reduced by giving 500 mL of lactated Ringer's solution intravenously before performing the block. Less common maternal complications are local anesthetic systemic toxicity, total spinal anesthesia, retroperitoneal hematoma, Horner's syndrome,[64] and post-dural puncture headache.[65]

Fetal complications are unlikely unless hypotension or increased uterine activity results in decreased uteroplacental perfusion.

PUDENDAL NERVE BLOCK

During the second stage of labor, pain results from distention of the lower vagina, vulva, and perineum. The pudendal nerve, which includes somatic nerve fibers from the anterior primary divisions of the second, third, and fourth sacral nerves, represents the primary source of sensory innervation for the lower vagina, vulva, and perineum. The pudendal nerve also provides motor innervation to the perineal muscles and to the external anal sphincter.

In 1916, King[66] reported the use of pudendal nerve block for vaginal delivery. This procedure did not become popular

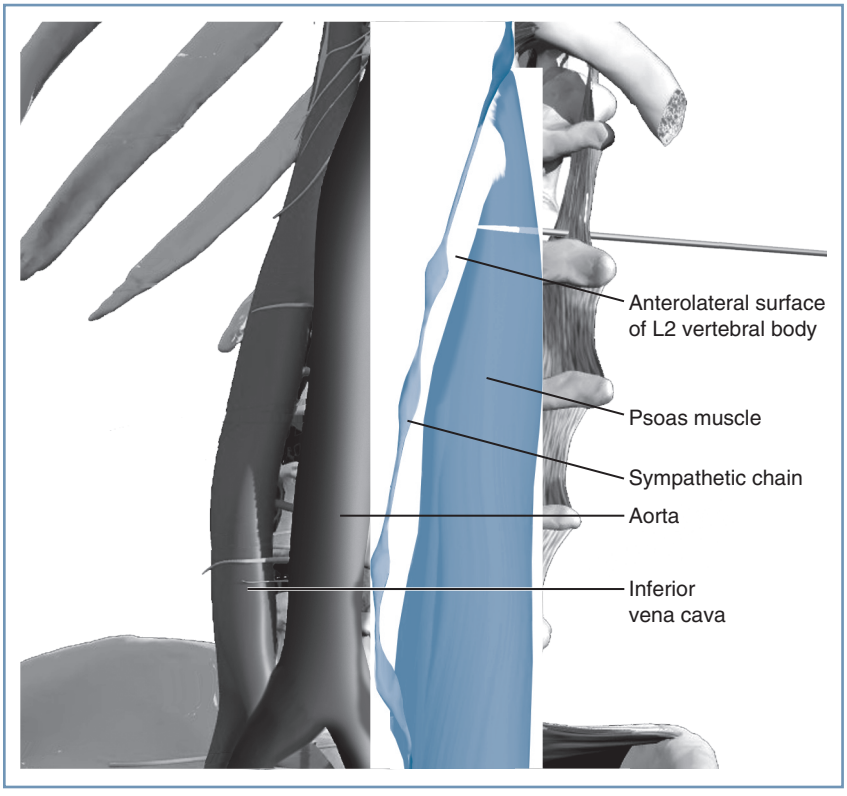

Fig. 24.3 Lateral view of needle placement for lumbar sympathetic block. The needle has been advanced so that the tip of the needle is near the anterolateral surface of the L2 vertebral body. The figure illustrates the proximity of the aorta. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

until 1953 and 1954, when Klink[67] and Kohl[68] described the anatomy and reported modified techniques. Obstetricians often perform pudendal nerve block in patients without epidural or spinal analgesia. The goal is to block the pudendal nerve distal to its formation by the anterior divisions of S2 to S4 but proximal to its division into its terminal branches (i.e., dorsal nerve of the clitoris, perineal nerve, and inferior hemorrhoidal nerve). Pudendal nerve block may provide satisfactory anesthesia for spontaneous vaginal delivery and perhaps for outlet-forceps delivery, but it provides inadequate anesthesia for mid-forceps delivery, postpartum examination and repair of the upper vagina and cervix, and manual exploration of the uterine cavity.[69]

Efficacy and Timing

The efficacy of pudendal nerve block varies according to the training and experience of the obstetrician. Many obstetric trainees receive little or no formal training in performance of pudendal block. A 2013 audit of 57 obstetricians in the United Kingdom revealed that the majority of participants were unable to correctly identify the ideal point of injection and were unaware of the lag time required for the onset of effective anesthesia.[70] It is not surprising that unilateral or bilateral failure is common. Thus, obstetricians typically perform simultaneous infiltration of the perineum, especially if the performance of pudendal nerve block is delayed until delivery. Scudamore and Yates[71] reported bilateral success rates of approximately 50% after use of the transvaginal route and of approximately 25% after use of the transperineal route. They concluded[71]:

> *The term "pudendal block" is often a misnomer.… If this limitation were more widely appreciated, then many mothers would be spared the unnecessary pain which is caused when relatively complicated procedures are attempted under inadequate anesthesia.*

In the United States, performance of pudendal nerve block typically occurs immediately before delivery. This practice reflects obstetrician concern that perineal anesthesia prolongs the second stage of labor. Early performance of the procedure allows time for successful neuroblockade to occur. Subsequently the obstetrician may repeat the block on one or both sides if it should fail, provided that the maximum safe dose of local anesthetic is not exceeded. European obstetricians seem more willing to perform pudendal nerve block at the onset of the second stage of labor. Langhoff-Roos and Lindmark[72] administered pudendal nerve block before or just after complete cervical dilation in 551 (64%) of 865 women. In a nonrandomized study, Zador et al.[73] evaluated obstetric outcome in 24 patients who received pudendal nerve block when the cervix was completely dilated and in 24 patients who did not receive pudendal block. Pudendal nerve block slightly prolonged the second stage of labor, but it did not increase the incidence of instrumental vaginal delivery.[73]

It is barbaric to withhold analgesia during the second stage of labor. Obstetricians need not delay the administration of pudendal nerve block until delivery. Rather, for those patients without epidural or spinal analgesia, it seems appropriate to perform pudendal nerve block when the patient complains of vaginal and perineal pain. A 2004 study suggested that pudendal nerve block does not provide reliable analgesia during the second stage of labor but has greater efficacy for episiotomy and repair.[74] In a randomized, double-blind, placebo-controlled study, Aissaoui et al.[75] observed that unilateral, nerve stimulator-guided pudendal nerve block with ropivacaine was associated with decreased pain and less need for supplemental analgesia during the first 48 hours after performance of mediolateral episiotomy at vaginal delivery.

Technique

The transvaginal approach is more popular than the transperineal approach in the United States. The obstetrician uses a needle guide (either the Iowa trumpet or the Kobak needle guide) to prevent injury to the vagina and fetus. In contrast to the technique for paracervical block, the needle must protrude 1.0 to 1.5 cm beyond the needle guide to allow adequate penetration for injection of the local anesthetic. The obstetrician introduces the needle and needle guide into the vagina with the left hand for the left side of the pelvis and with the right hand for the right side (Fig. 24.4). The needle is introduced through the vaginal mucosa and sacrospinous ligament, just medial and posterior to the ischial spine. The pudendal artery lies in close proximity to the pudendal nerve; thus, the obstetrician must aspirate before and during the injection of local anesthetic. The obstetrician typically injects 7 to 10 mL of local anesthetic solution on each side. (Some obstetricians inject 3 mL of local anesthetic just above the ischial spine on each side.[76]) The obstetrician should pay attention to the total dose of local anesthetic given, especially when repetitive pudendal nerve blocks or both pudendal nerve block and perineal infiltration are performed.

Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament *(S)* to reach the pudendal nerve *(N)*. (From Cunningham FG, MacDonald PC, Gant NF, et al. *Williams Obstetrics*. 20th ed. Stamford, CT: Appleton & Lange; 1997:389.)

Choice of Local Anesthetic

Rapid maternal absorption of the local anesthetic occurs after the performance of pudendal nerve block.[73,76] Zador et al.[73] detected measurable concentrations of lidocaine in maternal venous and fetal scalp capillary blood samples within 5 minutes of the injection of 20 mL of 1% lidocaine. They detected peak concentrations between 10 and 20 minutes after injection. Kuhnert et al.[77] reported that after pudendal nerve block, neonatal urine concentrations of lidocaine and its metabolites were similar to those measured in neonatal urine after epidural administration of lidocaine.

Some physicians favor the administration of 2-chloroprocaine. Its rapid onset of action provides an advantage when pudendal nerve block is performed immediately before delivery. Its rapid metabolism and short intravascular half-life lower the likelihood of maternal or fetal systemic toxicity. 2-Chloroprocaine has the disadvantage of a short duration of action. However, if the obstetrician performs pudendal nerve block with 2-chloroprocaine at the onset of the second stage of labor, the block can be repeated as needed. When the block is performed immediately before delivery, the brief duration of action of 2-chloroprocaine is not a disadvantage for the experienced obstetrician.

Merkow et al.[78] evaluated neonatal neurobehavior in infants whose mothers received 30 mL of 0.5% bupivacaine, 1% mepivacaine, or 3% 2-chloroprocaine for pudendal nerve block and perineal infiltration before delivery. Neonatal response to pinprick at 4 hours was better in the mepivacaine group; otherwise, there were no significant differences among groups in neurobehavioral scores at 4 and 24 hours after delivery.

Regardless of the choice of local anesthetic, there is no indication for the administration of a concentrated solution. For example, it is unnecessary, and perhaps dangerous, to give 0.5% bupivacaine, 2% lidocaine, or 3% 2-chloroprocaine. Rather, the obstetrician should use 2% 2-chloroprocaine or 1% lidocaine.

Some obstetricians contend that the addition of epinephrine to the local anesthetic solution improves the quality of pudendal nerve block. Langhoff-Roos and Lindmark[72] reported a randomized, double-blind study of 865 patients who received pudendal nerve block with 16 mL of 1% mepivacaine, 1% mepivacaine with epinephrine, or 0.25% bupivacaine. Mepivacaine with epinephrine provided effective anesthesia more often and also caused a greater "loss of the urge to bear down" than did the other two local anesthetic solutions. However, there was no significant difference among groups in the duration of the second stage of labor or the incidence of instrumental vaginal delivery. Schierup et al.[79] randomly assigned 151 patients to receive pudendal nerve block with 20 mL of 1% mepivacaine either with or without epinephrine. The addition of epinephrine did not improve the quality of anesthesia, but it slightly prolonged the interval between pudendal nerve block administration and delivery. Maternal venous blood mepivacaine concentrations were slightly higher in the no-epinephrine group, but there was no difference between groups in umbilical cord blood concentrations of mepivacaine.

BOX 24.2 Maternal Complications of Pudendal Nerve Block

- Laceration of the vaginal mucosa
- Local anesthetic systemic toxicity
- Vaginal, ischiorectal, or retroperitoneal hematoma
- Retropsoal or subgluteal abscess

Complications

Maternal complications of pudendal nerve block are uncommon but may be serious (Box 24.2). Local anesthetic systemic toxicity may result from either direct intravascular injection or systemic absorption of an excessive dose of local anesthetic. Toxicity may occur if the obstetrician exceeds the safe dose of local anesthetic during repetitive injections performed to obtain a successful block. Vaginal, ischiorectal, and retroperitoneal hematomas may result from trauma to the pudendal artery.[80] These hematomas are typically small and rarely require operative intervention. Subgluteal and retropsoal abscesses are rare but can result in significant morbidity or mortality.[21,22]

Fetal complications are rare. The primary fetal complications result from fetal trauma and/or direct fetal injection of local anesthetic. Pages et al.[81] reported three cases of neonatal lidocaine intoxication following maternal pudendal nerve block before delivery. Two infants required mechanical ventilation, and lidocaine was detected in the serum of two infants, but all three infants had complete recovery.

As with paracervical block, the performance of pudendal nerve block requires the obstetrician to make several blind needle punctures within the vagina. The needle guide does not uniformly protect the physician from a needle-stick injury. Thus, performance of pudendal nerve block may entail a risk for physician exposure to HCV, HIV, or another infectious agent.

PERINEAL INFILTRATION

Perineal infiltration is perhaps the most common local anesthetic technique used for vaginal delivery. Given the frequent failure of pudendal nerve block, obstetricians often perform pudendal nerve block and perineal infiltration simultaneously. Perineal infiltration also may be required in patients with incomplete neuraxial anesthesia. The obstetrician injects several milliliters of local anesthetic solution into the posterior fourchette. There are no large nerve fibers to be blocked, so the onset of anesthesia is rapid. However, perineal infiltration provides anesthesia only for episiotomy and repair. Anesthesia is often inadequate even for these limited procedures. Moreover, perineal infiltration provides no muscle relaxation. In a prospective randomized trial, perineal infiltration of saline-placebo provided postpartum analgesia that was equivalent to that provided by infiltration of either ropivacaine or lidocaine in women who underwent mediolateral episiotomy at vaginal delivery.[82]

Choice of Local Anesthetic

Philipson et al.[83] evaluated the pharmacokinetics of lidocaine after perineal infiltration. They gave 1% or 2% lidocaine without epinephrine during the crowning phase of the second stage of labor in 15 healthy parturients. The mean ± SD dose of lidocaine was 79 ± 3 mg, and the mean drug-to-delivery interval was 7.8 ± 7.0 minutes. The investigators detected lidocaine in maternal plasma as early as 1 minute after injection. Peak maternal plasma concentrations of lidocaine occurred between 3 and 15 minutes after injection. Despite the administration of small doses of lidocaine and the short drug-to-delivery intervals, there was rapid placental transfer of significant amounts of lidocaine. The mean fetal-to-maternal lidocaine concentration ratio of 1.32 was significantly higher than the ratio reported after administration of lidocaine for paracervical block, pudendal nerve block, or epidural anesthesia for vaginal or cesarean delivery. There was a significant correlation between the fetal-to-maternal lidocaine concentration ratio and the length of the second stage of labor. These investigators speculated that fetal tissue acidosis increased the fetal-to-maternal lidocaine ratio after perineal infiltration in this study. Finally, they noted the persistence of lidocaine and its pharmacologically active metabolites for at least 48 hours after delivery.[83]

Subsequently, Philipson et al.[84] evaluated the placental transfer of 2-chloroprocaine after perineal administration of 1% or 2% 2-chloroprocaine to 17 women shortly before delivery. The mean ± SD dose of 2-chloroprocaine was 81.8 ± 27.0 mg, and the mean drug-to-delivery interval was 6.7 ± 4.3 minutes. Perineal infiltration of 2-chloroprocaine provided adequate anesthesia for episiotomy repair except in two patients who required additional local anesthetic for repair of fourth-degree lacerations. The investigators did not detect 2-chloroprocaine in maternal plasma after infiltration or at delivery. Further, they detected 2-chloroprocaine at delivery in only one umbilical cord venous blood sample and no 2-chloroprocaine in neonatal plasma. In contrast, they consistently detected the drug's metabolite, chloroaminobenzoic acid, in maternal plasma, umbilical cord venous plasma, and neonatal urine. The fetal-to-maternal ratio of chloroaminobenzoic acid (0.80) was similar to that reported after the administration of 2-chloroprocaine for paracervical block and epidural anesthesia for cesarean delivery. The investigators suggested that very little, if any, unchanged 2-chloroprocaine reaches the fetus after perineal infiltration. They concluded that 2-chloroprocaine may be preferable to lidocaine for antepartum perineal infiltration.[84]

Complications

The obstetrician must take care to avoid injecting the local anesthetic into the fetal scalp. Kim et al.[85] reported a case of newborn lidocaine toxicity after maternal perineal infiltration of 6 mL of 1% lidocaine before vaginal delivery. Similarly, De Praeter et al.[86] reported a case of lidocaine toxicity in a newborn whose mother received perineal infiltration with 10 mL of 2% lidocaine 4 minutes before delivery. In both cases, the infants were initially vigorous but required endotracheal intubation 15 minutes after delivery. No lidocaine was detected in umbilical cord blood, but neonatal blood samples revealed concentrations of 14 μg/mL at 2 hours and 13.8 μg/mL at 6.5 hours. Small scalp puncture wounds suggested that the lidocaine toxicity resulted from direct fetal scalp injection. Pignotti et al.[87] reported two cases of neonatal local anesthetic toxicity. In one case, lidocaine and prilocaine cream had been applied to the maternal perineum. In the second case, 10 mL of 2% mepivacaine had been injected into the perineum. Both infants required endotracheal intubation and mechanical ventilation, but in both cases, neurodevelopmental outcome was normal at 12 months of age. Kim et al.[85] suggested that the presence of a molded head in the occiput posterior position may predispose to unintentional direct injection of the fetal scalp. These cases support the recommendation for use of 2-chloroprocaine for perineal infiltration.

KEY POINTS

- Paracervical block and lumbar sympathetic block may provide effective analgesia for the first stage of labor. Neither technique relieves pain during the second stage.
- Fetal bradycardia is the most worrisome complication of paracervical block.
- Paracervical block is contraindicated in patients with uteroplacental insufficiency or preexisting fetal compromise.
- For patients without epidural or spinal analgesia, it is appropriate to perform pudendal nerve block when the patient complains of pelvic floor pain.
- Pudendal nerve block may provide satisfactory anesthesia for spontaneous vaginal delivery and outlet-forceps delivery, but it provides inadequate anesthesia for mid-forceps delivery, postpartum repair of the cervix, and manual exploration of the uterine cavity.
- Perineal infiltration provides anesthesia only for episiotomy and repair.
- It is unnecessary—and perhaps dangerous—to give concentrated solutions of local anesthetic for paracervical block, pudendal nerve block, or perineal infiltration.
- Some cases of fetal injury result from direct fetal scalp injection of local anesthetic during attempted paracervical block, pudendal nerve block, or perineal infiltration.
- 2-Chloroprocaine is most likely the safest choice of local anesthetic for paracervical block, pudendal nerve block, and perineal infiltration.
- The performance of either paracervical block or pudendal nerve block requires the obstetrician to make several blind needle punctures within the vagina. Thus, there is a risk for physician needle-stick injury during the performance of either procedure.

Postpartum Tubal Sterilization

Joy L. Hawkins, MD

CHAPTER OUTLINE

Many women choose tubal sterilization for permanent contraception. Of the approximately 700,000 cases performed annually in the United States, data from 1995-2006 found that half were performed postpartum and half as ambulatory interval procedures.[1] Although the interval sterilization rate has declined by 12% in the United States, the postpartum sterilization rate remains stable, and postpartum sterilization is performed after 8% to 9% of all live births.[1] The considerations and controversies regarding the administration of anesthesia for postpartum tubal sterilization are discussed in this chapter.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS GUIDELINES

The American Society of Anesthesiologists (ASA) has published Practice Guidelines for Obstetric Anesthesia,[2] which includes a discussion of postpartum tubal ligation (see Appendix B). The Task Force recommendations can be summarized as follows:

1. Before a postpartum tubal ligation, the patient should have no oral intake of solid foods within 6 to 8 hours of the surgery, depending on the type of food ingested (e.g., fat content).
2. Consider aspiration prophylaxis.
3. Both the timing of the procedure and the decision to use a specific anesthetic technique (i.e., neuraxial versus general) should be individualized, based on anesthetic and obstetric risk factors (e.g., blood loss at delivery), and patient preferences.
4. Consider selecting neuraxial techniques in preference to general anesthesia for most postpartum tubal ligations.
5. Be aware that gastric emptying will be delayed in patients who have received opioids during labor.
6. Be aware that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals.
7. If a postpartum tubal ligation is to be performed before the patient is discharged from the hospital, do not attempt the procedure at a time when it might compromise other aspects of patient care on the labor and delivery unit.

SURGICAL CONSIDERATIONS

Tubal sterilization can be performed satisfactorily at any time, but the early postpartum period has several advantages for women who have had an uncomplicated vaginal delivery.[3] The patient avoids the cost and inconvenience of a second hospital visit. The uterine fundus remains near the umbilicus for several days postpartum, which allows easy access to the fallopian tubes via a mini-laparotomy. Mini-laparotomy and laparoscopy have similar rates of serious complications (e.g., bowel laceration, vascular injury), although postpartum tubal ligation is associated with lower failure rates than interval laparoscopic tubal ligation.[4,5] Finally, costs may be lower with postpartum mini-laparotomy.

There are at least two potential disadvantages to immediate postpartum sterilization. First, parous women are at increased risk for uterine atony and postpartum hemorrhage. This risk decreases substantially 12 hours after delivery. Second, immediate surgery results in sterilization before assessment of the newborn is complete. Postpartum tubal ligation is not wise if the patient is ambivalent regarding permanent sterilization. However, women who undergo postpartum sterilization have a similar probability of regret

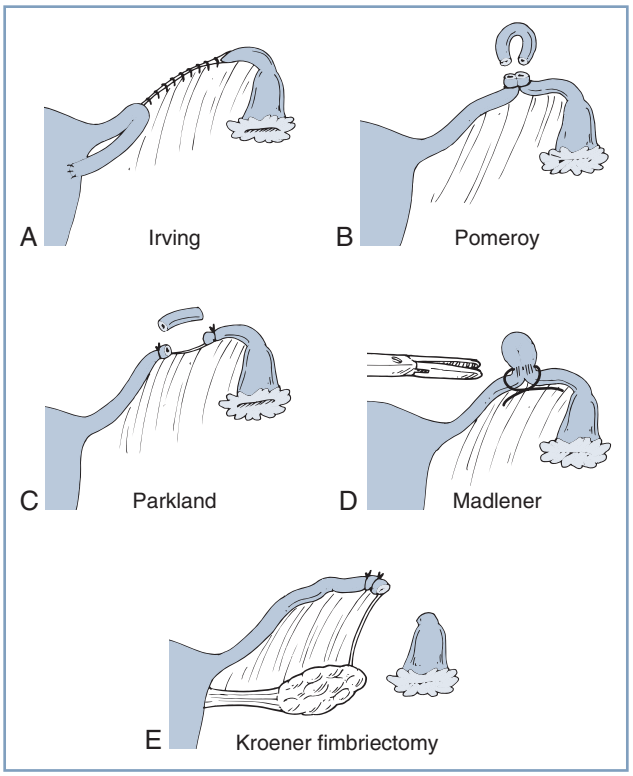

Fig. 25.1 Techniques for tubal sterilization. (A) Irving procedure. The medial cut end of the oviduct is buried in the myometrium posteriorly, and the distal cut end is buried in the mesosalpinx. (B) Pomeroy procedure. A loop of oviduct is ligated, and the knuckle of tube above the ligature is excised. (C) Parkland procedure. A mid-segment of tube is separated from the mesosalpinx at an avascular site, and the separated tubal segment is ligated proximally and distally and then excised. (D) Madlener procedure. A knuckle of oviduct is crushed and then ligated without resection; this technique has an unacceptably high failure rate of approximately 7%. (E) Kroener procedure. The tube is ligated across the ampulla, and the distal portion of the ampulla, including all of the fimbria, is resected; some studies have reported an unacceptably high failure rate with this technique. (From Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics,* 24th ed. Columbus, OH: McGraw-Hill Education; 2014: 720–727.)

within 1 year of delivery (23.7%) as women who undergo interval sterilization (22.3%), although the risk is markedly increased when the woman is younger than 25 years of age.[5] Women should be counseled about failure, regret, and alternatives. Younger age and lower parity should not be a barrier to sterilization.[5]

Several techniques are used for postpartum tubal sterilization (Fig. 25.1).[6] Puerperal sterilization has a failure rate that is lower than most interval procedures, and the failure rate is lowest (approximately 0.75%) if some form of tubal resection occurs.[5,7] With the Irving procedure, the obstetrician buries the cut ends of the tubes in the myometrium and mesosalpinx. This technique is least likely to fail, but it requires more extensive exposure and increases the risk for hemorrhage. The Pomeroy procedure is simplest. The surgeon ligates a loop of oviduct and excises the loop above the suture. With the Parkland procedure, the obstetrician ligates the tube proximally and distally and then excises the mid-segment. The last two methods are most commonly performed during postpartum tubal ligations. Regardless of the technique, the obstetrician should document that fimbriae are present to preclude ligation of another structure such as the round ligament. The excised portions typically are sent to a pathologist for verification. Recently, surgical technique has changed and instead of performing a tubal ligation for sterilization some surgeons are recommending a salpingectomy because bilateral salpingectomy reduces the incidence of ovarian cancer to a greater degree than tubal ligation, and it adds only approximately 10 minutes to the procedure without additional complications.[8]

NONMEDICAL ISSUES

Nonmedical issues affect decisions regarding the timing of tubal sterilization. The obstetrician must obtain and document informed consent for surgery.[5] Tubal ligation should be considered an irreversible procedure. Therefore, most obstetricians require a discussion with the patient before labor and delivery. Physicians should be aware of state laws or insurance regulations that may require a specific interval between obtaining consent and performance of sterilization procedures. Regulations often do not allow the woman to give consent while in labor or immediately after delivery. For example, the Medicaid reimbursement program includes the following requirements for sterilization[9]:

- The patient must be at least 21 years of age and mentally competent when consent is obtained.
- Informed consent may not be obtained while the patient is in labor or during childbirth.
- Consent may not be obtained while the patient is undergoing an abortion or under the influence of alcohol or other substances.
- A total of 30 days must pass between the date the consent is signed and the date the procedure is performed. (Exceptions to the 30-day waiting period can be made for preterm delivery or emergency abdominal surgery.)
- Consent is valid for only 180 days.

An ethical analysis of the Medicaid sterilization consent regulations notes: "…the regulations are ethically flawed: by preventing women from accessing needed family planning services, the Medicaid consent rules violate the standards of beneficence and non-maleficence; by treating publically insured women differently from privately insured women, they fail the justice standard; and by placing constraints on women's free choice of contraceptive methods, they run afoul of the autonomy standard."[10]

In some cases the obstetrician may schedule a patient for a postpartum tubal sterilization because of a fear that the patient will not return for interval tubal sterilization 6 weeks after delivery. Concerns regarding patient compliance should not prompt the performance of postpartum tubal sterilization in patients with significant medical or obstetric complications. However, women who request postpartum tubal sterilization but do not receive it are more likely to become

pregnant within 1 year of delivery (46.7%) than are women who did not request the procedure (22.3%).[11]

The American College of Obstetricians and Gynecologists (ACOG) has stated that given the consequences of a missed procedure and the limited time frame in which it may be performed, postpartum sterilization should be considered an urgent surgical procedure.[12] They also stated that obstetrician-gynecologists should identify and eliminate barriers that restrict access to postpartum sterilization. The ACOG concluded that obstetrician-gynecologists should be champions or patient advocates for postpartum sterilization in their respective hospitals and help to coordinate administration and health care staff in streamlining access to the procedure. Increasing access and availability of postpartum sterilization may not only directly improve outcomes for women desiring the procedure, but may decrease overall costs to the health care system.[12]

PREOPERATIVE EVALUATION

The patient scheduled for postpartum tubal sterilization requires a thorough preoperative evaluation, and a reevaluation should be performed even if the patient is known to the anesthesia provider as a result of the provision of labor analgesia. A cursory evaluation should not be performed simply because the patient is young and healthy. Patients with preeclampsia may safely receive neuraxial or general anesthesia for postpartum tubal sterilization provided that there is no evidence of pulmonary edema, oliguria, or thrombocytopenia.[13]

Physicians and nurses often underestimate blood loss during delivery.[14] Excessive blood loss from uterine atony is not uncommon in parous women. Orthostatic changes in blood pressure and heart rate should be excluded, especially if an immediate postpartum procedure is to be performed. At the University of Colorado, for surgery performed the day after delivery, the patient's hematocrit is determined several hours after delivery (to allow for equilibration) and compared with the antepartum measurement. A hematocrit is not obtained before an immediate postpartum tubal sterilization (performed less than 8 hours after delivery), provided that the antepartum hematocrit was acceptable, there are no orthostatic vital sign changes, and there was no evidence of excessive blood loss during delivery.

No absolute value of hematocrit requires a delay of surgery, but physical signs of hemodynamic instability or laboratory evidence of excessive blood loss should prompt postponement of the procedure until 6 to 8 weeks postpartum. Fever may signal the presence of endometritis or urinary tract infection and may also require postponement of surgery until a later date. Finally, the condition of the neonate should be confirmed before surgery to exclude any unexpected problems.

Mothers may be concerned that medications administered during surgery might affect their ability to breast-feed or that these medications might harm the newborn. Any drug present in the mother's blood will be present in breast milk, with the concentration dependent on factors such as protein binding, lipid solubility, and degree of ionization.[15] Typically, the amount of drug present in breast milk is small. Opioids, barbiturates, and propofol administered during anesthesia are excreted in insignificant amounts. (See Chapter 14 for a detailed discussion of interactions between drugs and breast-feeding.)

RISK FOR ASPIRATION

Historically, anesthesiologists have considered maternal aspiration the major risk associated with anesthesia for postpartum tubal sterilization, although the evidence for this is scant and conflicting. A review of anesthesia-related maternal mortality found no maternal deaths associated with aspiration during postpartum tubal ligation, despite tracking deaths for an entire year after delivery.[16] A review of serious complications related to obstetric anesthesia sponsored by the Society for Obstetric Anesthesia and Perinatology also did not identify any cases of maternal death related to aspiration during postpartum tubal ligation.[17] However, several factors may place the pregnant woman at increased risk for aspiration. Some but not all of these factors are resolved at delivery. The placenta is the primary site of progesterone production, and progesterone concentrations fall rapidly after delivery of the placenta (Fig. 25.2).[18] Typically, progesterone concentrations decline within 2 hours of delivery; and by 24 hours postpartum, progesterone concentrations are similar to those found during the luteal phase of the menstrual cycle.

Two important questions to address during the preanesthetic evaluation are (1) What is the duration of the fast for solids? (2) Were parenteral opioids administered during labor?

Gastric Emptying

Several studies have assessed gastric emptying in pregnant and postpartum women. O'Sullivan et al.[19] used an epigastric impedance technique to compare gastric emptying times for solids and liquids in women during the third trimester of pregnancy, in women during the first hour postpartum, and in nonpregnant controls. The investigators observed that the overall rate of gastric emptying was lower in the postpartum patients than in the pregnant or nonpregnant patients. However, when patients who had received parenteral opioids in labor were separated from those who had not, rates of gastric emptying for women who had not received opioids were similar to those for nonpregnant controls. The investigators concluded that the rate of gastric emptying in postpartum women is delayed only if opioids have been administered during labor.

Other studies have used the acetaminophen (paracetamol) absorption technique to assess gastric emptying. Gin et al.[20] studied women on the first and third days after delivery and at 6 weeks postpartum. They found comparable times to peak concentration of acetaminophen in all three groups. They concluded that gastric emptying was no different in the immediate postpartum period than 6 weeks later, and they

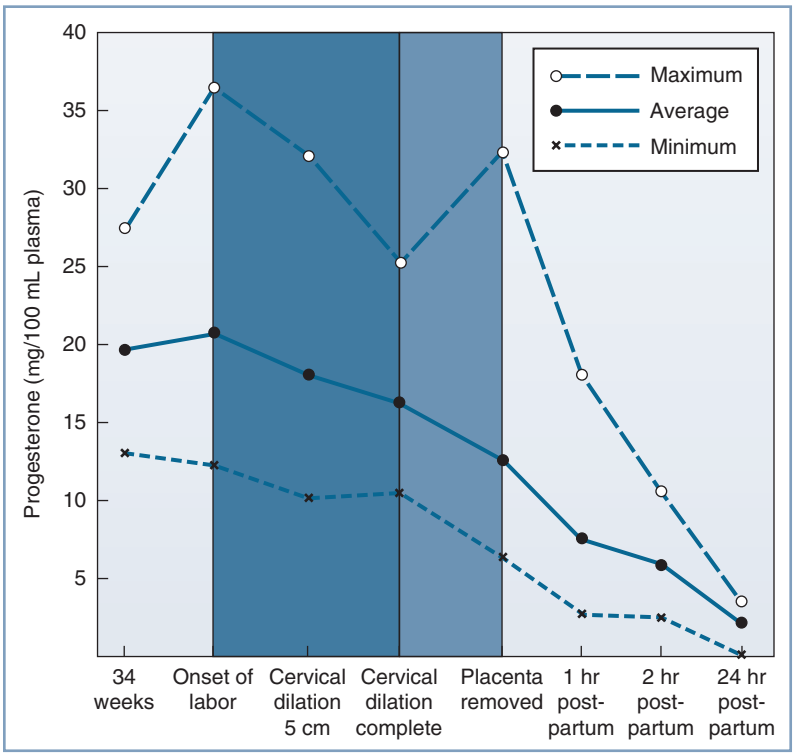

Fig. 25.2 Average progesterone concentrations with the highest and lowest measurements of 13 pregnant women at given time intervals. (From Llauro JL, Runnebaum B, Zander J. Progesterone in human peripheral blood before, during and after labor. *Am J Obstet Gynecol.* 1968;101:871.)

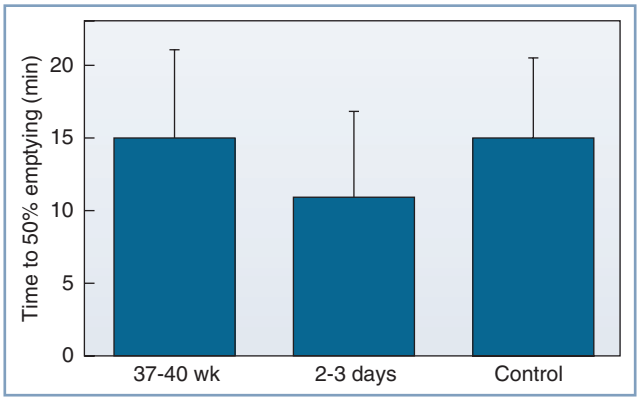

Fig. 25.3 Mean (SEM) times to 50% gastric emptying (min). No significant differences were noted between term pregnant, postpartum, and nonpregnant control women. (From Sandhar BK, Elliott RH, Windram I, Rowbotham DJ. Peripartum changes in gastric emptying. *Anaesthesia.* 1992;47:197.)

recommended that "the approach to prophylaxis against acid aspiration should be more consistent between nonpregnant and postpartum patients."

Sandhar et al.[21] used applied potential tomography to measure gastric emptying in 10 patients at term gestation, 2 to 3 days postpartum, and 6 weeks postpartum. The 6-week measurement served as each woman's control value. All measurements were made after administration of an H_2-receptor antagonist. The times to 50% emptying after ingestion of 400 mL of water were not different among the three periods of testing (Fig. 25.3).

Wong et al.[22] assessed gastric emptying in nonlaboring pregnant women at term gestation, after ingestion of either 50 or 300 mL of water, by using two techniques: (1) serial assessment of acetaminophen absorption and (2) use of ultrasonography to determine gastric antrum cross-sectional areas. Gastric emptying was significantly faster after ingestion of 300 mL of water, consistent with the observation that a liquid meal may actually accelerate gastric emptying. Repeating the study in obese women showed similar results.[23] Kubli et al.[24] compared the effects of isotonic "sport drinks" versus water on residual gastric volume in women in early labor. Women who received isotonic sport drinks had similar gastric volumes and a similar incidence of vomiting as compared with those who received water, but the ingestion of sport drinks prevented the increase in ketone production that occurred in the control (water) group.

In contrast, Jayaram et al.[25] found that 39% of women presenting for postpartum tubal ligation had solid food particles in the stomach, as demonstrated by ultrasonography, but they did not find solid food particles in a control group of nonpregnant women presenting for gynecologic surgery. They also found that 4 hours after a standardized meal in women not scheduled for surgery, 95% of postpartum women—compared with only 19% of nonpregnant subjects—still had solid food particles in the stomach. Prior administration of an opioid did not seem to be a risk factor in this study. Scrutton et al.[26] randomized 94 women presenting in early labor to receive either a light diet or water only during labor. The mothers who ate a light diet had significantly larger gastric antrum cross-sectional areas (determined by ultrasonography) and were twice as likely to vomit at or around delivery as those who had water only. Also, the volumes vomited were significantly larger in the women who ate a light diet.

During the preoperative assessment of any woman scheduled for postpartum tubal sterilization, the anesthesia provider should determine when the patient last consumed solids and whether opioids were administered by any route. Systemic absorption of an opioid occurs after epidural administration. However, published studies have provided conflicting results regarding the effect of epidural opioid administration on gastric emptying. Wright et al.[27] observed that epidural administration of 10 mL of 0.375% bupivacaine with fentanyl 100 μg caused a modest prolongation of gastric emptying during labor when compared with epidural administration of bupivacaine alone. However, Kelly et al.[28] found that intrathecal, but not epidural, fentanyl delayed gastric emptying.

In summary, the preponderance of evidence suggests that (1) administration of an opioid during labor increases the likelihood of delayed gastric emptying during the early postpartum period; (2) gastric emptying of *solids* is delayed during labor and in the immediate postpartum period in all parturients; and (3) gastric emptying of clear liquids is probably not delayed unless parenteral opioids were administered.

Gastric Volume and pH

There is little evidence that postpartum women are at greater risk for sequelae if aspiration occurs than patients undergoing elective surgery, based solely on pregnancy-induced changes in gastric pH and volume. The conventional wisdom is that a gastric volume of more than 25 mL and a gastric pH of less than 2.5 are risk factors for aspiration pneumonitis. Coté[29] noted that this dogma was derived from unpublished animal studies and that it assumes that every milliliter of gastric fluid is directed into the trachea. A marked disparity exists between the incidence of patients labeled "at risk" and the incidence of patients with clinically significant aspiration pneumonitis.

Blouw et al.[30] measured gastric volume and pH in nonpregnant women undergoing gynecologic surgery and postpartum women 9 to 42 hours after delivery. They found no significant difference between the groups. Approximately 75% of women in both groups had a gastric pH of less than 2.5. When the combination of volume and pH was used to determine the risk for aspiration, 64% of the control patients but only 33% of postpartum patients were at risk. The researchers concluded that 8 hours after delivery, postpartum patients are not at greater risk than nonpregnant patients undergoing elective surgery. They did not examine patients earlier than 8 hours after delivery. In addition, they observed that a large number of patients in both groups are at risk based on their gastric volumes and pH.

James et al.[31] attempted to determine the "safe" interval after delivery. They compared gastric pH and gastric volume in postpartum women 1 to 8 hours, 9 to 23 hours, and 24 to 45 hours after delivery with a control group of nonpregnant women undergoing elective surgery. There were no significant differences in either parameter between the group of patients undergoing elective surgery and any of the postpartum groups (Table 25.1). Approximately 60% of all patients were considered "at risk" for aspiration pneumonitis. The investigators concluded that there was no difference in the risk for sequelae if aspiration should occur, but they speculated that hormonal changes or mechanical factors might make aspiration more likely during the postpartum period.

TABLE 25.1 Gastric Volume and pH at Intervals after Delivery

	Volume > 25 mL (%)	pH < 2.5 (%)	At Risk* (%)
Group 1 (1–8 h)	73	100	73
Group 2 (9–23 h)	40	100	40
Group 3 (24–45 h)	73	80	67
Group 4 (control)	67	80	60

*Gastric contents with pH < 2.5 and volume > 25 mL.
From James CF, Gibbs CP, Banner T. Postpartum perioperative risk of aspiration pneumonia. *Anesthesiology*. 1984;61:756-759.

Finally, Lam et al.[32] administered 150 mL of water to 50 women 2 to 3 hours before tubal ligation that was performed 1 to 5 days postpartum. Another 50 postpartum and 50 nonpregnant women fasted after midnight. The authors found no differences in gastric pH or volume among the postpartum-water group, the postpartum-fasted group, and the group of nonpregnant controls undergoing elective surgery.

Gastroesophageal Reflux

Women in the third trimester of pregnancy have decreased lower esophageal barrier pressures as compared with nonpregnant controls.[33] Those with symptoms of heartburn have even lower pressures and a higher incidence of gastric reflux. Vanner and Goodman[34] asked parturients to swallow a pH electrode to measure lower esophageal pH at term and on the second postpartum day. Patients were placed in four positions: supine with tilt, left lateral, right lateral, and lithotomy, and were then asked to perform a Valsalva and other maneuvers to promote reflux. A total of 17 of 25 patients had reflux at term, whereas only 5 of 25 had reflux after delivery. The investigators concluded that the incidence of reflux returns toward normal by the second day after delivery. However, this conclusion is arguable given the fact that they did not determine *normal* by defining the incidence of reflux before or 6 to 8 weeks after pregnancy.

Summary of Aspiration Risk

No data indicate that the postpartum patient's safety is enhanced by delaying surgery or is compromised by proceeding with surgery immediately after delivery. This situation has led to confusion and inconsistency in the development of policies for the performance of postpartum tubal sterilization.[35] No particular waiting interval guarantees that the postpartum patient is free of risk for aspiration. It is probably

prudent to use some form of aspiration prophylaxis in all patients undergoing postpartum tubal sterilization. However, significant aspiration pneumonitis is so rare that it will be difficult to document cost-effectiveness and decreased rates of morbidity and mortality from the use of these measures. H_2-receptor antagonists and antacids do not reduce the possibility of regurgitation and aspiration, but they may make the consequences less severe. Metoclopramide (a prokinetic agent) may decrease the incidence of reflux by increasing lower esophageal sphincter tone and hastening gastric emptying.[33] None of these medications can guarantee that gastric contents will not enter the lungs. Aspiration is best prevented by an experienced anesthesia provider using careful airway management or by use of a neuraxial anesthetic technique.

Performance of an immediate postpartum tubal sterilization (within 8 hours of delivery) may decrease both length of hospital stay and hospital costs. In this era of health care cost-containment, any decision to postpone surgery that requires an extra day of hospitalization must be evaluated carefully. Anesthesia providers and obstetricians have questioned the need to wait 8 or more hours after delivery if gastric emptying time and gastric volume and pH are no different in the postpartum patient from those in nonpregnant women. Possible reasons to consider an 8-hour delay are as follows. First, women may remain at increased risk for gastroesophageal reflux immediately after delivery. Second, delays in gastric emptying due to the antepartum administration of opioids will resolve during this period. Third, an 8-hour delay allows the administration of aspiration prophylaxis drugs, although they might also be given during labor. Fourth, maximal hemodynamic stress and potential instability occur immediately postpartum when central blood volume suddenly increases because of contraction of the evacuated uterus, relief of aortocaval compression, and loss of the low-resistance placental circuit; indeed, the patient with cardiovascular disease is at greatest risk for hemodynamic decompensation immediately postpartum. Fifth, if there are concerns about excessive blood loss at delivery, an 8-hour delay allows the physician to assess serial hemodynamic measurements (including the presence or absence of orthostatic changes), obtain an equilibrated postpartum hematocrit, and, if necessary, restore intravascular volume. Sixth, delay allows a more thorough evaluation of the infant. Finally, delay allows the woman more time to assess her decision. However, it is important to remember that women who request postpartum tubal sterilization but do not receive it before discharge from the hospital are twice as likely to become pregnant within 1 year of delivery than women who did not request the procedure.[11] The ACOG has stated that given the consequences of a missed procedure, postpartum sterilization should be considered an urgent surgical procedure.[12]

At the University of Colorado, we follow standard NPO guidelines (i.e., no solid foods for 6 to 8 hours [depending on fat content] and no clear liquids for 2 hours) before postpartum tubal sterilization. NPO policies for postpartum tubal sterilization should not differ from those used for elective surgery in the main operating rooms. Immediate postpartum tubal sterilization may be performed in patients who have a functioning epidural catheter in place. These patients are given an H_2-receptor antagonist and metoclopramide intravenously during labor or immediately after delivery, and a clear (nonparticulate) antacid is administered just before taking the patient to the operating room. In other patients who do not want (or are unable to receive) epidural analgesia for labor, similar precautions are used. This is an elective procedure, and patients should not have consumed solid food for 6 to 8 hours preoperatively. Before surgery, estimated blood loss is reviewed and orthostatic vital signs may be assessed. Most of these patients (without preexisting epidural analgesia) receive spinal anesthesia for postpartum tubal sterilization. However if the patient strongly prefers, general anesthesia can be provided using rapid-sequence induction with cricoid pressure.

ANESTHETIC MANAGEMENT

Local, general, or neuraxial anesthesia may be used successfully for postpartum tubal sterilization. Physiology remains altered in the postpartum patient and requires some modification in anesthetic technique. It seems reasonable to give all postpartum patients some form of aspiration prophylaxis.[2] This may include a clear (nonparticulate) antacid, an H_2-receptor antagonist, and/or metoclopramide to increase lower esophageal sphincter tone and hasten gastric emptying. Metoclopramide also may prevent emesis during and after surgery. Patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes mellitus) warrant prophylaxis with all three classes of drugs. Tubal sterilization does not require administration of preoperative antibiotics.[36]

Local Anesthesia

Local anesthesia is used for more than 75% of tubal sterilizations worldwide, although neuraxial anesthesia is most often administered for postpartum tubal sterilization in the United States.[3] Several reports have documented the efficacy and safety of local anesthesia for postpartum or laparoscopic tubal ligation in the hospital operating room or a free-standing outpatient facility. Cruikshank et al.[37] described the use of intraperitoneal lidocaine for postpartum tubal ligation. After intravenous administration of diazepam, lidocaine 100 mg was used to infiltrate the skin and subcutaneous tissue. The peritoneum was entered, and 400 mg of lidocaine (80 mL of 0.5% solution) was instilled into the peritoneal cavity. A Pomeroy tubal ligation was performed 5 minutes later. All patients had complete peritoneal anesthesia, and all patients stated they would have the same procedure again. None recalled any pain or discomfort 24 hours later. There were no signs of lidocaine toxicity in any patient, and the maximum lidocaine blood level obtained was 5.3 μg/mL (the toxic blood level is generally considered greater than 5 μg/mL). Surgeons rated the conditions excellent. This study was published in 1973, when anesthesiologists may or may not have been involved and before ASA monitoring standards such as pulse oximetry existed.

Poindexter et al.[38] described almost 3000 *laparoscopic* tubal sterilization procedures performed with local anesthesia in an ambulatory surgical facility. After intravenous sedation with midazolam (5 to 10 mg) and fentanyl (50 to 100 μg), the skin was infiltrated with 10 mL of 0.5% bupivacaine. After insertion of the trocar, the abdomen was insufflated with nitrous oxide. Each tube was sprayed with 5 mL of 0.5% bupivacaine, and a Silastic ring was applied. Patients were discharged home after approximately 1 hour in the postanesthesia care unit. The authors reported a technical failure rate of 0.14% and no unintended laparotomies or intraoperative complications. They reported that this technique reduced surgical time by 33% and cost by 68% to 85% when compared with general anesthesia. The investigators presented no data regarding patient satisfaction, and they made no comment on the use of pulse oximetry or blood pressure monitors. Four percent of patients, however, required oxygen therapy for "adequate tissue perfusion." This study was done in the 1980s, before many ambulatory surgery facilities had institutional guidelines for sedation.

General Anesthesia

Much of the impetus for performing sterilization procedures under local anesthesia came from two reports in 1983 indicating that morbidity and mortality were much higher when general anesthesia was used. It is important to realize that these reports preceded the mandatory use of pulse oximetry and capnography and do not reflect modern anesthesia care. The first report involved 3500 interval (not postpartum) laparoscopic tubal sterilizations at nine university medical centers.[39] Among all patients, the risk for intraoperative or postoperative complications was 1.75%, but the risk was five times higher with general anesthesia than with local anesthesia. (In this report, local anesthesia included local, epidural, and spinal anesthesia.) The reason(s) for the difference was unclear. In the second report, the U.S. Centers for Disease Control and Prevention examined deaths attributed to tubal sterilization procedures from 1977 to 1981.[40] Both immediate postpartum laparotomies and interval laparoscopic procedures were included. Of the 29 deaths, 11 followed complications of general anesthesia and were caused by hypoventilation or cardiorespiratory arrest. Aspiration was not reported as a cause of death. Of the six patients whose deaths were definitely attributed to hypoventilation, none had undergone tracheal intubation. Five of the 11 deaths attributed to general anesthesia occurred during postpartum laparotomy. Of these, only one woman had undergone tracheal intubation; all others underwent mask ventilation. The investigators concluded, "It appears that for tubal sterilization, like abortion, the greatest risk for death is that associated with the anesthesia used during the procedure."[40]

In the 35 years since those reports, appropriate airway management with tracheal intubation has become standard practice. Thorough adherence to ASA standards for basic anesthesia monitoring (including use of pulse oximetry and capnography to monitor oxygenation and ventilation) should help reduce morbidity and mortality associated with general anesthesia. At the University of Colorado, rapid-sequence induction (with cricoid pressure) is performed and all patients undergo tracheal intubation during administration of general anesthesia for postpartum tubal sterilization.

Volatile anesthetic agents cause uterine relaxation and could potentially increase the risk for postpartum hemorrhage if administered to women in the immediate postpartum period. Therefore, the question arises as to whether the anesthesia provider should use an inhalation or an intravenous technique to maintain general anesthesia for postpartum tubal sterilization. Marx et al.[41] measured postpartum uterine activity and the response to oxytocin with different concentrations of halothane or enflurane (Fig. 25.4). Impairment of spontaneous uterine activity occurred at 0.5 minimum alveolar concentration (MAC) of both agents, and loss of the response to oxytocin occurred near 1 MAC. Spontaneous contractions reappeared when anesthetic concentrations were reduced below these levels. Parous women are at risk for postpartum uterine atony, and administration of a high concentration of a volatile halogenated agent may precipitate postpartum hemorrhage.

Two studies have determined the MAC of isoflurane during the postpartum period. Chan and Gin[42] found a positive correlation between MAC and the length of time after delivery, with nonpregnant values achieved by 72 hours postpartum. Zhou et al.[43] determined that the MAC of isoflurane was approximately 0.75% in the first 12 hours postpartum and 1.04% in patients who were 12 to 24 hours postpartum. No significant difference in MAC existed between the latter group and a control group of nonpregnant gynecologic patients. Together these results demonstrate that the reduced MAC observed during pregnancy persists for a variable period between 12 and 36 hours postpartum.

Propofol has advantages (e.g., rapid awakening, decreased incidence of emesis) that make it attractive as an induction agent for short sterilization procedures. When propofol was used for induction and maintenance of anesthesia for cesarean delivery, breast milk samples obtained at 4 and 8 hours postpartum had a low concentration of the drug, which suggested a negligible newborn exposure to propofol.[44] Use of sodium thiopental for induction of anesthesia also results in negligible newborn exposure during subsequent breast-feeding.

Alterations occur in the activity of both depolarizing and nondepolarizing muscle relaxants during the postpartum period. Evans and Wroe[45] described the changes in plasma cholinesterase activity during pregnancy. A rapid decline in activity occurred during the first trimester. This low level of activity was maintained until delivery and was followed by an even lower level of activity during the first week postpartum. Ganga et al.[46] found that a lower dose of succinylcholine was required to achieve 80% twitch suppression in postpartum women than in nonpregnant women. Time to recovery also was prolonged and correlated with lower cholinesterase activity in the postpartum patients. Leighton et al.[47] studied four groups of patients: nonpregnant, nonpregnant using oral contraceptives, term pregnant, and postpartum women.

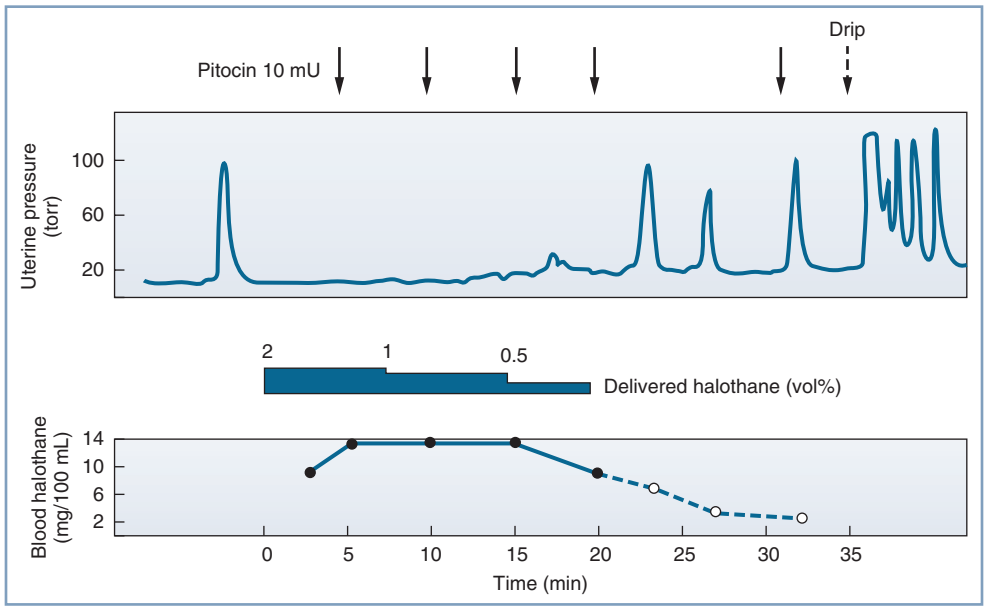

Fig. 25.4 Halothane anesthesia blocked the normal response to oxytocin when arterial blood levels exceeded 10.5 mg/100 mL or approximately 0.8 MAC. (From Marx GF, Kim YI, Lin CC, et al. Postpartum uterine pressures under halothane or enflurane anesthesia. *Obstet Gynecol.* 1978; 51:697.)

Cholinesterase activity was significantly lower in both term pregnant and postpartum women. Recovery time was 25% longer in the postpartum patients than in other groups (685 seconds versus approximately 500 seconds). Although a 3-minute prolongation of paralysis may not seem clinically significant, it could be important if airway difficulties occur.[47] Metoclopramide prolongs neuromuscular block with succinylcholine by 135% to 228% because of its inhibition of plasma cholinesterase.[48] Ranitidine does not affect either plasma cholinesterase activity or the duration of action of succinylcholine.[49]

Several studies have evaluated the use of the nondepolarizing muscle relaxants rocuronium, mivacurium, vecuronium, atracurium, and cisatracurium in postpartum patients. Rocuronium's duration of action is prolonged by approximately 25% in postpartum patients,[50] and mivacurium's duration of action is prolonged by approximately 20%.[51] In postpartum patients, the duration of action of vecuronium is prolonged by more than 50%.[51] In contrast, the duration of action for atracurium is unchanged[52] (Fig. 25.5) and that of cisatracurium is significantly shorter in the postpartum period.[53] Prolongation of neuromuscular block could be clinically significant during a short procedure. Khuenl-Brady et al.[52] suggested that a relative decrease in hepatic blood flow and/or competition between vecuronium and steroid hormones for hepatic uptake may interfere with the hepatic clearance of vecuronium in postpartum women. Alternatively, Gin et al.[54] concluded that the duration of action for rocuronium is not prolonged in postpartum women if lean body mass—rather than total body weight—is used to calculate dose. These researchers speculated that the prolonged duration noted earlier[50] might be explained by relative drug overdose if the dose of rocuronium is based on the patient's

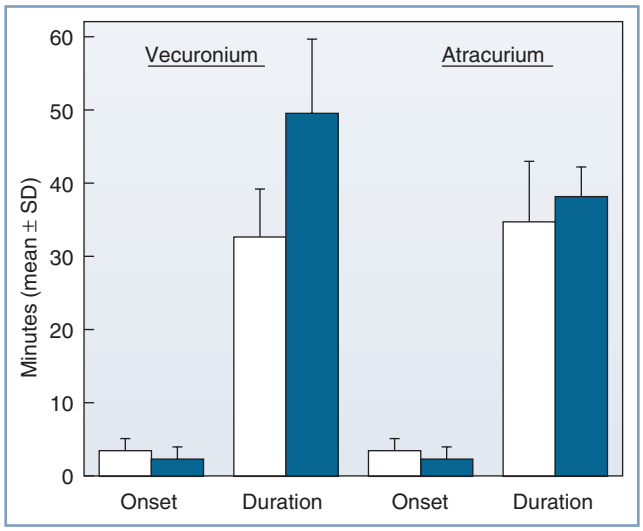

Fig. 25.5 Onset and duration of action of vecuronium (0.1 mg/kg) and atracurium (0.5 mg/kg) in postpartum *(solid bar)* and nonpregnant control *(open bar)* patients. $P < .001$ for duration of vecuronium in postpartum compared with nonpregnant patients. (From Khuenl-Brady KS, Koller J, Mair P, et al. Comparison of vecuronium- and atracurium-induced neuromuscular blockade in postpartum and nonpregnant patients. *Anesth Analg.* 1991;72:112.)

temporarily increased body weight.[54] Sugammadex has been used to reverse neuromuscular blockade with rocuronium after cesarean delivery, and it can be used to reverse neuromuscular blockade after postpartum tubal sterilization as well. Data from adult patients having abdominal surgery showed that sugammadex reversal, when compared to reversal with neostigmine, shortened the time until the patient was ready for discharge from the operating room and eliminated residual neuromuscular blockade in the PACU.[55]

Neuraxial Anesthesia

Spinal and epidural anesthesia both provide excellent operating conditions for postpartum tubal sterilization. Airway obstruction, hypoventilation, and aspiration are much less likely during and after neuraxial anesthesia. A sensory level of T4 is needed to block visceral pain during exposure and manipulation of the fallopian tubes. The choice between spinal and epidural anesthesia is a matter of personal preference for the patient and the anesthesia provider.

Epidural Anesthesia

When the performance of postpartum tubal sterilization is anticipated in a parous patient, I encourage administration of epidural analgesia for labor and delivery. The epidural anesthetic can be extended for immediate postpartum tubal sterilization if appropriate. I avoid administration of parenteral opioids during labor if immediate postpartum tubal sterilization is planned. Immediate postpartum tubal sterilization may save the patient the cost and inconvenience of an extra day in the hospital, allow her to eat shortly after delivery (and surgery), and enable her to avoid the apprehension of undergoing a surgical procedure the following day. The avoidance of opioids helps maintain normal gastric emptying, which should decrease any risk for aspiration during postpartum surgery. If the patient is stable and personnel are available, the procedure may be performed soon after delivery. The obstetrician must exclude excessive intrapartum blood loss and document that the patient has given informed consent.[5] The patient should also be asked whether the epidural catheter provided adequate analgesia for her delivery. A catheter that was inadequate for labor analgesia is unlikely to provide adequate surgical anesthesia.

At the time the patient is moved to the operating room, an epidural test dose is given to rule out intrathecal or intravascular migration of the epidural catheter, and the sensory level is extended with a concentration of local anesthetic suitable for surgical anesthesia. A short-acting local anesthetic (e.g., 3% 2-chloroprocaine) is usually appropriate because the procedure is short in duration. An alternative choice is 2% lidocaine with epinephrine 1:200,000, although this may prolong her PACU stay while the block resolves. The addition of 100 µg epidural fentanyl may also improve the quality of the block. Appropriate sedative drugs also may be given, if the patient requests.[56]

If surgery is not performed immediately after delivery, the catheter may be left in place for later postpartum tubal sterilization. Several studies have evaluated the efficacy of using a previously placed epidural catheter for a tubal ligation performed several hours after delivery. Vincent and Reid[57] found that the mean delivery-to-surgery interval was shorter in those patients who had adequate epidural anesthesia than in those without adequate anesthesia (10.6 versus 14.8 hours). The chance of successful epidural anesthesia was greatest if the catheter was used within 4 hours of delivery. In contrast, Lawlor et al.[58] reported an 87% success rate using an indwelling epidural catheter for postpartum tubal ligation, and they observed no difference in the catheter placement-to-surgery interval between the successful epidural and failed epidural groups (21.4 versus 20.5 hours). In this study, each epidural catheter was threaded 4 to 7.5 cm into the epidural space. Similarly, Goodman and Dumas[59] reported an overall success rate of 92% with the use of an indwelling epidural catheter for postpartum tubal ligation. The success rate was 93% among patients who underwent surgery less than 24 hours after delivery but only 80% among the 10 patients who underwent surgery more than 24 hours after delivery (Fig. 25.6). This difference was not significant; however, this study lacked sufficient power to identify a difference of this magnitude. Clinical experience suggests that if the anesthesia provider uses an epidural catheter placed for labor, the risk for anesthesia failure may be greater if surgery is delayed more than 10 hours after delivery. To ensure maximal success when using a multi-orifice catheter, the anesthesia provider should thread the catheter 4 to 6 cm into the epidural space and have the patient assume a deflexed position before taping the catheter to the skin.[60,61]

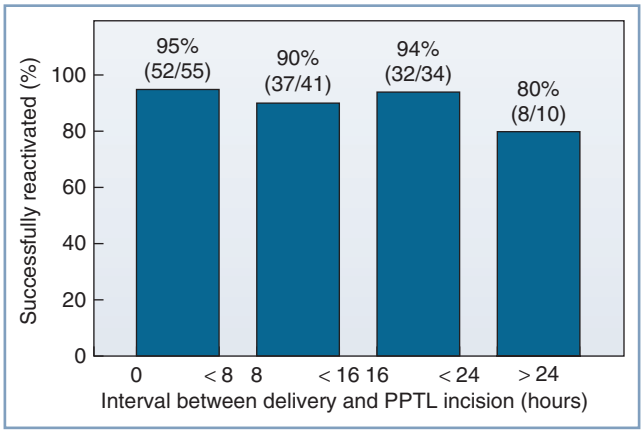

Fig. 25.6 Rate of successful reactivation of epidural catheters for various intervals between delivery and the incision for postpartum tubal ligation (PPTL). There was no difference among groups in the success rate. (From Goodman EJ, Dumas SD. The rate of successful reactivation of labor epidural catheters for postpartum tubal ligation surgery. *Reg Anesth Pain Med.* 1998;23:260.)

Spinal Anesthesia

Spinal anesthesia for postpartum tubal sterilization has several advantages over epidural anesthesia. Epidural anesthesia requires the use of a large volume of concentrated local anesthetic and thereby introduces the risk for intravascular injection and cardiotoxicity.[62] Epidural anesthesia also is time-consuming; the induction of epidural anesthesia may require more time than the tubal sterilization itself. Spinal anesthesia is simple to perform, is rapid in onset, and provides dense sensory and motor block. In one study, spinal anesthesia for postpartum tubal ligation was associated with lower professional fees and operating room charges than attempted reactivation of an epidural catheter placed during labor.[63] There is no need to reinject a catheter intraoperatively for a short procedure such as postpartum tubal sterilization, and

TABLE 25.2 Risk for Post–Dural Puncture Headache after Spinal and Epidural Anesthesia in Obstetric Patients

Needle Used[a]	Number of Anesthetics	Incidence of PDPH (%)	Patients with PDPH Who Required Epidural Blood Patch (%)
Quincke 26-gauge	2256	5.2	33
Quincke 27-gauge	852	2.7	39
Whitacre 25-gauge	1000	1.2	13
Epidural 17-gauge	21,578	1.3	75

PDPH, Post–dural puncture headache.
Quincke needles have a cutting bevel. Whitacre needles have a pencil-point tip.
[a]There was a significant difference in the incidence of post–dural puncture headache between the 26-gauge Quincke needle and the epidural needle ($P < .05$), but not between the Whitacre needle or the 27-gauge Quincke needle and the epidural needle.
Data from Lambert DH, Hurley RJ, Hertwig L, Datta S. Role of needle gauge and tip configuration in the production of lumbar puncture headache. *Reg Anesth.* 1997;22:66–72.

there is no need for prolonged postoperative analgesia. The risk for post–dural puncture headache is low if a small-gauge (25- or 27-gauge) pencil-point or noncutting spinal needle is used. Indeed, some studies have suggested that the incidence of post–dural puncture headache in obstetric patients is no different after spinal anesthesia with a 25-gauge Whitacre needle from that after planned epidural anesthesia (Table 25.2).

Local anesthetic requirements for spinal and epidural anesthesia are decreased during pregnancy, but studies have demonstrated a return to nonpregnant requirements by 36 hours postpartum. Assali and Prystowsky[64] demonstrated a return to nonpregnant requirements by 36 to 48 hours postpartum. Abouleish[65] prospectively compared the dose of spinal bupivacaine required for cesarean delivery with that required for postpartum tubal ligation. He noted that 30% more bupivacaine was required to achieve a T4 dermatomal level in women who were 8 to 24 hours postpartum. The reason for the rapid decrease in sensitivity to local anesthetics is unclear but may be related to the rapid fall in progesterone levels after delivery of the placenta.

Datta et al.[66] examined plasma and cerebrospinal fluid (CSF) progesterone concentrations and spinal lidocaine requirements in nonpregnant, term pregnant, and postpartum women 12 to 18 hours after delivery. Plasma progesterone levels in pregnant women were 60 times higher than in nonpregnant women but only seven times higher than those in postpartum women. CSF progesterone concentrations were eight times higher in term pregnant women and three times higher in postpartum women than in nonpregnant women. Intrathecal lidocaine requirements were similar in pregnant and postpartum patients, even though plasma and CSF progesterone concentrations were lower in the postpartum women. The authors suggested "that a minimum level of progesterone in the CSF and/or plasma is necessary for this heightened local anesthetic activity" associated with progesterone. Together these studies suggest that local anesthetic requirements return to nonpregnant requirements 12 to 36 hours after delivery.[64–66]

Huffnagle et al.[67] gave hyperbaric intrathecal lidocaine 75 mg to postpartum women to determine whether age, weight, height, body mass index, vertebral column length, or time from delivery to placement of the block correlated with the spread of sensory block. Only patient height had a weak positive correlation, and it accounted for less than 15% of the variance in height of the block. Because of the large variation in the spread of sensory block among patients of the same height, the investigators concluded that there was little use in adjusting the dose of local anesthetic on the basis of height.

Many anesthesia providers have discontinued the use of hyperbaric lidocaine for spinal anesthesia because of concern about transient neurologic symptoms or transient radicular irritation, but obstetric patients may be at lower risk for this complication. A prospective nonrandomized study of 303 obstetric patients who received spinal anesthesia during a 9-month period observed a 0% incidence of transient radicular irritation (95% confidence interval 0% to 4.5%).[68] Patients underwent a variety of procedures, including cesarean delivery, postpartum tubal ligation, cerclage, and other cases. The number of patients was too small to determine the true incidence of transient radicular irritation in obstetric patients, but the investigators concluded that the true incidence is likely less than 5%. In a randomized controlled trial, Philip et al.[69] compared spinal administration of hyperbaric 5% lidocaine with that of hyperbaric 0.75% bupivacaine for postpartum tubal ligation. They observed a 3% incidence of transient neurologic symptoms with the use of lidocaine, compared with a 7% incidence with bupivacaine, a nonsignificant difference. In an editorial accompanying their report, Schneider and Birnbach[70] acknowledged that "there are no very short-acting hyperbaric spinal local anesthetics that have taken the place of lidocaine for these short procedures and many believe that spinal bupivacaine lasts too long to be a reasonable choice of anesthetic for a procedure that will last less than 20 minutes." However, they concluded, "Because pregnant patients represent a population that lies to the extreme in terms of the criteria for safety and lack of morbidity, we believe that for the present, there is still insufficient safety evidence to suggest that spinal hyperbaric 5% lidocaine be routinely used in obstetrics." At the University of Colorado, some anesthesia providers use 5% lidocaine because of its short duration of action, whereas others prefer to avoid spinal lidocaine despite the low risk for transient neurologic symptoms in obstetric patients.

Postpartum women seem to be at lower risk for hypotension during spinal anesthesia than pregnant women, and

maintenance of uteroplacental perfusion is not a concern after delivery. Abouleish[65] gave ephedrine to correct maternal hypotension in 83% of pregnant women who received spinal bupivacaine anesthesia for cesarean delivery. In contrast, only 7% of postpartum women who received spinal anesthesia for tubal ligation required ephedrine. An autotransfusion of blood occurs immediately after delivery. The greater intravascular volume and the lack of aortocaval compression may help protect postpartum patients from hypotension during spinal anesthesia. Sharma et al.[71] compared the use of crystalloid with the use of 6% hetastarch for the prevention of hypotension during spinal anesthesia for postpartum tubal ligation. They observed a 52% incidence of hypotension in the crystalloid group and a 16% incidence in the hetastarch group. However, they acknowledged that the greater expense of colloid, as well as the risk for an allergic reaction, might not be justifiable. Suelto et al.[72] compared normotensive and hypertensive patients receiving hyperbaric lidocaine for postpartum tubal ligation and found no difference in the use or dose of ephedrine for treatment of hypotension.

Preservative-free intrathecal meperidine can be used as an alternative to local anesthetic for postpartum tubal sterilization. The typical dose is 1 mg per kilogram prepregnant weight (50 to 80 mg) for cesarean delivery or tubal sterilization. With an onset time of 3 to 5 minutes and a duration of 30 to 60 minutes, intrathecal meperidine compares favorably with 5% lidocaine. In a study that compared intrathecal lidocaine 70 mg with intrathecal meperidine 60 mg for postpartum tubal ligation, patients who received meperidine had more pruritus but longer postoperative analgesia (448 versus 83 minutes, respectively).[73] There was no difference between groups in rates of nausea, hemoglobin desaturation, or patient satisfaction. Intrathecal meperidine may be an alternative to lidocaine or bupivacaine for postpartum tubal sterilization.

Box 25.1 summarizes anesthetic management for postpartum tubal sterilization.

BOX 25.1 Anesthetic Management for Postpartum Tubal Sterilization

Management During Labor

- Encourage use of epidural analgesia.
- Avoid administration of parenteral opioids.
- Keep patient on *nil per os* (NPO) status except for clear liquids.
- Give aspiration prophylaxis if the procedure is to be performed immediately after delivery.

Timing of Surgery

- Consider performing surgery immediately postpartum if the patient is hemodynamically stable and has received aspiration prophylaxis.
- An epidural catheter placed for labor may provide more reliable anesthesia if used within 10 hours of delivery.

General Anesthesia

- Perform a rapid-sequence induction with cricoid pressure.
- Intubate the trachea and control ventilation.
- Avoid high concentrations (greater than 0.5 minimum alveolar concentration [MAC]) of a volatile anesthetic agent.
- Monitor neuromuscular blockade if a nondepolarizing muscle relaxant is used.

Epidural Anesthesia

- Requires a T4 sensory level of anesthesia.
- After a negative test dose result, consider using 3% 2-chloroprocaine unless a longer procedure is planned.
- If a catheter placed during labor is used, beware of a higher risk for failure if the delivery-to-surgery interval is prolonged more than 10 hours.
- Give fentanyl 50 to 100 µg via the epidural catheter for intraoperative and postoperative analgesia.

Spinal Anesthesia

- Requires a T4 sensory level of anesthesia.
- It is the preferred technique for delayed postpartum tubal sterilization, or for immediate surgery in patients who did not have epidural labor analgesia, or in whom epidural analgesia during labor and delivery was ineffective.
- Use a small-gauge, noncutting, pencil-point spinal needle.
- Give lidocaine 75 mg with fentanyl 10 to 25 µg or bupivacaine 10 to 12 mg with fentanyl 10 to 25 µg.

Postoperative Pain Management

- Consider infiltration of the skin and the mesosalpinx with bupivacaine.
- Administer a nonsteroidal anti-inflammatory drug such as ketorolac or ibuprofen perioperatively.
- Begin oral analgesics before complete block regression after spinal or epidural anesthesia.

POSTOPERATIVE ANALGESIA

Postpartum tubal sterilization produces modest postoperative pain of short duration. Patients may receive one dose of parenteral opioid postoperatively, followed by oral analgesics. Optimal analgesia encourages early ambulation, interaction with the newborn, and early discharge from the hospital. An oral nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen may be given to supplement other analgesics. When epinephrine 0.2 mg was added to lidocaine with fentanyl 10 µg for spinal anesthesia, the duration of complete and effective analgesia was prolonged and the incidence of pruritus was decreased, but the time to complete motor recovery was also prolonged.[74] Habib et al.[75] reported that adding intrathecal morphine 0.05 mg to intrathecal bupivacaine and fentanyl for postpartum tubal ligation resulted in less intense pain at rest and with movement at 4 hours after surgery than with saline control. However, patients who received morphine had more vomiting and pruritus. Despite side effects, patients who received morphine were significantly more satisfied. Similarly, Marcus et al.[76] found that epidural morphine 2 mg provided better analgesia without increasing the need to treat side effects, in comparison with a regimen of oral opioids and NSAIDs without epidural morphine. Although effective, spinal and epidural morphine analgesia should be used with caution because these patients could be

discharged within hours after postpartum tubal sterilization, before the risk for delayed respiratory depression has lapsed. The method of postoperative analgesia chosen should not delay patient discharge because of side effects or the need for postoperative respiratory monitoring.

Local anesthetic infiltration of the mesosalpinx with bupivacaine or topical application of a local anesthetic to the fallopian tubes significantly decreases opioid requirements postoperatively.[77] These are simple, rapid techniques that can be used by the obstetrician. A systematic review and meta-analysis of the application of topical or injectable local anesthetic during laparoscopic tubal ligation found that use of local anesthetic decreased pain substantially for up to 8 hours after surgery.[78] NSAIDs also improve postoperative pain control. The manufacturer of ketorolac has stated that ketorolac is contraindicated in nursing mothers because of the possible adverse effects of prostaglandin synthetase inhibitors including ductal closure and gastrointestinal bleeding on neonates. In contrast, the American Academy of Pediatrics considers NSAIDs to be compatible with breast-feeding.[79]

KEY POINTS

- Postpartum tubal sterilization is an elective procedure. No data indicate that the postpartum patient's safety is enhanced by a delay of surgery or compromised by the performance of tubal sterilization immediately after delivery.
- Postpartum tubal sterilization (versus interval laparoscopic tubal sterilization) offers several advantages including convenience for the patient and technical simplicity for the surgeon.
- Postpartum patients do not have lower gastric pH or higher gastric volumes than nonpregnant patients undergoing elective surgery. Some studies suggest that gastric emptying is delayed postpartum only if the patient has received opioid analgesics during labor.
- The incidence of gastroesophageal reflux returns toward normal by the second postpartum day.
- Modern anesthetic drugs do not appear in breast milk in amounts that affect the newborn.
- The duration of succinylcholine-, rocuronium-, mivacurium-, and vecuronium-induced neuromuscular blockade is prolonged during the postpartum period. In contrast, the duration of action for atracurium is unchanged and that of cisatracurium is shorter.
- An epidural catheter placed for labor may be used for postpartum tubal sterilization, but the risk for failure to provide adequate surgical anesthesia may be greater if surgery is delayed more than 10 hours after delivery.
- Spinal anesthesia is preferred for delayed postpartum tubal sterilization (greater than 10 hours after delivery), regardless of whether an epidural catheter was placed for labor analgesia.
- The local anesthetic dose for spinal anesthesia returns to nonpregnant requirements by 12 to 36 hours postpartum.
- Postoperative multimodal analgesia including local anesthetic infiltration improves maternal mobilization and infant bonding and may facilitate earlier hospital discharge.

Anesthesia for Cesarean Delivery

Lawrence C. Tsen, MD, Brian T. Bateman, MD, MSc

CHAPTER OUTLINE

HISTORY

Cesarean delivery is defined as the birth of an infant through incisions in the abdomen (laparotomy) and uterus (hysterotomy). Although the technique is commonly associated with the birth of the Roman Emperor Julius Caesar, medical historians question this possibility, given his birth in an era (100 BC) when such operations were invariably fatal and the acknowledged presence of Caesar's mother in his later life.[1]

Morbidity and mortality, most often associated with hemorrhage and infection, limited the use of cesarean delivery until the 20th century, when advances in aseptic, surgical, and anesthetic techniques improved the safety for both mother and baby. Today, cesarean delivery is the most common major surgical procedure performed worldwide, with an estimated 23 million procedures performed each year.[2] However, the rate of cesarean delivery varies dramatically by country, ranging from 0.6% (South Sudan) to 56% (Brazil) of all deliveries (Fig. 26.1).[2] Maternal, obstetric, fetal, medicolegal, health-system, and social factors are largely responsible for this variability, resulting in significant differences in cesarean delivery rates even among individual obstetricians and institutions (Box 26.1).[3] A recent analysis suggested that the optimal cesarean delivery rate for minimizing neonatal and maternal morbidity is 19%.[2]

BOX 26.1 Factors Contributing to the Increasing Cesarean Delivery Rate

Maternal
- Increasing proportion of deliveries in nulliparous women
- Delayed childbearing and increasing maternal age
- Increasing prevalence of obesity

Obstetric
- Increasing use of labor induction
- Fewer vaginal breech deliveries
- Fewer instrumental vaginal deliveries
- Fewer attempts at trial of labor after cesarean delivery
- Increasing availability of cesarean delivery in developing nations

Fetal
- Increasing incidence of fetal macrosomia
- Increasing incidence of multiple gestation
- *Ex utero* intrapartum treatment (EXIT) procedures

Practice Environment
- Concern for malpractice litigation
- Increased use of electronic fetal heart rate monitoring
- Concern for pelvic floor injury associated with vaginal birth
- Desire for scheduled procedures (convenience)

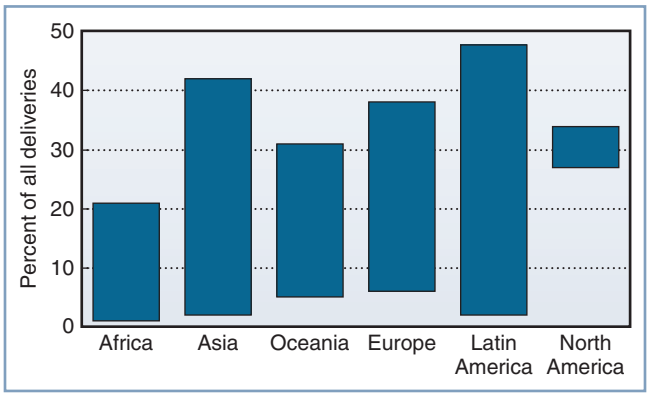

Fig. 26.1 The range of cesarean delivery rates by world region as collected in surveys or vital registration system reports. (Data modified from Gibbons L, Belizan JM, Lauer JA, et al. Inequities in the use of cesarean section deliveries in the world. *Am J Obstet Gynecol.* 2012;206:331.e1–e19.)

INDICATIONS

An *elective* (scheduled) cesarean delivery can be performed for obstetric or medical indications or at the request of a patient, and it is typically planned and performed *before* the onset of labor.[4] A cesarean delivery performed during labor for a planned vaginal delivery can also occur for a wide range of maternal and fetal indications but may need to be conducted in an urgent or emergent manner. The most common reasons for a primary cesarean are labor arrest (34%), nonreassuring fetal heart rate (FHR) tracing (23%), malpresentation (e.g., breech) (17%), and multiple gestation (7%) (Box 26.2).[5] A prior cesarean delivery does not necessitate cesarean

BOX 26.2 Indications for Cesarean Delivery

Maternal
- Antepartum or intrapartum hemorrhage
- Arrest of labor
- Breech presentation
- Chorioamnionitis
- Deteriorating maternal condition (e.g., severe preeclampsia)
- Dystocia
- Failure of induction of labor
- Genital herpes (active lesions)
- High-order multiple gestation (or twin gestation in which twin A has a breech presentation)
- Maternal request
- Placenta previa
- Placental abruption
- Previous myomectomy
- Prior classic uterine incision
- Uterine rupture

Fetal
- Breech presentation or other malpresentation
- Fetal intolerance of labor
- Suspected macrosomia
- Nonreassuring fetal status
- Prolapsed umbilical cord

Obstetrician
- Desire to avoid difficult forceps or vacuum delivery

delivery in a subsequent pregnancy. A trial of labor after cesarean (TOLAC), which if successful is called a vaginal birth after cesarean (VBAC), is an alternative option; validated algorithms for predicting the probability of successful VBAC have been developed.[6] Similar to cesarean delivery rates, VBAC rates vary substantially among countries with a reported range of 9% (United States) to 55% (Netherlands) (see Chapter 19).[7]

OPERATIVE TECHNIQUE

The technical aspects of performing a cesarean delivery are comparable worldwide, with minor variations. A midline vertical *abdominal* incision allows rapid access and greater surgical exposure; however, the horizontal *suprapubic* (Pfannenstiel) incision offers better cosmesis and wound strength. Similarly, a low transverse *uterine* incision, compared with a vertical incision, allows for a lower incidence of uterine dehiscence or rupture in subsequent pregnancies, as well as a reduction in the risks for infection, blood loss, and bowel and omental adhesions. Vertical uterine incisions are most often used in the following situations: (1) if the lower uterine segment is underdeveloped (typically before 34 weeks' gestation), (2) for delivery of a preterm infant in a woman who has not labored, and (3) in selected patients with multiple gestation and/or malpresentation. In some cases, a vertical uterine

incision is performed high on the anterior uterine wall (i.e., classical incision), especially in the patient with a low-lying anterior placenta previa or when a cesarean hysterectomy is planned.

Uterine exteriorization following delivery facilitates visualization and repair of the uterine incision, particularly when the incision has been extended laterally. Although the effect of exteriorization on blood loss and febrile morbidity remains controversial,[8] higher rates of intraoperative nausea, emesis, and venous air embolism as well as postoperative pain have been reported.[9,10]

MORBIDITY AND MORTALITY

Complications of cesarean delivery include hemorrhage, infection, thromboembolism, ureteral and bladder injury, abdominal pain, and increased risk for abnormal placentation and uterine rupture in subsequent pregnancies (Box 26.3).[11] Maternal morbidity and mortality vary widely from country to country (see Chapter 39). In most developed nations, the rate of maternal death associated with all cesarean deliveries remains higher than that associated with vaginal deliveries, although this is in large measure attributable to the underlying conditions that necessitate cesarean delivery (Table 26.1).[12,13] Planned cesarean delivery also appears to be associated with a higher risk for many measures of maternal morbidity compared with planned vaginal delivery, although the absolute differences in risk are small.[14] Neonatal morbidity, in particular respiratory system morbidity, is greater with elective cesarean delivery than with vaginal delivery.[15] Performance of cesarean delivery also places the mother at higher risk for morbidity (and perhaps mortality) in subsequent pregnancies and cesarean deliveries.[16]

PREVENTION OF CESAREAN DELIVERY

Neuraxial labor analgesia was earlier thought to increase the cesarean delivery rate compared with nonmedicated labor or other analgesic techniques; however, randomized controlled trials indicate that neuraxial analgesia is not associated with a higher cesarean delivery rate than systemic opioid analgesia

BOX 26.3 Complications of Cesarean Delivery

Intraoperative Complications

Hemorrhage

- Uterine atony
- Uterine lacerations
- Broad ligament hematoma

Infection

- Endometritis
- Wound infection

Postoperative Complications

- Cardiovascular: venous thromboembolism
- Gastrointestinal: ileus, adhesions, injury
- Genitourinary: bladder or ureteral injury
- Respiratory: atelectasis, aspiration pneumonia
- Chronic pain

Future Pregnancy Risks

- Placenta previa
- Placenta accreta
- Uterine rupture
- Obstetric hysterectomy

TABLE 26.1 Relationship between Route of Delivery and Maternal Death

		Association of Delivery Route with Maternal Death[a]		Causal Relationship of Delivery Route with Maternal Death[b]	
Delivery Type	Number of Procedures	NUMBER OF DEATHS	FREQUENCY OF DEATH (PER 100,000 PROCEDURES)	NUMBER OF DEATHS	FREQUENCY OF DEATH (PER 100,000 PROCEDURES)
Vaginal	1,003,173	17	1.7	2	0.2
Primary cesarean	282,632	46	16.3	7	2.5
Repeat cesarean	175,465	12	6.8	2	1.1
Total cesarean	458,097	58	12.7	9	2.0
Not delivered/dilation and curettage	NA	20	NA	NA	NA
Total	1,461,270	95	6.5[c]	11	0.8

NA, not applicable.

[a]*Association relationships:* For vaginal birth versus total cesarean, vaginal birth versus primary cesarean, and vaginal birth versus repeat cesarean, $P < .001$. For primary cesarean versus repeat cesarean, $P = .01$.

[b]*Causal relationships:* For vaginal birth versus total cesarean and vaginal birth versus primary cesarean, $P < .001$. For vaginal birth versus repeat cesarean, $P = .12$. For primary cesarean versus repeat cesarean, $P = .50$. For vaginal birth versus primary, repeat, and total cesarean delivery, excluding pulmonary embolism deaths preventable with universal prophylaxis, $P = .07$, $P = .38$, and $P = .08$, respectively.

[c]Deaths per 100,000 pregnancies.

Modified from data in Clark SL, Belfort MA, Dildy GA, et al. Maternal death in the 21st century: causes, prevention, and relationship to cesarean delivery. *Am J Obstet Gynecol.* 2008;199:36.e1–e5.

(see Chapter 23).[17] Moreover, the combined spinal-epidural (CSE) technique for labor analgesia, despite its association with fetal bradycardia, does not result in an increase in the total cesarean delivery rate.[18] Some cesarean deliveries may be avoided through the provision of (1) adequate labor analgesia, including analgesia for trial of labor after cesarean delivery and instrumental vaginal delivery; (2) analgesia for external cephalic version (see Chapter 34); and (3) intrauterine resuscitation, including pharmacologic uterine relaxation in cases of uterine tachysystole.

Maternal Labor Analgesia

The National Institutes of Health State-of-the-Science statement on cesarean delivery on maternal request emphatically concluded that "maternal request for cesarean delivery should not be motivated by unavailability of effective [labor] pain management."[4] While most hospitals in the United States now offer labor analgesia,[19] this is not necessarily the case in many parts of the world, and studies suggest that the introduction of epidural analgesia may be an effective approach to decrease the cesarean delivery rate in these settings.[20]

Adequate maternal analgesia and perineal relaxation are also important for instrumental (forceps, vacuum) vaginal deliveries. Neuraxial techniques can optimize anesthetic conditions for these obstetric procedures (see Chapter 23).

External Cephalic Version

Singleton breech presentations occur in 3% to 4% of term pregnancies. The Royal College of Obstetricians and Gynaecologists[21] and the American College of Obstetricians and Gynecologists (ACOG)[22] caution against a vaginal breech delivery, given poorer neonatal outcomes compared with planned cesarean delivery.[23] External cephalic version (ECV), a procedure by which manual external pressure is applied to the maternal abdomen to change the fetal presentation from breech to cephalic, remains a viable option. ECV is usually performed between 36 and 39 weeks' gestation[24] (see Chapter 34).

Meta-analyses of available trial data support the finding that neuraxial analgesia or anesthesia increases the success rate of attempted ECV.[25,26] Moreover, these studies show that the use of neuraxial blockade does not appear to compromise maternal and fetal safety, and specifically it does not increase the risk for fetal bradycardia, placental abruption, or fetal death.

Intrauterine Resuscitation

Evidence of intrapartum fetal compromise (nonreassuring fetal status) should prompt the obstetric team (including obstetric, anesthesia, and nursing providers) to attempt intrauterine fetal resuscitation (Box 26.4). These actions include changing maternal position to relieve aortocaval compression, administering vasopressors and intravenous fluid to treat maternal hypotension, discontinuing exogenous oxytocin administration, and, in cases of uterine tachysystole, administration of a tocolytic agent such as terbutaline or nitroglycerin (see Chapter 8).

BOX 26.4 Obstetric Management of Nonreassuring Fetal Status

- Optimize maternal position:
  - To avoid or relieve aortocaval compression.
  - To relieve umbilical cord compression.
- Administer supplemental oxygen.
- Maintain maternal circulation:
  - Perform rapid intravenous administration of a non–dextrose-containing balanced salt solution.
  - Treat hypotension with either ephedrine or phenylephrine.
- Discontinue oxytocin.
- Consider administration of a tocolytic agent for treatment of uterine tachysystole.

PREPARATION FOR ANESTHESIA

The anesthetic management of cesarean delivery may depend in part on the obstetric indications for operative delivery. The anesthesia provider should consider the patient's medical, surgical, and obstetric history, the presence or absence of labor, the urgency of the delivery, and the resources available in preparing for a cesarean delivery.

Preanesthetic Evaluation

All women admitted for labor and delivery are potential candidates for the emergency administration of anesthesia, and an anesthesia provider ideally should evaluate every woman shortly after admission. Optimally, for high-risk patients, preanesthesia consultation should occur in the late second or early third trimester, even if a vaginal delivery is planned. This practice offers the opportunity to provide patients with information, solicit further consultations, optimize medical conditions, and discuss plans and preparations for the upcoming delivery.[27] Early communication among the members of the multidisciplinary team is encouraged. In some cases, the urgent nature of the situation allows limited time for evaluation before induction of anesthesia and commencement of surgery; nonetheless, essential information must be obtained and risks and benefits of alternative anesthetic management decisions should be considered.

A focused preanesthetic history and physical examination includes (1) a review of maternal health and anesthetic history, relevant obstetric history, allergies, and baseline blood pressure and heart rate measurements; and (2) performance of an airway, heart, and lung examination consistent with the American Society of Anesthesiologists (ASA) guidelines (see Appendix B).[28]

Blood Products

Peripartum hemorrhage remains a leading cause of maternal mortality worldwide (see Chapters 37 and 39).[29] There is little difference in blood loss between an uncomplicated elective cesarean delivery and an uncomplicated planned vaginal birth[23]; however, a cesarean delivery performed during labor or in the setting of abnormal placentation is associated with

BOX 26.5 Selected Risk Factors for Peripartum Hemorrhage

- Abnormal placentation
- Advanced maternal age
- Anticoagulation
- Bleeding disorder
- Chorioamnionitis
- Fetal demise
- Fetal malpresentation
- General anesthesia
- Increased parity/grand multiparity
- Instrumental vaginal delivery
- Internal trauma (e.g., curettage, internal version)
- Oxytocin augmentation of labor
- Placental abruption
- Precipitous delivery
- Preeclampsia
- Premature rupture of membranes
- Previous uterine surgery (e.g., cesarean delivery, myomectomy)
- Prolonged labor
- Retained placenta
- Tocolytic therapy
- Trauma
- Uterine distention (e.g., macrosomia, multiple gestation, polyhydramnios)
- Uterine leiomyoma

greater blood loss.[30] Risk factors for peripartum hemorrhage are listed in Box 26.5.

Preparation for obstetric hemorrhage includes (1) reviewing the patient's history for anemia or risk factors for hemorrhage; (2) consulting with the obstetric team regarding the presence of risk factors; (3) reviewing reports of ultrasonographic or magnetic resonance images of placentation; (4) obtaining a blood sample for a type and screen or cross-match; (5) contacting the blood bank to ensure the availability of blood products; (6) obtaining and checking the necessary equipment (blood filters and warmers, infusion pumps and tubing, compatible fluids and medications, and standard clinical laboratory collection tubes; and (7) consulting with a blood bank pathologist, hematologist, and/or interventional radiologist in selected cases (Box 26.6).

Currently, there is a lack of consensus as to which patients require a blood type and screen and which patients require a cross-match. The maternal history (previous transfusion, existence of known red blood cell antibodies) and anticipated hemorrhagic complications, as well as local institutional policies, should guide decision-making. In certain high-risk cases (e.g., suspected placenta accreta), blood products (e.g., 2 to 4 units of packed red blood cells) should be physically present near or in the operating room before making the surgical incision, if possible.

Monitoring

Attention should be given to the availability and proper functioning of equipment and monitors for the provision of

BOX 26.6 Suggested Resources for Obstetric Anesthesia

Monitors
- Electrocardiogram
- Noninvasive blood pressure
- Pulse oximetry
- Capnography
- Oxygen and volatile agent analyzers
- Ventilator (with appropriate pressure and disconnection sensors/alarms)
- Peripheral nerve stimulator

For Hemorrhage
- Large-bore intravenous catheters
- Fluid warmer
- Forced-air body warmer
- Availability of blood bank resources
- Equipment for infusing intravenous fluids and blood products rapidly (e.g., hand-squeezed fluid chambers, hand-inflated pressure bags, automatic infusion devices)
- Availability of interventional radiology service

For Routine Airway Management
- Laryngoscope and assorted blades
- Videolaryngoscope
- Oral airways of assorted sizes
- Endotracheal tubes of assorted sizes (6.5 and 7.0 mm) with stylets
- Oxygen source
- Suction source with tubing and catheters
- Self-inflating bag and mask for positive-pressure ventilation
- Medications for blood pressure support, hypnosis, and muscle relaxation

For Difficult Airway Management
- Rigid laryngoscope blades of alternative design and size from those routinely used
- Supraglottic airway devices (e.g., laryngeal mask airway)
- Endotracheal tube guides (e.g., semirigid stylets with or without hollow cores for jet ventilation, light wands, and forceps designed to manipulate the distal portion of the endotracheal tube)
- Retrograde intubation equipment
- At least one device suitable for emergency nonsurgical airway ventilation (e.g., hollow jet ventilation stylet with a transtracheal jet ventilator; supraglottic airway device, such as a Combitube [Sheridan Catheter Corporation, Argyle, NY] or intubating LMA [Fastrach LMA, LMA North America, San Diego, CA])
- Fiberoptic intubation equipment
- Equipment suitable for emergency surgical airway access (e.g., cricothyrotomy)
- Topical anesthetics and vasoconstrictors

Modified from the American Society of Anesthesiologists; Society for Obstetric Anesthesia and Perinatology. Practice guidelines for obstetric anesthesia: an updated report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia and the Society for Obstetric Anesthesia and Perinatology. *Anesthesiology*. 2016;124:270–300. (The full practice guidelines are published as Appendix B, found at the end of this textbook.)

anesthesia and the management of potential complications (e.g., failed tracheal intubation, cardiopulmonary arrest).[28] Equipment should be checked on a daily basis and serviced at recommended intervals. The equipment and facilities available in the labor and delivery operating room suite should be comparable to those available in the main operating room.[28]

The ASA standards for basic monitoring apply to the provision of anesthesia for all patients.[31] Within obstetrics, basic monitoring consists of maternal pulse oximetry, electrocardiography (ECG), and noninvasive blood pressure monitoring,[a] as well as FHR monitoring.

ECG abnormalities are often observed in late pregnancy and are believed to be caused by hyperdynamic circulation, circulating catecholamines, and/or altered estrogen and progesterone concentration ratios (see Chapter 2). During cesarean delivery with neuraxial anesthesia, ECG changes have a reported frequency of 25% to 60%[32,33]; in this setting, administration of droperidol, ondansetron, and oxytocin may be associated with prolongation of the QTc interval,[34,35] and oxytocin administration may be associated with ST-segment depression.[36] The significance of these ECG findings as an indicator of cardiac pathology remains unclear, because only a small minority of parturients experience myocardial ischemia as measured by elevated serum cardiac troponin levels or echocardiographic wall motion abnormalities.[32,37] The placement of five ECG leads improves the sensitivity of detecting ischemic events; combining leads II, V_4, and V_5 resulted in a sensitivity of 96% for detecting ST-segment changes in a nonobstetric population.[38] In a prospective study of 254 healthy women undergoing cesarean delivery with spinal anesthesia, Shen et al.[39] determined the incidence of first- and second-degree atrioventricular block (3.5% for each), severe bradycardia (< 50 bpm; 6.7%), and multiple premature ventricular contractions (1.2%). The investigators speculated that a relative increase in parasympathetic activity occurred as a result of spinal blockade of cardiac sympathetic activity. Most of the dysrhythmias were transient and resolved spontaneously.

Processed electroencephalogram monitors used to indicate the depth of anesthesia have received only limited evaluation in women undergoing cesarean delivery.[40] Whether routine use of these monitors can reduce the incidence of intraoperative awareness during general anesthesia for cesarean delivery is unclear (see later discussion).

An indwelling urinary catheter is used in almost all women undergoing cesarean delivery.[41] A urinary catheter helps avoid overdistention of the bladder during and after surgery. In cases associated with hypovolemia and/or oliguria, or anticipated significant blood loss, a collection system that allows precise measurement of urine volume is helpful.

The FHR is often assessed by a qualified individual before and after administration of anesthesia. However, data are insufficient to determine the value of FHR monitoring before elective cesarean delivery in patients without risk factors. Our practice is to monitor FHR until the abdominal skin preparation for cesarean delivery has begun.

In some cases of *emergency* cesarean delivery, a previously placed fetal scalp (or buttock) ECG electrode can be used to monitor the FHR before, during, and after the initiation of anesthesia. Typically, the fetal scalp electrode is removed when the surgical drapes are applied to the abdomen, but in some cases the scalp electrode may be left in place until just before delivery, when the circulating nurse reaches under the drapes to disconnect the electrode. Continuous FHR monitoring is useful in this setting for at least three reasons. First, the FHR abnormality often resolves; in some cases, the obstetrician will then elect to forgo the performance of a cesarean delivery. In other cases, the obstetrician may continue with plans to perform a cesarean delivery, but continuous FHR monitoring may facilitate the administration of neuraxial anesthesia. For example, an improved FHR tracing allows time for extension of epidural anesthesia or administration of spinal anesthesia. Second, continuous FHR monitoring may guide management in cases of failed tracheal intubation. If intubation fails and there is no evidence of fetal compromise, both the anesthesia provider and the obstetrician will have greater confidence in a decision to awaken the patient and proceed with an alternative anesthetic technique. By contrast, if there is evidence of ongoing fetal compromise, the anesthesia provider may decide to provide general anesthesia by means of a face mask or supraglottic airway, and the obstetrician may proceed with cesarean delivery (see Chapter 29). Third, intraoperative FHR monitoring allows the obstetrician to modify the surgical technique according to the urgency of delivery.

Invasive monitoring (e.g., arterial catheter), noninvasive cardiac output monitoring, or echocardiography may be indicated for individual patients at high risk for cardiopulmonary compromise.

Equipment

Labor and delivery units may be adjacent to or remote from the main operating rooms. In some facilities, the unit is located on a separate floor but shares a common operating room facility (used for other surgical procedures), whereas in others it is a geographically separate, self-contained unit with its own operating room facilities. Regardless of location, the equipment, facilities, and support personnel available in the labor and delivery operating room should be comparable to those available in the main operating room.[28] In addition, personnel and equipment should be available to care for obstetric patients recovering from major neuraxial or general anesthesia.

Resources for the conduct and support of neuraxial anesthesia and general anesthesia should include those necessary

[a]Outside the operating room, and before the onset of labor, maternal blood pressure is ideally measured (using an appropriately sized cuff with a bladder length that is 80% and a width that is at least 46% of the arm circumference) after a rest period of 10 minutes or more, with the pregnant woman sitting or lying on her left side with her arm at the level of the right atrium. The onset (phase 1) and disappearance (phase 5) of Korotkoff sounds correspond to systolic and diastolic pressures, respectively

for the basic delivery of anesthesia and airway management as well as those required to manage complications (e.g., failed tracheal intubation). The *immediate* availability of these resources is particularly important, given the frequency and urgency of anesthesia care. Consideration should be given to having some of the equipment and supplies immediately available in one location or in a cart (e.g., difficult airway cart, massive hemorrhage cart, malignant hyperthermia box) specifically located on the labor and delivery unit. Equipment and supplies should be checked on a frequent and regular basis. Securing special-situation equipment and supplies in a cart with a single-use breakthrough plastic tie helps ensure that the cart is kept in a fully stocked state.

Aspiration Prophylaxis

The patient should be asked about oral intake, although insufficient evidence exists regarding the relationship between recent ingestion and subsequent aspiration pneumonitis (see Chapter 28). Gastric emptying of clear liquids during pregnancy occurs relatively quickly; the residual content of the stomach (as measured by ultrasonographic assessment of the cross-sectional area of the gastric antrum 60 minutes after the ingestion of 300 mL of water) does not appear to be different from baseline fasting levels in either lean or obese nonlaboring pregnant women.[42,43] Moreover, when measured by serial gastric ultrasonographic examinations and acetaminophen (paracetamol) absorption, the gastric emptying half-time of 300 mL of water is shorter than that of 50 mL of water in healthy, nonlaboring, nonobese pregnant women (24 ± 6 versus 33 ± 8 minutes, respectively).[42]

The healthy patient undergoing *elective* cesarean delivery may drink modest amounts of clear liquids up to 2 hours before induction of anesthesia.[28] Examples of clear liquids are water, fruit juices without pulp, carbonated beverages, clear tea, black coffee, and sport drinks. The volume of liquid ingested is less important than the absence of particulate matter. Patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes, difficult airway) or laboring patients at increased risk for cesarean delivery (e.g., nonreassuring FHR pattern) may have further restrictions of oral intake, determined on a case-by-case basis.[28]

Ingestion of solid foods should be avoided in laboring patients and patients undergoing elective surgery (e.g., scheduled cesarean delivery or postpartum tubal sterilization). A fasting period for solids of 6 to 8 hours, depending on the fat content of the food, has been recommended.[28]

A reduction in gastric content acidity and volume is believed to decrease the risk for damage to the respiratory epithelium if aspiration should occur. Oral administration of a nonparticulate antacid (0.3 M **sodium citrate**, pH 8.4) causes the mean gastric pH to increase to greater than 6 for 1 hour; it does not affect gastric volume.[44,45] **Histamine-2 (H_2)-receptor antagonists (e.g., ranitidine, famotidine)**, **proton pump inhibitors (e.g., omeprazole),** and **metoclopramide** reduce gastric acid secretion and volume but require at least 30 to 40 minutes to exert their effects.[46] A systematic review of interventions used to reduce the risk for aspiration pneumonitis in women undergoing cesarean delivery found a significant reduction in the risk for gastric pH less than 2.5 with antacids (relative risk [RR], 0.17; 95% confidence interval [CI], 0.09 to 0.32), H_2-receptor antagonists (RR, 0.09; 95% CI, 0.05 to 0.18), and proton-pump inhibitors (RR, 0.26; 95% CI, 0.14 to 0.46), compared with no treatment or placebo.[47] The combined use of an antacid and an H_2-receptor antagonist was found to be more effective in reducing pH less than 2.5 than administration of placebo or an antacid alone.[47] However, in a randomized evaluation, sodium citrate was associated with a higher incidence and severity of nausea than an H_2-receptor antagonist (famotidine), suggesting that a H_2-receptor antagonist may be the preferred agent in selected patients.[48] **Metoclopramide** is a promotility agent that hastens gastric emptying, increases lower esophageal sphincter tone, and decreases nausea and vomiting.[49,50] Before surgical procedures, the timely administration of a nonparticulate antacid, an H_2-receptor antagonist, and metoclopramide should be considered, especially for nonelective procedures.[28]

Prophylactic Antibiotics

Prophylactic antibiotic administration results in a 60% decrease in the incidence of endometritis, a 25% to 65% decrease in the incidence of wound infection, and fewer episodes of fever and urinary tract infections for both elective (nonlaboring) and nonelective (laboring) cesarean deliveries.[51] The ACOG[52] has recommended the prophylactic administration of a narrow-spectrum antibiotic, such as a first-generation cephalosporin, within 1 hour of the start of cesarean delivery.

Antibiotics with efficacy against gram-positive, gram-negative, and some anaerobic bacteria are commonly used for prophylaxis for cesarean delivery. Appropriate coverage includes intravenous ampicillin 2 g, cefazolin 1 g, or ceftriaxone 1 g. Appropriate antibiotic coverage should last for 3 to 4 hours; therefore, ampicillin may be less appropriate owing to a shorter half-life than the cephalosporins.[52,53] In parturients with a significant allergy to beta-lactam antibiotics (e.g., history of anaphylaxis, angioedema, respiratory distress, or urticaria), intravenous clindamycin with gentamicin is a reasonable alternative.

Because of the greater volume of distribution, higher doses of antibiotics may be considered in women with a body mass index (BMI) greater than 30 kg/m^2 or an absolute weight greater than 120 kg.[52,54] After administration of cephazolin 2 g, Pevzner et al.[54] observed that the minimum inhibitory tissue concentration for gram-negative rods was not achieved at the time of skin incision or closure in 20% of obese women and 33% of morbidly obese women.

A 2016 randomized controlled trial addressed whether surgical site infection prophylaxis should be broadened to cover species commonly associated with postcesarean infection (e.g., ureaplasma).[55] Women undergoing cesarean delivery after labor or rupture of membranes were randomized to receive standard antibiotics with or without the addition of azithromycin (500 mg). Although the addition of azithromycin decreased the prevalence of the composite infection endpoint

by one-half (6.1% versus 12.0%), almost three-fourths of the trial participants were obese, raising concern that the standard antibiotics may have been underdosed.[55] The 2018 ACOG guidelines suggest that prophylactic azithromycin administration may be considered for nonelective cesarean delivery.[52]

In the past, prophylactic antibiotics were typically administered after umbilical cord clamping because of concern that fetal antibiotic exposure might mask a nascent infection and/or increase the likelihood of a neonatal sepsis evaluation. However, a meta-analysis demonstrated that preincision antibiotic prophylaxis reduces the incidence of postcesarean endometritis and total maternal infectious morbidity, without evidence of adverse neonatal effects.[56] Thus, current guidelines recommend administration of prophylactic antibiotics within 60 minutes before the start of the cesarean delivery.[52]

Aseptic Technique

In the early 19th century, Ignác Semmelweis observed that puerperal fever, known as "childbed fever," was most likely transmitted when the first stage of labor was prolonged and multiple individuals performed vaginal examinations with contaminated hands. Since that time, the practice of hand hygiene has caused a significant reduction in maternal and neonatal infectious morbidity.

The immunologic changes of pregnancy may impair clearance of infections.[57] Epidural abscess and meningitis have been reported as complications of neuraxial procedures in obstetric patients (see Chapter 31). As a consequence, obstetric anesthesia providers should always give careful attention to aseptic technique, especially during performance of a neuraxial procedure. Proper sterile technique for neuraxial procedures includes wearing a face mask, performing hand hygiene, and donning sterile gloves (see Chapter 12).[58] Attention should also be given to the careful preparation of anesthetic drugs during administration of either general or neuraxial anesthesia. An increasing number of institutions are using premixed solutions of local anesthetic and opioid (prepared under aseptic conditions in a hospital or compounding pharmacy) to limit breaches in aseptic technique during the administration of neuraxial anesthesia.

Intravenous Access and Fluid Management

The establishment of functional intravenous access is of critical importance to the successful outcome of many clinical situations in obstetric anesthesia practice. According to the Hagen-Poiseuille equation, the infusion rate of fluid through a catheter is directly related to the pressure gradient of the fluid and the fourth power of the catheter's radius, and inversely related to the viscosity of the fluid and the catheter's length. Because the size of the catheter, more than the size of the vein, dictates the flow rate, the use of a short, large-diameter catheter (e.g., 16- or 18-gauge) is associated with the best flow.[59]

In general, a smaller but functional catheter is more important than a larger catheter that is unreliable or requires frequent manipulation. Smaller catheters may be acceptable in an emergency; volume and blood resuscitation can be satisfactorily achieved using 20- and 22-gauge catheters (without evidence of greater red blood cell destruction) with the use of dilution, pressurization, or both.[60] However, in situations when more rapid resuscitation is needed, especially when large blood loss is anticipated, or administration of multiple blood products is required, the anesthesia provider may choose to insert a central venous catheter.

Although the administration of intravenous fluids may decrease the incidence of neuraxial anesthesia-associated hypotension, initiation of anesthesia should not be delayed to administer a fixed volume of fluid,[28] particularly in the case of an emergency cesarean delivery, in which the life and health of the mother and the infant are best preserved with timely delivery. Vasopressors can be used for both prophylaxis and treatment of hypotension. The type of fluid (crystalloid, colloid) and the volume, rate, and timing of administration are relevant factors in the prevention and treatment of hypotension.[61,62] In most situations, a balanced salt solution such as lactated Ringer's solution is acceptable. Blood products are most often administered with normal saline. Crystalloid or colloid solutions that contain calcium or glucose should not be administered with blood products, owing to the risks for clotting (caused by reversal of the citrate anticoagulant) and clumping of red blood cells, respectively.

Traditionally, approximately 1 L of crystalloid solution has been administered intravenously (as "prehydration" or "preload") to prevent or reduce the incidence and severity of hypotension during neuraxial anesthesia for cesarean delivery. However, prehydration, even with large volumes (30 mL/kg), is minimally effective in preventing neuraxial anesthesia-induced hypotension. Although an initial study found that administering crystalloid solution at the time of the intrathecal injection ("co-load") was more efficacious than prehydration in preventing hypotension,[63] later studies did not support this finding,[64] likely because the infusion rate was too slow.[62] Colloid, administered before or at the time of the intrathecal injection, is more effective than crystalloid for preventing hypotension.[65] Colloid administered before the intrathecal injection (preload) is equally efficacious as commencing administration at the time of injection (co-load).[64] In healthy patients, we rapidly administer approximately 1 L of crystalloid starting at the time of initiation of neuraxial anesthesia. For patients at high risk for hypotension or the consequences of hypotension, colloid may be administered before or at the time of initiation of neuraxial blockade.[62] Hypotension despite fluid administration is treated with vasopressors (see later discussion).

Supplemental Medications for Anxiety

The administration of benzodiazepines, even low doses (e.g., midazolam 0.02 mg/kg), may result in amnesia[66,67]; as a consequence, benzodiazepines are typically avoided during awake cesarean delivery. However, on occasion, particularly in women with severe anxiety or undergoing an emergency cesarean delivery, the use of low doses of intravenous midazolam or an opioid may facilitate performance of a neuraxial technique, awake tracheal intubation, or the induction of general anesthesia. Anxiolytics may also assist in mitigating the feelings of distress during the birthing experience, which

may lessen the risk for developing posttraumatic stress disorder.[68] The use of low doses of sedative or anxiolytic agents has minimal to no neonatal effects. In a trial of healthy women randomized to receive intravenous midazolam (0.02 mg/kg) and fentanyl (1 μg/kg[b]) or saline before administration of spinal anesthesia for cesarean delivery, no differences in neonatal Apgar scores, neurobehavioral scores, or oxygen saturation were observed between the two treatment groups.[69]

Positioning

After 20 weeks' gestation, most practitioners position patients with left uterine displacement to minimize aortocaval compression. The **supine hypotension syndrome,** which is caused by compression of the aorta and inferior vena cava by the gravid uterus, can manifest as pallor, tachycardia, sweating, nausea, hypotension, and dizziness.[70,71] Uteroplacental blood flow is compromised by decreased venous return and cardiac output, increased uterine venous pressure, and compression of the aorta or common iliac arteries.[72]

The full lateral position minimizes aortocaval compression but does not allow performance of cesarean delivery. Fifteen degrees of **left lateral tilt (left uterine displacement)** has been proposed to significantly reduce the adverse hemodynamic consequences of the supine position, although both the aorta and inferior vena cava may remain partially compressed.[73] However, most anesthesia providers overestimate the degree of lateral tilt. These elements may explain the results of a 2013 systematic review that concluded that left compared with right lateral tilt was associated with some maternal and fetal benefit, but outcomes were not dramatically different among different positions.[74] Overall, data were insufficient to prove or disprove the benefits of tilting or flexing the operating room table or using wedges or mechanical displacers during positioning for cesarean delivery.[74]

Whether left uterine displacement is necessary in the context of patients receiving a co-load of fluid and a prophylactic phenylephrine infusion at the time of induction of spinal anesthesia has been questioned.[75] In healthy, term women undergoing elective cesarean delivery, there was no difference in neonatal acid-base status in women randomized to the supine position versus left uterine displacement, despite mean maternal cardiac output being lower in the supine group.[75] The trial excluded women at increased risk for aortocaval compression (e.g., polyhydramnios, multiple gestation, obesity) or women with impaired placental perfusion (e.g., fetal growth restriction, preeclampsia). Given these limitations, and the apparent absence of adverse maternal or fetal effects with lateral uterine displacement, the routine use of this technique should not be abandoned.[76] Anesthesia providers should recognize that (1) susceptibility to aortocaval compression varies among individuals,[77] (2) visual estimates of lateral tilt may be in error,[78] and (3) in symptomatic women, increasing the extent of left uterine displacement may be beneficial. Lateral tilt should be used in all women in mid- to late pregnancy after the administration of neuraxial or general anesthesia, with greater tilt used when feasible if aortocaval compression is suspected as the cause for maternal or fetal compromise.[79]

The use of a slight (10 degrees) **head-up position** may help reduce the incidence of hypotension after initiation of hyperbaric spinal anesthesia.[80] A 30-degree head-up position significantly increases functional residual capacity compared with the supine position in term parturients, although this effect diminishes with increasing BMI.[81] In morbidly obese patients receiving general anesthesia, a 25-degree head-up position may be particularly useful to improve denitrogenation and glottic view during direct laryngoscopy[82]; this position can be accomplished with blankets or commercially available devices (see Chapters 29 and 49). If blankets are used to create the ramp position, they should be stacked rather than interlaced, to allow for rapid removal and readjustment of the head and neck position if necessary. The ideal position aligns the external auditory meatus and the sternal notch in a horizontal plane; this position (1) aligns the oral, pharyngeal, and tracheal axes ("sniffing position") and (2) facilitates insertion of the laryngoscope blade (see Fig. 29.7).[83]

Theoretically, the **Trendelenburg (head-down) position** may augment venous return and increase cardiac output. The value of this approach in *preventing* hypotension during neuraxial anesthesia has been questioned.[74] After the initiation of hyperbaric spinal anesthesia, the Trendelenburg position has been reported to result in more cephalad spread of anesthesia in one study[84] but not in others.[85,86] However, this position had no effect on the incidence of hypotension after administration of hyperbaric spinal anesthesia.[84,86]

The optimal patient position for initiation of neuraxial anesthesia may depend on clinical circumstances and the preferences and skills of the anesthesia provider (see Chapter 12). Whether the use of the **lateral** or the **sitting position** is best for routine initiation of neuraxial anesthesia is controversial.[87,88] Advocates of the lateral position cite a reduction of vagal reflexes, which can result in dizziness, diaphoresis, pallor, bradycardia, and hypotension.[89] Moreover, the lateral position may allow better uteroplacental blood flow than the sitting position,[90] but this is controversial.[91] The lateral position may also be associated with a small increase in maternal cardiac index, stroke volume index, heart rate, and systolic blood pressure compared with the sitting or supine positions.[92] Further, in a randomized controlled trial, the severity

[b]The Institute for Safe Medicine Practices (ISMP) has recommended that health care providers never use μg as an abbreviation for micrograms, but rather they should use mcg (http://www.ismp.org/tools/errorproneabbreviations.pdf, accessed April 6, 2018). The use of the symbol μg is frequently misinterpreted and involved in harmful medication errors. The abbreviation may be mistaken for mg (milligrams), which would result in a 1000-fold overdose. The symbol μg should never be used when communicating medical information, including pharmacy and prescriber computer order entry screens, computer-generated labels, labels for drug storage bins, and medication administration records. However, most scholarly publications have continued to use the abbreviation μg. The editors have chosen to retain the use of the abbreviation μg throughout this text. However, the editors recommend the use of the abbreviation mcg in clinical practice.

and duration of hypotension were greater in women randomly assigned to receive CSE anesthesia (hyperbaric spinal bupivacaine with fentanyl) in the sitting position than the lateral position, despite no differences in the level of sensory blockade.[93]

Some parturients find the lateral position more comfortable during administration of neuraxial anesthesia, whereas others find the sitting position more comfortable.[94] Moreover, because uterine compression of the vena cava diverts blood into the epidural venous plexus,[95] the use of the lateral position can reduce hydrostatic pressure and engorgement of the epidural venous plexus.[96] Studies suggest that epidural catheter placement in the lateral recumbent head-down position results in lower risk for lumbar epidural venous plexus cannulation than the sitting or the lateral recumbent horizontal position in both obese and nonobese parturients.[97,98]

Magnetic resonance imaging and computed tomography studies show that the cross-sectional area and the anteroposterior diameter of the dural sac at the level of the L3–L4, L4–L5, and L5–S1 interspaces are significantly influenced by posture.[99] Lumbar cerebrospinal fluid (CSF) pressure is lower and dural sac cross-sectional area smaller in the recumbent compared with the upright position. Theoretically, the lateral position may be of value during advancement of an epidural needle because it minimizes the prominence of the dural sac. By contrast, a bulging dural sac might be preferable during administration of spinal or CSE anesthesia. Bulging of the lumbar dural sac—particularly in the sitting position—may decrease the force required to create a dural puncture with a Tuohy epidural needle, but this possibility is unproven.

The sitting position also has some advantages, including easier landmark recognition in obese parturients and ease of positioning patients in a symmetrical position (the spine is often rotated in the lateral position because the bottom shoulder is fixed).[88] Given that there is no evidence that one position is universally better than the other, patient position for initiating neuraxial anesthesia is largely a matter of practitioner preference. However, anesthesia providers should be facile with the placement of needles for neuraxial techniques in both the sitting and lateral positions, because the sitting position should not be used in some situations (e.g., umbilical cord prolapse, footling breech presentation).[87]

Supplemental Oxygen

The routine administration of supplemental oxygen during elective cesarean delivery with neuraxial anesthesia is controversial. It became a common practice following the seminal report by Fox and Houle[100] that demonstrated improved oxygenation, better umbilical cord blood acid-base measurements, and less time to sustained respiration in the neonate, when mothers undergoing cesarean delivery with neuraxial anesthesia breathed 100% oxygen instead of air for at least 10 minutes. However, later evidence suggested that routine oxygen administration may be unnecessary, ineffective[101] and possibly detrimental.[102] A 2016 meta-analysis of randomized trials performed in low-risk women undergoing elective cesarean delivery found that the administration of supplemental oxygen compared with room air was associated with higher maternal oxygen saturation, maternal Pao_2, umbilical vein Po_2, and umbilical artery Po_2, but no differences in 1- and 5-minute Apgar scores.[103]

The use of a fractional inspired concentration of oxygen (Fio_2) of 0.35 to 0.4 (which cannot be obtained by using a nasal cannula or a simple face mask with a flow rate less than 6 L/min[104]) does not improve fetal oxygenation during labor or elective cesarean delivery. Although respiratory function can deteriorate in parturients receiving neuraxial anesthesia,[105,106] maternal or fetal hypoxemia does not normally occur when parturients breathe room air.[106] An Fio_2 of 0.6 in nonlaboring women undergoing elective cesarean delivery with spinal anesthesia increases the umbilical venous oxygen content by only 12%; an increase in oxygen content is not observed when the uterine incision-to-delivery (U-D) interval exceeds 180 seconds.[107]

Supplemental oxygen may have detrimental effects.[102] High levels of maternal Fio_2, are necessary for significant maternal-fetal oxygen transfer, but also result in the formation of reactive oxygen species and subsequent peroxidation of lipids, alteration of cellular enzymatic functions, and destruction of genetic material.[108] Known to extend ischemia-reperfusion injury, deplete antioxidants, and suppress immune function,[102] free radicals have also been implicated in the pathogenesis of disorders related to prematurity, including neonatal retinopathy, bronchopulmonary dysplasia, necrotizing enterocolitis, and intraventricular hemorrhage.

Nonetheless, the emergency cesarean delivery of the compromised fetus should include maternal oxygen administration of high Fio_2, particularly in the setting of uterine contractions, which can exacerbate fetal compromise; in these situations, supplemental oxygen may reduce the severity of fetal hypoxia with limited oxygen free-radical effects.[109] Term (but not preterm) fetuses may be able to withstand the adverse effects of these reactive oxygen species through a compensatory increase in antioxidants during labor.[110,111] Antioxidants, the defense against reactive oxygen species, consist of enzymatic inactivators (superoxide dismutase, catalase, peroxidase) and scavengers (ascorbate, glutathione, transferrin, lactoferrin, ceruloplasmin). The activity of these compensatory mechanisms and their relationship to gestational age and labor suggest that the highest risk for ischemia-reperfusion injury occurs in preterm fetuses before the onset of labor.[102,111]

The a use of high Fio_2 (greater than 0.6) improves oxygen transfer to hypoxic fetuses for a limited period (approximately 10 minutes); beyond this time, continued hyperoxia, especially in the setting of restored perfusion, increases reactive oxygen species, placental vasoconstriction, and fetal acidosis.[112,113] A lower Fio_2 may be of benefit in some situations. Of interest, when asphyxiated infants are immediately resuscitated at birth with air instead of 100% oxygen, better short-term outcomes have been observed[114,115]; this finding may be a result of the shift in the balance between beneficial oxygenation and detrimental free radicals.

All women who are at risk for requiring general anesthesia for emergency cesarean delivery should receive an Fio_2 of 1.0

after transfer to the operating table to simultaneously promote maternal oxygenation and denitrogenation; denitrogenation significantly reduces the risk for maternal hypoxemia during apnea before tracheal intubation.

Although the value of supplemental oxygen use during *elective* cesarean delivery with neuraxial anesthesia of a noncompromised fetus is questionable, some obstetric anesthesia providers place nasal cannulae or a mask to monitor ventilation using expired carbon dioxide analysis.

ANESTHETIC TECHNIQUE

Providing anesthesia to the parturient is a dynamic, multistep process (Table 26.2). The most appropriate anesthetic technique for cesarean delivery depends on maternal, fetal, and obstetric factors (Table 26.3). The urgency and anticipated duration of the operation play an important role in the selection of an anesthetic technique. A standardized four-grade classification system may be used to communicate the degree of urgency among providers (Table 26.4).[116] Using such a classification system also facilitates comparing data and outcomes among providers and institutions.[116]

In cases of dire fetal compromise, the anesthesia provider may need to perform a preanesthetic evaluation simultaneously with other tasks (i.e., establishing intravenous access and placing a blood pressure cuff, pulse oximeter probe, and ECG electrodes). Regardless of the urgency, the anesthesia provider should not compromise maternal safety by failing to obtain critical information about previous medical and anesthetic history, allergies, and the airway. Effective communication with the obstetric team is critical to establish the degree of urgency, which helps guide decisions regarding anesthetic management. Further, contemporary standards for patient safety require that all members of the surgical team participate in a preoperative "time-out" to verify (1) the correct patient identity, position, and operative site; (2) agreement on the procedure to be performed; and (3) the availability of special equipment, if needed.

In cases of emergency cesarean delivery, the emotional needs of the mother and father are also important. Parental distress commonly occurs in this setting, and the anesthesia provider is often the best person to give reassurance. All members of the obstetric care team should remember that chaos does not need to accompany urgency.

Neuraxial versus General Anesthesia

Overall, neuraxial (epidural, spinal, CSE) techniques are the preferred method of providing anesthesia for cesarean delivery; specific benefits and risks of each technique dictate the eventual choice. In contemporary practice, neuraxial anesthesia is administered to some patients who would have received general anesthesia in the past. Umbilical cord prolapse, placenta previa, and preeclampsia with severe features are no longer considered absolute indications for general anesthesia. For example, in some cases a prolapsed umbilical cord can be decompressed, and if fetal status is reassuring, a neuraxial technique can be used. In an analysis of obstetric anesthesia trends in the United States between 1981 and 2012, a progressive increase was noted in the use of neuraxial anesthesia, especially spinal anesthesia, for both elective and emergency cesarean deliveries.[19] Neuraxial anesthesia is now used for more than 95% of elective cesarean deliveries and 80% of emergent cesarean deliveries in the United States.[19,117] Similar increases have occurred in other developed as well as developing countries.[118–120]

The greater use of neuraxial anesthesia for cesarean delivery has been attributed to several factors, including (1) the growing use of epidural techniques for labor analgesia, (2) an awareness of the possibility that an *in situ* epidural catheter may decrease the necessity for general anesthesia in an urgent situation, (3) improvement in the quality of neuraxial anesthesia with the addition of an opioid to the local anesthetic, (4) appreciation of the risks of airway complications during general anesthesia in parturients, (5) the desire for limited neonatal drug transfer, and (6) the ability of the mother to remain awake to experience childbirth and to have a support person present in the operating room. Spinal anesthesia is considered an appropriate technique even in the most urgent settings; in a tertiary care institution with an average of 9500 cesarean deliveries annually, neuraxial anesthesia was used in more than 99% of cesarean deliveries over a 6-year period.[121] In the setting of a category 1 (immediate threat to life of woman or fetus) cesarean delivery, Kinsella et al.[122] described a "rapid-sequence spinal" technique, by which skin preparation, spinal drug combinations, and the spinal technique were simplified; the median time from positioning until satisfactory neuroblockade was 8 minutes (interquartile range [IQR] 7 to 8, range 6 to 8).

Maternal *mortality* following general anesthesia has been a primary motivator for the transition toward greater use of neuraxial anesthesia for cesarean delivery. A study compared the anesthesia-related maternal mortality rate from 1979 to 1984 with that for the period from 1985 to 1990 in the United States.[123] The estimated case-fatality risk ratio for general versus neuraxial anesthesia was as high as 16.7 in the years 1985 to 1990; however, a similar analysis by the same group of investigators found a nonsignificant risk ratio of 1.7 in the years 1991 to 2002.[124] This shift may reflect technological advances in the devices available for airway management and their widespread dissemination (e.g., supraglottic airways, fiberoptic bronchoscopes). Of interest, these data may overstate the relative risk associated with general anesthesia, because this method of anesthesia is used principally when neuraxial anesthetic techniques are contraindicated for medical reasons or time constraints.

The type of maternal *morbidity* differs with the use of neuraxial anesthetic techniques and general anesthesia. A systematic review of randomized and quasi-randomized controlled trials comparing major maternal and neonatal outcomes with the use of neuraxial anesthesia and general anesthesia for cesarean delivery found less maternal blood loss and shivering but more nausea in the neuraxial anesthesia group.[125] The intraoperative "perception" of pain was greater in the neuraxial group, but the time elapsed before the first

TABLE 26.2 Provision of Anesthesia for Cesarean Delivery[a]

Phase	Issues	Specific Concerns
Preparation	Preanesthetic evaluation	History and physical examination
		Indicated laboratory measurements
		Imaging studies
	Oral intake	No clear liquids and solid foods for 2 hours and 6–8 hours, respectively, before elective surgery (the presence of comorbid conditions may warrant a longer fasting interval)
	Communication with obstetric team	Indication(s) for cesarean delivery, including degree of urgency
		Anticipated surgical complications
	Informed consent	Threshold, information, and consent elements
		Informed refusal
	Blood products	Risk factors for hemorrhage
		Baseline hematocrit or hemoglobin measurement
		Blood type and screen or cross-match
		Equipment for rapid transfusion
	Monitoring	Pulse oximetry, electrocardiogram, blood pressure, fetal heart rate, urinary catheter
		Consider electroencephalographic (bispectral index) monitoring during general anesthesia (controversial)
		Invasive monitoring in selected patients
	Medication availability	Anesthetic (general and neuraxial anesthetic drugs, vasopressors)
		Obstetric (uterotonic agents)
		Emergency (advanced cardiac life support, malignant hyperthermia)
	Equipment availability	Anesthesia, airway management
	Aspiration prophylaxis	Fasting guidelines, nonparticulate antacid, H_2-receptor antagonist, metoclopramide
	Prophylactic antibiotics[b]	Within 60 minutes *before* incision
	Intravenous access and fluid management	Intravenous catheter: 16- or 18-gauge
		Fluid type, volume, and rate
	Supplemental medications	Consider anxiolysis for severe anxiety
	Positioning	Lateral or sitting position for neuraxial needle/catheter placement
		Left uterine displacement, slight head up for surgery
		"Sniffing" position if general anesthesia is planned
	Supplemental oxygen	Preoxygenation/denitrogenation required before general anesthesia
		Of unclear benefit during neuraxial anesthesia for elective delivery of a noncompromised fetus
Selection of anesthetic technique	Neuraxial	Adequate sacral and cephalad spread (T4) and density of neuroblockade
		Prevention or treatment of hypotension
	General	Airway management
		Prevention of awareness and recall
		Prevention of anesthesia-associated uterine atony
	Local	Usually a supplement for inadequate neuraxial anesthesia
		Can facilitate emergency delivery in absence of an anesthesia provider
		Rarely provides satisfactory anesthesia as a primary technique
Recovery	Oral intake	Fluids and foods allowed within 4 to 8 hours of surgery, in absence of complications
	Removal of urinary catheter	Typically within 24 hours
	Postoperative assessment and discharge	Hemodynamic stability
		Resolution of neuroblockade
		Effective analgesia
		Recognition and treatment of surgical and anesthetic complications

[a]Procedures, techniques, and drugs may need to be modified for individual patients and circumstances.
[b]Evidence suggests that administration of prophylactic antibiotics *before* incision (rather than after cord clamping) reduces the incidence of postcesarean endometritis and total maternal infectious morbidity.[52]

TABLE 26.3 Selection of Anesthetic Technique for Cesarean Delivery

Indication(s)	Comments/Examples
For Neuraxial Anesthesia[a]	
Maternal desire to witness birth and/or avoid general anesthesia	Most common maternal preference
Risk factors for difficult airway or aspiration	Physical examination predicts possible difficult airway History of difficult tracheal intubation High body mass index (obesity) History of gastroesophageal reflux (common in pregnancy)
Presence of comorbid conditions	Malignant hyperthermia history Pulmonary disease
General anesthesia intolerance or failure	History of significant side effects with general anesthesia Attempted general anesthesia with failed intubation; patient awakened
Other benefits	Plan for neuraxial analgesia after surgery Less fetal drug exposure Less blood loss Allows presence of husband or support person
For General Anesthesia[a]	
Maternal refusal or failure to cooperate with neuraxial technique	Strong maternal preference, in the absence of factors that predict a difficult airway Severe psychiatric disorder Severe developmental delay Severe emotional immaturity or lability
Presence of comorbid conditions that contraindicate a neuraxial technique	Coagulopathy Local infection at neuraxial insertion site Sepsis Severe uncorrected hypovolemia (e.g., hemorrhage from placenta previa or uterine rupture) Intracranial mass with increased intracranial pressure Known allergy to local anesthetic (rare)
Insufficient time to induce neuraxial anesthesia for urgent delivery	Umbilical cord prolapse with persistent fetal bradycardia
Failure of neuraxial technique	Multiple needle placement failures Missed spinal segments Persistent intraoperative pain that is not treated successfully
Fetal issues	Planned *ex utero* intrapartum treatment (EXIT) procedure

[a]Many indications for or contraindications to specific anesthesia techniques are relative, and the choice of anesthetic must be tailored to individual circumstances.

TABLE 26.4 Classification for Urgency of Cesarean Delivery

Grade	Label	Definition	Example
1	Emergency	Immediate threat to life of mother or fetus	Prolonged fetal bradycardia
2	Urgent	Maternal or fetal compromise that is not immediately life-threatening	Deep variable decelerations with cervical dilation of 3 cm
3	Scheduled	Needing early delivery but no maternal or fetal compromise	Ruptured membranes with previously undiagnosed breech presentation
4	Elective	At a time to suit the mother and delivery team	Elective repeat cesarean delivery

Modified from Lucas DN, Yentis SM, Kinsella SM, et al. Urgency of caesarean section: a new classification. *J R Soc Med.* 2000;93:346–350.

postoperative request for analgesia was longer. Prospective audits of post-cesarean delivery outcomes have indicated that in the first postoperative week, patients who received neuraxial anesthesia had less pain, gastrointestinal stasis, coughing, fever, and depression and were able to breast-feed and ambulate more quickly than patients who received general anesthesia.[126]

Neonatal outcomes associated with maternal anesthetic selection require further study. Apgar and neonatal neurobehavioral scores are relatively insensitive measures of neonatal well-being, and umbilical cord blood gas and pH measurements may reflect the reason for the cesarean delivery rather than differences in the effect of the anesthetic technique on fetal/neonatal well-being. In a meta-analysis, lower umbilical

cord blood pH measurements were associated with spinal, but not epidural, anesthesia compared with general anesthesia.[127] However, the study included both randomized and nonrandomized trials and both elective and nonelective procedures, and most trials were conducted in an era when ephedrine was used to support maternal blood pressure (see later discussion). In a systematic review of randomized trials in which the indication for cesarean delivery was not urgent, no differences in umbilical cord arterial blood pH measurements were found among general and neuraxial anesthetic techniques.[125]

Overview of Neuraxial Anesthetic Techniques

Table 26.5 outlines the advantages and disadvantages of the various neuraxial anesthetic techniques for cesarean delivery. With all neuraxial techniques, an adequate sensory level of anesthesia is necessary to minimize maternal pain and avoid the urgent need for administration of general anesthesia. Because motor nerve fibers are typically larger and more difficult to block, the complete absence of hip flexion and ankle dorsiflexion most likely indicates that a functional sensory and sympathetic block is also present in a similar (primarily lumbosacral) distribution. However, because afferent nerves innervating abdominal and pelvic organs accompany sympathetic fibers that ascend and descend in the sympathetic trunk (T5 to L1), a sensory block that extends rostrally from the sacral dermatomes to T4 should be the goal for cesarean delivery anesthesia.

The manner in which the level of sensory blockade is assessed has implications for the success of a neuraxial technique. The different methods of assessing the extent of sensory blockade (i.e., sensation to light touch, pinprick, cold) may indicate levels of blockade that differ by several spinal segments. A prospective study of 102 women undergoing cesarean delivery with spinal anesthesia indicated that although sensory blockade to light touch differed from sensory blockade to pinprick or cold sensation by 0 to 11 spinal segments, no constant relationship among these levels could be determined.[128] The investigators concluded that a T6 blockade to touch would likely provide a pain-free cesarean delivery for most women.

Sensory examination should move caudad to cephalad in the mid-axillary line on the lower extremities but can be performed in the mid-clavicular line on the torso. The time at which an adequate block is achieved, as well as the cephalad level of the block and the presence of surgical anesthesia of the lower abdomen, should be documented on the anesthetic record.

Because the undersurface of the diaphragm (C3 to C5) and the vagus nerve may be stimulated by surgical manipulation during cesarean delivery,[129] maternal discomfort (including shoulder pain) and other symptoms (e.g., nausea and vomiting) may occur despite a T4 level of blockade. Neuraxial or systemic opioids help prevent or alleviate these symptoms (see later discussion).

TABLE 26.5 Advantages and Disadvantages of Neuraxial Anesthetic Techniques for Cesarean Delivery

Neuraxial Technique	Advantages	Disadvantages
Epidural	No dural puncture required Can use *in situ* catheter placed for earlier administration of labor analgesia Ability to titrate extent of sensory blockade Continuous intraoperative anesthesia Continuous postoperative analgesia	Slow onset of anesthesia Larger drug doses required than for spinal techniques: • Greater risk for maternal local anesthetic systemic toxicity • Greater fetal drug exposure
Combined spinal-epidural	May be technically easier than spinal anesthesia in obese patients Low doses of local anesthetic and opioid Rapid onset of dense lumbosacral and thoracic anesthesia Ability to titrate extent of sensory blockade Continuous intraoperative anesthesia Continuous postoperative analgesia	Delayed verification of functioning epidural catheter
Continuous spinal	Low doses of local anesthetic and opioid Rapid onset of dense anesthesia Ability to titrate extent of sensory blockade Continuous intraoperative anesthesia	Large dural puncture increases risk for post–dural puncture headache Possibility of overdose and total spinal anesthesia if the spinal catheter is mistaken for an epidural catheter
Single-shot spinal	Technically simple Low doses of local anesthetic and opioid Rapid onset of dense lumbosacral and thoracic anesthesia	Limited duration of anesthesia Limited ability to titrate extent of sensory blockade

Spinal Anesthesia

Spinal anesthesia is a simple and reliable technique that allows visual confirmation of correct needle placement (by visualization of CSF) and is technically easier to perform than an epidural technique. Spinal anesthesia provides rapid onset of dense neuroblockade that is typically more profound than that provided with an epidural technique, resulting in a reduced need for supplemental intravenous analgesics or conversion to general anesthesia.[130,131] Only a small amount of local anesthetic is needed to establish functional spinal blockade; therefore, spinal anesthesia is associated with negligible maternal risk for systemic local anesthetic toxicity and with minimal drug transfer to the fetus. Given these advantages, spinal anesthesia is the most commonly used anesthetic technique for cesarean delivery in the developed world.[19] Spinal anesthesia is also associated with predictable and relatively prompt recovery that enables patients to quickly transition through the postanesthesia care unit (PACU); in some settings, such a recovery may result in a cost savings to the institution.[130]

Spinal anesthesia is usually administered as a single-injection procedure ("single-shot" technique) through a noncutting, pencil-point needle that is 24-gauge or smaller. A number of different needle designs are available (see Chapter 12); the size and design of the needle tip affect the incidence and severity of post–dural puncture headache (see Chapter 30).

The spinal technique should be performed at the L3–L4 interspace or below (see Chapter 12). This space is used to avoid the potential for spinal cord trauma; although the spinal cord ends at L1 in most adults, it extends to the L2–L3 interspace in a small minority (see Chapter 31). Additionally, anesthesia providers often misidentify the location of the needle insertion site on the spinal column, and the needle is more frequently introduced at a higher level than intended.

On occasion, a continuous spinal anesthetic technique is used, particularly in the setting of an unintentional dural puncture with an epidural needle. Intentional continuous spinal anesthesia may be desirable in certain settings, when the reliability of a spinal technique and the ability to precisely titrate the initiation and duration of anesthesia are strongly desired (e.g., a morbidly obese patient with a difficult airway). Continuous spinal anesthesia may be administered through purpose-intended spinal catheters or through an "epidural catheter" that is sited in the subarachnoid space through an epidural needle that is advanced into the subarachnoid space (see Chapter 12).

Local Anesthetic Agents

The choice of local anesthetic agent (and adjuvants) used to provide spinal anesthesia depends on the expected duration of the surgery, the postoperative analgesia plan, and the preferences of the anesthesia provider. For cesarean delivery, the local anesthetic agent of choice is typically **bupivacaine** (Table 26.6). In the United States, spinal bupivacaine is formulated as a 0.75% solution in dextrose 8.25%; in other countries use of 0.5% concentration is common. Intrathecal administration of bupivacaine results in a dense block of long duration.

TABLE 26.6 Drugs Used for Spinal Anesthesia for Cesarean Delivery

Drug	Dose Range	Duration (min)[a]
Local Anesthetics		
Lidocaine	60–80 mg	45–75
Bupivacaine	7.5–15 mg	60–120
Levobupivacaine	7.5–15 mg	60–120
Ropivacaine	15–25 mg	60–120
Opioids		
Fentanyl	10–25 µg	180–240
Sufentanil	2.5–5 µg	180–240
Morphine	100–200 µg (0.1–0.2 mg)	720–1440
Hydromorphone	60–75 µg (0.060–0.075 mg)	720–875
Meperidine[b]	60–70 mg	60
Adjuvant Drugs		
Epinephrine[c]	100–200 µg (0.1–0.2 mg)	

[a]For the local anesthetics, the duration is defined as the time to two-segment regression. For the opioids, the duration is defined as the period of analgesia (or time to first request for a supplemental analgesic drug).
[b]Meperidine has both local anesthetic and opioid properties and can provide surgical anesthesia without the addition of a local anesthetic. The dose indicated represents meperidine used without a local anesthetic.
[c]The addition of epinephrine may augment the duration of local anesthetics by 15 to 20 minutes.

The dose of intrathecal bupivacaine that has been successfully used for cesarean delivery ranges from 4.5 to 15 mg. In general, pregnant patients require smaller doses of spinal local anesthetic than nonpregnant patients. Reasons include (1) a smaller CSF volume in pregnancy, (2) cephalad movement of hyperbaric local anesthetic in the supine pregnant patient, and (3) greater sensitivity of nerve fibers to the local anesthetic during pregnancy.[132] Overall, the mass of local anesthetic, rather than the concentration or volume, is thought to influence the spread of the resulting blockade[133]; however, the specific influence of the dose/concentration and baricity on the efficacy of the block is controversial. The necessary dose may be influenced by other factors, such as coadministration of neuraxial opioids and surgical technique. (Exteriorization of the uterus during closure of the uterus is more stimulating than closure *in situ*.)

A dose-finding study in 48 women undergoing cesarean delivery demonstrated that the effective dose for 95% of recipients (ED_{95}) for plain bupivacaine with fentanyl 10 µg and morphine 0.2 mg was 13 mg; the effective dose for 50% of recipients (ED_{50}) was 7.25 mg.[134] However, other studies have suggested that lower doses can be used successfully. Low doses of hyperbaric or plain bupivacaine (9 mg with

fentanyl 20 μg,[135] 6.6 mg with sufentanil 3.3 μg[136]) have been demonstrated to provide adequate spinal anesthesia for most patients; whether hyperbaric or plain bupivacaine provides better anesthesia remains unclear. Reducing the dose of plain bupivacaine from 10 to 5 mg has been observed to decrease the incidence of hypotension and nausea; however, these findings were obscured by the variable use of opioids in the low-dose group.[137] Finally, in a comparison of plain bupivacaine 4.5 mg with hyperbaric bupivacaine 12 mg (both with fentanyl 50 μg and morphine 0.2 mg), similar cephalad sensory levels (C8), incidence of hypotension (approximately 75%), side effects, and patient satisfaction scores were found with the two approaches.[138] Five of 27 (19%) patients in the bupivacaine 4.5-mg group and 1 of 25 (4%) patients in the bupivacaine 12-mg group required supplemental analgesia; no conversion to general anesthesia occurred. Altogether, while these data indicate that lower anesthetic doses *can* be used, whether they *should* be used is controversial. The anesthesia provider should consider whether adjuvant drugs will be used and whether the risks of giving supplemental analgesia or conversion to general anesthesia that are associated with low doses of bupivacaine outweigh the potential benefits (i.e., less hypotension, faster recovery).

For a single-shot spinal technique, most clinicians use a dose of bupivacaine between 10 and 15 mg, in combination with an opioid. Studies of hyperbaric bupivacaine (12 to 15 mg) have determined that the patient's age, height, weight, body mass, and vertebral column length do not affect the resulting neuraxial blockade.[139,140] The use of the larger dose (15 mg) results in a longer duration of surgical anesthesia; however, cervical sensory blockade is achieved more frequently (Fig. 26.2). In patients with extremes of height (less than 5 feet [152 cm], or greater than 6 feet [183 cm]), some anesthesia providers alter the dose of local anesthetic. The baricity of the local anesthetic *does* affect the extent of spread of blockade. When the cephalad spread of hyperbaric local anesthetic is desired, the patient can be placed in a slight head-down position.

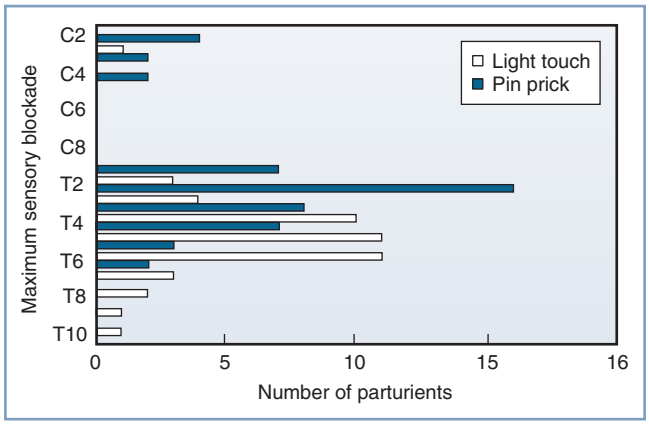

Fig. 26.2 Maximum cephalad sensory level for analgesia or anesthesia in 52 term parturients after spinal injection of hyperbaric bupivacaine 15 mg with morphine 0.15 mg. (Modified from Norris MC. Patient variables and the subarachnoid spread of hyperbaric bupivacaine in the term patient. *Anesthesiology*. 1990;72:478–482.)

Ropivacaine is approximately 40% less potent than bupivacaine after spinal injection in nonpregnant individuals.[141] In a dose-finding study of 72 patients undergoing elective cesarean delivery with CSE anesthesia randomly assigned to receive plain ropivacaine 10, 15, 20, or 25 mg,[142] the ED_{50} and ED_{95} were determined to be 16.7 mg and 26.8 mg, respectively. Subsequently, the same investigators demonstrated that hyperbaric spinal ropivacaine 25 mg produced a more rapid block with faster recovery and fewer requirements for supplemental epidural anesthesia than the same dose of plain ropivacaine in women undergoing cesarean delivery with spinal anesthesia.[143]

The value of ropivacaine compared with bupivacaine for spinal anesthesia, however, is doubtful. Given the low doses, there is minimal, if any, reduction in risk for local anesthetic systemic toxicity. Further, it is not clear whether ropivacaine produces spinal anesthesia of similar quality to that provided by bupivacaine. An assessment of plain spinal ropivacaine 0.5% versus bupivacaine 0.5%, both administered with morphine 0.15 mg, found that ropivacaine was associated with a slower onset, less hypotension, and faster recovery.[144]

Similarly, spinal **levobupivacaine** may not be as effective as bupivacaine. A randomized trial assigned 90 parturients to receive bupivacaine 8 mg, levobupivacaine 8 mg, or ropivacaine 12 mg (all with sufentanil 2.5 μg); effective anesthesia was achieved in 97%, 80%, and 87% of patients, respectively.[145] The duration of levobupivacaine and ropivacaine sensory and motor blockade was shorter than that with bupivacaine.[145] The U.S. Food and Drug Administration (FDA) has not approved ropivacaine or levobupivacaine for intrathecal administration. Thus, in the United States, bupivacaine remains the predominant agent for spinal anesthesia for cesarean delivery.

Hyperbaric spinal **lidocaine** or **mepivacaine** (60 to 80 mg) may be used when the obstetrician can reliably perform cesarean delivery in less than 45 minutes. The use of hyperbaric lidocaine for spinal anesthesia remains controversial because of concerns about transient neurologic symptoms (see Chapter 31).

Adjuvant Agents

Adjuvant medications contribute to spinal anesthesia by different mechanisms from those of local anesthetics. For cesarean delivery, adjuvant agents improve the quality of intraoperative anesthesia, prolong postoperative analgesia, and reduce the dose, and therefore the side effects, of local anesthetics. Opioids, dextrose, and epinephrine are commonly used adjuvants; neostigmine and clonidine are two agents undergoing clinical investigation.

Opioids have been observed to improve intraoperative and postoperative comfort for patients undergoing spinal anesthesia for cesarean delivery. Intraoperatively, this effect can be observed through a reduction in local anesthetic drug doses and the need for analgesic supplementation. In a systematic review of intraoperative and postoperative analgesic efficacy

and adverse effects of intrathecal opioids, 24% of patients undergoing cesarean delivery with spinal hyperbaric bupivacaine alone required supplemental intraoperative analgesia compared with 4% who also received intrathecal opioids.[146] Opioids augment the quality and prolong the duration of local anesthetic–induced blockade, an effect most likely modulated by A-delta (pinprick) and C (cold) nerve fibers; muscle function (A-alpha nerve fibers) does not appear to be affected.[147] The mechanism for the opioid-induced prolongation of sensory block remains unclear but may include modulation of sensory input at the spinal and supraspinal level as well as an alteration of consciousness of peripheral sensations.[148]

An additional advantage of intrathecal opioid administration is its salutary effect on the incidence of *intraoperative* nausea and vomiting. During periods of visceral stimulation (i.e., exteriorization of the uterus and fascial stimulation during closure), patients often complain of nausea. The addition of spinal fentanyl in doses of 10 to 25 μg to lidocaine or bupivacaine decreases the incidence of nausea and/or vomiting during cesarean delivery.[149,150]

Clinicians commonly add both a lipid- and water-soluble opioid to the local anesthetic for spinal anesthesia for cesarean delivery. This practice takes advantage of the fast onset of the lipid-soluble agent and the prolonged duration of the water-soluble agent (Fig. 26.3) (see Chapter 13). However, there is some evidence that the administration of a lipid-soluble agent (e.g., fentanyl, sufentanil) with a water-soluble agent (e.g., morphine) leads to acute spinal opioid tolerance. In a study of 60 patients undergoing cesarean delivery, there was no difference in intravenous patient-controlled analgesia morphine consumption within the first 6 hours in patients randomized to receive spinal fentanyl 25 μg or saline added to plain bupivacaine 10 mg.[151] However, between 6 and 23 hours, there was a 63% increase in morphine use in the group that received fentanyl.[151] In another a study of 40 women undergoing cesarean delivery using intrathecal fentanyl (0, 5, 10, or 25 μg) combined with hyperbaric bupivacaine 12 mg and morphine 0.2 mg, higher postoperative pain scores were observed in the patients who received fentanyl, but no differences were observed among groups in postoperative intravenous patient-controlled analgesia morphine consumption.[152] Women who did not receive fentanyl had a higher incidence of intraoperative nausea and vomiting, suggesting that fentanyl is an important adjunct for *intraoperative* anesthesia.[152] In general, we believe the improvement of intraoperative analgesia outweighs the potential for acute opioid tolerance. We therefore recommend the administration of both a lipid- and a water-soluble opioid when spinal anesthesia is administered for cesarean delivery.

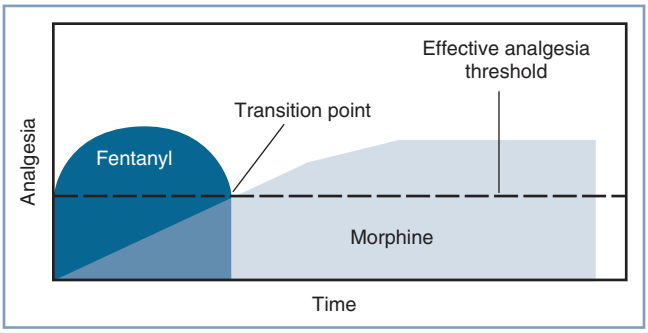

Fig. 26.3 Schematic illustration of the pharmacokinetic and pharmacodynamic activities resulting from the neuraxial administration of a lipid-soluble opioid (e.g., fentanyl) and a water-soluble opioid (e.g., morphine) for analgesia. The transition point varies according to the opioid drugs and doses administered. For most commonly used opioids, this transition point occurs in the postoperative period.

The optimal dose of spinal opioids is influenced by the type, dose, and baricity of the accompanying local anesthetic and the presence of other adjuvants. In a systematic review and meta-analysis of studies examining the use of spinal **fentanyl** (2.5 to 60 μg) to augment spinal anesthesia for cesarean delivery, studies were pooled into two groups based on spinal fentanyl dose (15 to 35 μg and 40 to 60 μg)[146]; no difference between groups in the need for supplemental intraoperative analgesia was observed. Postoperative pruritus, nausea, and vomiting were significantly lower with administration of doses less than 35 μg, although no meaningful postoperative analgesia was produced at these doses. Spinal doses of fentanyl 10 to 25 μg are commonly used for cesarean delivery anesthesia (see Table 26.6).[146,153]

Spinal **sufentanil** 2.5 to 20 μg has been used with bupivacaine for cesarean delivery. A study of 37 parturients undergoing elective cesarean delivery with sufentanil (0, 10, 15, or 20 μg) added to hyperbaric bupivacaine 10.5 mg found better quality and longer duration of analgesia in all sufentanil groups than in the control group; Apgar scores, umbilical cord blood gas measurements, and Early Neonatal Neurobehavioral Scale (ENNS) scores were similar among groups.[154] No cases of respiratory depression occurred. A randomized study assigned parturients to receive hyperbaric bupivacaine 12.5 mg with sufentanil (0, 2.5, 5, or 7.5 μg).[155] Analgesia lasted longer with sufentanil 5 and 7.5 μg, and pruritus and somnolence were more pronounced with 7.5 μg. Thus, there appears to be little justification for giving a dose of sufentanil greater than 5 μg in this setting.

Preservative-free **morphine, hydromorphone,** and **diamorphine** can improve intraoperative comfort of parturients during cesarean delivery; however, these drugs are primarily used for providing prolonged (12 to 24 hours) postcesarean analgesia (see Chapter 27). Spinal morphine has a latency of 30 to 60 minutes for onset of analgesia,[156] and it produces significant analgesia with acceptable side-effect profiles when given in doses ranging from 0.05 to 0.25 mg. In a dose-response study of morphine added to hyperbaric bupivacaine 12.75 mg, morphine 0.1 mg provided analgesia comparable to that provided by doses as high as 0.5 mg.[157] The incidence of pruritus, but not nausea and vomiting, appeared to be dose-related. A more recent study that randomized patients to morphine 0.05, 0.10, or 0.15 mg combined with hyperbaric bupivacaine 12 mg and fentanyl 15 μg, and intravenous ketorolac, found no difference in measures of analgesia among the three groups; pruritus was more common at doses

of 0.10 and 0.15 mg than 0.05 mg.[158] **Hydromorphone**, while used less commonly than morphine, also appears to provide effective postcesarean analgesia, with an intrathecal potency ratio of 2:1 compared with morphine.[159]

Intrathecal **diamorphine** is used in the United Kingdom for postoperative analgesia. It is metabolized to the two active compounds 6-acetyl morphine and morphine. Diamorphine is more lipophilic than morphine, enabling a rapid onset (6 to 9 minutes, similar to fentanyl) but a potentially shorter duration of action.[160] In a study of intrathecal diamorphine 0.4 mg combined with bupivacaine 12.5 mg, the intraoperative supplementation rate was less than 5%; however, the incidence of nausea and vomiting was 56%, and the incidence of pruritus was 80%.[161]

Neuraxial administration of water-soluble opioids such as morphine may be associated with delayed respiratory depression (6 to 18 hours after administration) (see Chapter 27). Postoperative monitoring protocols should observe for respiratory depression, which although infrequent, can lead to mortality, particularly in high-risk patients (e.g., those with sleep apnea or obesity).[146,162] The respiratory depressant effects of many opioids, including morphine and diamorphine, outlast the antagonism provided by naloxone (approximately 90 minutes).[163]

Spinal local anesthetics are often prepared in **dextrose** to make the agents hyperbaric. For example, commercially available hyperbaric bupivacaine contains 8.25% dextrose (82.5 mg/mL). The amount of dextrose required to make a meaningful clinical difference in a spinal technique with local anesthetic agents has not been well characterized. *Baricity* is defined as the ratio of the density of the local anesthetic solution to the density of CSF measured at the same temperature. The density of CSF is lower in women than in men, particularly during pregnancy and the immediate postpartum period[164]; even so, CSF density is significantly greater than that of local anesthetics and opioids in the absence of dextrose.[164]

The intrathecal administration of an alpha-adrenergic agonist (e.g., epinephrine, clonidine) increases the density of sensory and motor blockade and may prolong the duration of blockade as well as contribute to postcesarean analgesia. A randomized trial involving 63 women undergoing elective cesarean delivery showed that intrathecal **epinephrine** 0.1 to 0.2 mg, when combined with hyperbaric bupivacaine, improved the quality of intraoperative analgesia and prolonged both sensory and motor blockade by approximately 15% compared with bupivacaine alone.[165] However, another study found that the addition of epinephrine 0.3 mg to hyperbaric bupivacaine 12.5 mg for elective cesarean delivery increased the incidence of nausea.[166]

Spinal **clonidine,** in doses of 60 to 150 μg, improves intraoperative analgesia, decreases shivering, and reduces peri-incisional hyperalgesia in women undergoing cesarean delivery; however, it has been associated with hypotension and sedation.[167] This agent is not used commonly in the United States, although it may be considered in specific circumstances (e.g., when patients are expected to be tolerant to the effects of neuraxial opioid analgesia). The FDA has issued a "black box" warning against its use in obstetric patients because of concern for hypotension.

In women undergoing cesarean delivery, spinal **neostigmine** in doses up to 100 μg significantly reduced postoperative pain with no effect on FHR or Apgar scores. However, multiple studies have demonstrated a high incidence of nausea and emesis associated with intrathecal neostigmine, which may be refractory to treatment with antiemetic agents.[168–170] This side effect significantly limits its clinical use.

At many institutions, the spinal agents and doses are standardized so that consistent results are obtained during the provision of spinal anesthesia for cesarean delivery. Such standardization enables the anesthesia, obstetric, and nursing staff to anticipate predictable onset and recovery characteristics and respond to physiologic responses that are outside the norm. Standardization of drugs and doses may also result in fewer errors. At our institution, spinal anesthesia for cesarean delivery is provided with 0.75% hyperbaric bupivacaine 12 mg, fentanyl 10 μg, and morphine 0.1 mg. Intrathecal opioids are drawn in a tuberculin or insulin syringe to insure measurement accuracy. Another common practice is the administration of 0.75% hyperbaric bupivacaine 12 mg, fentanyl 15 μg, and morphine 0.15 mg.

Epidural Anesthesia

The use of epidural anesthesia for nonelective cesarean delivery has increased, primarily because of the greater use of epidural analgesia during labor. However, the use of epidural anesthesia is less common for *elective* cesarean delivery when an epidural catheter is not already *in situ* (e.g., for labor analgesia), in part because the resulting block is less reliable than that with spinal anesthesia. Initiation of CSE anesthesia offers both rapid onset and reliable spinal anesthesia coupled with the ability to augment or prolong the blockade through the epidural catheter (e.g., cases that are high-order repeat cesarean deliveries, have greater risk for hemorrhage, or include tubal sterilization or additional procedures).

Epidural local anesthetic and opioid doses are generally 5 to 10 times greater than doses given intrathecally; this difference results from the requirement for penetration of nerve roots as they traverse the epidural space, the greater capacity of the epidural space, and the presence of the epidural venous plexus, which becomes progressively more engorged during pregnancy. Greater systemic absorption of anesthetic agents occurs with epidural anesthesia than with spinal anesthesia, and the risk for local anesthetic systemic toxicity is a real possibility with local anesthetic injection for epidural anesthesia, but not for spinal anesthesia.

Possible advantages of the epidural technique include a slower onset of sympathetic blockade; this may allow compensatory mechanisms to attenuate the severity of hypotension. This approach has utility in the care of patients with severe cardiac disease for whom even transient hypotension may be poorly tolerated. A catheter-based technique also allows titration of the level, density, and duration of anesthesia. Continuous postcesarean analgesia can be provided through an epidural catheter.

TABLE 26.7 Drugs Used for Epidural Anesthesia for Cesarean Delivery

Drug	Dose Range[a]	Duration (min)[b]
Local Anesthetics		
Lidocaine 2% with epinephrine 5 µg/mL	300–500 mg	75–100
2-Chloroprocaine 3%	450–750 mg	40–50
Bupivacaine 0.5%	75–125 mg	120–180
Ropivacaine 0.5%	75–125 mg	120–180
Opioids		
Fentanyl	50–100 µg	120–240
Sufentanil	10–20 µg	120–240
Morphine	3–4 mg	720–1440
Hydromorphone	0.6–1.5 mg	780–1090
Meperidine	50–75 mg	240–720

[a]Both the mass and volume of local anesthetic affect the extent and quality of anesthesia. The usual volume of local anesthetic solution administered into the epidural space at the indicated concentrations is 15 to 25 mL. More mass/volume is required for initiating epidural anesthesia *de novo;* conversely, less is required if epidural labor analgesia is being extended to surgical anesthesia.
[b]For the local anesthetics, the duration is defined as the time to two-segment regression. For the opioids, the duration is defined as the period of analgesia (or time to first request for a supplemental analgesic drug).

Local Anesthetic Agents

The most common local anesthetic used in the United States for the initiation and maintenance of epidural anesthesia for cesarean delivery is 2% **lidocaine with epinephrine** (Table 26.7). The epidural administration of lidocaine in concentrations less than 2%, or without the addition of epinephrine (which augments the analgesia through alpha-adrenergic receptor blockade[171]), may result in anesthesia that is inadequate for surgery.[172]

The epidural administration of a 3% solution of **2-chloroprocaine** has the most rapid onset and the shortest duration of action of available local anesthetics. These characteristics make it an excellent choice for emergency cesarean delivery (see later discussion) because the dose is administered rapidly, and even if unintentional intravenous administration of drug were to occur, the sequelae are likely to be less severe than the similar administration of an amide local anesthetic agent. Administration of 2-chloroprocaine has been associated with neurologic sequelae, possibly associated with the antioxidant sodium bisulfite, and paralumbar muscle spasms and pain, believed to be a result of calcium chelation by the preservative EDTA. Current preparations of 2-chloroprocaine do not contain an antioxidant or a preservative (see Chapter 13). Epidural administration of 2-chloroprocaine may be associated with a rapid onset of hypotension and an apparent reduction in the clinical efficacy of subsequently administered epidural opioids (see Chapter 13).[173] The pharmacokinetic characteristics of the drug likely play a role. The analgesic effect of epidural morphine administered 30 minutes *before* 2-chloroprocaine does not appear to be mitigated; however, administration of morphine before 2-chloroprocaine in the setting of emergency cesarean delivery is not possible.[173] These considerations limit the use of 2-chloroprocaine to those situations in which the rapid onset of anesthesia is paramount.

Surgical anesthesia can be produced with epidural administration of 0.5% **bupivacaine**; however, the slow onset of neuroblockade and the risk for cardiovascular sequelae from unintentional intravascular injection (or systemic absorption) have limited the contemporary use of this agent in the United States. (The risk for cardiovascular sequelae resulted in a proscription against the epidural administration of 0.75% bupivacaine in obstetric patients by the FDA.[174]) The single-isomer, levorotatory local anesthetics 0.5% to 0.75% **ropivacaine** and 0.5% **levobupivacaine** may be preferable to racemic bupivacaine because of their better safety profiles and earlier recovery, although a significant portion of the improved safety profile is caused by the lower potency of these agents (0.5% bupivacaine is more potent than 0.5% levobupivacaine or 0.5% ropivacaine).[175] A randomized controlled trial of 60 patients compared 30 mL of epidural 0.5% levobupivacaine with racemic 0.5% bupivacaine in women undergoing elective cesarean delivery; no differences in the block onset or resolution, signal-averaged ECG results, complications, or maternal and fetal plasma pharmacokinetic profiles between the treatment groups was found.[176] Another study involving 62 patients undergoing cesarean delivery with epidural anesthesia reported no difference in onset, spread, or duration of sensory block in women who received 25 mL of 0.5% levobupivacaine or 0.5% racemic bupivacaine,[177] although levobupivacaine produced lower limb motor blockade of longer duration and less intensity. Finally, a study of 60 patients demonstrated that the onset, duration, and regression of sensory blockade with 0.5% ropivacaine was similar to that provided by 0.5% bupivacaine, although a faster onset and longer duration of motor blockade was observed with bupivacaine.[178] The free concentrations of ropivacaine were approximately twice those of bupivacaine in both maternal and neonatal blood at delivery; however, these measurements were less than the concentrations shown to be toxic in animals.

Adjuvant Agents

As with spinal anesthesia, adjuvant medications are used for their intrinsic analgesic properties and to reduce the dose and side effects of local anesthetic agents. The use of epidural adjuvants can improve the quality of intraoperative anesthesia and result in less motor blockade as well as enhance postoperative analgesia (see Chapter 27).

Although some anesthesia providers administer an epidural opioid with the initial therapeutic dose of local anesthetic, others delay opioid administration until after the umbilical cord is clamped to prevent transfer of opioid to the fetus. The onset of analgesia is dictated by complex pharmacokinetics; however, the lipid-soluble opioids (e.g., fentanyl, sufentanil) have more rapid onset and more rapid clearance than the water-soluble opioids (e.g. morphine).[179]

The administration of epidural **fentanyl** (50 to 100 µg) results in activity at both spinal and supraspinal sites of action,[180] improves the intraoperative quality of anesthesia during cesarean delivery,[181,182] and does not appear to adversely affect the neonate.[183] The optimal dose of epidural fentanyl has not been determined for patients undergoing cesarean delivery; however, in an experimental pain study in nonpregnant patients, there was an analgesic effect at the segmental level of injection for epidural fentanyl 100 µg, but not 50 µg.[184]

Epidural **sufentanil** (10 to 20 µg) added to 0.5% bupivacaine with epinephrine 5 µg/mL, provides significantly better intraoperative anesthesia and longer postoperative analgesia than bupivacaine and epinephrine alone, with minimal maternal side effects and no adverse neonatal effects.[185] Epidural sufentanil is approximately five times more potent than epidural fentanyl, but when equipotent doses are administered, no differences between the agents in onset, quality, or duration of analgesia have been observed.[186,187]

Epidural administration of the hydrophilic drug **morphine** provides prolonged postcesarean analgesia. A dose-response study of epidural morphine (1.25, 2.5, 3.75, and 5 mg) found 3.75 mg to be an optimal dose beyond which postcesarean analgesia (as measured by patient-controlled analgesia morphine demands) was no better.[188] Extended-release epidural morphine 10 mg provides better postoperative analgesia than epidural morphine 4 mg, with no differences in nausea, pruritus, or sedation scores.[189]

Epidural **hydromorphone** is sometimes used as an alternative to morphine. Doses between 0.6 and 1.5 mg are commonly used. Studies suggest a similar analgesia effect and side-effect profile compared with epidural morphine analgesia, although the duration of analgesia may be slightly shorter.[190–192]

Epidural **diamorphine** (2.5 to 3 mg) is commonly used in the United Kingdom for providing prolonged postcesarean analgesia.[193] Optimal dose-finding studies of epidural diamorphine have not been performed; however, the duration and quality of analgesia from epidural diamorphine 3 mg appears to similar to that provided by spinal diamorphine 0.3 mg, with significantly less pruritus.[194]

Epidural **clonidine** (75 to 200 µg) combined with morphine or fentanyl reduces the requirement for postcesarean morphine analgesia.[195] The effect of co-administering clonidine and fentanyl appears to be additive rather than synergistic in producing postcesarean analgesia. Common side effects include hypotension and sedation. Currently, epidural clonidine has only one specific neuraxial indication in the United States (intractable cancer pain), and the package insert has a "black box" warning from the FDA stating that "epidural clonidine is not recommended for obstetrical, postpartum and perioperative pain management."

Epidural **neostigmine** produces a modest amount of postcesarean analgesia when given after umbilical cord clamping. A dose-finding study investigated the administration of 75, 150, or 300 µg of epidural neostigmine in women undergoing elective cesarean delivery.[196] An increase in intraoperative shivering and sedation was observed in the 300-µg group only; a dose-independent reduction in postoperative pain and sedation was observed in all groups.

Epinephrine may be added to the local anesthetic agent to minimize systemic absorption and peak blood level of the local anesthetic, increase the density of sensory and motor blockade, and prolong the duration of anesthesia.[171,197,198] The pharmacokinetic effects of epinephrine co-administered with an opioid vary with the opioid and the sampling site. In the lumbar epidural space, epinephrine lengthened the mean residence time of morphine but shortened that of fentanyl and sufentanil.[199]

The epidural administration of epinephrine in preeclamptic women is controversial (see Chapter 35).[200] Animal and clinical studies suggest that epidural epinephrine 0.1 mg does not decrease uterine blood flow in normotensive pregnancies.[201-203] By contrast, in *hypertensive* women, the addition of epidural epinephrine 5 µg/mL (1:200,000) to bupivacaine significantly reduced uteroplacental blood flow; however, this did not affect umbilical arterial blood flow or pH measurements at delivery.[204]

When combined with local anesthetic for epidural anesthesia, the usual epinephrine concentration is 2.5 or 5 µg/mL (i.e., 1:400,000 or 1:200,000). The addition of epinephrine to a solution of plain local anesthetic just before administration results in a solution that has a higher pH than commercially prepared epinephrine-containing products, which use (low-pH) antioxidants to preserve the efficacy of the epinephrine (see Chapter 13). Thus, use of freshly prepared solutions hastens the onset of anesthesia.

The addition of **sodium bicarbonate** results in a solution with more local anesthetic molecules in a non-ionized state, which hastens the onset and augments the quality of the local anesthetic blockade, particularly if sodium bicarbonate is added to a low-pH solution (see later discussion).

Combined Spinal-Epidural Anesthesia

The CSE technique incorporates the rapid and predictable onset of spinal blockade with the ability to augment anesthesia by injection of additional drug through the epidural catheter.[205,206] In 1981, Brownridge[205] reported the first use of the CSE technique for cesarean delivery through separate spinal and epidural needles introduced at different interspaces. Carrie and O'Sullivan[206] subsequently described the needle-through-needle technique via a single interspace for cesarean delivery; this has become the more popular technique. Compared with a conventional epidural anesthetic technique for cesarean delivery, the advantages of the CSE technique include faster onset and lower pain scores at delivery.[207]

Additional advantages of the CSE technique include (1) use of the epidural needle as an introducer for a longer spinal needle when attempts with a traditional introducer and spinal needle have failed and (2) use of a spinal needle (and return of CSF through the needle) to "confirm" the correct positioning of the epidural needle in the epidural space. The CSE technique also allows use of a low dose of local anesthetic to

initiate spinal anesthesia (associated with a lower incidence of hypotension), followed by use of the epidural catheter to extend intraoperative anesthesia or provide postoperative analgesia.

Conventional spinal doses (e.g., 12 mg) of hyperbaric bupivacaine are most often used to provide CSE anesthesia for cesarean delivery; however, a satisfactory block has been reported with plain bupivacaine drug doses as low as 4.5 mg.[138] Although the use of lower doses of local anesthetic is enabled by the presence of the epidural catheter (because additional agents can be administered if discomfort occurs), the block achieved with the CSE technique may be inherently different from the block achieved with a single-shot spinal technique with the same dose(s) of medication. One study, in which men undergoing surgery were positioned in the right lateral position for initiation of neuraxial anesthesia, demonstrated that the median effective doses of intrathecal hyperbaric bupivacaine (to achieve a T6 sensory level of anesthesia for 60 minutes) for the CSE and spinal techniques were 9.2 mg and 11.4 mg, respectively.[208] The investigators speculated that the use of the loss-of-resistance to air (during introduction of the epidural needle) resulted in a reduction in lumbar CSF volume and a subsequently higher sensory blockade. Similarly, in another study that initiated neuraxial analgesia with intrathecal bupivacaine 10 mg in parturients undergoing *elective* cesarean delivery, median sensory levels were C6 and T3 with the CSE and spinal techniques, respectively.[209] The CSE technique was performed with loss-of-resistance to air (2 mL); however, after administration of the spinal medications, the epidural catheter was not inserted. The investigators speculated that the loss of negative pressure in the epidural space created by the introduction of the epidural needle was responsible for the observed differences. However, when investigators from the same institution performed the same anesthetic techniques for cesarean delivery in *laboring* women, no differences in the block characteristics were observed.[210] The reasons for these differences are unclear.

The *sequential* CSE technique uses a lower dose of spinal bupivacaine (7.5 to 10 mg) followed by incremental injection of local anesthetic through the epidural catheter to achieve a T4 level of anesthesia.[211,212] The purported advantage of this approach is a lower incidence of hypotension. In a study involving 42 patients comparing sequential CSE anesthesia using 1.5 mL of 0.5% of hyperbaric bupivacaine (followed by extension with fractionated doses of 0.5% bupivacaine administered through the epidural catheter as needed) versus single-shot spinal anesthesia using 2.5 mL of 0.5% of hyperbaric bupivacaine, more gradual onset of hypotension and a lower initial sensory level was observed with the CSE compared with the single-shot spinal technique (T7 and T4, respectively).[212] The sequential CSE technique may be of particular advantage in high-risk parturients (e.g., significant cardiac disease) in whom avoidance of severe hypotension can be vitally important.

Another CSE technique is the *extradural volume extension* (EVE) technique.[211,213] Intrathecal administration of a small dose of local anesthetic is followed by the administration of saline through the epidural catheter. Studies have observed a higher cephalad spread of one to four dermatomal segments associated with the use of this technique, presumably because of thecal compression.[211] However, the effect of EVE may depend on the initial dose and baricity of local anesthetic, the time interval between spinal and epidural injection, the volume of epidural saline, and the outcomes measured, as several studies have failed to find a difference in sensory blockade using this technique.[213,214]

Potential drawbacks of CSE techniques include an untested epidural catheter and hypotension. Administering the CSE technique in the sitting position may result in greater severity and duration of hypotension than the left lateral decubitus position.[93] The hypotension may be related to the delay in moving the patient from the sitting to the supine (with leftward tilt) position.

Extension of Epidural Labor Analgesia

The extension of epidural labor *analgesia* to surgical *anesthesia* sufficient for cesarean delivery can be accomplished with several local anesthetic agents. The selection of agent often depends on the urgency of the case. Extension of epidural analgesia can be initiated as preparations are being made to move the patient from the labor room to the operating room. Whether an *in situ* epidural catheter should be used for an extension attempt depends on several factors, including the quality of the existing labor analgesia. If obtaining satisfactory epidural labor analgesia has been problematic (e.g., one-sided or "patchy" analgesia), replacing the catheter or using a spinal or CSE technique may be a better method to attain rapid and effective anesthesia. A systematic review and meta-analysis found that the incidence of failed conversion of labor analgesia to cesarean delivery anesthesia is greater when an increasing number of epidural boluses have been required to produce sufficient labor analgesia, a greater urgency for cesarean delivery exists, and a nonobstetric anesthesiologist is managing the case.[215]

Specific local anesthetic and adjuvant solutions may influence whether the quality and level of epidural anesthesia is adequate for cesarean delivery. A meta-analysis of 11 randomized controlled trials examining the type of local anesthetic used to "top-up" epidural labor analgesia for emergency cesarean delivery[216] compared 0.5% bupivacaine or levobupivacaine, lidocaine with epinephrine (with and without fentanyl), and 0.75% ropivacaine. The pooled analysis suggested that lidocaine with epinephrine resulted in the fastest onset of sensory block; the addition of fentanyl further hastened block onset, but not quality as measured by the need for intraoperative supplementation. Compared with bupivacaine, ropivacaine was associated with a lower need for intraoperative supplementation, and lidocaine demonstrated a trend toward lower need. The epidural administration of 2% lidocaine with freshly added epinephrine 5 μg/mL was compared with 3% 2-chloroprocaine in a randomized trial involving 40 women undergoing elective cesarean delivery.[217] This study observed no significant difference in the onset of anesthesia between the two groups, although the study was likely underpowered; the

median onset was 8 minutes (range of 4 to 13 minutes) in the 2-chloroprocaine group and 5 minutes (range of 2 to 22 minutes) in the lidocaine group. However, given the time taken to prepare the lidocaine with epinephrine solution, the investigators concluded that use of a pre-prepared solution, such as 2-chloroprocaine, may be preferred.

Alkalinization of the local anesthetic solution not only increases the speed of onset but also improves the quality and prolongs the duration of neuroblockade.[218] Alkalinization shifts more of the local anesthetic molecules to the nonionized, lipid-soluble form, which allows the local anesthetic to pass more easily through the lipophilic neuronal membrane. Although this phenomenon can be demonstrated for all local anesthetics, alkalinization is most often performed with local anesthetic agents of short and medium duration (e.g., 2-chloroprocaine, lidocaine). Typically, 1 mL of 8.4% sodium bicarbonate (1 mEq/mL) is added to 10 mL of lidocaine or 2-chloroprocaine. Longer-acting agents (e.g., bupivacaine, ropivacaine, levobupivacaine) easily precipitate with the addition of sodium bicarbonate. Precipitation occurs with the addition of less than 0.2 mEq of bicarbonate to 20 mL of 0.5% bupivacaine.[219] Alkalinization exerts the greatest effect when it is freshly mixed with the local anesthetic solution; however, the mixture is relatively stable.[220]

The addition of sodium bicarbonate to local anesthetics has been demonstrated to result in a clinically significant reduction in the time until an adequate anesthetic level is obtained (Fig. 26.4). In a randomized trial, 40 women with functioning epidural labor analgesia received a 3-mL epidural test dose of 2% lidocaine with epinephrine, followed by

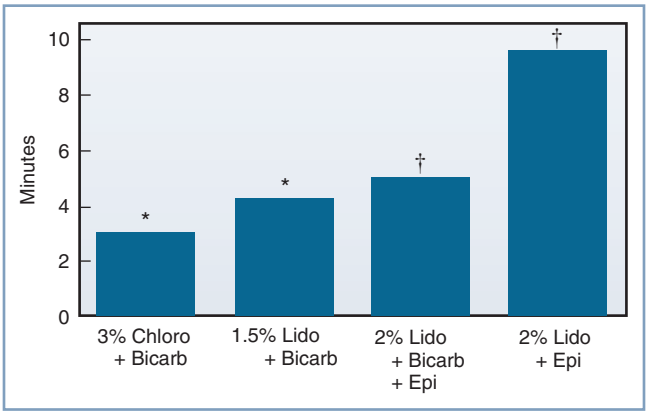

Fig. 26.4 Onset time for extension of existing labor analgesia blockade (T10 sensory level) with different local anesthetic preparations. Results between the two studies cannot be directly compared owing to differences in labor analgesia regimens, different sensory testing methods and target levels, and presence of epidural opioids. The 2% lidocaine with epinephrine solution was premixed. The epinephrine concentration was 5 µg/mL. *Chloro,* 2-chloroprocaine; *Bicarb,* bicarbonate; *Lido,* lidocaine; *Epi,* epinephrine 5 µg/mL. **To T4 sensory level.* (Data modified from Gaiser RR, Cheek TG, Gutsche BB. Epidural lidocaine versus 2-chloroprocaine for fetal distress requiring urgent cesarean section. *Int J Obstet Anesth.* 1994;3:20–210.) †*To T6 sensory level.* (Data modified from Lam DT, Ngan Kee WD, Khaw KS. Extension of epidural blockade in labour for emergency Caesarean section using 2% lidocaine with epinephrine and fentanyl, with or without alkalinisation. *Anaesthesia.* 2001;56:790–794.)

12 mL of premixed 2% lidocaine with epinephrine 5 µg/mL (1:200,000) and fentanyl 75 µg with 1.2 mL of 8.4% sodium bicarbonate or saline.[218] The mean times to attain a T6 anesthesia level with and without bicarbonate were 5.2 minutes and 9.7 minutes, respectively.

Extension of a T10 level of *analgesia* to a T4 level of *anesthesia* typically requires a volume of 15 to 20 mL of local anesthetic with one or more adjuvants. At our institution, the extension of epidural labor analgesia begins with assessment of the quality of analgesia. For emergency cesarean delivery, we initiate the extension of epidural anesthesia in the labor room by giving 10 mL of alkalinized 2% lidocaine (with epinephrine) or 3% 2-chloroprocaine. The sensory blockade is assessed after transfer of the patient to the operating room; if the blockade is bilateral and moving in a cephalad direction, an additional 5 to 10 mL is administered to bring the sensory level to T4. The use of this fractionated dosing schedule offers several advantages, including (1) greater hemodynamic stability during patient transfer; (2) assessment of the evolving sensory level before administration of the full dose of local anesthetic; (3) minimization of dural sac compression (by a large volume epidural injection),[221] which enables a less difficult and safer conversion to spinal anesthesia if extension of epidural anesthesia is not successful (see later discussion); and (4) early sensory blockade at the incision site, so that surgery can be initiated in emergency cases before establishment of a full T4 sensory level.

The extension of epidural analgesia to epidural anesthesia in the labor room is controversial.[222] Some anesthesia providers delay epidural administration of additional local anesthetic until the patient has arrived in the operating room. However, this practice may increase the risk for failed epidural anesthesia, necessitating the induction of general anesthesia with its attendant risks (see later discussion).

General Anesthesia

Although neuraxial techniques are typically preferred when anesthesia is provided for cesarean delivery, there are some clinical situations in which the administration of general anesthesia is considered the most appropriate option (see Table 26.3). In addition, general anesthesia offers an advantage in cases in which uterine relaxation would be beneficial (e.g., cesarean delivery as part of an *ex utero* intrapartum treatment [EXIT] procedure).

The basic elements for preparation and care of the obstetric patient undergoing cesarean delivery apply to the patient undergoing general anesthesia (Box 26.7, see Table 26.2). The preanesthetic evaluation should focus on assessment of physical characteristics (e.g., airway) and comorbidities. The consent process should feature the risks associated with airway management, aspiration, and awareness. The importance of a careful airway evaluation cannot be overemphasized (see Chapter 29); pregnancy-induced changes in the upper airway may be exacerbated during labor. Acoustic reflectometry shows that soft tissue mucosal edema in both the oral (incisor teeth to oropharyngeal junction) and pharyngeal (oropharyngeal junction to the glottis) tissue

BOX 26.7 Steps for Initiating General Anesthesia for Cesarean Delivery[a]

1. Discuss the operative plan with the multidisciplinary team.
2. Perform preanesthetic assessment, and obtain informed consent.
3. Prepare necessary medications and equipment.
4. Place patient supine with left uterine displacement.
5. Secure 16- or 18-gauge intravenous access. Send blood specimen for baseline laboratory measurements; consider type and screen (or cross-match) if risk factors for peripartum hemorrhage are present.
6. Give metoclopramide 10 mg and/or ranitidine 50 mg intravenously more than 30 minutes before induction, if possible.
7. Give a nonparticulate antacid orally less than 30 minutes before induction.[b]
8. Administer antibiotic prophylaxis (with 60 minutes before incision).[c]
9. Initiate monitoring.
10. Perform a team "time-out" to verify patient identity, position, and operative site; procedure to be performed; and availability of special equipment, if needed.
11. Provide 100% oxygen with a tight-fitting face mask for 3 minutes or longer, when possible, for denitrogenation/preoxygenation. Otherwise, instruct the patient to take four to eight vital-capacity breaths immediately before induction of anesthesia.
12. After the abdomen has been prepared and operative drapes are in place, verify that the surgeon and assistant are ready to begin surgery.
13. Initiate rapid-sequence induction:
    a. Cricoid pressure 10 N while awake; increase to 30 N after loss of consciousness.
    b. Thiopental 4 to 6 mg/kg or propofol 2 to 2.8 mg/kg and succinylcholine 1 to 1.5 mg/kg; wait 30 to 40 seconds.[d]
14. Perform tracheal intubation. Confirm correct placement of endotracheal tube.
15. Provide maintenance of anesthesia:
    a. Use isoflurane, sevoflurane, or desflurane (approximately 1 MAC) in 100% oxygen or oxygen/nitrous oxide (up to 50%).
    b. Treat hypotension (e.g., phenylephrine, ephedrine).
    c. If additional muscle relaxant (e.g., rocuronium, vecuronium) is necessary, titrate dose according to response to peripheral nerve stimulator.
16. Observe delivery of infant.
17. Administer a bolus and/or a continuous infusion of oxytocin; consider other uterotonic agents (e.g., methylergonovine, 15-methyl prostaglandin $F_{2\alpha}$) if uterine tone is inadequate. Monitor blood loss, and respond as necessary.
18. Adjust maintenance technique after delivery of the infant:
    a. Administer a reduced concentration of a volatile halogenated agent (0.5 to 0.75 MAC).
    b. Supplement anesthesia with nitrous oxide and an intravenous opioid.
    c. Give attention to risk for awareness and recall. Consider administration of a benzodiazepine (e.g., midazolam).
19. Perform tracheal extubation when neuromuscular blockade is fully reversed and the patient is awake and responds to commands.
20. Evaluate postoperative issues (e.g., pain, nausea).

IV, Intravenously; *MAC,* minimum alveolar concentration.

[a]The events and sequence of events may need to be modified and tailored to individual circumstances. In an emergency, some tasks may have to be performed simultaneously.

[b]Some anesthesiologists suggest that sodium citrate should be administered within 20 minutes of induction of general anesthesia (see Chapter 28).

[c]Evidence suggests that administration of prophylactic antibiotics *before* incision (rather than after umbilical cord clamping) reduces the incidence of postcesarean endometritis and total maternal infectious morbidity.[52]

[d]Drugs and doses may have to be modified for individual patients and circumstances.

increases during labor and results in worsening of the airway classification compared with the prelabor evaluation.[223] Failed tracheal intubation, failed ventilation and oxygenation, and pulmonary aspiration of gastric contents remain leading anesthesia-related causes of maternal death.[124] If the airway evaluation suggests the possibility of a difficult intubation, consideration should be given to the placement of a neuraxial catheter during early labor, even if it is not used to provide labor analgesia.[28]

Preparation

All pregnant patients requiring surgical anesthesia should be considered at risk for pulmonary aspiration of gastric contents (see Chapter 28). Attempts should be made to minimize both the risk for maternal aspiration and the risk for pulmonary injury if aspiration occurs. Fasting policies should be shared with all members of the obstetric care team. We administer metoclopramide 10 mg and ranitidine 50 mg intravenously between 30 and 60 minutes before induction of general anesthesia, when possible, to diminish gastric volume and gastric acid secretion, respectively.[47] A clear, nonparticulate antacid (sodium citrate 30 mL) should also be administered within 30 minutes of surgery to neutralize gastric acid[45]; the antacid may be particularly important in the emergent situation when metoclopramide and ranitidine have not had the necessary time to exert their pharmacologic effects.

If the patient has airway characteristics that herald difficult mask ventilation or intubation, consideration should be given to performing an awake tracheal intubation (see Chapter 29). Preparations include administering an antisialagogue (e.g., glycopyrrolate), judicious sedation (e.g., midazolam), and topical airway anesthesia (e.g., aerosolized lidocaine or benzocaine). Glossopharyngeal and laryngeal nerve blocks may also be considered, although these should be avoided in patients at excess risk for bleeding (e.g., Hemolysis, Elevated Liver enzymes and Low Platelet count [HELLP] syndrome).

The patient should be placed supine with left uterine displacement. The head, neck, and shoulders should be optimally positioned for airway management (i.e., the sniffing position) (see Fig. 29.7). Routine monitoring should be established, including ECG, pulse oximetry, blood pressure, and capnography. Preoxygenation (denitrogenation) with 100% oxygen should be performed to delay the onset of hypoxemia during apnea; this hypoxemia occurs more rapidly because of the pregnancy-induced decrease in functional residual capacity and increase in oxygen consumption. In a computer simulation of the respiratory and cardiovascular systems during pregnancy, the presence of labor, high BMI, and sepsis further accelerated oxyhemoglobin desaturation during apnea; by contrast, multiple gestation and hemorrhage appeared to have minimal effects.[224] Ideally, preoxygenation is accomplished by 3 minutes of tidal-volume breathing with a tight-fitting face mask. Although four maximal deep breaths over 30 seconds with an F_{IO_2} of 1.0 can achieve a similar Pao_2, the same protection against rapid oxyhemoglobin desaturation is not afforded, owing to differences in tissue and venous compartment oxygen reserves.[224] The method of eight deep breaths over 1 minute appears to provide better protection from oxyhemoglobin desaturation during apnea than the four deep breaths over 30-second method.[225]

In contrast to most surgical procedures, the patient's abdomen is prepared and draped *before* induction of general anesthesia to minimize fetal exposure to general anesthesia. After the surgical drapes have been applied and the operating personnel are ready at the tableside, the surgeon should be instructed to delay the incision until the anesthesia provider confirms correct placement of the endotracheal tube and gives verbal instructions to proceed with surgery.

Induction

A rapid-sequence induction is initiated with denitrogenation/preoxygenation followed by administration of an induction agent, paralysis, and cricoid pressure. Mask ventilation is traditionally not performed, because when it is applied without the application of cricoid pressure and with pressures greater than 20 cm H_2O, insufflation of the stomach can occur (see Chapter 29). Some guidelines[226] have suggested modification of the rapid-sequence induction to include gentle, low-pressure (P_{max} 20 cm H_2O) mask ventilation to confirm that ventilation is possible and to maximize oxygen reserve while awaiting induction and paralysis. Whether rapid-sequence induction with or without modification should be employed, particularly in an appropriately fasted, nonlaboring patient presenting for elective cesarean delivery, has been questioned.[227] Further, the value of cricoid pressure has been challenged owing to (1) physiologic evidence demonstrating that cricoid pressure reduces lower esophageal sphincter pressure, (2) anatomic investigations showing an inability to completely occlude the esophagus, (3) a lack of clinical outcome data that confirm that cricoid pressure reduces the incidence of aspiration, and (4) the frequent misapplication of the technique itself.[228] The technique for cricoid pressure begins with an assistant applying 10 newtons (N) of force, 1 N being the unit of force required to accelerate a mass of 1 kg by 1 m/s^2 (force cannot be represented by mass alone, but as a practical guide to the amount of force to apply, 10 N is approximately equivalent to the downward force exerted by a weight of 1 kg). Following loss of consciousness, the amount of force is increased to 30 N. Application of the full amount of force while the patient is still awake can provoke active retching and regurgitation. In some cases, cricoid pressure may be briefly released to enable a successful intubation; not infrequently the benefit of release outweighs the risk for regurgitation. Cricoid pressure should then be reapplied until the correct endotracheal tube position is confirmed.

Historically, **thiopental** (4 to 6 mg/kg) has been the most frequently used induction agent. Because of recent lack of availability, it is now rarely used in the United States, although it is still used in other countries. **Propofol** (2 to 2.8 mg/kg) is now commonly used to induce general anesthesia for cesarean delivery. Propofol, in a dose sufficient for induction and to prevent maternal awareness (2.5 mg/kg), may depress the infant more than thiopental. In the presence of hemodynamic instability, **ketamine** (1 to 1.5 mg/kg) or **etomidate** (0.3 mg/kg) should be substituted for propofol. Paralysis is achieved by **succinylcholine** (1 to 1.5 mg/kg) in 30 to 40 seconds. Administration of a defasciculating dose of a nondepolarizing muscle relaxant is *not* recommended, because it may delay the onset of neuromuscular blockade with succinylcholine. Pregnancy appears to be associated with less severe succinylcholine-induced fasciculations and muscle pain.[229]

Rocuronium (1 mg/kg) may provide intubating conditions similar to those provided with succinylcholine (1 mg/kg) for cesarean delivery[230,231] and is a suitable alternative in situations in which succinylcholine should be avoided (e.g., malignant hyperthermia, myotonic dystrophy, spastic paraparesis). Some recent data suggest its use in cesarean delivery may be associated with a lower frequency of myalgia compared with succinylcholine.[231] The use of a priming preinduction dose of a nondepolarizing muscle relaxant is not recommended during pregnancy, because it may result in complete paralysis and increase the risk for aspiration.[232] Enhanced activity of nondepolarizing agents may also be observed in patients receiving magnesium sulfate (e.g., for seizure prophylaxis in women with preeclampsia or for fetal neuroprotection).[233]

Sugammadex, a modified gamma-cyclodextrin, has been demonstrated to be effective in providing rapid recovery (a train-of-four ratio of greater than 0.9) without recurarization from moderate and profound rocuronium-induced neuromuscular blockade in parturients undergoing cesarean delivery.[234]

A small-diameter cuffed endotracheal tube (i.e., 6.5 or 7.0 mm) should be used during pregnancy; the use of a videolaryngoscopy device (e.g., C-MAC, Glidescope), a flexible stylet within the endotracheal tube, and a bougie on standby, allows a "first and best" attempt at tracheal intubation. Tissue trauma and airway edema may occur with repeated attempts at intubation. Correct endotracheal tube placement should be confirmed by checking for a normal

capnographic tracing. Auscultation should be performed to rule out inadvertent endobronchial intubation. The anesthesia provider should also observe ongoing evidence of adequate maternal oxyhemoglobin saturation as well as bilateral thoracic movement and breath sounds. If there is doubt, fiberoptic bronchoscopy can confirm the correct placement of the endotracheal tube in the trachea. If incorrect endotracheal tube placement is promptly recognized, extubation (with continued cricoid pressure) will often allow another attempt without the need for additional muscle relaxant. Anticipation of a difficult endotracheal intubation, or a failed intubation attempt, should invoke the difficult airway algorithm and a call for assistance (see Chapter 29). Options include (1) allowing the patient to awaken, (2) using alternative techniques to place an endotracheal tube, and (3) using alternative airway devices. Emergency airway equipment should be immediately available in all obstetric operating rooms.[28]

Some authors suggest that a supraglottic airway device (e.g., laryngeal mask airway[LMA]) can be used routinely for cesarean delivery performed under general anesthesia. One series reported clinically effective airway management with a classic LMA which was placed successfully on the first attempt in 98% of 1067 healthy parturients undergoing elective cesarean delivery with general anesthesia.[235] Cricoid pressure was maintained throughout the cesarean delivery, and no adverse sequelae occurred. Utilizing an LMA with a higher seal pressure than a classic LMA and a built-in gastric draining tube, another study reported successful placement of the airway in 98% of 3000 healthy parturients undergoing elective cesarean delivery; they observed only one case of regurgitation without aspiration.[236] Cricoid pressure was not maintained after confirmation of successful airway placement. In both of these studies, patients were excluded if they had symptoms of gastropharyngeal reflux, known/predicted difficult airway, and a prepregnancy BMI greater than 30 kg/m^2. As supraglottic airway devices do not prevent pulmonary soiling with gastric contents as efficiently as an endotracheal tube, and high morbidity rate is associated with aspiration, we do not routinely use these devices for cesarean delivery. However, any device that can facilitate ventilation should be used as a lifesaving device in situations of failed intubation. A number of variations to the classic LMA have been developed that may facilitate airway management in specific situations (see Chapter 29).

Maintenance

The goals for anesthetic maintenance include (1) adequate maternal and fetal oxygenation, with maintenance of normocapnia for pregnancy; (2) appropriate depth of anesthesia to promote maternal comfort and a quiescent surgical field and to prevent awareness and recall; (3) minimal effects on uterine tone after delivery; and (4) minimal adverse effects on the neonate. These goals can be accomplished using inhalational anesthesia or, less commonly, total intravenous anesthesia.

Fetal oxygenation appears maximal when a maternal F_{IO_2} of 1.0 is used[237]; however, in the absence of fetal compromise, an F_{IO_2} of 0.3 appears to provide sufficient oxygenation while minimizing the production of oxygen free radicals (see earlier discussion). Although the use of a higher F_{IO_2} can increase maternal arterial and umbilical venous blood oxygen content, this action has not been observed to result in differences in 1- or 5-minute Apgar or neurobehavioral scores.[238,239] As a consequence, in the absence of fetal compromise, inspired oxygen concentrations should be guided by pulse oximetry rather than provision of an arbitrarily set level of F_{IO_2}.

Maternal ventilation should maintain normocapnia, which at term gestation is a P_{aCO_2} of 30 to 32 mm Hg (4.0 to 4.3 kPa). Excessive ventilation can cause uteroplacental vasoconstriction and a leftward shift of the oxyhemoglobin dissociation curve, which may result in compromised fetal oxygenation.[240] On the other hand, hypercapnia can lead to maternal tachycardia and is also undesirable.

Initially, high fresh-gas flows should be used to ensure an adequate end-tidal concentration of the volatile halogenated agent. No specific volatile halogenated agent has been demonstrated to be superior to another. The anesthetic requirements for volatile halogenated agents are diminished 25% to 40% during pregnancy.[241] A bispectral index measurement less than 60 typically requires more than 0.75 minimum alveolar concentration (MAC) of a volatile halogenated agent combined with 50% nitrous oxide and has been suggested to prevent intraoperative awareness and recall in parturients undergoing general anesthesia[242]; however, this target bispectral index value requires further study in pregnant women. Several studies suggest the need for lower volatile agent requirements to maintain a target bispectral index value in women with prior labor compared with women without prior labor[243,244]; these results could not be explained by differences in plasma concentrations of progesterone, prolactin, or cortisol.[244]

In clinical practice, approximately 1.0 MAC of a volatile halogenated agent is typically administered between tracheal intubation and delivery. Halogenated agents cause dose-dependent depression of uterine contractility,[243,245,246] which may lead to greater blood loss after delivery.[247] Therefore, the concentration of the volatile agent is reduced to 0.5 to 0.75 MAC after delivery. Nitrous oxide 50% in oxygen is often added to reduce the required concentration of volatile agent, thereby mitigating adverse effects on uterine tone; intravenous propofol or ketamine can also be administered to maintain an appropriate depth of anesthesia. The administration of a benzodiazepine (e.g., midazolam) after delivery may reduce the risk for maternal awareness.

Intravenous opioids are often withheld until after delivery to minimize the potential for neonatal respiratory depression; however, there may be circumstances in which maternal hemodynamic stability or blunting of responses to airway manipulation and surgical stimulation favor the administration of opioids during the induction of general anesthesia. The rapid onset and efficacy of intravenous lipid-soluble agents (e.g., remifentanil, fentanyl, alfentanil) make them ideal for mitigating the responses to laryngoscopy and intubation.[248] Intraoperatively, the prolonged activity of water-soluble agents (e.g., morphine, hydromorphone) can be

useful to minimize volatile anesthetic use and for the provision of intraoperative and postoperative analgesia (see Chapter 27).

Given the pregnancy-induced stretching of the abdominal wall, additional neuromuscular blockade may not be necessary in the parturient who has an adequate depth of anesthesia (with administration of both a volatile agent and an opioid). A small dose of a short-acting nondepolarizing agent (or an infusion of succinylcholine) may be administered, with maternal response monitored with a peripheral nerve stimulator, if additional muscle relaxation is indicated.

General anesthetic agents can redistribute from the neonatal fat to the central circulation and lead to secondary depression of neonatal ventilatory effort; thus, the presence of a pediatrician (or another neonatal provider) is advisable until a normal ventilatory pattern is observed. Although differences in maternal and umbilical artery acid-base status have been observed in women who underwent elective general anesthesia compared with epidural anesthesia for cesarean delivery, similar neonatal outcomes were demonstrated.[249] Similarly, epidemiologic data suggest that brief exposure to general anesthetics at the time of cesarean delivery is not associated with an increase for abnormal neonatal neurodevelopment and later learning difficulties.[250]

Emergence and Tracheal Extubation

When the patient awakens, tracheal extubation should be performed with the patient in a semi-recumbent position. The patient should demonstrate purposeful response to verbal commands and return of protective airway reflexes before tracheal extubation. In a review of anesthesia-related maternal deaths between 1985 and 2003 in the state of Michigan,[251] deaths associated with hypoventilation or airway obstruction did not occur at induction and tracheal intubation but rather during emergence, extubation, or recovery from anesthesia. Risk factors associated with mortality were obesity and African-American race, which may have delayed the visual recognition of cyanosis; medical management and medication issues were also identified. The ASA Practice Guidelines for Postanesthetic Care suggest that pulse oximetry is associated with early detection of hypoxemia; the guidelines recommend periodic assessment of airway patency, respiratory rate, and oxygen saturation during emergence and recovery.[252] If repeated airway manipulation, massive hemorrhage, or emergency hysterectomy has occurred, delayed extubation and/or transfer to an intensive care unit (ICU) should be considered.

Pharmacology

Thiopental. Historically, the barbiturates (e.g., thiopental [thiopentone], methohexital, thiamylal) have been the induction agents most commonly used for cesarean delivery. Extensive published data have confirmed the safety and efficacy of thiopental for induction of anesthesia in patients undergoing cesarean delivery at various gestational ages. Thiopental 4 to 6 mg/kg provides a rapid and reliable induction of anesthesia. As a negative inotrope and vasodilator, thiopental can cause decreased cardiac output and blood pressure,[253] which may result in significant hypotension in hypovolemic patients. Some investigators have attempted to minimize this effect by using a lower dose of thiopental in combination with ketamine or propofol, with varying success.

Thiopental rapidly crosses the placenta. In 11 healthy subjects who underwent induction of general anesthesia with thiopental, the mean umbilical vein-to-maternal vein (UV/MV) ratio was 1.08 with an induction-to-delivery (I-D) interval that ranged from 8 to 22 minutes.[254] Fetal-to-maternal concentration ratios after a single thiopental dose exposure in other studies in term infants exhibited a range of 0.43 to 0.96.[255] The equilibration of thiopental occurs relatively rapidly in the fetus; however, fetal brain concentrations rarely exceed the threshold required for neonatal depression. With a maternal induction dose of 4 mg/kg, umbilical vein concentrations of thiopental are well below the arterial plasma concentrations necessary to produce anesthesia in adults.[256] However, with large induction doses (8 mg/kg), thiopental can produce significant neonatal depression.[257]

Several theories have been proposed to explain the clinical occurrence of an unconscious mother but an awake neonate: (1) preferential uptake of thiopental by the fetal liver, which is the first organ perfused by blood coming from the umbilical vein[257]; (2) the higher relative water content of the fetal brain[258]; (3) rapid redistribution of the drug into the maternal tissues, which causes a rapid reduction in the maternal-to-fetal concentration gradient; (4) nonhomogeneity of blood flow in the intervillous space; and (5) progressive dilution by admixture with the various components of the fetal circulation. Because of this rapid equilibration of thiopental and the low fetal brain concentration of thiopental, there is no advantage in delaying delivery until thiopental concentrations decline. There is no evidence that thiopental causes adverse fetal effects when the incision-to-delivery interval is prolonged.

Propofol. Propofol is an intravenous induction agent with a rapid onset, rapid recovery, and favorable side-effect profile, which includes a low incidence of nausea and vomiting. Induction with propofol can result in pain on injection and a reduction in maternal blood pressure and cardiac output. The pharmacokinetics of propofol are similar in pregnant and nonpregnant women, except for a more rapid clearance observed during pregnancy, which may partially reflect drug removal through blood loss and the delivery of the infant and placenta.

When given as an intravenous bolus, by continuous infusion, or both, propofol rapidly crosses the placenta and results in an UV/MV ratio of approximately 0.7.[259] In an *in vitro* human placenta study,[260] propofol produced vasodilation of fetal placental blood vessels and decreased the effect of various vasoconstrictors, most likely through the inhibition of calcium influx through the smooth muscle sarcolemma; lipid emulsion, the propofol carrier solution, was not responsible for these effects. One randomized trial of women undergoing cesarean delivery with general anesthesia reported significantly lower Apgar and neurobehavioral scores in neonates

delivered of mothers who received propofol compared with thiopental[261]; however, this finding was not replicated in a more recent randomized trial.[262] Other studies have found no effect of propofol on neurobehavioral scores or the time to sustained spontaneous respiration with an induction bolus dose of propofol 2.5 mg/kg or with infusion doses less than 6 mg/kg/h.[263,264] However, higher doses of propofol (9 mg/kg/h) have been correlated with a low Neurologic and Adaptive Capacity Score (NACS).[265]

Compared with thiopental, propofol results in a greater incidence of maternal hypotension,[266] which may more effectively attenuate the response to laryngoscopy and tracheal intubation at the risk for reduced uteroplacental blood flow. Care must be given to closely monitor maternal blood pressure following induction with propofol and, if needed, supporting the blood pressure with vasopressors. Maternal heart rate needs to also be carefully monitored; one report noted a transient but severe episode of maternal bradycardia after administration of propofol followed by succinylcholine for rapid-sequence induction.[267] This effect has also been demonstrated in pregnant ewes; one animal experienced severe bradycardia that led to a sinus arrest.[268]

In a study of nonpregnant women, the interaction of propofol and ketamine was found to be additive at hypnotic and anesthetic endpoints; the cardiostimulant effects of ketamine appear to offset the cardiodepressant effects of propofol.[269]

Ketamine. The sympathomimetic properties of ketamine make it an ideal induction agent in the setting of an urgent cesarean delivery in a patient with hypotension or an acute exacerbation of asthma.[270] Ketamine is an analgesic, hypnotic, and amnestic agent associated with minimal respiratory depression; it is often used to supplement a neuraxial technique that may not be providing optimal anesthesia. Ketamine's effect is likely related to antagonism of the *N*-methyl-D-aspartate (NMDA) receptor.

An induction dose of ketamine 1 mg/kg is associated with an increase in blood pressure and heart rate immediately after induction, and a further increase is observed after laryngoscopy and tracheal intubation.[271] Such an increase can be desirable in the bleeding hypotensive patient but should be avoided in the parturient with hypertension (e.g., preeclampsia) or heart disease in which tachycardia or hypertension is not well tolerated. In experimental animal models, ketamine was sometimes associated with direct myocardial depression and decreased cardiac output[253]; care must therefore be exercised when using this medication to induce patients with severe shock or impaired cardiac function.

Studies in pregnant ewes suggest that the use of ketamine is not associated with a reduction in uterine blood flow.[272] Ketamine is associated with dose-dependent increases in uterine tone, but a single induction dose does not increase uterine tone at term gestation.[273] Using an induction dose of ketamine 0.7 mg/kg in gravid ewes, a 39% increase in resting uterine tone with no effect on uterine blood flow was observed.[272]

Ketamine rapidly crosses the placenta. No neonatal depression is observed with doses less than 1 mg/kg.[274] At higher doses, low Apgar scores, neonatal respiratory depression, and need for resuscitation have been reported.[274] Apgar scores and umbilical cord blood gas and pH measurements at delivery with ketamine are similar to those with thiopental.[275,276] A formulation of the purified S+ isomer of ketamine is available for clinical use in some countries outside the United States. In chronically instrumented pregnant sheep, Strumper et al.[277] found that the effects of the isomer were similar to those of the racemic mixture in terms of maternal and fetal hemodynamics and uterine perfusion; however, the S+ isomer was associated with a smaller increase in maternal and fetal P_{CO_2} than that seen with racemic ketamine in spontaneously breathing animals.

The emergence delirium and hallucinations experienced with ketamine, particularly in the unpremedicated patient, have limited the adoption of this drug as a routine induction agent for cesarean delivery. If ketamine is used, a benzodiazepine may be administered to decrease the incidence of these psychomimetic effects.[278] Maternal awareness may still occur after an induction dose of ketamine 1 to 1.5 mg/kg,[279] but the incidence is lower than with thiopental 4 mg/kg or a mixture of ketamine 0.5 mg/kg and thiopental 2 mg/kg.[280] The incidence of maternal awareness can also be diminished with the co-administration of a benzodiazepine.

When used to maintain general anesthesia with 50% nitrous oxide in oxygen for cesarean delivery, a continuous infusion of ketamine (70 μg/kg/min) was followed by a higher incidence of factual recall and postoperative pain than seen with a volatile anesthetic technique, suggesting this approach is not preferred for the maintenance of anesthesia.[281] Whether ketamine, given as a bolus or infusion initiated after infant delivery, can provide postcesarean analgesia and pain modulation remains controversial (see later discussion). One study found that patients who received ketamine 1 mg/kg for induction had lower postoperative morphine consumption than patients who received thiopental 4 mg/kg (anesthesia was maintained with nitrous oxide and isoflurane).[275]

Etomidate. Etomidate is an intravenous induction agent that produces rapid onset of anesthesia with minimal effects on cardiorespiratory function. This property makes it ideal for parturients who are hemodynamically unstable or who would not tolerate hemodynamic aberrations (e.g., patients with severe cardiac disease).[282] With an induction dose of 0.2 to 0.3 mg/kg, etomidate undergoes rapid hydrolysis, thereby allowing rapid recovery.[283] Intravenous administration of etomidate may cause pain and involuntary muscle movements in unpremedicated patients; etomidate is also associated with nausea and vomiting, potential activation of seizures in patients with an epileptogenic foci, and an impaired glucocorticoid response to stress.[284]

Etomidate crosses the placenta rapidly; however, large variations in the UV/MV ratio (0.04 to 0.5) have been reported.[283] An induction dose of etomidate 0.3 mg/kg was associated with better neonatal acid-base measurements and overall clinical condition than with thiopental 3.5 mg/kg.[285] A transient (less than 6 hours) reduction in neonatal cortisol production has been observed when an induction dose of

etomidate is used for cesarean delivery[286]; however, the clinical relevance of this finding is unclear.

Midazolam. Midazolam is a short-acting, water-soluble benzodiazepine that has few adverse hemodynamic effects and provides hypnosis and amnesia. It is commonly used as a premedicant before anesthesia but also can be used as an induction agent for cesarean delivery, although there are few indications for this purpose (e.g., when there are relative or absolute contraindications to the use of other agents). Data suggest that compared with thiopental, midazolam (at a dose of 0.2 mg/kg) for induction of anesthesia results in a higher incidence of low Apgar scores and longer time to spontaneous respiration, as well as lower neurobehavioral scores, body temperature, general body tone, and arm recoil.[287] However, these differences are short lived and do not persist beyond 4 hours after delivery.

Muscle relaxants. Muscle relaxants are commonly used before delivery to provide optimal tracheal intubation and operating conditions. Most muscle relaxants are highly ionized with low lipid solubility; thus, they do not undergo significant placental transfer.

The depolarizing agent **succinylcholine (suxamethonium)** at a dose of 1 to 1.5 mg/kg is the muscle relaxant of choice for most parturients undergoing rapid-sequence induction of general anesthesia. Maternal administration provides adequate intubating conditions within approximately 45 seconds of intravenous administration. Succinylcholine is highly ionized and water-soluble, and only small amounts cross the placenta. Although high doses of succinylcholine (2 to 3 mg/kg) can result in detectable levels in umbilical cord blood, very large doses (10 mg/kg) are required for placental transfer sufficient to cause neonatal muscle weakness.[288]

Succinylcholine is rapidly metabolized by plasma pseudocholinesterase, the concentration of which is decreased during pregnancy; however, in most patients this effect is offset by the pregnancy-induced increase in volume of distribution. Thus, recovery from succinylcholine is not prolonged, unless the patient has extremely low levels of pseudocholinesterase or atypical pseudocholinesterase.[289] The administration of metoclopramide may also prolong succinylcholine-induced neuromuscular blockade, perhaps by inhibiting plasma pseudocholinesterase[290]; this effect is rarely (if ever) clinically significant. The return of neuromuscular function should be confirmed before additional doses of muscle relaxant are given.

Rocuronium is a suitable alternative to succinylcholine when a nondepolarizing agent is preferred for rapid-sequence induction (e.g., history of malignant hyperthermia), particularly with the option of rapid reversal using **sugammadex** (16 mg/kg). According to one study, rocuronium (0.6 mg/kg) can provide good to excellent intubating conditions in pregnant women after a mean interval of 79 seconds and maximal intubating conditions in 98 seconds.[291] Another study demonstrated that rocuronium 1.2 mg/kg resulted in an onset of paralysis similar to that provided by succinylcholine (55 seconds), but it had a significantly longer clinical duration of action.[292] Rocuronium does not appear to adversely affect Apgar scores, acid-base measurements, time to sustained respiration, or neurobehavioral scores.[291]

Although the onset of action is slower than that of rocuronium,[292] **vecuronium** 0.1 mg/kg is another alternative to succinylcholine. However, its onset of action is significantly slower than succinylcholine, even after a priming dose is administered.[293] The mean duration of action of vecuronium is significantly longer in peripartum patients compared with nonpregnant controls.[294] Vecuronium crosses the placenta in small amounts; however, neonatal outcome, as assessed by Apgar scores and NACS, does not appear to be adversely affected.[295]

Atracurium is a less desirable agent for rapid-sequence induction because the high dose required for a rapid onset of action may result in significant histamine release, which may cause hypotension. **Cisatracurium** does not have these undesirable side effects, but its relatively slow onset makes it less optimal than other alternatives.[296]

Regardless of the choice of agent, laryngoscopy and tracheal intubation should not be attempted until adequate muscle relaxation has occurred. The use of a nerve stimulator allows an objective assessment of the onset and duration of the neuromuscular blockade. Residual neuromuscular blockade can be reversed with neostigmine (with atropine or glycopyrrolate) or sugammadex. To diminish the risk for aspiration, the anesthesia provider should confirm that the patient responds appropriately to verbal commands before tracheal extubation.

Nitrous oxide. Nitrous oxide is an inhalational agent commonly used for cesarean delivery because of its minimal effects on maternal blood pressure and uterine tone. The use of nitrous oxide allows for a reduction in the concentration of the volatile halogenated agent (high concentrations of a volatile halogenated agent decrease uterine tone). Administration of 50% to 67% nitrous oxide in oxygen *without* another anesthetic agent does not provide complete anesthesia and can result in maternal awareness in 12% to 26% of cases.[297,298]

Nitrous oxide is transferred rapidly across the placenta, where fetal tissue uptake reduces the fetal arterial concentration for the first 20 minutes. In an evaluation of the relationship between duration of exposure to nitrous oxide 67% and the resulting umbilical vein-to-maternal artery nitrous oxide concentration ratios, the observed ratios differed according to duration of exposure, as follows: 2 to 9 minutes (0.37), 9 to 14 minutes (0.61), and 14 to 50 minutes (0.70).[299] Apgar scores at 1 minute inversely correlated with duration of anesthesia, an effect observed in other studies.[300] The use of a lower concentration (e.g., 50%) of nitrous oxide may reduce but not eliminate these neonatal effects. A randomized trial of parturients undergoing general anesthesia compared 100% oxygen with 50% nitrous oxide in oxygen, both supplemented by isoflurane (1.5 MAC for the first 5 minutes and 1.0 MAC thereafter).[237] Neonates exposed to nitrous oxide required more resuscitation, although no significant differences were observed in Apgar scores.

Volatile halogenated agents. Volatile halogenated agents are the most commonly used agents for maintaining general anesthesia for cesarean delivery. Volatile halogenated agents produce central nervous system and cardiovascular effects in a dose-dependent manner; of particular concern for the obstetric patient are the resulting decreases in blood pressure (which may result in reduced uterine blood flow) and uterine tone. The uptake and delivery of a volatile halogenated agent is determined by inspired partial pressure, blood flow, and the blood/gas/tissue partition coefficient. The alveolar partial pressure of volatile agents during pregnancy follows known patterns of equilibration; the following commonly used agents are listed in order of more rapid to slower equilibration: desflurane, sevoflurane, and isoflurane. Volatile halogenated agents cross the placenta rapidly and equilibrate quickly with fetal tissues.[301] Neonatal depression may occur. This is typically not a clinical issue when volatile anesthetic agents are used for emergency cesarean delivery, because the delivery usually occurs before much of the volatile agent crosses the placenta (particularly if uteroplacental insufficiency is the reason for emergency delivery). Volatile halogenated agents cause dose-dependent depression of uterine contractility. These effects may influence maternal blood loss after delivery.

Lower concentrations of volatile halogenated agents are required during pregnancy, with an approximately 30% reduction in MAC compared with nonpregnant women.[302,303] These findings were correlated with an increase in progesterone level. Animal models demonstrate that long-term administration of progesterone is associated with a reduction in MAC.[304] This reduction in MAC persists for 24 to 36 hours postpartum, with a gradual return to normal values by 72 hours.[305]

Opioids. All opioids, particularly those with high lipid solubility (e.g., remifentanil, fentanyl, sufentanil), readily pass through the placenta to the fetus. Consequently, the administration of opioids is usually avoided until after delivery to reduce the risk for neonatal depression. However, the hemodynamic stability provided by opioids during airway manipulation and surgery may be valuable in select settings, particularly in the presence of maternal cardiac disease, neurologic conditions, and preeclampsia or hypertension.

The administration of **remifentanil** has been observed to mitigate the hemodynamic responses to tracheal intubation and surgery but can result in significant neonatal depression. Even with the administration of relatively low doses of remifentanil (0.5 µg/kg bolus followed by 0.15 µg/kg/min continuous infusion until peritoneal incision), Apgar scores and umbilical cord blood pH measurements were observed to be lower in the infants exposed to remifentanil than in the infants whose mothers received fentanyl 5 µg/kg after delivery; some neonates exposed to remifentanil required tracheal intubation.[306]

The highly lipid-soluble agent **fentanyl** rapidly crosses the placenta. Fentanyl is 60% to 80% protein bound; thus, approximately one-third is available for transfer across the placenta.[307] Despite its low lipid solubility, **morphine** has a UV/MV blood concentration ratio of 0.96 at 5 minutes[308]; this rate of equilibration and the production of active metabolites are relevant considerations in the use and timing of intravenous morphine administration.

Meperidine (pethidine) is highly lipid soluble and is 50% to 70% protein bound; maternal administration results in a mean UV/MV blood concentration ratio of 0.75.[309] The production of the active metabolite normeperidine, which can accumulate in both the mother and neonate and result in respiratory and neurobehavioral alterations, limits the use of meperidine as a principal analgesic agent during cesarean delivery; however, after delivery of the neonate, an intravenous dose of 12.5 to 25 mg is useful for treatment of shivering in the mother.

Maternal respiratory depression, as well as nausea and emesis during the intraoperative and postoperative periods, represent significant concerns in parturients given intravenous opioids.

Local Anesthesia

As a method used primarily for supplementation of neuraxial anesthesia, the infiltration of local anesthesia can also be used to facilitate an emergency cesarean delivery. This technique has been well described and is used predominantly in low-resource settings, where contemporary anesthesia techniques may not be readily available. Few contemporary obstetricians are familiar or proficient with this technique in developed countries.

The success of local infiltration depends on the obstetrician making a midline abdominal incision, avoiding use of retractors, and not exteriorizing the uterus. In settings in which an anesthesia provider might not be readily available, the obstetrician might begin surgery with the aid of local infiltration; after delivery of the infant, the achievement of temporary hemostasis, and the arrival of the anesthesia provider, surgery may be completed once general anesthesia has been induced.

Local infiltration is performed in sequential steps as the operation progresses (Box 26.8).[310] The use of 0.5% lidocaine with epinephrine is recommended; the use of a more concentrated solution may result in local anesthetic systemic toxicity. A 25-gauge spinal needle is used to make the intracutaneous injection; the needle is inserted just below the umbilicus and is directed in the midline toward the symphysis pubis. Approximately 10 mL of local anesthetic is required to create a skin wheal that extends from the symphysis pubis to the umbilicus. The subcutaneous injection is also performed for the full length of the planned incision with 10 to 20 mL of local anesthetic. Ideally, the obstetrician should then wait for 3 to 4 minutes to allow the local anesthetic agent to exert its effect before making the skin incision.

A vertical skin incision is made between the umbilicus and the symphysis pubis and is extended down to the rectus fascia. The obstetrician then infiltrates local anesthetic into the rectus fascia and rectus muscles by making three to five laterally directed injections on each side. The needle should be passed between the rectus sheath and the transversus

BOX 26.8 Steps for Initiating Local Infiltration Anesthesia for Cesarean Delivery

1. Professional support person with patient
2. Infiltration with 0.5% lidocaine with epinephrine (total dose should not exceed 500 mg)
3. Intracutaneous injection in the midline from the umbilicus to the symphysis pubis
4. Subcutaneous injection
5. Incision down to the rectus fascia
6. Rectus fascia blockade
7. Parietal peritoneum infiltration and incision
8. Visceral peritoneum infiltration and incision
9. Paracervical injection
10. Uterine incision and delivery
11. Administration of general anesthesia for uterine repair and abdominal closure, if needed

muscle at an angle of 10 to 15 degrees and a depth of 3 to 5 cm; aspiration is performed, and 2 to 3 mL of local anesthetic is injected at each site with an additional 1 mL injected with needle withdrawal. The obstetrician should also make oblique injections at the upper and lower poles of the incision. The local anesthetic will spread freely in the rectus sheath, but it takes 4 to 5 minutes for anesthesia to be complete. The suprapubic area must also be generously infiltrated to ensure blockade of the branches of the iliohypogastric nerve. The disadvantage of the rectus sheath block is the large volume (40 to 50 mL) of local anesthetic required; a less effective alternative that requires less volume and time is to raise a longitudinal paramedian wheal in the rectus fascia on each side of the midline and to infiltrate the suprapubic region.

The obstetrician then extends the incision through the rectus sheath, and the peritoneum is grasped with forceps clamps. If the patient has pain, the parietal peritoneum may be infiltrated with 5 to 10 mL of local anesthetic and then incised. The visceral peritoneum overlying the area of the uterine incision is injected with 10 mL of local anesthetic and is then incised and reflected appropriately. Paracervical infiltration with 5 to 10 mL of local anesthetic may block pain impulses from the uterus and cervix.

A uterine incision is made, and the infant is delivered. The surgeon must avoid forceful retraction and blunt dissection of tissue planes, and uterine manipulation should be kept to a minimum. A support person at the head of the table who can provide coaching and reassurance to the mother is invaluable.

The major disadvantages of local infiltration anesthesia are patient discomfort and the potential for local anesthetic systemic toxicity, given that as much as 100 mL of local anesthetic solution is required. The risk for local anesthetic systemic toxicity may be especially problematic in the absence of a skilled anesthesia provider to assist with maternal resuscitation. Another disadvantage is the amount of time required for maximal anesthesia to develop; maternal discomfort often accompanies an urgent delivery performed with this form of anesthesia. Finally, local infiltration does not provide satisfactory operating conditions in the event of a surgical complication (e.g., uterine laceration, broad ligament hematoma).

Cesarean delivery with use of local infiltration, if successful, has the advantages of preserving maternal cardiovascular stability and a patent airway while allowing the initiation of surgery in emergency cases. However, the technique is frequently associated with incomplete maternal anesthesia, which subsequently presents significant management issues, because the surgical procedure has commenced, positioning options are limited, and the consequences of the operative procedure (e.g., hemorrhage) may require immediate attention.

Additional peripheral nerve blockade techniques (e.g., transversus abdominis plane blockade[311]) may successfully augment local anesthesia infiltration; however, the degree to which the maternal experience is enhanced and the timing required to place these blocks deserve further investigation.

RECOVERY FROM ANESTHESIA

Cesarean delivery is a major abdominal surgical procedure with significant anatomic, physiologic, and hormonal sequelae, even when it is performed electively without complications in a healthy parturient. The risk for adverse outcomes is greater in the presence of significant maternal comorbidity or in the setting of surgical complications (e.g., massive blood loss, cesarean hysterectomy).[312]

A study at a single, tertiary care center found that the majority of patients who received neuraxial anesthesia for cesarean delivery could meet revised discharge criteria (i.e., presence of a normal level of consciousness, stable vital signs, adequate analgesia, and ability to flex the knees) within 60 minutes, which could shorten the average duration of PACU stay and result in cost savings.[313] However, 26% to 36% of patients remained in the PACU for up to 180 minutes because of pain, sedation, nausea and vomiting, pruritus, prolonged neuroblockade, and/or drug treatment. In addition, 16% to 22% remained in the PACU for up to 210 minutes for cardiovascular (e.g., bleeding, hypertension, hypotension, tachycardia) or respiratory events. Moreover, the study did not include the most seriously ill or highest-risk patients, who were transferred directly to an ICU.

The 2001 National Sentinel Caesarean Section Audit in the United Kingdom reported that 10% of women undergoing cesarean delivery required admission to a high-dependency unit.[314] Moreover, 3.5% of these women required subsequent transfer to an ICU. Preexisting comorbid conditions accounted for the majority (80%) of these ICU admissions; a smaller fraction were caused by the medical emergency (e.g., uterine rupture, placental abruption) that prompted the cesarean delivery.[314] Although ICU admission is uncommon in obstetric patients, it occurs more frequently (approximately 9 per 1000 patients) after cesarean delivery; the risk for ICU admission following cesarean delivery is greater in patients with high BMI.[314,315]

Of concern, inadequate postoperative care has been cited as a recurring factor in maternal deaths (see Chapter 39). The ASA Practice Guidelines for Obstetric Anesthesia state that "appropriate equipment and personnel should be available to care for obstetric patients recovering from neuraxial or general anesthesia."[28] Similarly, the National Obstetric Anaesthetic Service Guidelines from the United Kingdom state that postoperative care of the patient undergoing cesarean delivery should meet the same standard of care as required for any postoperative patient.[316]

There is increasing interest in enhanced recovery after surgery (ERAS) protocols for women who have undergone cesarean delivery. Further study is required to identify the components of the protocols that actually enhance recovery. Common components in current protocols include excellent analgesia combined with early ambulation, oral intake, and removal of urinary catheters.[317]

Oral Intake

A systematic review of six randomized clinical trials comparing early with delayed oral intake of fluid and food after cesarean delivery found that the early oral consumption (within 4 to 8 hours) was associated with a shorter time to return of bowel sounds and a shorter hospital stay.[318] No differences were reported in nausea and vomiting, abdominal distention, time to bowel activity, paralytic ileus, or need for analgesia. Guidelines from the National Institute for Health and Clinical Excellence (NICE) state that "women who are recovering well and who do not have complications … can eat and drink when they feel hungry or thirsty."[319]

Removal of Urinary Catheter

There are no differences in the incidence of urinary retention after general anesthesia and epidural anesthesia following cesarean delivery.[320] Risk factors for postpartum urinary retention after cesarean delivery include the use of postoperative opioid analgesia (particularly when given via an epidural catheter), multiple gestation, and a low BMI.[321] Most urinary catheters are removed either immediately after cesarean delivery or within 24 hours; there are no differences between these two options in regard to postoperative urinary retention, dysuria, urgency, fever, positive microscopy, or length of hospital stay[322]; immediate removal does appear to decrease the risk for urinary infection and lead to earlier ambulation.[323] In obstetric patients, the return of bladder sensation of fullness after neuraxial techniques appears to be a function of time, rather than urinary volume.[324] The return of bladder sensation after spinal anesthesia for cesarean delivery (with hyperbaric bupivacaine and fentanyl) takes longer (mean of 374 minutes [IQR 172 to 692]) than return of sensation after patient-controlled epidural analgesia for vaginal delivery (mean of 234 minutes [IQR 95 to 382]).[324]

Postoperative Assessment and Discharge

The anesthesia provider should assess for recovery of motor and sensory function if a neuraxial technique was administered. Women should be reassured that breast-feeding is safe, even after general anesthesia, and that postoperative analgesics have a favorable safety profile. Early mobility and ambulation should be encouraged.

ANESTHETIC COMPLICATIONS

Awareness and Recall

Cesarean delivery is a high-risk procedure for the occurrence of intraoperative awareness, defined as the spontaneous postoperative recall of an event that occurred during general anesthesia.[40] The following factors contribute to the risk for maternal awareness during cesarean delivery: (1) the avoidance of sedative premedication, (2) the deliberate use of a low concentration of a volatile halogenated agent, (3) the use of muscle relaxants, (4) the reduction in dose of anesthetic agents during hypotension or hemorrhage, (5) the presence of partial neuraxial blockade in parturients requiring conversion to general anesthesia after failed neuraxial anesthesia, and (6) the (mistaken) assumption that high baseline sympathetic tone is responsible for intraoperative tachycardia in parturients.

Concern for neonatal depression and uterine atony associated with volatile halogenated agents has led to administration of relatively low doses of these agents. Administration of a barbiturate induction agent followed by nitrous oxide 50% in oxygen resulted in maternal awareness in 12% to 26% of cases.[297,298] Using an isolated forearm technique, King et al.[325] assessed 30 women undergoing cesarean delivery with thiopental 250 mg, succinylcholine infusion, and 0.5% halothane in 50% nitrous oxide; the majority of patients signaled pain in the first minute. The incidence of recall with this anesthetic regimen was approximately 1%.[326] The use of higher concentrations of a volatile halogenated agent has subsequently become a more common practice, leading to an incidence of maternal awareness of approximately 0.26%.[40] However, the result of increasing the depth of maternal anesthesia is that neonates born to women who receive general anesthesia tend to have lower Apgar and neurobehavioral scores, particularly when the incision-to-delivery interval exceeds 8 minutes.[327]

The optimal doses and concentrations of anesthetic agents to prevent awareness remain unclear, in part because of the difficulty in assessing awareness. Studies have evaluated several tools for assessment of depth of maternal anesthesia, including the electroencephalogram, brainstem auditory evoked potentials, and the bispectral index.[40,243,280] The bispectral index is an empirically derived electroencephalographic parameter in which values less than 60 are suggested to predict a low probability of intraoperative recall and awareness.[328] With each of these monitoring devices, the threshold for awareness will need further validation, particularly during pregnancy[329]; some data suggest that these types of monitors are not reliable for monitoring anesthesia depth in the setting of cesarean delivery.[330] Moreover, many of these devices are not suitable for use for the emergency conditions under which most general anesthetics for cesarean delivery are administered.

Although pregnancy diminishes anesthetic requirements by 25% to 40%,[241] administration of 0.5 MAC of a volatile halogenated agent may not reliably provide adequate depth of anesthesia to prevent maternal awareness. Some commentators recommend larger doses of induction agents than are administered to nonpregnant patients (e.g., thiopental 5 to 7 mg/kg instead of 3 to 4 mg/kg), an end-tidal volatile anesthetic concentration greater than 0.8 MAC, the highest concentration of nitrous oxide compatible with appropriate oxygenation, and the administration of an opioid and a benzodiazepine after delivery.[40] Intravenous induction or infusion techniques that may reduce the risk for maternal awareness include the administration of repeat doses of induction agents,[331] the use of ketamine,[279] or a combination of these.[332] Midazolam 0.075 mg/kg provides 30 to 60 minutes of anterograde amnesia when given to women undergoing elective cesarean delivery under epidural anesthesia.[333] Propofol exhibits an amnestic effect that is not dependent on the degree of sedation; however, the effect is significantly less than that with midazolam.[334]

The psychological morbidity associated with awareness should not be underestimated.[40] Further investigations into the anesthetic regimens and monitoring necessary to prevent awareness and recall in pregnant women undergoing operative procedures are needed. These studies should incorporate the growing data on gender- and pregnancy-related differences in pharmacokinetics and pharmacodynamics of drugs used for anesthesia.[335,336]

Paradoxically, the issue of recall is not limited to the administration of general anesthesia. In women undergoing cesarean delivery with a neuraxial technique who desire treatment for anxiety, the administration of anxiolytic or hypnotic agents may result in a lack of recall of delivery, which is typically undesirable.

Dyspnea

After the initiation of neuraxial anesthesia, the patient may complain of dyspnea. The most common cause of this complaint is hypotension (causing hypoperfusion of the brainstem); therefore, the complaint of difficulty in breathing should prompt immediate assessment of blood pressure and treatment, if appropriate. Other causes of dyspnea are blunting of thoracic proprioception, partial blockade of abdominal and intercostal muscles, and the recumbent position, which increases the pressure of the abdominal contents against the diaphragm. The sensation of dyspnea appears related to the cephalad extent of the sensory blockade and may be mitigated by using a low-dose hyperbaric spinal bupivacaine technique in women undergoing cesarean delivery.[337]

Despite these changes, significant respiratory compromise is unlikely, primarily because the neuraxial blockade rarely affects the cervical nerves that control the diaphragm. A study examining the pulmonary effects of various spinal regimens including bupivacaine 10 mg, ropivacaine 20 mg, and levobupivacaine 10 mg, all with fentanyl 15 μg, in women undergoing cesarean delivery reported small reductions in the functional vital capacity (3 to 6%) and peak expiratory flow rate (6 to 13%).[338] However, the findings had no apparent clinical significance, were similar for all local anesthetics, and did not differ for sensory blockade that extended higher, versus no higher, than the T4 dermatome.

If the patient loses the ability to vocalize, demonstrate a strong hand grip, and/or maintain normal oxyhemoglobin saturation (e.g., symptoms suggestive of high spinal anesthesia), a rapid-sequence induction of anesthesia with cricoid pressure and placement of an endotracheal tube should be performed to maintain ventilation and prevent aspiration of gastric contents.

Hypotension

Hypotension is a common sequela of neuraxial anesthesia and, if severe and sustained, may lead to impairment of uteroplacental perfusion and result in fetal hypoxia, acidosis, and neonatal depression or injury.[339] Severe maternal hypotension can also have adverse maternal outcomes, including altered consciousness, pulmonary aspiration, apnea, and cardiac arrest.

Although not universally accepted, most investigators accept the following definitions for maternal hypotension: (1) a decrease in systolic blood pressure of more than 20% to 30% from baseline measurements or (2) a systolic blood pressure lower than 100 mm Hg.[340] Neuraxial anesthetic techniques produce hypotension through blockade of sympathetic nerve fibers, which control vascular smooth muscle tone. Several studies using noninvasive measures of cardiac output have demonstrated that cardiac output commonly *increases* after spinal anesthesia, even in the presence of a phenylephrine infusion and fluid administration.[341–343] These studies emphasize that spinal anesthesia–induced hypotension is principally related to a marked decrease in systemic vascular resistance, rather than decreased cardiac output. The rate and extent of the sympathetic involvement, and subsequently the severity of hypotension, are determined by the onset and extent of the neuraxial blockade[344]; hypotension may be less common with epidural anesthesia than with spinal anesthesia because of the slower onset of neuroblockade and the earlier recognition and treatment.[345]

Risk Factors for Hypotension

A number of studies have attempted to identify pregnant women at increased risk for development of hypotension. Of interest, women with severe preeclampsia[346] or in established labor appear less likely to experience hypotension during administration of spinal anesthesia for cesarean delivery (see Chapter 35).

Studies using a modified orthostatic challenge (i.e., "tilt test") have been unable to establish a correlation in the observed change in orthostatic blood pressure or heart rate with hypotension after spinal anesthesia.[347,348] However, the investigators have found that patients with a baseline heart rate higher than 90 bpm had a 83% chance (positive predictive value) of experiencing marked hypotension (decrease in blood pressure greater than 30%), whereas patients with a baseline heart rate lower than 90 bpm had a 75% chance

(negative predictive value) of *not* experiencing marked hypotension.[348]

One study found that the response of pregnant women to a preoperative *supine stress test* (i.e., placing the patient in the supine position to potentially cause aortocaval compression) predicts the occurrence of symptomatic hypotension, the need for ephedrine, and a decrease in systolic blood pressure below 80 mm Hg during administration of spinal anesthesia for cesarean delivery.[349] The supine stress test was considered positive if it was associated with (1) an increase in maternal heart rate greater than 10 bpm, (2) a decrease in systolic blood pressure of more than 15 mm Hg, or (3) signs and symptoms related to the supine position (e.g., nausea, dizziness). These investigators found that the preoperative stress test had a sensitivity of 69% and a specificity of 92% in identifying women who would have symptomatic hypotension.

Investigators have used other methods, including assessment of heart rate variability[350,351] and noninvasive measurements of systemic vascular resistance (e.g., thoracic impedance[352]) in an attempt to identify parturients at risk for neuraxial anesthesia–induced hypotension for cesarean delivery. To date, predicting which parturients will have hypotension after neuraxial anesthesia for cesarean delivery has not proven clinically feasible and will likely require more sophisticated studies that employ a number of different methodologies. Such prediction is likely to be challenging given the myriad of factors that control the autonomic, physiologic, and hormonal changes and hemodynamic responses that occur during pregnancy.

Prevention of Hypotension

A number of strategies can mitigate hypotension after spinal anesthesia for cesarean delivery, including fluid administration, vasopressor administration, lower local anesthetic doses, leg elevation or wrapping, and left uterine displacement.

The use of **intravenous fluid** to prevent hypotension can be manipulated by (1) timing of administration, either before (preload) or coincident with (co-load) the intrathecal injection; and/or (2) type of fluid, either crystalloid or colloid. Rate of fluid administration may also play a role. Crystalloid preload is minimally effective, even when volumes as great as 30 mL/kg are infused.[62] By contrast, colloid preload consistently reduces the incidence and severity of hypotension. A randomized trial of 36 healthy women undergoing elective cesarean delivery compared the administration of 1500 mL of lactated Ringer's solution and 500 mL and 1000 mL of hydroxyethyl starch solution (HES) 6% before spinal anesthesia for cesarean delivery.[353] The frequency of hypotension (systolic blood pressure less than 100 mm Hg and less than 80% of baseline) was 75%, 58%, and 17%, respectively. Significant increases in intravascular volume and cardiac output, as measured by indocyanine green spectrophotometry, were observed in the HES groups (Fig. 26.5). At 30 minutes, 100% of the HES volume, versus 28% of the lactated Ringer's volume, remained within the intravascular space.

Whether crystalloid fluid is given as a preload or co-load does not appear to affect the frequency of hypotension. A meta-analysis of randomized trials comparing crystalloid preload to co-load did not find a difference in the incidence of hypotension.[64] Similarly, no difference in the incidence of hypotension is observed with a colloid preload versus co-load, likely reflecting the intravascular dwell time of colloid.[64]

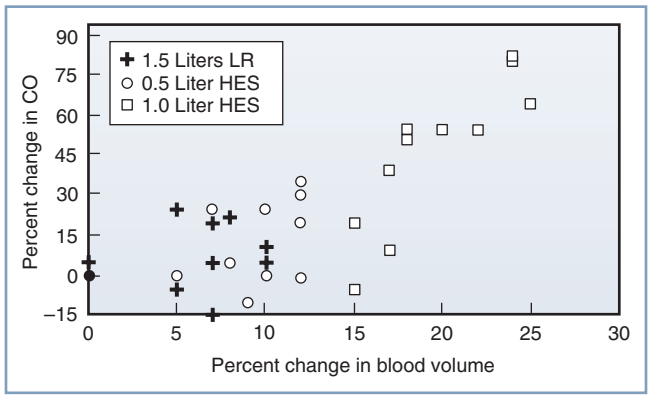

Fig. 26.5 The relationship between the changes (%) in blood volume and cardiac output after volume preload in parturients undergoing spinal anesthesia. Cardiac output *(CO)* was estimated with indocyanine green pulse spectrophotometry methodology. *HES,* hydroxyethyl starch solution; *LR,* lactated Ringer's solution. (Modified from Ueyama H, He Y, Tanigami H, et al. Effects of crystalloid and colloid preload on blood volume in the parturient undergoing spinal anesthesia for elective cesarean section. *Anesthesiology.* 1999;91: 1571–1576.)

Both preload and co-load administration of colloid are more effective than co-load administration of crystalloid in mitigating hypotension.[341] However, the cost and associated pruritus, mild coagulation abnormalities, and potential for allergic reaction to colloid starch solutions, particularly with first-generation agents, have tempered their widespread use. Possible fetal and neonatal effects related to the type and timing of maternal fluid administration deserve further investigation; for example, the rapid administration of 1500 to 2000 mL of fluid can release atrial natriuretic peptide, which may result in vasodilation and reduced sensitivity to vasoconstrictors.[354]

Our current practice is to administer rapid crystalloid co-load (approximately 15 mL/kg) to healthy parturients undergoing elective cesarean delivery with spinal anesthesia. Parturients at high risk for hypotension (e.g., history of supine hypotension syndrome) or at high risk for the adverse consequences of hypotension (e.g., hypertrophic cardiomyopathy) receive colloid preload (500 mL).

Vasopressor agents, including ephedrine and phenylephrine, can be titrated to maintain maternal blood pressure and have been observed to be more effective than crystalloid solution or placebo in preventing spinal anesthesia–induced hypotension. In a meta-analysis, Lee et al.[355] concluded that ephedrine was superior to placebo in the prevention of spinal anesthesia–induced hypotension for women undergoing cesarean delivery. Although greater doses of ephedrine provided more effective prophylaxis, hypotension was still observed and reactive hypertension and umbilical artery metabolic acidosis were more common with higher doses.

Traditionally, ephedrine was used to prevent and treat the hypotension associated with neuraxial anesthesia because of fear that pure alpha-adrenergic agonists would decrease uterine blood flow. However, phenylephrine is greater or equally efficacious to ephedrine for the prevention and treatment of hypotension, and it is less likely to depress umbilical arterial blood pH and base excess.[356] Phenylephrine crosses the placenta less than ephedrine[357]; presumably, ephedrine contributes to stimulation of fetal metabolism, resulting in lower pH and base excess than phenylephrine.[358]

There is some controversy as to whether vasopressors should be administered as a continuous infusion or bolus, particularly for the prevention of hypotension. When administered as an infusion, phenylephrine infusion rates of 25 to 100 μg/min are usually used to prevent hypotension.[359,360] However, the number of interventions to maintain systolic blood pressure within 20% of baseline are lower for phenylephrine infusions of 25 and 50 μg/min than for infusions of 75 and 100 μg/min because of the number of interventions required to treat hypertension with the higher doses. Using an up-down sequential allocation study design, the effective phenylephrine *bolus* dose for *preventing* hypotension in 95% of patients (ED_{95}) was estimated at 159 μg (95% CI, 122 to 371 μg).[361] Reflex decreases in heart rate and reductions in cardiac output may occur with phenylephrine; however, this does not appear to affect umbilical cord blood gas values or Apgar scores in uncompromised infants delivered electively.[360]

One study demonstrated a salutary effect of a prophylactic infusion of ephedrine combined with phenylephrine compared with infusion of ephedrine alone.[362] However, another study comparing infusions of different ephedrine-to-phenylephrine ratios found that as the proportion of ephedrine increased, the incidence of hypotension and nausea/vomiting also increased, whereas umbilical cord blood pH and base excess decreased.[363]

The titration of vasopressor infusions may require frequent infusion rate adjustments, and this mode of administration may be considered by some to be more cumbersome than bolus administration of the same agents. Thus, some clinicians prefer to administer a bolus dose of vasopressor to prevent or treat hypotension. Various ratios of ephedrine combined with phenylephrine, administered as a bolus, have been tested, but investigators have been unable to identify a combination that reliably prevented hypotension yet avoided hypertension.[364] Methods under investigation include a closed-loop feedback computer-controlled infusion of phenylephrine for maintaining blood pressure during spinal anesthesia.[365]

The combination of fluid and vasopressor administration may be the most effective regimen to prevent hypotension. In a study by Ngan Kee et al.,[366] the incidence of spinal anesthesia–associated hypotension was almost zero (1.9%) in the group randomized to receive a rapid crystalloid co-load combined with a prophylactic phenylephrine infusion (beginning at 100 μg/min); the incidence of hypotension was 28% in the women who received phenylephrine without the co-load. No difference in neonatal outcome was observed between groups.

The initial studies comparing ephedrine to phenylephrine enrolled healthy women undergoing elective cesarean delivery. In a randomized trial comparing ephedrine to phenylephrine in women with preeclampsia undergoing cesarean delivery with spinal anesthesia, there was no difference in umbilical artery pH between prophylactic phenylephrine and ephedrine infusions.[367]

Several studies have investigated prophylactic norepinephrine for the prevention of spinal anesthesia–induced hypotension.[368,369] In a randomized controlled trial of computer-controlled infusions of norepinephrine compared with phenylephrine in women with spinal anesthesia undergoing cesarean delivery, women who received norepinephrine had higher cardiac output (primary outcome) and a lower incidence of bradycardia, with similar neonatal outcomes.[368] The median (IQR) norepinephrine infusion rate was 2.35 μg/min (1.95 to 2.90).[368] Further study of the safety of norepinephrine for this purpose is indicated.

The use of lower doses of spinal local anesthetic is associated with a lower incidence of hypotension, particularly when high and low doses are compared (e.g., hyperbaric bupivacaine 6.5 mg versus 9.5 mg, or 3.75 mg versus 9 mg; and plain bupivacaine 5 mg versus 10 mg combined with fentanyl 25 μg).[370] However, the desire to use a low dose of spinal local anesthetic (e.g., bupivacaine less than or equal to 8 mg) should be tempered by the potential for an increased requirement for intraoperative supplemental analgesia or conversion to general anesthesia.[371] The optimal local anesthetic dose is likely influenced by a number of factors, including technical factors (e.g., precision of dose, spinal level of injection, concomitant opioid use, positioning of patient during and after the block), and other factors (e.g., genetic sensitivity, patient expectations, differences in operative technique); these factors are often not controlled in studies of local anesthetic dose.[370] Anesthesia providers who administer an intermediate or low dose of local anesthetic should consider the use of a catheter-based technique (continuous spinal or CSE anesthesia), given the frequent need (up to 40%) for supplemental administration of additional local anesthetic through the catheter.[370]

Physical methods to prevent hypotension include the use of lower limb compression bandages or pneumatic compression devices, which have demonstrated some success[340] and may assist in preventing thromboembolic complications.

Treatment of Hypotension

The ideal treatment of hypotension would be reliable, titratable, easy to use, and devoid of maternal and fetal side effects. Almost 45 years ago, ephedrine, a mixed alpha- and beta-adrenergic receptor agonist, emerged as the leading choice for the treatment of hypotension on the basis of studies demonstrating its efficacy and apparent superiority (over other agents) in protecting and/or restoring uterine blood flow in gravid ewes and other pregnant animal models.[372] By contrast, other agents, including metaraminol and phenylephrine, while restoring maternal blood pressure, were associated with a decrease in uterine artery blood flow and fetal pH.[372]

Contemporary animal studies have provided a mechanistic understanding of these effects. During pregnancy, vasopressors appear to constrict the femoral artery more than the uterine artery, which increases blood pressure and protects uterine blood flow. This differential pressor effect is greater for ephedrine than for metaraminol.[373] A second mechanism appears to be the up-regulation of nitric oxide synthase (NOS) in the uterine artery during pregnancy.[374] The presence of NOS potentially makes this artery less sensitive to vasopressors; this effect may be further augmented by ephedrine, a drug observed to independently cause the release of NOS.

In a quantitative systematic review, Lee et al.[356] noted that the use of ephedrine for treatment of maternal hypotension during administration of spinal anesthesia for cesarean delivery was associated with lower umbilical cord blood pH measurements than the use of phenylephrine. This surprising clinical result (which differs from results in animal studies) may reflect interspecies differences in vascular smooth muscle physiology, control of blood flow, and drug metabolism. This finding may also reflect the fetal effects of ephedrine administered to the mother. Cooper et al.[358] subtracted the umbilical vein P_{CO_2} from the umbilical artery P_{CO_2} to calculate an index that reflected fetal CO_2 generation; the index was higher, reflecting a higher metabolic production of CO_2, in newborns whose mothers received ephedrine. Ngan Kee et al.[357] observed that the greater depression of fetal pH and base excess with ephedrine compared with phenylephrine appears related to its ability to cross the placenta to a greater extent, undergo less early metabolism or redistribution in the fetus, and consequently produce greater fetal concentrations of lactate, glucose, and catecholamines.

A randomized trial compared phenylephrine and ephedrine for the treatment of hypotension in women with preeclampsia undergoing cesarean delivery with spinal anesthesia.[375] There were no differences between groups in umbilical artery and vein base excess values or Apgar scores. The NICE guidelines state that phenylephrine and ephedrine are equally effective as vasopressors.[376] Given the efficacy of phenylephrine in the treatment of hypotension and the better umbilical cord blood acid-base measurements associated with its use in healthy patients, and its lack of harm in women with preeclampsia, many anesthesia providers now use phenylephrine as a first-line agent for the prevention and treatment of maternal hypotension.[377] Regardless of the vasopressor agent selected to treat hypotension, therapy should be administered as soon as the blood pressure begins to decrease, rather than after the occurrence of clinically significant hypotension.[378] In addition, vasopressor administration strategies can optimize maternal, and potentially fetal, hemodynamics and well-being by maintaining blood pressure near baseline, instead of lower target goals such as 80% or 90% of baseline measurements.[379] Ephedrine is usually administered intravenously in bolus doses of 5 to 10 mg. Phenylephrine may be administered intravenously in bolus doses of 50 to 100 μg or by continuous infusion beginning at 25 to 50 μg/min,[359] with titration to maintain maternal arterial blood pressure at or near baseline and avoidance of maternal bradycardia.[343] Administration of ephedrine may lead to tachycardia, as well as tachyphylaxis. By contrast, phenylephrine may result in reflex maternal bradycardia, which, if treated with an anticholinergic agent in the absence of hypotension, may result in significant hypertension.

Failure of Neuraxial Blockade

"Failed" neuraxial anesthesia can be defined as neuroblockade insufficient in extent, density, or duration to provide anesthesia for cesarean delivery. Four to 13 percent of epidural anesthetics and 0.5% to 4% of spinal anesthetics fail to provide sufficient anesthesia for the initiation or completion of cesarean delivery.[215,380] Epidural techniques are more often associated with failure, given that the catheter is often placed during early labor, and over time the catheter may migrate out of the epidural space. Factors that correlate with failed extension of labor epidural anesthesia for cesarean delivery include a higher number of bolus doses for the provision of labor analgesia (i.e., treatment of breakthrough pain), patient characteristics (e.g., obesity, distance from the skin to the epidural space), and the time elapsed between placement of the epidural catheter and cesarean delivery.[215]

The causes of failure of neuraxial techniques include anatomic, technical, and obstetric factors. Steps to reduce the likelihood of epidural block failure include meticulous attention to technical detail, the administration of a solution that contains both a local anesthetic and an opioid, and a better understanding of the characteristics of epidural versus spinal blockade. Moreover, the patient should be prepared to expect the sensation of deep pressure and movement yet be reassured that reports of discomfort or pain will be addressed promptly. Initiation of surgery should be delayed until adequate thoracic and sacral sensory blockade have been achieved; on rare occasions, in the setting of an urgent procedure for which a developing epidural block is present at T10 but has yet to achieve a T4 level, surgery can commence with the understanding that adjuvant treatments or alternative forms of anesthesia may be required.

Evaluation of intraoperative pain requires (1) determination of the location and extent of discomfort, (2) evaluation of the sensory level of anesthesia, (3) assessment of the current status of the surgery (e.g., incision, delivery, uterine repair, skin closure), and (4) assessment of the presence of confounding factors (e.g., hemorrhage, anxiety). Shoulder pain can originate from irritation of the diaphragm (usually by amniotic fluid or blood) and is mediated by the phrenic nerve (C3 to C5); prolonged abduction and extension of the arms can also cause discomfort. Additional discomfort can occur from visceral stimulation such as uterine manipulation, which often involves the greater splanchnic nerve (T5 to T10). Alternatively, the extent of the block may be adequate but the density of neuroblockade of the large nerve fibers in the lumbosacral plexus may be inadequate. Inadequate anesthesia can result from regression of the block from a cephalad or caudad direction. Management of breakthrough pain should begin with acknowledgement of the patient's discomfort and

consideration of the fetal (e.g., presence of nonreassuring fetal status), surgical (e.g., ongoing or anticipation of prolonged surgery), and anesthetic (e.g., maternal airway examination, BMI) implications, as well as the anesthesia provider's experience. Emergent or ongoing surgery may require administration of general anesthesia. If no block exists, the surgery has not begun, and time allows, neuraxial anesthesia can be repeated; whether an epidural or spinal technique is attempted depends on the previously mentioned factors. If an inadequate, partial block exists in an elective situation, either the surgery can be postponed (to allow resolution of the partial block) or a second neuraxial technique may be performed *with caution.*

The disadvantages of replacing a failed neuraxial block with epidural anesthesia include (1) the potential for local anesthetic systemic toxicity (particularly after epidural administration of a large dose of local anesthetic for the initial attempt), (2) the time required to establish an adequate block, and (3) the unpredictable reliability and quality of the resulting block. As a consequence, many practitioners intent on replacing a failed epidural technique suggest the *cautious* use of a technique with an intrathecal component (i.e., spinal, CSE, or continuous spinal technique).[381]

The performance of a spinal technique in the setting of a partial but failed epidural or spinal anesthetic technique is controversial. In this setting, intrathecal administration of a standard intrathecal dose of bupivacaine may result in a high spinal block.[382,383] Radiographic evidence suggests that the dural sac is compressed by prior epidural drug administration.[221] Thus, when performing a spinal anesthetic technique after failed epidural or spinal anesthesia, the anesthesia provider should consider (1) using a different interspace to avoid possible anatomic distortions (e.g., from the loss of resistance to saline or previous needle passes) or abnormalities; (2) reducing the dose of bupivacaine (with the chosen dose depending on the extent of existing neuroblockade); (3) placing the patient in a semi-sitting (Fowler's) position to limit cephalad spread of the local anesthetic; (4) using a CSE technique with a small intrathecal dose of local anesthetic, and, if necessary, titrating the sensory level with additional drugs administered through the epidural catheter; and/or (5) intentionally placing a catheter into the intrathecal space for administration of continuous spinal anesthesia. This last strategy may be especially useful in obese patients in whom the technical difficulty of the neuraxial approach may otherwise limit success.

If discomfort is reported after the start of surgery, it is often helpful to ask the surgeons to halt the operation while an assessment is made. If an epidural catheter is in place, an alkalinized local anesthetic with an opioid (e.g., 3% 2-chloroprocaine with fentanyl) should be administered. The density of epidural anesthesia may be improved by "repainting the fence." An additional dose of local anesthetic (20% to 30% of the initial dose [e.g., 4 to 7 mL]) is administered approximately 20 minutes after the initial dose. This second dose serves to improve the density of neuroblockade without extending the sensory level. Some anesthesia providers routinely administer this supplemental dose, without waiting for a patient's complaint of breakthrough pain.

Intravenous administration of an opioid (e.g., fentanyl), inhalation of nitrous oxide (40% to 50% in oxygen), or intravenous anxiolysis (midazolam) may be helpful for the treatment of breakthrough pain. Severe pain may require intravenous ketamine in 5- to 10-mg increments. However, care should be taken, because the administration of multiple agents can result in significant sedation, loss of consciousness, and the presence of psychomimetic and amnestic effects. The obstetrician can infiltrate the wound or instill the peritoneal cavity with local anesthetic. In some instances, the induction of general anesthesia with tracheal intubation is necessary.

If the anesthesia provider anticipates that the duration of the surgical procedure will be longer than the predicted duration of epidural or CSE anesthesia, additional local anesthetic (with or without an opioid) should be administered *before* anticipated regression of neuroblockade (see Table 26.7). The usual dose to maintain neuroblockade is one-third to one-half of the initial dose.

High Neuraxial Blockade

It is not uncommon for the parturient to report mild dyspnea or reduced ability to cough, especially if the neuraxial blockade has achieved a T2 sensory level. If impaired phonation, unconsciousness, respiratory depression, or significant impairment of ventilation occurs, general anesthesia should be induced. High neuraxial blockade may also result in cardiovascular sequelae, including bradycardia and hypotension. An easy method to diagnose clinically significant high neuraxial blockade is to ask the patient to make a fist ("squeeze your fingers"). A weak hand grasp indicates high thoracic and cervical motor blockade.

High neuraxial block can be caused by several mechanisms, including an exaggerated spread of spinal or epidural drugs and unintentional intrathecal or subdural administration of an "epidural dose" of local anesthetic. The rapid epidural administration of a large volume of local anesthetic solution in the presence of a large-bore dural puncture (e.g., after a "wet tap") may also result in high neuroblockade.

Nausea and Vomiting

Nausea and vomiting are regulated by the chemoreceptor trigger zone and the vomiting center, which are located in the area postrema and the medullary lateral reticular formation, respectively. The vomiting center receives impulses from the vagal sensory fibers in the gastrointestinal tract, the semicircular canals and ampullae (labyrinth) of the inner ear, higher cortical centers, the chemoreceptor trigger zone, and intracranial pressure receptors. Impulses from these structures are influenced by dopaminergic, muscarinic, tryptaminergic, histaminic, and opioid receptors, which are subsequently the targets for antiemetic agents. Efferent impulses from the vomiting center are transmitted through the vagus, phrenic, and spinal nerves to the abdominal muscles, which causes the physical act of vomiting.

Preoperative Nausea and Vomiting

Nausea and vomiting may occur separately or in combination and are not uncommon during pregnancy. A number of metabolic, endocrine, and anatomic changes have been implicated in the genesis of gestational nausea and vomiting, including human chorionic gonadotropin, estrogen, progesterone, prostaglandins, and immune system dysregulation.[384] When vomiting is sufficiently severe to produce weight loss, dehydration, acidosis from starvation, alkalosis from loss of hydrochloric acid in vomitus, and hypokalemia, it is referred to as *hyperemesis gravidarum* (see Chapter 16). This disorder most commonly occurs in early pregnancy, but as many as 10% of pregnant women have nausea and vomiting that persist beyond 22 weeks' gestation.[384] Severe and persistent hyperemesis may result in maternal and fetal morbidity. The presence of delayed gastric emptying during labor and administration of opioids are risk factors for nausea and vomiting before cesarean delivery.

Intraoperative Nausea and Vomiting

Intraoperative nausea and vomiting associated with cesarean delivery can be variable in incidence and presentation, depending on preexisting symptoms, anesthetic and obstetric techniques, and preventive and therapeutic measures. The incidence of nausea may be as high as 80%, particularly when the anesthesia provider specifically assesses for the presence of intraoperative symptoms; symptoms occur frequently with exteriorization of the uterus.[9] Anesthetic causes of intraoperative nausea and vomiting include hypotension and increased vagal activity; nonanesthetic causes include surgical stimuli, bleeding, medications (e.g., uterotonic agents, antibiotics), and motion at the end of surgery.[385] Many of these elements occur simultaneously.

Hypotension is among the most common sequelae associated with the administration of neuraxial anesthesia. Centrally, hypotension may lead to cerebral and brainstem hypoperfusion, which results in stimulation of the medullary vomiting center. Peripherally, hypotension may cause gut ischemia with release of emetogenic substances (e.g., serotonin) from the intestine.[386] Strict maintenance of intraoperative blood pressure can reduce the occurrence of emesis; Datta et al.[378] observed that the incidence of intraoperative nausea and vomiting was 66% when the blood pressure decreased more than 30% from baseline, but was less than 10% when blood pressure was maintained at baseline with ephedrine. Similarly, Ngan Kee et al.[379] demonstrated progressive increases in intraoperative nausea and vomiting during spinal anesthesia for cesarean delivery when blood pressure control with an infusion of phenylephrine was less aggressive; the incidence of nausea and vomiting was 4% when blood pressure control targeted 100% of baseline, 16% for 90% of baseline, and 40% for 80% of baseline.

Uterotonic agents may also contribute to intraoperative nausea and vomiting. Ergot alkaloids (e.g., methylergonovine maleate) may cause nausea and vomiting by interacting with dopaminergic and serotoninergic receptors. Oxytocin causes nausea and vomiting primarily as a result of the hypotension produced through release of nitric oxide and atrial natriuretic peptide.[387] A 29% incidence of nausea and a 9% incidence of vomiting have been reported with an intravenous bolus of oxytocin 5 units during elective cesarean delivery with neuraxial anesthesia.[388] Administration of 15-methyl prostaglandin $F_{2\alpha}$ causes nausea through the stimulation of smooth muscles of the gastrointestinal tract; a 10% incidence of nausea and vomiting has been observed after administration of 250 μg intramuscularly.[385] Likewise, misoprostol is associated with a high risk for nausea and vomiting.[389]

Surgical stimuli, including exteriorization of the uterus, intra-abdominal manipulation, and peritoneal traction, can cause visceral pain and subsequent nausea through the stimulation of vagal fibers and activation of the vomiting center. Despite high levels of thoracic sensory block obtained for cesarean delivery anesthesia, visceral pain may still occur, particularly after the neuraxial administration of a local anesthetic without opioid.[390] The administration of neuraxial opioids reduces visceral pain–induced nausea and vomiting. Neuraxial fentanyl both improves the quality of neuraxial anesthesia and decreases intraoperative nausea; the minimal effective intrathecal and epidural doses are 6.25 μg and 50 μg, respectively.[146]

Postoperative Nausea and Vomiting

Risk factors for postoperative nausea and vomiting have not been specifically studied in obstetric patients; however, studies have identified risk factors in nonobstetric patients receiving general or neuraxial anesthesia (Box 26.9).[391,392] A multicenter observational study identified the following four highly predictive factors for postoperative nausea and vomiting in nonobstetric patients after general anesthesia, which may have relevance in the pregnant population: (1) female sex, (2) history of motion sickness or postoperative nausea and vomiting, (3) nonsmoking status, and (4) the use of perioperative

BOX 26.9 Risk Factors for Nausea and Vomiting

General Anesthesia–Related Factors

- Female sex
- History of motion sickness or postoperative nausea and vomiting
- Nonsmoking status
- Use of perioperative opioids

Spinal Anesthesia–Related Factors

- Block height of T5 or higher
- History of motion sickness
- Hypotension
- Omission of neuraxial opioids

Data from Gan TJ. Risk factors for postoperative nausea and vomiting. *Anesth Analg.* 2006;102:1884–1898; Apfel CC, Laara E, Koivuranta M, et al. A simplified risk score for predicting postoperative nausea and vomiting: conclusions from cross-validations between two centers. *Anesthesiology.* 1999;91:693–700.

opioids.[392] The incidence of postoperative nausea and vomiting was 10% if the patient had no risk factors, 21% for one, 39% for two, 61% for three, and 79% for four. A subset of pregnant women may have a lower threshold for nausea and vomiting associated with motion.[384] Changes in position and transfer to and on the stretcher may stimulate afferent neural pathways that trigger emesis. Because the histamine-1 (H_1) and muscarinic cholinergic pathways play primary roles in this response, antihistamine and anticholinergic agents should be considered first-line treatments.[393] Postoperative nausea and vomiting may be related to postoperative ileus, which in turn is influenced by the effect of opioids on the gastrointestinal tract, the activation of the sympathetic nervous system, the occurrence of intestinal wall inflammation, and the presence of volume overload or edema.[384]

Prophylaxis and Treatment of Nausea and Vomiting

Preventing maternal hypotension may be the best means of preventing nausea and vomiting (see earlier). Several options exist for the pharmacologic prophylaxis of nausea and vomiting, and several different classes of drugs are available (Table 26.8). Although various algorithms have been developed to prevent postoperative nausea and vomiting, primarily targeting the nonpregnant patient population, none has been universally successful.[394] However, the prophylactic use of these agents either before or after umbilical cord clamping during cesarean delivery with neuraxial anesthesia has been demonstrated to be highly effective. Balki and Carvalho[385] suggested an algorithm consisting of metoclopramide as a first-line agent, dimenhydrinate (a combination of diphenhydramine and 8-chlorotheophylline) as a second-line agent, and ondansetron or granisetron as a third-line agent. Multimodal therapies may eventually prove the most effective, as has been demonstrated in nonpregnant patients.[395]

Metoclopramide is the agent most frequently given, owing to its favorable prokinetic effects. Common side effects include dizziness, drowsiness, and fatigue; rarer side effects include extrapyramidal reactions and acute dystonias. A meta-analysis of 11 studies of 702 patients undergoing cesarean delivery found that intravenous metoclopramide 10 mg compared with placebo, administered before neuraxial blockade, resulted in a significant reduction in intraoperative nausea (RR, 0.27; 95% CI, 0.16 to 0.45) and vomiting (RR, 0.14; 95% CI, 0.03 to 0.56).[49] This approach was more effective than administering the metoclopramide after delivery, although administration after delivery also resulted in a significant reduction in perioperative nausea and vomiting. Early postoperative nausea (RR, 0.47; 95% CI, 0.26 to 0.87) and vomiting (RR, 0.45; 95% CI, 0.21 to 0.93) were also reduced with metoclopramide.

Ondansetron has been found to be more effective than placebo for the prevention of intraoperative nausea and vomiting during cesarean delivery with spinal anesthesia.[396] A study that compared ondansetron 4 mg to metoclopramide

TABLE 26.8 Agents for Prevention of Nausea and Vomiting in Women Undergoing Cesarean Delivery with Neuraxial Anesthesia[a]

Drug	Dose	Optimal or Recommended Timing	Comments
Dexamethasone	4–8 mg IV	Unknown for patients undergoing cesarean delivery[b]	Delayed onset of action; used infrequently in patients undergoing cesarean delivery
Dimenhydrinate[c]	25–50 mg IV	Unknown for patients undergoing cesarean delivery	Antihistamine
Dolasetron	12.5 mg IV	After umbilical cord clamping	Serotonin antagonist; not effective in the single published randomized controlled trial
Droperidol	0.625–1.25 mg IV	End of surgery	Butyrophenone with a package insert that contains an FDA "black box" warning regarding prolongation of corrected QT interval on electrocardiogram
Ephedrine[c]	0.5 mg/kg IM	End of surgery	Vasopressor
Granisetron	40 µg/kg IV	After umbilical cord clamping	Serotonin antagonist
Metoclopramide	10 mg IV	Before surgery or after umbilical cord clamping	Benzamide
Ondansetron	4 mg IV	After umbilical cord clamping	Serotonin antagonist
Scopolamine	1.5-mg transdermal patch	Unknown	Muscarinic antagonist

IM, Intramuscularly; *IV,* intravenously.

[a]If nausea and vomiting occur despite prophylaxis, the anesthesia provider should consider administration of a drug from a different pharmacologic class. There is no evidence that a second administration of the same drug within 6 hours provides additional benefit.

[b]Studies in nonobstetric patients suggest that administration of dexamethasone at induction of anesthesia results in better efficacy, but the optimal timing in obstetric patients is unclear.

[c]Has not been studied in patients undergoing cesarean delivery with neuraxial anesthesia; however, this drug has proved effective for prophylaxis of postoperative nausea and vomiting in studies of nonobstetric patients after administration of general anesthesia.

10 mg administered after umbilical cord clamping found ondansetron to be more effective in preventing nausea (26% versus 51%) but not vomiting (15% versus 18%).[397] A systematic review concluded that the use of a serotonin receptor antagonist (e.g., ondansetron, granisetron) in women undergoing neuraxial anesthesia for cesarean delivery was associated with a reduction in intraoperative nausea (but not vomiting) and postoperative nausea and vomiting, compared with placebo.[398] Furthermore, serotonin receptor antagonists were found to be more effective in reducing postoperative nausea than dopamine receptor antagonists (e.g., metoclopramide, droperidol).[398] Some studies have suggested that the administration of ondansetron decreases the incidence of bradycardia and hypotension following spinal anesthesia, potentially by blocking the Bezold-Jarisch reflex (which is mediated by 5-HT_3 serotonin receptors). However, the strength of the evidence for this effect has been questioned.[399]

Animal toxicology studies suggest that the epidural administration of ondansetron may be safe.[400] In a study of 80 women undergoing elective cesarean delivery with CSE anesthesia, the incidence of postoperative nausea was lower in women randomized to receive an epidural infusion of ondansetron than in women who received an intravenous infusion (8 mg over 48 hours) at both 24 and 48 hours.[400] However, future investigations are needed to validate the safety of the neuraxial administration of ondansetron before this route of administration can be recommended.

A 2012 meta-analysis of aggregated data suggests that a single intravenous dose of **dexamethasone** 5 to 10 mg (but not 2.5 mg) compared with placebo reduces the incidence of postoperative nausea (23% versus 41%, respectively) and vomiting (20% versus 36%, respectively) in women who received neuraxial morphine for cesarean delivery.[401] In a subgroup analysis, the authors identified a lower incidence of postoperative nausea and vomiting in women who received epidural morphine; however, they were unable to draw definitive conclusions regarding the effect of dexamethasone on postoperative nausea and vomiting in women who received spinal morphine because of the small sample size. In a later study, women randomized to receive preincision dexamethasone 10 mg after spinal anesthesia with bupivacaine and morphine 0.06 mg had a lower 24-hour cumulative incidence of both nausea and vomiting compared with a control group.[402]

Administration of a **transdermal scopolamine** 1.5-mg patch after umbilical cord clamping was shown to be as effective as ondansetron 4 mg in the prevention of nausea and vomiting after cesarean delivery with spinal anesthesia (bupivacaine 12 mg with fentanyl 10 μg and morphine 0.2 mg); compared with placebo, both drugs resulted in a reduction in the incidence of postoperative emesis from approximately 60% to approximately 40%.[403] The use of scopolamine may be limited by side effects, particularly dry mouth and blurry vision. The results of a systematic review suggest that the use of an anticholinergic agent (e.g., scopolamine, glycopyrrolate) in women undergoing neuraxial anesthesia for cesarean delivery results in a significant reduction in intraoperative nausea but not vomiting.[398]

Alternative therapies may play a role in preventing or treating perioperative nausea and vomiting. Several studies have found a favorable effect of **acupressure** on the P6 acupoint (on the anterior aspect of the wrist). After spinal anesthesia for cesarean delivery, acupressure has been observed to result in a lower incidence of nausea (36% and 15%, respectively) and vomiting (17% and 9%, respectively), compared with placebo.[404] Two systematic reviews of randomized controlled trials involving a total of 649 women undergoing neuraxial anesthesia for cesarean delivery concluded that despite heterogeneity in the data, P6 stimulation (compared with placebo) appears to reduce intraoperative nausea but not intraoperative vomiting or postoperative nausea or vomiting.[398,405]

One study found that the administration of **supplemental oxygen** (F_{IO_2} of 0.7) between umbilical cord clamping and the end of cesarean delivery with neuraxial anesthesia was not associated with a lower incidence of nausea and vomiting than the administration of room air.[406] This finding is consistent with the results of a meta-analysis[407] of randomized controlled trials in the nonobstetric population; there was no difference in the incidence of nausea and vomiting with the use of supplemental oxygen (F_{IO_2} of 0.8) compared with the use of lower oxygen concentrations (F_{IO_2} of 0.3 to 0.4).[407]

A systematic review[398] suggests that the administration of subhypnotic doses of **propofol** (0.5 to 1.5 mg/kg/h) for the reduction of intraoperative and postoperative nausea and vomiting in women undergoing neuraxial anesthesia for cesarean delivery is more effective than placebo; however, there are insufficient data to compare this method with other therapies.[398]

Perioperative Pain

In contrast to surveys performed in the general surgical patient population, in which patients have revealed a primary concern for postoperative nausea and vomiting, a survey performed in obstetric patients during their expectant parent class indicated that pain during and after cesarean delivery was their greatest concern.[408] Inadequate neuraxial anesthesia leading to pain during labor or cesarean delivery was the most frequent "damaging event" in obstetric claims (31%) against the National Health Service in the United Kingdom from 1995 to 2007.[409]

A preoperative discussion about pain and discomfort can help allay patient concerns. The anesthesia provider should (1) explain that there may be some deep pressure, pain, or discomfort during cesarean delivery performed with a neuraxial technique; (2) reassure the patient that the anesthesia provider will be present throughout the operation to administer additional analgesics or general anesthesia if necessary; (3) ensure and document adequacy of neuraxial blockade before the start of surgery; (4) communicate with the patient frequently during the procedure, specifically about pain or discomfort; and (5) treat pain when it arises, in agreement with the patient's wishes. During the postoperative visit, the anesthesia provider should address any concerns that may have arisen during or after surgery.

The anesthetic technique for the cesarean delivery may be altered because of postoperative pain management considerations. For example, an epidural catheter–based technique may be optimal for the patient with a significant pain history (e.g., sickle cell vaso-occlusive crises, chronic pain syndromes, opioid use disorder) so that the epidural catheter may be used for postoperative pain management.

By directly activating spinal and supraspinal opioid receptors, epidurally and spinally administered opioids blunt nociceptive input and produce analgesia of greater intensity than parenterally or intramuscularly administered doses.[180] A number of opioids have been used in the epidural and spinal spaces; however, morphine has emerged as the leading agent for postcesarean analgesia, owing to its long duration of action and low cost (see Chapter 27). When morphine is administered intrathecally or epidurally, doses of 0.1 mg and 3.75 mg, respectively, appear to provide optimal analgesia after cesarean delivery.[157,188] Higher doses slightly prolong analgesia, but result in a markedly higher risk for pruritus and vomiting.[410] Neuraxial morphine has a peak analgesic effect at 60 to 90 minutes but continues to provide effective analgesia for up to 24 hours.[188] Thus, intrathecal morphine is often co-administered with the local anesthetic and lipid-soluble opioid administered for spinal anesthesia, and epidural morphine is administered intraoperatively, after the umbilical cord is clamped, to allow sufficient time for the onset of epidural morphine analgesia before the regression of epidural anesthesia.

The local anesthetic selected for epidural anesthesia may influence postoperative analgesia. The epidural administration of 2-chloroprocaine has been observed to adversely affect the subsequent efficacy of epidural morphine analgesia,[411] although this remains a matter of some dispute.[173,412] The mechanism for this potential interaction remains unknown; however, the use of 2-chloroprocaine should be limited to emergency situations in which rapid augmentation of epidural anesthesia is desired (see earlier discussion).

Adverse effects of neuraxial morphine include pruritus, nausea and vomiting, urinary retention, and delayed respiratory depression. Frequent evaluations (hourly for the first 12 hours, and then every 2 hours for another 12 hours) should be conducted.[413] Postpartum women who are morbidly obese or have preexisting respiratory issues (sleep apnea) are at greater risk for respiratory depression.[414]

Postoperative pain has at least two components, somatic and visceral. A multimodal approach with different agents (e.g., ketamine) and techniques (e.g., tissue infiltration, peritoneal spraying, transversus abdominis plane [TAP] block) provides the most effective postcesarean analgesia (see Chapter 27). The administration of nonsteroidal anti-inflammatory drugs has been associated with potential adverse effects (platelet dysfunction, uterine atony), and some investigators have expressed concern related to neonatal exposure through breast milk. However, the American Academy of Pediatrics[415] has stated that ibuprofen and ketorolac are compatible with breast-feeding. Unless specifically contraindicated, nonsteroidal anti-inflammatory drugs are a usual component of multimodal postoperative analgesia.

Pruritus

The incidence of pruritus with the administration of opioids can be as high as 30% to 100%, and pruritus is more commonly observed when opioids are administered intrathecally than epidurally. Pruritus may be generalized or localized to regions of the nose, face, and chest and is typically self-limited in duration. The particular combinations and doses of opioid and local anesthetic may influence the incidence and severity of pruritus, and the addition of epinephrine to an opioid–local anesthetic solution has been observed to worsen pruritus.[416] Pruritus does not represent an allergic reaction to the neuraxial opioid. If flushing, urticaria, rhinitis, bronchoconstriction, or cardiac symptoms also occur, an allergic reaction to another substance should be considered.

The cause of neuraxial opioid–induced pruritus is not known, although multiple theories have been proposed. They include μ-opioid receptor stimulation at the medullary dorsal horn, antagonism of inhibitory transmitters, and activation of an "itch center" in the central nervous system.[417] Pharmacologic prophylaxis or treatment of pruritus may include an opioid receptor antagonist or agonist/antagonist, droperidol, a serotonin receptor antagonist (e.g., ondansetron), and/or a subhypnotic dose of propofol (Table 26.9).[417] Intravenous administration of granisetron 3 mg may reduce the severity but not the incidence of intrathecal morphine–induced pruritus compared with administration of ondansetron 8 mg.[418]

TABLE 26.9 Agents for Prevention or Treatment of Pruritus in Women Undergoing Cesarean Delivery

Drug Class	Drug and Dose	Comments
Opioid antagonists	Naloxone infusion 1–2 μg/kg/h IV Naltrexone 6–9 mg PO	May reverse analgesia
Opioid agonist/antagonist	Nalbuphine 2.5–5 mg IV	
Sedative/hypnotic agent	Propofol 10–20 mg IV	Subhypnotic dose with conflicting evidence regarding efficacy in treating pruritus
Serotonin antagonist	Ondansetron 0.1 mg/kg IV	Conflicting evidence regarding efficacy in treating pruritus
Butyrophenone	Droperidol 1.25 mg IV	Package insert contains an FDA "black box" warning regarding prolongation of corrected QT interval on electrocardiogram

IV, intravenously; *PO,* orally.

Dexamethasone in doses of 2.5 to 10 mg has not been found to reduce the incidence of pruritus associated with neuraxial morphine in women undergoing cesarean delivery.[401] Although opioid receptor antagonists, such as naltrexone and naloxone, and partial agonist/antagonists, such as nalbuphine, are currently the most effective treatments for pruritus, a single dose or continuous intravenous infusion of any of these agents may reverse analgesia. Because the primary mechanism of opioid-induced pruritus appears unrelated to histamine release, antihistamines seldom represent a viable treatment option, although some benefit may be derived from the accompanying sedative qualities of these agents.

Hypothermia and Shivering

Perioperative hypothermia and shivering are commonly observed in women undergoing cesarean delivery, with a reported incidence of 66% and 85%, respectively.[419,420] Hypothermia has been associated with a number of adverse outcomes in nonpregnant surgical patients, including wound infection, coagulopathy, increased blood and transfusion requirements, increased oxygen consumption, decreased metabolism, and prolonged recovery.[421] In a systematic evaluation of randomized trials of normothermic and mildly hypothermic (34° C to 36° C) nonpregnant surgical patients, Rajagopalan et al.[422] observed that even hypothermia less than 1° C below normal body temperature was associated with a 16% increase in blood loss (95% CI, 4% to 26%) and a 22% increase in risk for transfusion (95% CI, 3% to 37%).

Normally, core body temperature is tightly regulated within a narrow range of 36° C to 37° C. During pregnancy, despite an increase in maternal basal metabolic rate and energy released by the developing fetal and uteroplacental unit, maternal core temperature decreases, reaching a nadir at 12 weeks postpartum (36.4° C).[423] Major causes of hypothermia during cesarean delivery are most likely related to core-to-periphery heat redistribution caused by diminished vasoconstriction and shivering, particularly after neuraxial blockade, and impairment of centrally mediated thermoregulatory control.[421]

The onset and severity of hypothermia and shivering are associated with the patient's baseline thermal status, the perioperative environment, and the anesthetic technique and agents selected. A study showed that spinal anesthesia reduced the initial core temperature of patients undergoing cesarean delivery more rapidly than epidural anesthesia, but the overall incidence of shivering was similar. However, the severity of shivering was significantly less in the spinal group, possibly through the induction of a lower shivering threshold or the inhibition of thermoregulatory control as a function of the number of blocked dermatomes.[424]

The effect of neuraxial opioids on thermoregulation and shivering in patients undergoing cesarean delivery is not fully understood. Intravenously administered meperidine 12.5 to 25 mg is one of the most effective antishivering drugs and is unique among opioids in producing this effect at doses not typically associated with respiratory depression. The mechanism of this effect does not appear to be related to κ-opioid receptor activity or inhibition of cholinergic receptors; instead, central α_{2B}-adrenergic receptor stimulation may be involved.[425] The α_2-adrenergic receptor agonists clonidine (150 μg) and dexmedetomidine (0.5 μg/kg) are effective antishivering agents that can lower the shivering threshold,[425] although both agents may have limited use during pregnancy because of the potential to cause sedation, bradycardia, and hypotension.

Other modalities have been used to prevent and treat hypothermia and shivering. Preoperative patient warming using forced air has been shown to reduce the incidence of perioperative and postoperative core hypothermia and shivering in patients undergoing cesarean delivery with *epidural* anesthesia.[426] In contrast, a subsequent study found that perioperative forced-air warming did not prevent maternal hypothermia after cesarean delivery with *spinal* anesthesia.[419] The ambient operating room temperature has also been shown to impact the risk for hypothermia. One study showed that increasing the set temperature from 20° C (67° F) to 23° C (73° F) resulted in significant reduction in maternal hypothermia on arrival in the postoperative care area.[427] Lower limb wrapping has been observed to have no effect on the incidence of hypothermia or shivering.[428]

OBSTETRIC COMPLICATIONS

Postpartum Hemorrhage

A leading cause of maternal and fetal morbidity and mortality worldwide, mild to moderate obstetric hemorrhage can be masked by pregnancy-related physiologic changes. Underestimation of blood loss and inadequacy of resuscitation are common problems (see Chapter 37).

Failure of the uterus to contract (uterine atony) after delivery accounts for most cases of postpartum hemorrhage and remains a leading cause of postpartum hysterectomy and blood transfusion. Each minute, 600 to 700 mL of blood flows through the placental intervillous spaces; thus, obstetric hemorrhage can rapidly result in maternal shock. Uterine atony occurs more commonly after cesarean delivery than after vaginal delivery, perhaps as a reflection of the condition(s) that prompted the cesarean delivery or possibly because surgery disrupts the normal postpartum response to uterotonic hormones and pharmacologic agents. Risk factors for uterine atony include (1) high parity, (2) an overdistended uterus (multiple gestation, macrosomia, polyhydramnios), (3) prolonged labor (augmented by oxytocin), (4) chorioamnionitis, (5) abnormalities in placentation (placenta accreta, increta, or percreta), (6) retained placental tissue, (7) mechanical barriers to effective contraction (e.g., fibroids, uterine anomalies), and (8) poor perfusion of the uterine myometrium (e.g., hypotension).

Initial efforts to control uterine atony include uterine massage and exogenous **oxytocin** administration. Postpartum oxytocin is administered in a wide range of doses, methods, and timing patterns (e.g., before or after delivery of the placenta),[429] although small doses of oxytocin are

sufficient to produce adequate uterine contraction after cesarean delivery in most women.[429] The effective bolus dose necessary for adequate uterine tone in 90% (ED_{90}) of nonlaboring women undergoing cesarean delivery oxytocin is 0.35 unit[430]; in laboring women who have received approximately 10 hours of oxytocin augmentation, the ED_{90} is 2.99 units.[431] The ED_{90} of an oxytocin *infusion* in elective cesarean delivery patients is estimated to be 0.29 unit/min (95% CI, 0.15 to 0.43).[432] Women undergoing intrapartum cesarean delivery after exposure to exogenous oxytocin during labor require higher infusion rates (ED_{90} 0.74 units/min, 95% CI, 0.56 to 0.93).[433]

Women receiving oxytocin augmentation for labor have greater blood loss despite higher oxytocin doses; this appears to originate from signal attenuation and desensitization of the oxytocin receptors in a time- and concentration-dependent manner.[434–437] Continued high-dose oxytocin exposure in the postpartum period can lead to acute receptor desensitization and render the myometrium less responsive to additional oxytocin but not to other uterotonic agents.[437] Pregnancy causes a 180-fold increase in the concentration of oxytocin receptors, with a significant proportion of this increase occurring just before the onset of labor[438]; this change in receptor number may have relevance to parturients who are delivering preterm infants.

A randomized trial including 60 women undergoing elective cesarean delivery compared a "rule of 3's" (oxytocin 3 units, 3-minute evaluation intervals, 3 total doses, and oxytocin 3 units/h for maintenance) protocol for the administration of oxytocin after delivery with a "wide-open" infusion of oxytocin (30 units in 500 mL of normal saline).[439] In the "rule of 3's" approach, oxytocin 3 units is given as a slow bolus or as an infusion (30 units oxytocin in 500 mL of normal saline [50 mL]), at a rate no faster than over a period of 15 seconds. Uterine tone is reassessed again at 3 and 6 minutes; if inadequate, an additional dose of oxytocin 3 units is given. If uterine atony persists after three total doses of oxytocin, other uterotonic agents should be employed (see later discussion). The trial demonstrated that the "rule of 3's" algorithm results in lower oxytocin doses when compared with continuous-infusion oxytocin in women undergoing elective cesarean delivery, without changing measures of uterine tone, maternal hemodynamics, or blood loss.[439]

The specific timing of the initial dose of oxytocin varies by individual practitioner; insufficient data are available to determine whether oxytocin administration immediately on emergence of the infant's shoulder or body or after placental delivery makes a difference in overall blood loss during cesarean delivery. The optimal duration of oxytocin after delivery is not known. After the establishment of adequate uterine tone, an infusion of 3 units/h for up to 5 hours has been recommended.[429]

The administration of oxytocin as a rapid intravenous bolus causes hypotension and may result in cardiovascular collapse[440,441]; patients with preeclampsia may have an unpredictable hemodynamic response to oxytocin administration (e.g., decrease in cardiac output).[442] Oxytocin has a direct relaxing effect on vascular smooth muscle, which leads to decreased systemic vascular resistance, hypotension, and tachycardia.[443] Tachycardia also may result from a direct effect on specific oxytocin receptors in the myocardium and subsequently result in alterations in atrioventricular conduction and myocardial repolarization.[443] Chest pain and signs suggestive of myocardial ischemia and anaphylaxis may occur. Owing to the structural similarity of oxytocin to vasopressin, water intoxication may occur and, when severe, can lead to hyponatremia, confusion, convulsions, and coma.

If oxytocin proves ineffective, the administration of second-line uterotonics, including **methylergonovine, carboprost, and/or misoprostol,** should be considered. The ergot alkaloid derivative **methylergonovine** (0.2 mg) may be given intramuscularly to enhance uterine tone; onset time is within 10 minutes, and the effect persists for 3 to 6 hours. Intravenous administration (in small divided doses) should be performed only *with great caution,* because intense vasoconstriction may lead to acute hypertension, seizures, cerebrovascular accident, retinal detachment, and myocardial arrest[444]; this possibility is of special concern in patients with preeclampsia or cardiac disease. Methylergonovine also has additive hemodynamic effects when given with sympathomimetic agents, such as ephedrine and phenylephrine. Nausea and vomiting are common side effects, which most likely reflect a direct central nervous system effect. The co-administration of oxytocin and **ergometrine** has been demonstrated to improve uterine contractions (as measured by the requirement for additional uterotonic agents) compared with the administration of oxytocin alone; however, the estimated blood loss was not different between groups, and nausea and vomiting were more prevalent with the oxytocin-ergometrine combination.[445]

Carboprost (analogue of **15-methyl prostaglandin $F_{2\alpha}$**) causes a dose-dependent increase in the force and frequency of uterine contractions. The initial recommended dose is 250 μg given intramuscularly; this dose can be repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses.[446] Whether carboprost is more effective than oxytocin is controversial[447]; however, it clearly has a role in the treatment of refractory uterine atony.[448] In approximately 20% of women, the following side effects occur (listed in descending order of frequency): diarrhea, hypertension, vomiting, fever, flushing, and tachycardia.[448] Bronchospasm, pulmonary vasoconstriction, and oxyhemoglobin desaturation may also occur. Observational data suggest that methylergonovine is more effective than carboprost as a second-line uterotonic in preventing hemorrhage-related morbidity.[449]

Rectal or sublingual administration of **prostaglandin E_1 (misoprostol)** is a uterotonic agent with a rapid onset of action. A systematic review of prophylactic misoprostol (given orally or sublingually in doses ranging from 400 to 800 μg) administered for active management of the third stage of labor concluded that it is more effective than placebo in preventing severe postpartum hemorrhage but less effective than conventional injectable uterotonic agents.[450] Several

large studies have assessed misoprostol's role when given as an *adjunct* to standard uterotonics.[451,452] In these studies, the administration of misoprostol was no more effective than placebo, but was associated with high rates of side effects, including hyperthermia, severe shivering, and gastrointestinal symptoms. There may be a prophylactic role for this drug in low-resource settings where oxytocin is not available, but its utility in high-resource settings as a second-line uterotonic is likely limited.[389]

Preparation for Blood Loss

When risk factors for hemorrhage are identified, several preparatory steps can be considered. **Iron supplementation** and use of **recombinant human erythropoietin** are effective therapies for producing red blood cells, particularly in patients with preexisting anemia, renal failure, and/or reasons for preoperative donation of autologous blood.[453] Antepartum erythropoietin administration may be of value in pregnant women at high risk for hemorrhage or who refuse blood products (e.g., Jehovah's Witnesses); however, additional investigation is needed to determine the optimal dosing, goals of therapy, and side-effect profiles. Hypertension, a problem associated with the use of erythropoietin in patients with renal failure, is a relevant concern during pregnancy. Although normal pregnancy is associated with a twofold to fourfold increase in maternal erythropoietin levels, isolated studies of the effect of erythropoietin on placental vessels suggest that dose-dependent vasoconstriction occurs.[454] Observation of high erythropoietin levels in hypertensive and preeclamptic parturients has fueled speculation that erythropoietin participates in the humoral mechanisms responsible for preeclampsia and fetal growth restriction.[455] However, whether treatment with erythropoietin increases the risk for these complications remains unclear, and the safety data that have accumulated to date are reassuring.[456] A hyperglycosylated analogue of recombinant human erythropoietin (darbepoetin) has a threefold longer terminal half-life and results in a more rapid and greater erythropoietic response than recombinant human erythropoietin.[453]

The efficacy of preoperative **autologous blood donation** is limited by the maximum life span of stored blood; collection can start no sooner than 6 weeks before a planned delivery, with an average unit collection interval of 3 to 7 days. This method may be of some use in a woman with maternal antibodies to red blood cell antigens. The technique seems safe but has limited applicability and efficacy in obstetric patients (see Chapter 37).

Acute normovolemic hemodilution has the advantage of reducing the risk for administrative errors and bacterial contamination and allowing the infusion of whole blood replete with functional coagulation factors and platelets. This technique may reduce the need for transfusion in selected patients, and it may be acceptable to Jehovah's Witness patients at increased risk for blood loss during cesarean delivery.

The use of **intraoperative red blood cell salvage** in obstetric patients is gaining greater acceptance.[457] In the past, obstetric anesthesia providers have expressed concern that intraoperative cell salvage might precipitate amniotic fluid embolism. Data now suggest a very low risk for amniotic fluid contamination when a leucocyte depletion filter is employed.[458] However, the cell salvage process does not remove all fetal red blood cells and hemoglobin, and maternal isoimmunization may occur.[459] Intraoperative cell salvage may be used to prevent morbidity and mortality in parturients who refuse homologous blood or in cases of intractable hemorrhage that may overwhelm blood bank supplies (see Chapter 37).[28]

Response to Blood Loss

Underestimation of blood loss and inadequate resuscitation are common problems in the management of obstetric hemorrhage. Rapid volume replacement is more important for maintaining tissue perfusion and oxygenation than the type of administered fluid. Colloids and blood products should be considered early, along with a request for assistance, establishment of a second large-bore intravenous catheter, and use of pressurized transfusion equipment. Many institutions require performance of a blood type and screen for parturients at high risk for hemorrhage undergoing a trial of labor for a planned vaginal delivery and in all parturients undergoing cesarean delivery. The immediate availability of two to four units of cross-matched packed red blood cells should be considered when the potential for significant blood loss appears imminent, such as in women with suspected placenta accreta. In situations in which the need for emergency blood transfusion precedes the availability of cross-matched blood, type-specific (or type O, Rh-negative blood) should be administered. All institutions should have an obstetric massive transfusion protocol in place.[460] Continued blood loss and hemodynamic instability despite transfusion of packed red blood cells is often an indication for placement of an arterial line and invasive central venous pressure monitoring; however, restoration of circulating volume takes precedence. Urine output, heart rate, blood pressure, and transthoracic or transesophageal echocardiography (TTE or TEE)[461] assessments can assist in the rapid evaluation of the adequacy of volume resuscitation.

Fortunately, most pregnant women are healthy and tolerate modest blood loss well. Concerns about uteroplacental perfusion and fetal oxygenation are no longer present after delivery of the infant. The ASA Task Force on Perioperative Blood Management[462] states that red blood cell transfusion for hemoglobin concentrations between 6 and 10 g/dL should be based on potential or actual ongoing bleeding, intravascular volume status, signs of organ ischemia, and adequacy of cardiopulmonary reserve. It is important to note that in the setting of acute blood loss, the measured hemoglobin may not accurately reflect the degree of loss. The hemorrhaging patient should be monitored for the development of coagulopathy. Coagulopathy should be treated with the appropriate blood products or factor concentrates. Transfusion of platelets is not indicated unless the platelet count is less than 100,000/mm^3 (unless platelet dysfunction and microvascular bleeding are present), and replacement of fibrinogen is not indicated unless the fibrinogen concentration is less than

150 to 200 mg/dL in the presence of microvascular bleeding. However, a decrease in fibrinogen concentrations may serve as an early predictor of the severity of obstetric hemorrhage (baseline fibrinogen concentration is higher in pregnancy).[463]

The prophylactic placement of **intravascular balloon occlusion catheters** can facilitate the timely control of obstetric bleeding in some parturients at high risk for hemorrhage.[464] Harnett et al.[465] have recommended the placement of an epidural catheter before an intravascular balloon catheter for the following reasons: (1) once the balloon catheter is placed, flexion of the hips (during positioning for a neuraxial anesthetic technique) is discouraged, because it may result in balloon dislodgement or occlusion and subsequent thrombosis; (2) epidural anesthesia seems preferable to the use of local anesthesia with sedation for balloon catheter placement; (3) during balloon catheter placement, small amounts of heparin are sometimes used, and it seems preferable to have the epidural catheter in place before anticoagulation; and (4) should untoward events (e.g., fetal compromise, vessel rupture) occur during the procedure, the epidural catheter allows for rapid extension of anesthesia for cesarean delivery. With prior planning, operative procedures, including cesarean delivery, can be performed successfully under neuraxial anesthesia in the interventional radiology suite.[465]

When uterine bleeding occurs postpartum, the use of **uterine tamponade balloon catheters** has been demonstrated to tamponade and potentially treat intrauterine sources of bleeding and allow time to correct coagulopathy.[466] Commercially available balloon catheters designed specifically for uterine tamponade allow for uterine cavity drainage, with variable success in function and ability to identify ongoing, significant bleeding.[466] The balloons are often left in place for 24 to 48 hours, along with a vaginal pack and continued antibiotic administration. Distention of the uterus causes discomfort, and pain relief should be provided, either with systemic agents or epidural analgesia if a catheter is *in situ*. We typically provide continuous epidural analgesia, or patient-controlled epidural analgesia, with a dilute solution of local anesthetic and a lipid-soluble opioid, similar to that used for labor analgesia. The epidural catheter, regardless if used for analgesia, is typically kept in place until the uterine balloon is deflated to allow for rapid transition to surgical anesthesia if necessary.

Obstetric Hysterectomy

The incidence of cesarean hysterectomy and emergency postpartum hysterectomy ranges from 0.03% to 0.33% in different hospital settings and countries.[467] Over a 14-year period in the United States, the rate of peripartum hysterectomy per 100,000 deliveries increased from 71.6 (1994 to 1995) to 82.6 (2006 to 2007); this increased rate was associated with an increased rate of hysterectomy for abnormal placentation (e.g., placenta previa, placenta accreta) from 32.9 to 40.5, and an increased rate of hysterectomy for uterine atony from 11.2 to 25.9 per 100,000 deliveries.[468] Increasing rates of cesarean delivery, failed trial of labor, infection, intrauterine fetal death, and disseminated intravascular coagulation are other factors associated with cesarean hysterectomy. Improvements in ultrasonography, color flow Doppler ultrasonography, and magnetic resonance imaging have allowed earlier identification of women with placenta accreta; however, limitations in diagnostic sensitivity and specificity exist.[469]

Cesarean hysterectomy is considered a high-risk procedure owing to the vascularity and size of the uterus and the distorted anatomic relationships. Bladder and ureteral injuries are common. Before performance of hysterectomy, various conservative medical and surgical treatment modalities may be attempted (see Chapter 37). The ligation or embolization of major and collateral uterine vessels with the assistance of an interventional radiologist is becoming more common, particularly in tertiary care settings.[464]

The amount of blood loss depends in part on whether the hysterectomy is elective or an emergency. In a prospective review of all obstetric hysterectomies performed at five university hospitals (1984 to 1987), Chestnut et al.[470] found an average blood loss of 1319 mL and 2526 mL in 25 elective and 21 emergency cases, respectively, with an average replacement of 1.6 units and 6.6 units of blood, respectively. In a more recent study, Briery et al.[471] performed a multicenter retrospective review of operative and postoperative outcomes in 30 elective and 35 emergency cesarean hysterectomies; the mean (± SD) blood loss for elective and emergency cases was 1963 ± 1180 mL and 2597 ± 1369 mL, with 33% and 66% of the patients requiring blood transfusion, respectively.

The anesthesia provider should consult with the obstetric team to discuss risk factors and the planned course of management. Preparations for the management of potentially massive blood loss should be made, which may include the placement of an epidural catheter and prophylactic intravascular balloon catheters (see earlier discussion). An elective cesarean hysterectomy, or a cesarean delivery in which the patient is at high risk for emergency hysterectomy, is not a contraindication to a neuraxial anesthetic technique, although a catheter-based technique is recommended. Moreover, the occurrence of an emergency cesarean hysterectomy does not always necessitate immediate conversion to general anesthesia. Consideration should be given to (1) maternal history (e.g., number of prior abdominal operative procedures, which may lead to more scarring and adhesions); (2) the presence of risk factors (e.g., extent of placentation abnormality, coagulation status); (3) the potential difficulty of conversion to general anesthesia if required (e.g., presence of difficult airway, level of assistance available); (4) the desires and experience of the obstetric team; and (5) the desires of the patient. Chestnut et al.[470] observed in their review that none of the 12 patients who received continuous epidural anesthesia for cesarean delivery (8 patients from the elective group and 4 from the emergency group) required intraoperative induction of general anesthesia for hysterectomy. In addition, there was no evidence that epidural anesthesia significantly affected blood loss, crystalloid replacement, or requirement for transfusion. In women with suspected placenta percreta at high risk for major blood loss, some anesthesiologists favor administration of neuraxial anesthesia for cesarean delivery

of the infant, followed by administration of general anesthesia (to secure the airway) after delivery, before hysterectomy begins.

Given the morbidity and mortality associated with a peripartum hysterectomy, particularly if it is accompanied by significant blood loss, postoperative observation of the patient in a critical care setting should be considered. An investigation using nationwide administrative data compared women who underwent a peripartum hysterectomy (n = 4967) with women who had a nonobstetric hysterectomy (n = 578,179)[472]; women in the peripartum hysterectomy group were nine and five times more likely to have bladder and ureteral injuries, respectively, and they had greater rates of reoperation, postoperative hemorrhage, wound complications, and venous thromboembolism. Perioperative cardiovascular, pulmonary, gastrointestinal, renal, and infectious morbidities were also higher for women who had peripartum hysterectomy. In addition, women undergoing peripartum hysterectomy had a higher rate of blood transfusion (46% versus 4%), a longer hospital stay, and a higher rate of perioperative mortality.[472]

Thromboembolic Events

Thromboembolic events constitute a major reason for peripartum maternal mortality, and risks for the development of pregnancy-associated thrombosis include an operative delivery, physiologic changes of pregnancy, and medical history and comorbidities (e.g., obesity, hemoglobinopathies, hypertension, smoking).[473] The risk for venous thromboembolism appears highest in the first postpartum week.[473] A number of prophylactic interventions have been evaluated; however, the trials have been small and unable to provide robust results.[474] Recommended thromboprophylaxis measures include hydration, early mobilization, pneumatic compression devices, and, in high-risk patients, pharmacologic prophylaxis (see Chapter 38).

KEY POINTS

- Cesarean delivery is the most common major surgical procedure performed in many developed countries. The rate of cesarean delivery is increasing worldwide.
- Some cesarean deliveries might be avoided through the provision of satisfactory neuraxial analgesia for labor (including a trial of labor after cesarean delivery), instrumental vaginal delivery, and external cephalic version.
- Gastric emptying is unchanged during pregnancy. The parturient without complications may drink modest amounts of clear liquids up to 2 hours before induction of anesthesia for *elective* cesarean delivery. The fasting period for solids should be 6 to 8 hours. Slower digestion is observed for foods with high fat content, during labor, and with the administration of opioid analgesic agents.
- An H_2-receptor antagonist or a proton-pump inhibitor may be given intravenously to increase gastric fluid pH, and intravenous metoclopramide may be given to both accelerate gastric emptying and increase lower esophageal sphincter tone. If possible, these agents should be administered *more than* 30 minutes before induction of anesthesia. Oral sodium citrate, which also increases gastric fluid pH, should be administered *less than* 30 minutes before induction.
- Antibiotic prophylaxis, administered within 60 minutes before abdominal incision, decreases the risk for maternal infectious complications after cesarean delivery.
- Although the use of intravenous fluids may reduce the frequency of maternal hypotension, initiation of neuraxial anesthesia should not be delayed to administer a fixed volume of fluid.
- The value of supplemental maternal oxygen during neuraxial anesthesia for the elective cesarean delivery of a noncompromised fetus is questionable.
- Left uterine displacement should be applied during cesarean delivery, regardless of the anesthetic technique.
- Umbilical cord prolapse (without fetal bradycardia), placenta previa, and severe preeclampsia (in a patient with an acceptable platelet count) are not absolute indications for general anesthesia.
- Among women receiving general anesthesia for cesarean delivery, maternal deaths associated with hypoventilation or airway obstruction are occurring with greater frequency during emergence, tracheal extubation, or recovery, rather than during induction and tracheal intubation; attention to airway and ventilation management should focus on both of these critical time periods.
- The combined spinal-epidural technique offers the benefits of both spinal and epidural anesthesia while minimizing the disadvantages of either technique alone. Advantages include the fast onset of dense anesthesia with a small dose of local anesthetic and the ability to provide prolonged anesthesia and continuous postoperative analgesia.
- Alkalinization of the local anesthetic solution not only increases the speed of onset but also improves the quality and prolongs the duration of neuroblockade. Administration of 3% 2-chloroprocaine with 8.4% sodium bicarbonate (10 mL of 2-chloroprocaine mixed with 1 mL [1 mEq] of bicarbonate) produces the fastest onset of epidural anesthesia.
- The application of cricoid pressure to prevent passive regurgitation during induction of general anesthesia is controversial. If used, pressure should be initiated with a force of 10 N on the cricoid cartilage and increased to 30 N once the patient loses consciousness.
- When choosing the concentration of a volatile halogenated agent to maintain general anesthesia, the anesthesia provider must consider the uterine relaxation caused by these agents as well as the reduced MAC of pregnancy and the potential for maternal awareness.

- Either phenylephrine or ephedrine may be used for the prevention and treatment of maternal hypotension during neuraxial or general anesthesia for cesarean delivery. Phenylephrine appears to exert less metabolic effect on the fetus and results in higher umbilical arterial blood pH at delivery compared with ephedrine.
- Underestimation of blood loss and inadequate intravascular volume resuscitation during peripartum hemorrhage are common occurrences that contribute to maternal morbidity and mortality.

Postoperative Analgesia

Ronald B. George, MD, FRCPC, Brendan Carvalho, MBBCh, FRCA, MDCH, Alexander Butwick, MBBS, FRCA, MS, Pamela Flood, MD

CHAPTER OUTLINE

The cesarean delivery rate in the United States and around the world has steadily increased as a result of changing patterns in obstetric practice.[1] Recent data indicate that more than 1 million cesarean deliveries are now performed annually in the United States.[2] With cesarean delivery accounting for 32% of all deliveries in the United States, strategies for reducing adverse postcesarean maternal outcomes, including postoperative pain, have important clinical and public health implications.[2]

Pain is a potential harm that can occur during and after any surgical procedure. Inadequately treated pain can cause numerous undesirable physiologic and psychologic consequences in women undergoing cesarean delivery, including impaired recovery, persistent and chronic pain, and increased cost.[3–5]

PAIN AFTER CESAREAN DELIVERY

Management of postoperative pain is frequently substandard, with 30% to 80% of patients experiencing moderate to severe postoperative pain.[6–8] Pain following cesarean delivery may be equivalent to that reported after a hysterectomy.[9] Postoperative pain results from direct tissue trauma and subsequent inflammation. Local and systemic inflammatory cytokines act to sensitize the peripheral nerves and enhance pain perception.[10] Inflammation likely plays a particularly significant role in pain after delivery because inflammatory cytokines are increased as a part of the normal labor and delivery process.[11,12] After cesarean delivery, wound cytokine concentration is positively correlated with analgesic drug consumption.[13] The range of pain reported after cesarean delivery is greater than that after vaginal delivery, but the pain burden and duration are remarkably similar (Fig. 27.1).[4,14] A sample of expectant mothers attending birthing classes identified pain during and after cesarean delivery as their most important concern (Table 27.1).[15] Measuring pain intensity and satisfaction with simple tools has not met the goals of preventing and treating moderate and severe pain.[4,8,14–18]

Severe acute postoperative pain is one of the most prominent factors associated with chronic postoperative pain.[3,5,19–21] Some studies suggest that the use of perioperative neuraxial blockade may prevent central sensitization and chronic pain.[22,23] Additional mechanistic and clinical research is needed to improve our understanding of persistent pain after cesarean delivery (see Chapter 42). Multimodal pharmacologic and nonpharmacologic treatment for pain is the optimal approach and should be offered whenever feasible and medically indicated.

SYSTEMIC ANALGESIA

Opioid Analgesia

In the United States, most women who undergo cesarean delivery with neuraxial anesthesia receive neuraxial opioids for postoperative analgesia. However, many women require systemic analgesia to augment neuraxial therapy, and some

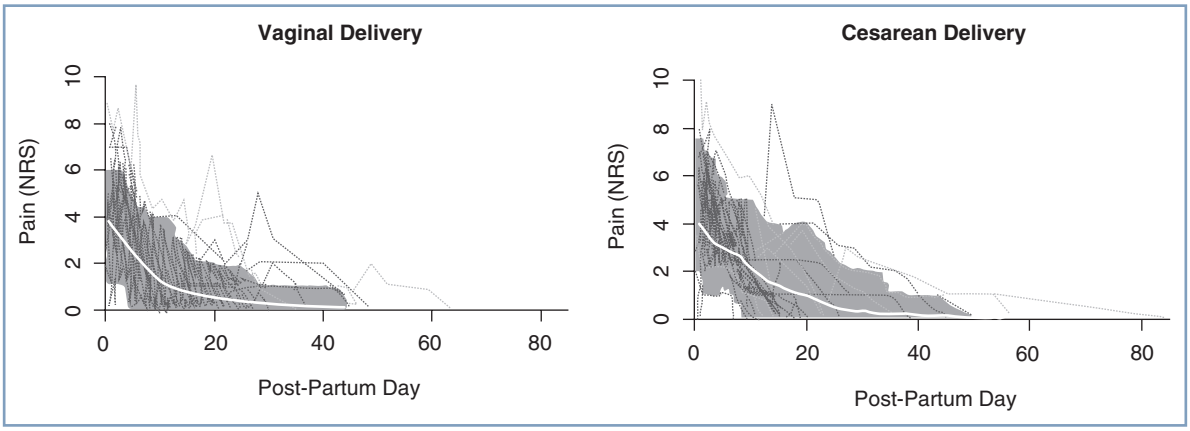

Fig. 27.1 Pain trajectory after vaginal and cesarean delivery. Dotted lines represent pain reports from individual subjects, and solid white line is a moving average. Shaded area covers the range from the 5th to 95th percentile of the data. NRS, verbal numerical rating scale from 0 to 10, with 0 = no pain and 10 = worst pain imaginable. (From Komatsu R, Carvalho B, Flood PD. Recovery after nulliparous birth: a detailed analysis of pain analgesia and recovery of function. *Anesthesiology*. 2017;127:684–694.)

TABLE 27.1 Women's Ranking and Relative Value of Potential Anesthesia Outcomes Assessed before Cesarean Delivery

Outcome	Rank[a]	Relative Value[b]
Pain during cesarean delivery	8.4 ± 2.2	27 ± 18
Pain after cesarean delivery	8.3 ± 1.8	18 ± 10
Vomiting	7.8 ± 1.5	12 ± 7
Nausea	6.8 ± 1.7	11 ± 7
Cramping	6.0 ± 1.9	10 ± 8
Itching	5.6 ± 2.1	9 ± 8
Shivering	4.6 ± 1.7	6 ± 6
Anxiety	4.1 ± 1.9	5 ± 4
Somnolence	2.9 ± 1.4	3 ± 3
Normal	1	0

Data are mean ± standard deviation.
[a]Rank = 1 to 10 from the most desirable (1) to the least desirable (10) outcome.
[b]Relative value = dollar value patients would pay to avoid an outcome (e.g., they would pay $27 of a theoretical $100 to avoid pain during cesarean delivery).
From Carvalho B, Cohen SE, Lipman SS, et al. Patient preferences for anesthesia outcomes associated with cesarean delivery. *Anesth Analg*. 2005;101:1182–1187.

TABLE 27.2 Opioid Equianalgesic Doses

Drug	Oral (mg)	Subcutaneous/ Intravenous (mg)
Morphine	30	10
Oxycodone	20	NA
Hydrocodone	20	NA
Hydromorphone	7.5	1.5
Fentanyl	NA	0.1 (100 µg)
	A 25-µg/h transdermal patch is equianalgesic to ≈50 mg of oral morphine per day	
Oxymorphone	10	1

NA, Not applicable.

women are unable to receive neuraxial anesthesia. In the United States it is common practice to prescribe oral opioids on discharge from the hospital, although this is not common practice in other parts of the world.[24]

Choice of Opioid

Factors that affect the choice of opioid are speed of onset, duration of action, overall efficacy, and the type and frequency of side effects. If side effects prevent adequate analgesia, other opioids or nonopioid adjuvants should be used. Patient preferences based on past experiences and desired analgesia should also be considered.[25]

Historically, **meperidine (pethidine)** has been a popular opioid for postoperative analgesia. However, the American College of Obstetricians and Gynecologists (ACOG)[26] and the American Pain Society[27] have discouraged the use of meperidine in obstetric patients because of the accumulation of normeperidine in the neonate and its subsequent effect on neurobehavioral scores. Table 27.2 shows commonly used alternatives to meperidine with equianalgesic doses.

Intravenous Patient-Controlled Analgesia

Intramuscular and subcutaneous opioids are inexpensive, easy to administer, and associated with a long history of safety but are not commonly used in the United States because of the need for repeated painful injections, delayed (and sometimes erratic) absorption of drug, and an inconsistent analgesic response caused by variation in plasma opioid concentration. Intravenous patient-controlled analgesia (PCA) allows patients to control their own pain management by self-administering small doses of intravenous opioids. A

2015 meta-analysis concluded that PCA is often preferred by patients compared with nurse-administered analgesia on request, and PCA was shown to provide better pain control and increased patient satisfaction compared with non–patient-controlled methods.[28] The American Society of Anesthesiologists (ASA) Task Force for Acute Pain Management in the Perioperative Setting recommended that "these modalities [epidural or intrathecal opioids, systemic opioid PCA, and peripheral regional techniques] should be used in preference to intramuscular opioids ordered 'as needed.'"[29] The American Pain Society has recommended the use of intravenous opioid PCA when parenteral administration of analgesics is necessary and the oral route is not available.[30]

PCA has been used via the intravenous and epidural routes after cesarean delivery. A study that compared intravenous and epidural PCA using **fentanyl** reported higher pain scores and greater fentanyl consumption with the intravenous route, although patient satisfaction was similar in the two groups.[31] In another study that compared intravenous versus epidural PCA using **hydromorphone,** drug requirement was 3- to 4-fold higher in the intravenous group; the two groups had similar pain and sedation scores, but patients in the intravenous group reported more frequent drowsiness and less pruritus.[32] Studies that compared intravenous morphine PCA to *single-shot* epidural morphine administration for postcesarean analgesia showed that analgesia and patient satisfaction were better and sedation was less with epidural morphine, although the incidence of pruritus was higher.[33–35]

Side Effects and Safety Considerations

The goal of opioid administration is to achieve maximum analgesia with minimal side effects. It is important to monitor the respiratory rate and sedation level before giving an additional dose or adjusting the PCA bolus dose. Patients with comorbidities such as hepatic or renal dysfunction (e.g., occurring with severe preeclampsia), morbid obesity, and/or obstructive sleep apnea are particularly susceptible to the respiratory depressant effects of opioids; these patients may need special alterations to pain management, especially the use of multimodal analgesia (see later discussion).

Health care professionals who prescribe PCA should (1) be able to evaluate candidates for PCA (e.g., mental state, level of consciousness, patient understanding); (2) know drug selection criteria, dosing schedules, lockout periods, and infusion devices; (3) be able to provide patient education on pain management and the use of PCA; (4) understand when to alter PCA settings and when to give or withhold additional (rescue) doses of medications; and (5) be able to respond to side effects and adverse events. Observational studies of nonobstetric cohorts have reported an incidence of respiratory depression with intravenous PCA of 0% to 11.5%, which is equivalent to or higher than that reported for neuraxial opioids.[36–41]

In December 2004, The Joint Commission[42] issued a Sentinel Event Alert on PCA "by proxy" (i.e., when other individuals, including family members, become involved in drug administration by PCA). The Joint Commission acknowledged that PCA is a safe and effective method of controlling pain when used as prescribed; however, serious adverse events, including oversedation, respiratory depression, and death, can result when analgesia is delivered "by proxy." The Joint Commission[42] made the following recommendations: (1) develop criteria for selecting appropriate candidates for PCA, (2) carefully monitor patients, (3) teach patients and family members about the proper use of PCA and the dangers of others pressing the button for the patient, (4) alert staff to the dangers of administering a dose outside a prescribed protocol, and (5) consider placing warning tags on all PCA delivery pendants stating "only the patient should press this button." The PCA settings (drug, demand dose, lockout interval, 4-hour limit, and the rate of continuous infusion, if used) are documented on a flow sheet, and any changes in PCA settings clearly documented.

Infusion Pump Settings

Programmable PCA parameters include drug choice, bolus dose, maximum dose, and lockout interval (Table 27.3).

TABLE 27.3 General Patient-Controlled Analgesia Settings in Opioid-Naïve Patients

Drug	Morphine	Hydromorphone	Fentanyl
Concentration	1 mg/mL	1 mg/mL	10 µg/mL
PCA Bolus Dose	1–1.5 mg	0.2 mg	20 µg
Lockout Interval (min)	5–10	5–10	5
4-Hour Dose Limit	Calculated by settings	Calculated by settings	Calculated by settings
Typical PCA Dose Change	0.5 mg	0.1 mg	5 µg
Rescue Doses	2 mg IV q 5 min (up to three doses)	0.3 mg IV q 5 min (up to three doses)	25 µg IV q 5 min (up to three doses)
Remarks	Relatively contraindicated in patients with impaired renal function	More potent than morphine	Shorter clinical effect than morphine

Recorded as: PCA bolus dose/lockout interval/4-hour limit/continuous infusion rate. A continuous background infusion is typically avoided except in selected cases (e.g., opioid tolerance).

Owen et al.[43–45] performed several PCA investigations in patients undergoing abdominal surgery. In an assessment of PCA morphine demand bolus doses (0.5, 1, or 2 mg with a 5-minute lockout interval), more patients in the 0.5-mg group had inadequate pain relief, whereas those in the 2-mg group had more side effects, including respiratory depression (respiratory rate less than 10 breaths/min).[45] These outcomes correlated with the total dose of self-administered morphine. Although the role of the lockout interval was not addressed in this study, the investigators suggested that inadequate analgesia could be produced by lockout intervals that are too long or demand doses that are too small. By contrast, larger doses or shorter lockout intervals might lead to more opioid-related side effects.

Although patients who experience inadequate analgesia would be expected to make more PCA demands, this is often not the case.[45] Patients may be afraid to administer too much opioid or anticipate more severe side effects. Additionally, it has been suggested that patients are discouraged by an inadequate analgesic effect or they may expect a delayed response.[45]

Continuous basal (background) infusions are not necessary in opioid-naïve women.[45] The American Pain Society does not recommend routine use of basal infusions of opioid in opioid-naïve patients; most evidence does not demonstrate improved analgesia compared with patients who receive no basal infusion.[30] Basal infusions of opioids are associated with an increased incidence of nausea and vomiting, and some studies have shown an increased risk for respiratory depression.[30] Parker et al.[46] compared a group receiving an intravenous PCA morphine regimen (bolus dose 2 mg) with a group receiving the same intravenous PCA regimen and a nighttime continuous infusion (1 mg/h). There were no differences between groups in postoperative pain, sleep pattern, demand or delivered bolus dose per hour, opioid consumption, or recovery from surgery. The use of a continuous infusion resulted in six errors during the programming of the device. Three patients required discontinuation of the continuous infusion because of significant oxyhemoglobin desaturation.[46] The ASA Task Force on Acute Pain Management concluded that special caution should be taken when a continuous infusion is used because of the potential for adverse effects from opioid accumulation.[29]

During PCA, the ratio of patient demands to delivered bolus doses appears to be a good measure of analgesia and is strongly correlated with pain scores.[47] A high ratio likely reflects patient misunderstanding or inadequate analgesia; a ratio close to 1 signifies adequate pain relief. Analgesia may be improved by an increase in the bolus dose, a shorter lockout interval, or a change of opioid.

Because of the significant morbidity associated with high doses of opioids, use of these drugs should invoke the application of algorithms for pain assessment, management, and monitoring. Acute postoperative pain is limited in duration; therefore, a plan should be devised for the transition from intravenous opioids to oral analgesic agents when the patient's pain is controlled and she is able to take medication by mouth.

Oral Opioid Analgesia

Some investigators have advocated the use of **oral analgesics** rather than intravenous PCA as there is seldom a requirement for a prolonged fasting period after cesarean delivery.[48–51] Most evidence suggests intravenous administration of opioids is not superior to oral opioids for postoperative analgesia.[30] In fact, patients randomized to oral oxycodone experienced less pain, nausea, and drowsiness 6 hours after cesarean delivery compared with those who received intravenous PCA morphine.[51] Dieterich et al.[52] found intravenous PCA and oral opioids provided similar degrees of satisfaction and pain scores after cesarean delivery. Therefore, when tolerated, oral administration of opioids may be the preferred route of administration. Advantages of this approach are cost savings, facilitation of early mobility, and, perhaps, greater patient satisfaction. Long-acting oral opioids are not recommended in the immediate postoperative period.[30]

Multimodal Analgesia

Multimodal analgesia balances the effectiveness of individual analgesics, maximizing their efficacy while attempting to minimize side effects. The rationale of multimodal analgesia is the optimization of additive or synergistic effects of different modes of analgesia or drug classes, while reducing the dose and minimizing the side effects of individual drugs with different mechanisms of action.[53] Although analgesic efficacy is the primary goal, important secondary goals include minimizing transfer of drugs to breast milk and reducing maternal side effects that may interfere with breastfeeding or infant care. Various combinations of opioids, nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen (paracetamol), and local anesthetics are among drugs that have been used with varying degrees of success.[54–56] Several studies have demonstrated superior analgesia when oral analgesics are administered at a predetermined fixed interval rather than on demand.[48,57]

Acetaminophen

Acetaminophen is used extensively for postoperative analgesia and provides an opioid-sparing effect of approximately 10% to 20%.[58–60] A 2012 meta-analysis identified four randomized controlled trials evaluating acetaminophen and its effect on opioid consumption after major surgery; only one study included obstetric patients.[61] The meta-analysis showed that acetaminophen was less effective than NSAIDs for decreasing opioid consumption and postoperative nausea and vomiting (PONV).[61] A comparison of intravenous acetaminophen with oral ibuprofen in postcesarean patients found similar pain scores, opioid consumption, and patient satisfaction.[62] The combination of NSAIDs and acetaminophen has been shown to be synergistic in human experimental pain studies.[63–65]

In 2009, the U.S. Food and Drug Administration (FDA) lowered the recommended maximum daily dose of acetaminophen from 4000 mg to 3250 mg because of concern for toxicity.[66] Avoiding opioid/acetaminophen combination medication is recommended to decrease unnecessary opioid use and avoid exceeding recommended maximum doses of

acetaminophen. The change forced the replacement of combination oral opioid-acetaminophen analgesics with scheduled acetaminophen and as-needed opioids for postcesarean analgesia. Valentine et al.[67] performed a retrospective medical record review of women who underwent cesarean delivery before and after a change in clinical practice at their institution. All patients in their study received spinal anesthesia containing intrathecal morphine 0.2 mg and scheduled NSAIDs for 48 h postoperatively. After the change, the women received oral acetaminophen 650 mg every 6 h for 48 h postoperatively with oral oxycodone administered as needed for breakthrough pain.[67] The scheduled acetaminophen cohort used less opioid than the historical as-needed cohort in the first 48 hours (Fig. 27.2).[67]

Intravenous acetaminophen has gained popularity, with earlier and higher plasma and cerebrospinal fluid levels compared with more slowly absorbed oral acetaminophen.[68,69] However, in patients with a functioning gastrointestinal system, there is no documented analgesic advantage of intravenous versus oral administration.

Nonsteroidal Antiinflammatory Drugs

NSAIDs suppress inflammation by inhibition of the cyclooxygenase (COX) enzymes and are a key component of multimodal analgesia. They are effective for perineal pain after vaginal delivery and postcesarean abdominal pain; when coadministered with opioids, they produce a 30% to 50% opioid-sparing effect[60,70] that can reduce opioid-related side effects.[71] A 2016 systematic review and meta-analysis showed that the use of NSAIDs resulted in lower pain scores up to 24 hours postoperatively, less opioid consumption, and less sedation after cesarean delivery.[72] Fixed-interval dosing of NSAIDs provides more effective analgesia and results in better patient satisfaction than on-demand dosing.[48]

Ibuprofen is one of the most widely used NSAIDs that is available without prescription. Because it nonselectively inhibits COX-1 and COX-2 isoenzymes, in addition to its anti-inflammatory, analgesic, and antipyretic properties, ibuprofen also inhibits platelet adhesion and causes renal artery vasoconstriction and gastrointestinal irritation. Therefore, NSAID use in patients at risk for hemorrhage and renal failure warrants caution. Nonetheless, in most parturients without risk factors for hemorrhage or renal failure, use of NSAIDs is considered safe. Because of limited transfer to breast milk, NSAIDs are particularly beneficial for lactating mothers. In a small study (oral ibuprofen 400 mg every 6 hours for 24 hours), less than 1 mg of ibuprofen was excreted in breast milk in a 36-hour period.[73] Many centers administer 600 to 800 mg every 6 to 8 hours as a standard dose. Ibuprofen is approved as a therapeutic drug for children and therefore is considered compatible with breast-feeding.[71]

Oral **naproxen** 500 mg every 12 hours has been shown to reduce incisional pain compared with placebo and decrease opioid consumption (Fig. 27.3).[74]

Diclofenac has also been extensively studied; rectal suppositories (100 mg twice a day) decreased morphine consumption (14 mg versus 22 mg in 32 hours) compared with placebo after cesarean delivery.[75] A single rectal dose of diclofenac 100 mg prolonged the mean time to first analgesic administration by more than 5 hours in patients who received intrathecal morphine.[76] Patients who received intrathecal morphine doses as small as 0.025 mg required no rescue analgesic when intramuscular diclofenac 75 mg was administered every 8 hours.[77] Munishankar et al.[78] randomized patients who received spinal anesthesia with bupivacaine and fentanyl to receive one of three analgesic modalities:

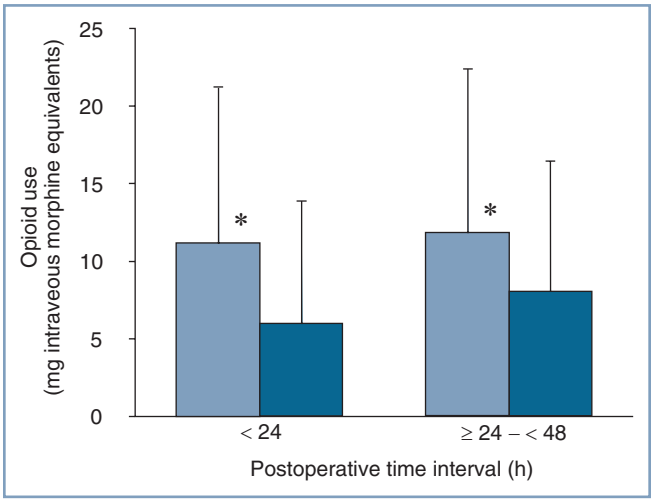

Fig. 27.2 Opioid use in milligram intravenous morphine equivalents after cesarean delivery in 24-hour increments in patients who received scheduled acetaminophen with as-needed opioid *(dark bars)* versus patients who received as-needed combination opioid-acetaminophen *(light bars)*. Data are mean *(bar)* and standard deviation *(whisker)*. *Significant difference between groups ($P < .001$). (Redrawn from Valentine AR, Carvalho B, Lazo TA, Riley ET. Scheduled acetaminophen with as-needed opioids compared to as-needed acetaminophen plus opioids for post-cesarean pain management. *Int J Obstet Anesth.* 2015;24:210–216.)

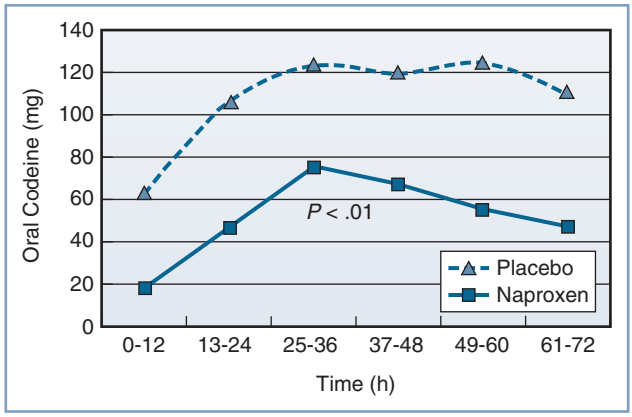

Fig. 27.3 Effect of naproxen on requirement for oral codeine after cesarean delivery: oral codeine use in milligram equivalents (expressed as mean) over time by group. (From Angle PJ, Halpern SH, Leighton BL, et al. A randomized controlled trial examining the effect of naproxen on analgesia during the second day after cesarean delivery. *Anesth Analg.* 2002;95:741–745.)

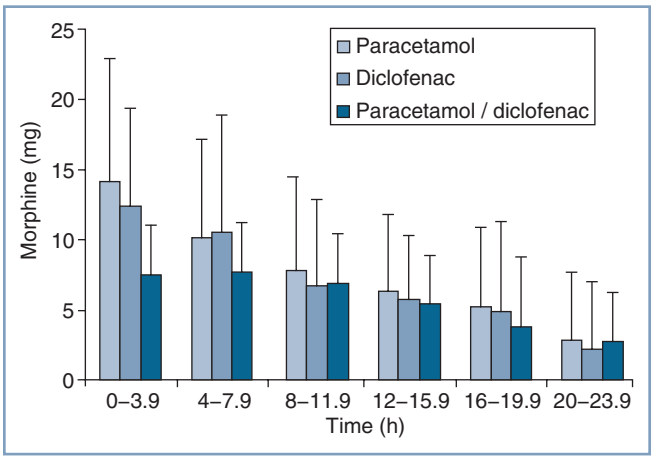

Fig. 27.4 Morphine consumption in milligrams in consecutive 4-hour periods after cesarean delivery in women randomized to receive acetaminophen (paracetamol), diclofenac, or both. Data were analyzed using repeated measures analysis of variance; patients in the acetaminophen/diclofenac group used less morphine per 4-hour period than patients in the acetaminophen but not the diclofenac group. (Redrawn from Munishankar B, Fettes P, Moore C, McLeod GA. A double-blind randomised controlled trial of paracetamol, diclofenac or the combination for pain relief after caesarean section. *Int J Obstet Anesth.* 2008;17:9–14).

acetaminophen, diclofenac, or diclofenac and acetaminophen. Women who received both diclofenac and acetaminophen required less morphine than those who received acetaminophen alone (Fig. 27.4).[78]

Lowder et al.[79] showed that **ketorolac** decreased pain scores at 2, 3, 4, 6, 12, and 24 hours after cesarean delivery and also decreased opioid consumption. Ketorolac previously had a "black box" warning that it was "contraindicated in nursing mothers," but current recommendations are to use it with caution. The American Academic of Pediatrics (AAP) considers NSAIDs safe for nursing mothers.[80] Use of NSAIDs in pregnant and breast-feeding women is discussed in detail in Chapter 14.

Cyclooxygenase-2-Selective Inhibitors

COX-2–selective inhibitors have a potential benefit compared with traditional nonselective NSAIDs in that they have minimal effects on platelet adhesion and thus are less likely to interfere with blood clot formation and contribute to hemorrhage. This category of NSAIDs has similar analgesic effectiveness and opioid dose-sparing to traditional NSAIDs in nonobstetric settings.[81] However, in the setting of cesarean delivery, they do not appear to be as effective as NSAIDs.[82,83] Additionally, concerns about the potential to increase the risk for cardiovascular and thrombotic events, combined with the baseline elevated risk for these events during pregnancy and postpartum, have prevented COX-2 inhibitors from playing a major role in postpartum analgesia. **Celecoxib** is the only widely available COX-2–selective inhibitor in the United States. The breast milk content of **parecoxib** and its primary active metabolite **valdecoxib** was very low, and neonatal neurologic and adaptive scores were normal, after a single 40-mg intravenous dose following cesarean delivery.[84]

Alpha$_2$-Adrenergic Receptor Agonists

Alpha$_2$-adrenergic receptor agonists have been used for the treatment of acute and chronic pain in nonobstetric patients.[85] Intravenous **dexmedetomidine** has been used as an adjunct to opioids as a component of general anesthesia for cesarean delivery.[86] Dexmedetomidine is excreted in breast milk in extremely small concentrations; the relative infant dose was 0.034%.[87] Neuraxial **clonidine** has been used for labor analgesia but is not commonly used for postcesarean analgesia. The epidural formulation of clonidine carries a "black box" warning from the FDA because of the incidence of hypotension at higher intrathecal doses.[88]

Magnesium Sulfate

Peripartum magnesium sulfate therapy is used for tocolysis for preterm labor, seizure prophylaxis in women with preeclampsia, and fetal neuroprotection in women at risk for preterm delivery.[89] A 2013 meta-analysis of trials of *intravenous* magnesium for the treatment of acute postoperative pain after nonobstetric surgery performed with general anesthesia concluded that magnesium sulfate administration resulted in a small reduction in postoperative pain scores and a substantial reduction in opioid use, although the incidence of nausea and vomiting was not reduced.[90] The use of intravenous magnesium as an adjunct to postcesarean analgesia has not been rigorously studied.

Gabapentin

Gabapentin is an anticonvulsant that has analgesic properties, particularly in the setting of neuropathic pain. It has been extensively studied in the management of chronic pain and for postoperative analgesia where it is associated with more rapid opioid cessation.[91] However, its role in opioid-naïve patients after cesarean delivery is less clear. As part of a multimodal analgesic regimen in patients undergoing cesarean delivery, a preoperative dose of oral gabapentin 600 mg was associated with lower pain scores with movement and at rest; however, the incidence of sedation was greater in the gabapentin group than in the placebo group (19% versus 0%).[92] In a follow-up study, two doses of gabapentin (300 mg and 600 mg) were compared with placebo in the hope of finding an efficacious dose associated with less sedation. Unfortunately, the trial failed to show efficacy in either gabapentin group.[93] These results were confirmed by Monks et al.[94] in a randomized trial comparing perioperative gabapentin (600 mg preoperatively followed by 200 mg every 8 hours for 2 days) with placebo when added to a multimodal postcesarean analgesic regimen. Gabapentin produced a clinically insignificant improvement in analgesia (difference in 100-mm visual analog scale pain score on movement –7 mm, 95% confidence interval [CI] –13 to 0; $P = .047$) after cesarean delivery but was associated with a higher incidence of sedation.

Gabapentin may play a role in postcesarean analgesia in patients with chronic pain and those with opioid tolerance.

Ketamine and Dextromethorphan

Ketamine, an *N*-methyl-D-aspartate (NMDA) antagonist, has analgesic properties and may play a role in the treatment of acute postoperative pain and prevention or reversal of central sensitization.[95] An evaluation of low-dose ketamine for postcesarean analgesia compared intravenous ketamine 0.15 mg/kg, intrathecal fentanyl 10 µg,[a] and placebo.[96] The study demonstrated prolonged duration of analgesia in both the fentanyl and ketamine groups compared with the placebo group (time to first analgesic request 145 minutes in the placebo group, 165 minutes in the fentanyl group, 199 minutes in the ketamine group). Ketamine was superior to fentanyl and placebo for reducing pain scores at 90 and 180 minutes, and reducing analgesic requirements in the first 24 hours, but not in the second 24 hours, after cesarean delivery.[96] In a setting in which intrathecal opioids were not available, the administration of intravenous ketamine 0.15 mg/kg immediately following bupivacaine spinal anesthesia resulted in better postoperative analgesia and reduced analgesic requirements compared with saline-placebo.[97] In contrast, in another study in which women undergoing cesarean delivery were randomized to receive intravenous ketamine 10 mg or placebo shortly after delivery as part of a multimodal regimen of intrathecal morphine and regular NSAID administration, the authors were unable to demonstrate a difference in breakthrough pain, time to first analgesic request, or cumulative rescue analgesic requirements.[98] However, pain scores were lower in the ketamine group 2 weeks after the surgery.

A 2015 systematic literature review and meta-analysis included seven studies of ketamine use during spinal anesthesia and five during general anesthesia.[99] Intravenous ketamine in the setting of spinal anesthesia delayed the time to first opioid request and reduced pain after cesarean delivery with no differences in the incidence of nausea, vomiting, pruritus, and psychomimetic effects.[99]

NEURAXIAL ANALGESIA

Efficacy and Benefits of Neuraxial Analgesia

Most cesarean deliveries in the developed world are performed with neuraxial anesthesia (spinal, epidural, or combined spinal-epidural [CSE] techniques).[100–102] This allows the administration of neuraxial drugs for postoperative analgesia.

Neuraxial opioid administration currently represents the "gold standard" for providing effective postcesarean analgesia. A 2010 systematic review found that a single dose of epidural morphine provides better analgesia than parenteral opioids after cesarean delivery.[103] A meta-analysis of studies involving a broad population of patients undergoing a variety of surgical procedures confirmed that opioids delivered by either patient-controlled epidural analgesia (PCEA) or continuous epidural infusion (CEI) provide postoperative pain relief that is superior to that provided by intravenous PCA.[104] Similar results have been reported in studies comparing intrathecal and epidural opioid administration with intravenous opioid PCA or intramuscular opioid administration after cesarean delivery (Fig. 27.5).[33,34,105,106]

Neuraxial opioids also provide superior postcesarean analgesia compared with non-neuraxial regional techniques (e.g., transversus abdominis plane block), local wound infiltration, and oral analgesics (e.g., NSAIDs and opioids).[54,107–109] Although neuraxial analgesia offers important benefits in optimizing postoperative analgesia, multimodal analgesic strategies augment the analgesic effect of neuraxial opioids.[109] Most commonly, neuraxial opioid analgesia serves as the central component of multimodal analgesia.

Although analgesia is superior, some opioid–related side effects (e.g., pruritus) are more common after neuraxial opioid administration.[105,110,111] Both higher[111,112] and lower[106,113] maternal satisfaction scores have been reported with neuraxial compared with systemic opioid analgesia. This variability in reported maternal satisfaction scores may be influenced by how patients judge analgesic quality against the presence and severity of side effects (e.g., pruritus, nausea and vomiting). Depending on individual priorities, women given a choice will choose lower intrathecal morphine if they wish

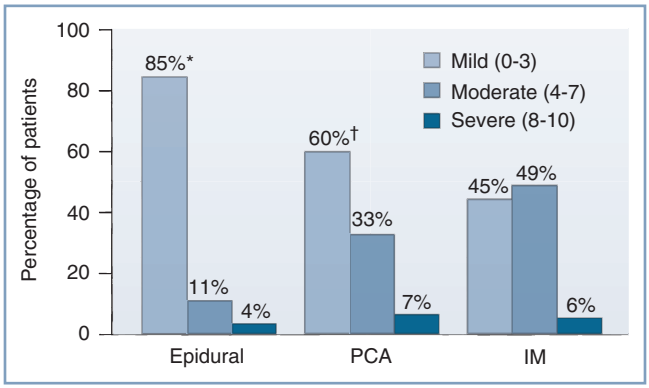

Fig. 27.5 Randomized trial of postcesarean analgesia with epidural analgesia, intravenous patient-controlled analgesia *(PCA),* or intramuscular *(IM)* administration of morphine. Percentage of patients reporting mild, moderate, or severe discomfort during a 24-hour study period. *$P < .05$, epidural versus PCA and IM; †P = NS, PCA versus IM. (From Harrison DM, Sinatra RS, Morgese L, Chung JH. Epidural narcotic and patient-controlled analgesia for post-cesarean section pain relief. *Anesthesiology.* 1988;68:454–457.)

[a]The Institute of Safe Medicine Practices (ISMP) has recommended that health care providers never use µg as an abbreviation for micrograms, but rather they should use mcg (http://www.ismp.org/tools/errorproneabbreviations.pdf, Accessed June 2018). The use of the symbol µg is frequently misinterpreted and involved in harmful medication errors. The abbreviation may be mistaken for mg (milligrams), which would result in a 1000-fold overdose. The symbol µg should never be used when communicating medical information, including pharmacy and prescriber computer order entry screens, computer-generated labels, labels for drug storage bins, and medication administration records. However, most scholarly publications have continued to use the abbreviation µg. The editors have chosen to retain the use of the abbreviation µg throughout this text. However, the editors recommend the use of the abbreviation mcg in clinical practice.

to avoid side effects or choose higher doses if they wish to optimize postcesarean delivery analgesia.[25]

Neuraxial techniques may confer other benefits in addition to better postoperative analgesia, including increased functional ability, earlier ambulation, and earlier return of bowel function.[114–118] Other potential benefits include a lower incidence of pulmonary infection and pulmonary embolism, fewer cardiovascular and coagulation disturbances, and a reduction in inflammatory and stress-induced responses to surgery.[114–116] Although a wealth of data from clinical studies and meta-analyses have shown a reduction in postoperative pain, there is less consistent evidence linking neuraxial anesthesia with a reduction in postoperative morbidity and mortality.[114,119]

Surgical trauma and postoperative immobility are associated with an increased risk for postoperative deep vein thrombosis and pulmonary embolism. The incidence of obstetric thromboembolism has increased 72% during hospitalizations for childbirth between 1998 and 2009.[120] Risk factors for thromboembolism, including obesity, advanced maternal age, and major medical comorbidities, are increasingly common in the obstetric population.[121–123] In theory, early ambulation and avoidance of prolonged immobility may reduce the risk for postpartum deep vein thrombosis and pulmonary embolism. Effective postoperative analgesia can reduce pain on movement, thereby facilitating deep breathing, coughing, and early ambulation. These beneficial effects may lead to a reduction in the incidence of pulmonary complications (i.e., atelectasis, pneumonia) after cesarean delivery.

Neuraxial analgesic techniques may be particularly useful for reducing perioperative morbidity in high-risk obstetric patients. Women with severe preeclampsia, cardiovascular disease, and morbid obesity may benefit from the reduction in cardiovascular stress and improved pulmonary function associated with effective postcesarean analgesia.[124,125] Investigators have found that CEI of a solution of opioid and dilute local anesthetic attenuates coagulation abnormalities, hemodynamic fluctuation, and stress hormone responses in nonpregnant patients.[126–128] Some studies suggest that opioid-based PCEA may improve postoperative outcome.[129–131] Patients treated with PCEA meperidine after cesarean delivery ambulated more quickly and experienced an earlier return of gastrointestinal function compared with similar patients who received intravenous meperidine PCA.[129] However, continuous postoperative neuraxial analgesia techniques also have disadvantages, including reduced mobility because of infusion pumps, more complicated management of postoperative thromboprophylaxis, and increased nursing workload.[132]

Neuraxial Opioids

The discovery that opioid receptors are localized within discrete areas of the spinal cord (laminae I, II, and V of the dorsal horn) suggested that exogenous opioids could be administered into the neuraxis to produce antinociception. Opioids administered to superficial layers of the dorsal horn produce selective analgesia of prolonged duration without affecting motor function, sympathetic tone, or proprioception.[133] In 1979, Wang et al.[134] published the first report of intrathecal morphine administration in humans that was followed shortly thereafter by a report of intrathecal meperidine. Intrathecal morphine (0.5 to 1 mg) produced complete pain relief for 12 to 24 hours in six of eight patients suffering from intractable cancer pain, with no evidence of sedation, respiratory depression, or impairment of motor function.[134] Subsequently, researchers and clinicians have validated the analgesic efficacy of neuraxial opioids.

Central Nervous System Penetration

Opioids administered epidurally must penetrate the dura, pia, and arachnoid membranes to reach the dorsal horn and activate the spinal opioid receptors. The arachnoid layer is the primary barrier to drug transfer into the spinal cord.[135] Drug movement through this layer is passive and depends on the physicochemical properties of the opioid (see Chapter 13). Drugs penetrating this arachnoid layer must first move into a lipid bilayer membrane, then traverse the hydrophilic cell, and finally partition into other cell membranes before entering the cerebrospinal fluid (CSF). Opioids that are highly lipid soluble (e.g., sufentanil, fentanyl) can easily pass through the hydrophobic cell membrane. However, these drugs have difficulty crossing through the hydrophilic cellular fluid. In contrast, drugs that are less lipid soluble (e.g., morphine) have a greater challenge crossing the cell membrane, but can easily traverse the cell interior. Thus, opioid penetration of the arachnoid mater is dependent on the drug's lipid solubility.[136] Highly lipid-soluble drugs have poor CSF bioavailability because of (1) poor penetration through the arachnoid layer, (2) rapid absorption and sequestration by epidural fat, and (3) rapid uptake by epidural veins.

Some investigators have questioned the neuraxial specificity of lipophilic opioids given epidurally and have suggested that the primary analgesic effect occurs via vascular uptake, systemic absorption, and redistribution of the drug to supraspinal sites.[137–142] Earlier studies suggested that parenteral fentanyl provides analgesia equivalent to that provided by epidural fentanyl,[142,143] but more recent evidence suggests that epidural fentanyl provides analgesia via a spinal mechanism.[144–146] Cohen et al.,[147] comparing a continuous infusion of intravenous fentanyl with epidural fentanyl after cesarean delivery, reported improved analgesia and less supplemental analgesic consumption despite lower plasma fentanyl levels with epidural administration. The difference may relate to speed of administration. There is evidence that bolus administration of lipophilic opioids has both spinal and supraspinal effects.[144–146,148] Sadurni et al.[148] randomized 30 patients undergoing abdominal surgery to receive intraoperative analgesia with boluses of fentanyl administered by either the thoracic epidural or intravenous route; patients who received epidural fentanyl required lower intraoperative fentanyl doses compared with those who received it by the intravenous route, suggesting that epidural fentanyl has a spinal as well as supraspinal effect. Additionally, after the administration of an epidural bolus of sufentanil

50 µg in a dog model, CSF concentration of sufentanil was 140 times greater than that found in plasma, and the amount detected in cisternal CSF was only 5% of that measured in lumbar CSF.[149]

Hydrophilic morphine has a greater CSF bioavailability, with better penetration into the CSF and less systemic absorption than the lipid-soluble opioids.[150] A bolus dose of epidural morphine 6 mg results in a peak plasma concentration of 34 ng/mL at 15 minutes after administration and a peak CSF concentration of approximately 1000 ng/mL at 1 hour.[151] A poor correlation between the analgesic effect and plasma levels of morphine has been observed after epidural administration, indicating a predominantly spinal location of action.[152,153] Intrathecal administration allows for injection of the drug directly into the CSF. This is a more efficient method of delivering opioid to spinal cord receptors than epidural or parenteral administration. A bolus dose of intrathecal morphine 0.5 mg resulted in a CSF concentration higher than 10,000 ng/mL, with barely detectable plasma concentrations.[154]

Distribution and Movement of Opioids within the Central Nervous System

The movement and distribution of opioids within the central nervous system (CNS) follows specific patterns. Movement in the spinal cord is such that lipophilic agents (e.g., fentanyl) are taken up by the white matter with much greater affinity than hydrophilic agents (e.g., morphine), and less drug will reach the gray matter of the dorsal horn.[135,136,155] Within the epidural space (and subsequently epidural fat or veins), lipophilic agents are more likely to be absorbed and transported from the epidural space to the systemic circulation. Rostral spread in the CSF is determined by CSF drug bioavailability and the drug concentration gradient; hydrophilic opioids (e.g., morphine) are associated with more rostral spread.[149,156]

Although opioid dose, volume of injectate, and degree of ionization are important variables, lipid solubility plays the key role in determining the onset of analgesia, the dermatomal spread, and the duration of activity (Table 27.4).[138,157] Highly lipid-soluble opioids penetrate the spinal cord more rapidly and have a quicker onset of action than more water-soluble agents. The duration of activity is affected by the rate of clearance of the drug from the sites of activity. Lipid-soluble opioids are rapidly absorbed from the epidural space, whereas hydrophilic agents remain in the CSF and spinal tissues for a longer time.[138,157]

Intrathecal and epidural opioids often produce analgesia of greater intensity than similar doses administered parenterally. The gain in potency is inversely proportional to the lipid solubility of the agent used. Hydrophilic opioids exhibit the greatest gain in potency; the potency ratio for intrathecal to systemic morphine is approximately 1 : 100.[157,158]

Epidural Opioids

The provision of cesarean delivery anesthesia using an epidural catheter (placed during labor or as part of a CSE technique) has prompted an extensive evaluation of epidural opioids to facilitate postoperative analgesia (Table 27.5).

Morphine

Preservative-free morphine received FDA approval for neuraxial administration in 1984, and subsequently epidural morphine administration has been widely investigated and extensively used.[159] Epidural administration of morphine provides postcesarean analgesia superior to that provided by intravenous or intramuscular morphine.[33,34,105,106] A meta-analysis concluded that epidural morphine administration prolongs the time to first analgesic request, decreases pain scores, and reduces postoperative analgesic requests during the first 24 hours after cesarean delivery compared with systemic opioid administration.[103] However, epidural morphine administration is associated with an increased risk for pruritus (relative risk [RR], 2.7; 95% CI, 2.1 to 3.6) and nausea (RR, 2.0; 95% CI, 1.2 to 3.3) compared with systemic opioid administration.[103]

Onset and duration. After epidural administration, plasma morphine concentration is similar to that observed after intramuscular injection. Epidural morphine has a relatively

TABLE 27.5 Epidural Opioids for Cesarean Delivery

Drug(s)	Dose	Onset (min)	Peak Effect (min)	Duration (h)	Advantages	Disadvantages
Morphine	2–4 mg	30–60	60–90	12–24	Long duration	Delayed onset Side-effect profile Potential for delayed respiratory depression
Fentanyl	50–100 µg	5	20	2–3	Rapid onset	Short duration
Sufentanil	10–25 µg	5	15–20	2–4	Rapid onset	Short duration
Meperidine	25–50 mg	15	30	4–6	Rapid onset	Nausea and vomiting
Hydromorphone	0.4–1 mg	15	45–60	10–20	Intermediate onset and duration	Side-effect profile similar to that of morphine
Morphine/fentanyl	3 mg/50 µg	10	15	12–24	Rapid onset Long duration Fewer side effects than morphine 5-mg dose	
Morphine/sufentanil	3 mg/10 µg	5	15	12–24	Rapid onset Long duration Fewer side effects than morphine 5-mg dose	

slow onset of action as a result of its low lipid solubility and slower penetration into spinal tissue.[138–140,157] The peak analgesic effect is observed 60 to 90 minutes after administration.[151] Many clinicians prefer to delay epidural morphine administration until immediately after delivery of the infant.

Morphine has a prolonged duration of analgesia, and analgesic efficacy typically persists long after plasma concentrations have declined to subtherapeutic levels.[138,151,157] Epidural morphine provides pain relief for approximately 24 hours after cesarean delivery[160–163]; however, there is wide variation in analgesic duration and efficacy among patients. Within the narrow range of doses studied, investigators have not demonstrated a correlation between the dose of morphine and the duration of analgesia.[161,163,164]

The volume of the diluent does not appear to affect the pharmacokinetics or clinical activity of epidural morphine. The quality and duration of analgesia, the need for supplemental analgesics, and the incidence of side effects were similar when epidural morphine 4 mg was administered with 2, 10, and 20 mL of sterile saline.[165]

Single-dose epidural regimens to optimize postcesarean analgesia and minimize opioid-related side effects. In a prospective dose-response study, Palmer et al.[164] observed that postcesarean analgesia (assessed by need for supplemental intravenous morphine by PCA) improved as the dose of epidural morphine increased from 0 to 3.75 mg. A further increase in dose (to 5 mg) did not significantly improve analgesia or reduce the amount of supplemental intravenous morphine used in the first 24 postoperative hours (Fig. 27.6).[164] Chumpathong et al.[161] did not observe any difference in pain relief, patient satisfaction, or side effects in women receiving epidural morphine 2.5 mg, 3 mg, or 4 mg for postcesarean analgesia. Rosen et al.[162] found that epidural morphine 5 mg and 7.5 mg provided similar analgesic efficacy, but a 2-mg dose provided ineffective analgesia. Fuller et al.[163] recommended epidural morphine 3 mg after a large retrospective study of epidural morphine in doses ranging from 2 to 5 mg for postcesarean analgesia.

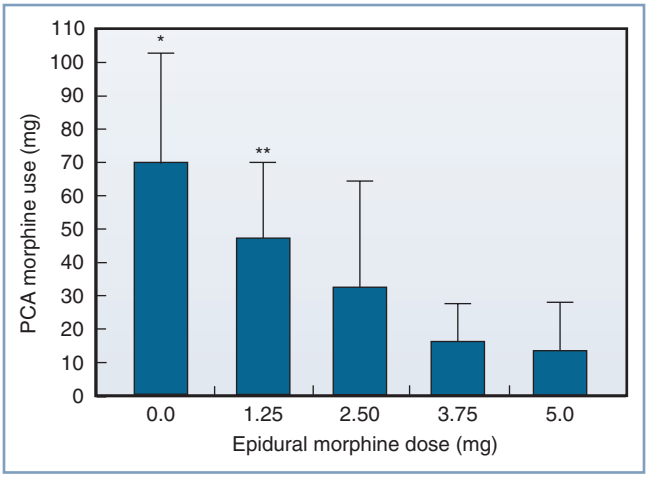

Fig. 27.6 Random allocation dose-response trial of epidural morphine 0, 1.25, 2.5, 3.75, and 5.0 mg for postcesarean delivery analgesia. Breakthrough pain as assessed by total 24-hour patient-controlled analgesia *(PCA)* morphine use. Data are mean ± 95% confidence interval. Groups were significantly different ($P < .001$). *Group 0.0 mg was significantly different from groups 2.5, 3.75, and 5.0 mg. **Group 1.25 mg was significantly different from groups 3.75 and 5.0 mg. (From Palmer CM, Nogami WM, Van Maren G, Alves DM. Postcesarean epidural morphine: a dose-response study. *Anesth Analg*. 2000;90:887–891.)

In contemporary clinical practice, doses of epidural morphine 2 to 4 mg are most commonly used. Lower doses may not provide effective analgesia, and women may require additional supplemental analgesia,[162,164] whereas higher doses may increase opioid-related side effects without improving analgesia. Singh et al.[166] conducted a randomized, noninferiority trial in which all women received scheduled

ketorolac and acetaminophen as well as epidural morphine. Morphine 1.5 mg was noninferior to 3 mg for postcesarean delivery analgesia. They found no difference in 24-hour opioid consumption between the 1.5-mg and 3-mg epidural morphine groups.[166] Thus, lower epidural morphine doses may be appropriate when multimodal analgesia is used and minimizing side effects is a priority.

Epidural versus intrathecal administration. A number of studies have compared the analgesic efficacy of epidural and intrathecal administration of opioids. Sarvela et al.[167] compared epidural morphine 3 mg with intrathecal morphine 0.1 mg and 0.2 mg; the two routes of administration provided postcesarean analgesia with similar efficacy and equal duration. Duale et al.[168] observed modest improvements in pain scores and lower morphine consumption with epidural morphine 2 mg than with intrathecal morphine 0.075 mg. In both studies, the incidence of side effects (e.g., sedation, pruritus, nausea and vomiting) was not different between the epidural and intrathecal routes.[167,168] A meta-analysis concluded that both epidural and intrathecal techniques provide effective postcesarean analgesia; neither technique is superior in terms of analgesic efficacy.[169] However, intrathecal administration results in less systemic drug exposure and less potential fetal drug exposure and has a faster onset of action than epidural administration of morphine. Profound sedation and respiratory depression requiring opioid reversal and intensive care monitoring has been reported after unintentional subdural or intrathecal administration of a dose intended for epidural administration.[170] If a CSE anesthetic is planned, intrathecal administration of the opioid may be preferable.

Fentanyl

Fentanyl is not approved by the FDA for neuraxial administration, but it is very commonly administered for short-term analgesia. Commercial preparations of fentanyl contain no preservative, are suitable for epidural or intrathecal administration, and have an excellent safety record. Grass et al.[171] reported that the 50% and 95% effective doses (ED_{50} and ED_{95}, respectively) of epidural fentanyl to reduce postcesarean pain scores to less than 10 mm (using a 100-mm visual analog scale) were 33 µg and 92 µg, respectively. An epidural fentanyl dose of 1 µg/kg has also been suggested to optimize *intra*operative analgesia.[172] In clinical practice, doses of 50 to 100 µg are given alone or in combination with epidural morphine.

The slow onset of action of morphine limits its ability to provide optimal intraoperative analgesia, and more lipophilic opioids (e.g., fentanyl) with a faster onset of analgesia are more appropriate for supplementation of intraoperative anesthesia (see Table 27.4).[157,173] Although single-dose epidural fentanyl improves intraoperative anesthesia, no meaningful postoperative pain relief occurs beyond 4 hours.[174] Duration is variable and dose dependent.[175,176] A dose-response study of epidural fentanyl 25, 50, 100, and 200 µg, administered at the time of first complaint of postoperative pain following epidural anesthesia (lidocaine with epinephrine), found that the duration of analgesia ranged from 1 to 2 hours.[171]

Local anesthetics may have a synergistic effect with epidurally administered opioids. The concurrent administration of local anesthetic reduces epidural fentanyl dose requirements after cesarean delivery.[177] Epidural fentanyl, administered either as a single dose or as a continuous or patient-controlled infusion, generally has fewer side effects than epidural morphine.[141,175,176] Some investigators have suggested that the administration of epidural fentanyl before incision may provide preemptive analgesia that improves postoperative analgesia.[172]

Sufentanil

Epidural sufentanil is a lipid-soluble opioid that provides a rapid onset of effective postcesarean analgesia. The potency ratio of epidural sufentanil to epidural fentanyl is approximately 5:1.[171] No differences in onset, quality, or duration of analgesia were found after epidural administration of equianalgesic doses of sufentanil and fentanyl.[171] Like fentanyl, epidural sufentanil does not provide postoperative analgesia of significant duration. Rosen et al.[178] compared epidural morphine 5 mg with epidural sufentanil 30, 45, or 60 µg. Although most patients who received sufentanil reported pain relief within 15 minutes, the duration of analgesia was 4 to 5 hours, in contrast to 26 hours of analgesia with epidural morphine.[178] The duration of analgesia is dose-dependent; an epidural bolus of sufentanil 25 µg produced less than 2 hours of analgesia, whereas 60 µg provided 5 hours of pain relief.[171,178]

Meperidine

Epidural meperidine has local anesthetic properties, and it has been used for postcesarean analgesia. Two clinical trials compared the safety and efficacy of epidural meperidine 50 mg and intramuscular meperidine 100 mg administered to patients after cesarean delivery.[179,180] Epidural meperidine provided a faster onset of analgesia with a duration (2 to 4 hours) similar to that provided by intramuscular meperidine. Paech[181] evaluated the quality of analgesia and side effects produced by a single epidural bolus of meperidine 50 mg or fentanyl 100 µg. The onset of pain relief was slightly faster with fentanyl; however, the duration of analgesia was longer with meperidine. Ngan Kee et al.[182,183] compared different doses of epidural meperidine (12.5, 25, 50, 75, and 100 mg) as well as varying volumes of diluent. They concluded that meperidine 25 mg diluted in 5 mL of saline was superior to 12.5 mg and that doses greater than 50 mg offered no improvement in the quality or duration of analgesia. Studies that have compared a single bolus dose of epidural or intrathecal morphine with PCEA meperidine have reported superior analgesia with morphine, but with a higher incidence of opioid-related side effects such as nausea, pruritus, and sedation.[184,185]

Other Epidural Opioids

Hydromorphone is a hydroxylated derivative of morphine with a lipid solubility intermediate between that of morphine

and meperidine.[186] The quality of epidural hydromorphone analgesia after cesarean delivery appears to be similar to that observed with epidural morphine; however, its onset is faster and its duration shorter.[187–189] Evidence suggests a potency ratio of 3:1 to 5:1 between epidural morphine and epidural hydromorphone.[186] Chestnut et al.[189] evaluated postcesarean analgesia with epidural hydromorphone 1 mg. Most patients reported good or excellent pain relief, and the mean time to first request for supplemental analgesia was 13 hours. Dougherty et al.[187] reported that epidural hydromorphone 1.5 mg provided 18 hours of postcesarean analgesia and that the duration was prolonged to 24 hours with the addition of epinephrine. Henderson et al.[188] observed 19 hours of postcesarean analgesia with epidural hydromorphone 1 mg. The incidence of pruritus was high in the two latter studies.[187,188] Halpern et al.[190] found no overall differences in quality of postcesarean analgesia or severity of side effects between patients who received epidural hydromorphone 0.6 mg or epidural morphine 3 mg. A meta-analysis suggested that epidural morphine and hydromorphone provide analgesia with similar efficacy and side effects when given for the treatment of acute or chronic pain.[191]

Diamorphine (heroin) is a lipid-soluble diacetylated derivative of morphine that is commonly administered neuraxially in the United Kingdom.[192] The lipid solubility of diamorphine provides rapid-onset analgesia, and its principal metabolite (morphine) facilitates prolonged duration of analgesia, although less than that of morphine. Roulson et al.[193] found that epidural diamorphine 2.5 mg provided postcesarean analgesia for 16 hours. Other investigators have found a duration of postcesarean analgesia of 6 to 12 hours after epidural diamorphine 5 mg.[194–196] In the United Kingdom, the National Institute for Health and Care Excellence (NICE) suggests a dose of epidural diamorphine of 2.5 to 5 mg for postcesarean analgesia.[197]

Epidural Opioid Combinations

Theoretically, the epidural administration of a lipophilic opioid combined with morphine should provide analgesia of rapid onset and prolonged duration. The use of lipophilic opioids administered intrathecally (e.g., fentanyl 15 µg) or epidurally (e.g., fentanyl 100 µg) in combination with epidural morphine 3.5 mg improves intraoperative anesthesia and reduces nausea and vomiting during cesarean delivery.[198,199] Some investigators have expressed concern that opioid interactions might reduce analgesic efficacy after epidural administration and that neuraxial fentanyl might initiate acute tolerance or affect the pharmacokinetic and receptor-binding characteristics of morphine. However, these concerns have not been confirmed in subsequent studies.[199,200] Epidural fentanyl, administered immediately after delivery of the infant, improved the quality of intraoperative analgesia without worsening epidural morphine analgesia after cesarean delivery.[199]

Studies of combined epidural morphine and sufentanil have produced mixed results. Dottrens et al.[201] compared a single epidural dose of either morphine 4 mg, sufentanil 50 µg, or morphine 2 mg with sufentanil 25 µg. The addition of sufentanil to epidural morphine provided a more rapid onset and similar duration of postcesarean analgesia than morphine alone.[201] In another study, morphine alone or in combination with sufentanil provided analgesia of longer duration than sufentanil alone. Sinatra et al.[202] were unable to show any potentiation when epidural sufentanil 30 µg was added to morphine 3 mg, and the duration of this combination was shorter than that of epidural morphine 5 mg alone.

Patient-Controlled Epidural Analgesia (PCEA)

The use of continuous epidural analgesia is a popular means of providing postoperative analgesia in patients undergoing thoracic or upper abdominal surgery. Better analgesia at rest and with movement has been reported in reviews of studies that compared epidural analgesia with intravenous PCA after nonobstetric surgery.[7,104] A systematic review of studies comparing PCEA, CEI, and intravenous PCA suggested that CEI provides better analgesia than PCA and PCEA in nonobstetric patients.[104] However, marked heterogeneity among studies prevented definitive conclusions.

PCEA is less frequently used for analgesia after cesarean delivery compared with single-dose epidural morphine. Fanshawe[203] compared PCEA **meperidine** with single-dose epidural morphine. Postoperative pain scores were better with epidural morphine at 6, 8, and 24 hours.[203] However, lipophilic opioids have been widely evaluated for PCEA after cesarean delivery (Table 27.6) and can be used when requirement for long-lasting analgesia is anticipated.[204,205] Epidural morphine's prolonged latency and risk for delayed respiratory depression make it a less safe option for continuous epidural infusion. Previous investigations have compared meperidine PCEA with other routes of parenteral administration (PCA, intramuscular). Paech et al.[206] performed a crossover study comparing PCEA with intravenous PCA meperidine after cesarean delivery; patients were randomly assigned to either PCEA or intravenous PCA for 12 hours before crossing over to the other route of drug administration for the next 12 hours. The PCEA and PCA meperidine protocols in this study were identical (20-mg bolus, 5-minute lockout). Patients receiving meperidine PCEA had lower pain scores at rest and with coughing than patients receiving intravenous PCA. Ngan Kee et al.[31] observed that PCEA (fentanyl or meperidine) regimens were associated with lower pain scores compared with the respective PCA regimens. Goh et al.[207] observed similar analgesic profiles among patients receiving fentanyl and meperidine PCEA, but noted more favorable side-effect profiles and better patient satisfaction among patients receiving meperidine PCEA.

Cooper et al.[130] postulated that the combination of epidural **fentanyl** with local anesthetic (fentanyl 2 µg/mL with 0.05% bupivacaine) would provide better analgesia than that provided by a single-drug PCEA regimen (fentanyl 4 µg/mL or 0.1% bupivacaine). The combination drug regimen was associated with lower pain scores at rest and significantly lower total drug requirements. However, no significant differences in pain scores during coughing were reported among

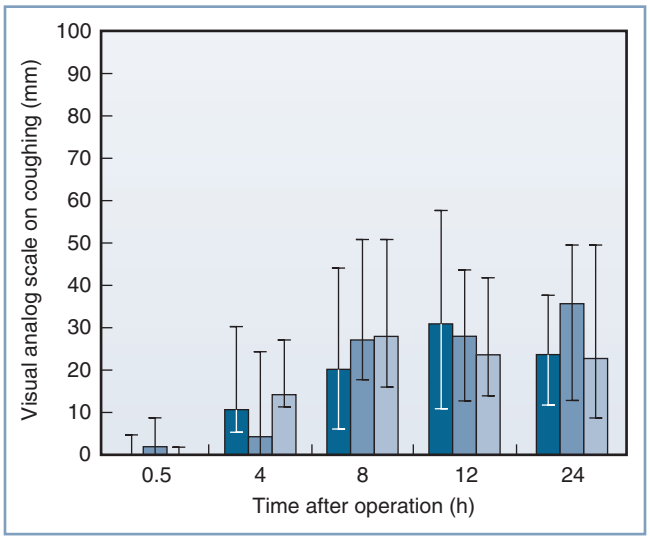

Fig. 27.7 Randomized trial of postcesarean delivery patient-controlled epidural analgesia *(PCEA)* with fentanyl 4 μg/mL, 0.1% bupivacaine, or both fentanyl 2 μg/mL and 0.05% bupivacaine. Pain scores during coughing on a 100-mm visual analog scale. Median score *(bars)* and interquartile range *(whiskers)* for groups who received epidural bupivacaine *(dark blue bars),* fentanyl *(medium blue bars),* and bupivacaine plus fentanyl *(light blue bars).* There were no differences in scores among the three groups. (From Cooper DW, Ryall DM, McHardy FE, et al. Patient-controlled extradural analgesia with bupivacaine, fentanyl, or a mixture of both, after caesarean section. *Br J Anaesth.* 1996;76:611–615.)

the three groups (Fig. 27.7). Cohen et al.[205] compared four different concentrations of ropivacaine (0.025%, 0.05%, 0.1%, 0.2%) with fentanyl 3 μg/mL and epinephrine 0.5 μg/mL. The lowest-dose group (0.025%) received the largest volume in the epidural space, and had the lowest 24-hour pain scores and highest satisfaction scores with no immobility or urinary retention.

Parker and White[32] compared **hydromorphone** PCEA with intravenous PCA; no differences in pain scores were found between the two treatment groups. In a follow-up study, these investigators assessed hydromorphone PCEA, with and without a background infusion, and hydromorphone combined with 0.08% bupivacaine, with and without a background infusion.[131] No differences in pain scores, PCEA usage, or 24-hour PCEA requirements were noted, and the combination of hydromorphone-bupivacaine PCEA with a background infusion was associated with a greater degree of lower extremity numbness and weakness.

Cohen et al.[208] compared fentanyl 2 μg/mL and **sufentanil** 0.8 μg/mL PCEA with 0.01% bupivacaine and epinephrine 0.5 μg/mL after cesarean delivery. Pain scores and side effects (nausea, pruritus, and sedation) were similar in the two groups; however, vomiting occurred more commonly in the sufentanil group. Vercauteren et al.[209] compared sufentanil PCEA (bolus 5 μg, lockout 10 minutes) with an identical PCEA regimen accompanied by a background infusion of sufentanil 4 μg/h.[209] Pain was lower at 6 hours in the group receiving PCEA with a background infusion, but no other differences in analgesia were reported between 6 and 24 hours. It is not surprising that the overall incidence and severity of sedation were higher in the background infusion group that received considerably more sufentanil.

Although CEI or PCEA can provide satisfactory postoperative analgesia, these techniques may diminish maternal satisfaction as a result of local anesthetic–induced motor block in lower limbs and the lack of physical independence from infusion devices in the postpartum period. They increase cost and potentially increase the risk for catheter-related complications (e.g., hematoma, infection) in comparison with single-dose administration of neuraxial morphine.[101,210] Neuraxial morphine may facilitate early discharge after elective cesarean deliveries, a strategy suggested by the NICE guidelines, which state that "women who are recovering well, are apyrexial and do not have complications following cesarean should be offered early discharge."[197]

Extended-Release Epidural Morphine

Extended-release epidural morphine (EREM) is an FDA-approved drug that delivers standard morphine sulfate via DepoFoam (Pacira Pharmaceuticals, Inc., San Diego, CA). DepoFoam is a drug-delivery system composed of multivesicular lipid particles containing nonconcentric aqueous chambers that encapsulate the active drug.[211,212] These naturally occurring lipids are broken down by erosion and reorganization, resulting in a sustained release of morphine for up to 48 hours after epidural administration of a single dose.[212–214]

After treatment with EREM, lower pain scores and lower requirement for supplemental analgesia over 48 hours were reported compared with standard epidural morphine.[160,215] Supplemental analgesia consumption was reduced by 60% in women who received a single dose of EREM 10 mg compared with standard epidural morphine 4 mg after cesarean delivery.[160] However, caution is required as pooled data from EREM studies for nonobstetric surgery suggest that EREM is associated with more opioid-related side effects, especially with higher doses, including a significantly higher risk for respiratory depression compared with intravenous opioid PCA (odds ratio [OR], 5.8; 95% CI, 1.1 to 31.9; $P = .04$).[212,216,217] Use of EREM requires extended monitoring for respiratory depression (48 hours compared with 24 hours with standard epidural morphine).[218] Unintentional intrathecal EREM administration has the potential to result in profound and prolonged opioid-related side effects, although a case report of unintentional intrathecal administration of a standard dose of EREM did not result in significant side effects or respiratory depression.[219]

Caution should be exercised when the administration of EREM follows the use of any epidural local anesthetic. A 2011 study found that epidural lidocaine administration (20 to 35 mL) for cesarean delivery, administered 1 hour before EREM administration, increased peak venous blood morphine levels and increased the incidence of vomiting, use of supplemental oxygen, and hypotension, compared with a control group that did not receive epidural lidocaine.[220] However, Gambling et al.[221] demonstrated no differences in the pharmacokinetic and pharmacodynamic profiles of EREM when administered 15, 30, and 60 minutes after epidural bupivacaine 0.25%. Any analgesic advantage must be weighed against the potential risk for serious side effects associated with EREM administration. The role of EREM for postcesarean analgesia remains unclear.

Intrathecal Opioids

Spinal anesthesia has become the preferred anesthetic technique for patients undergoing elective cesarean delivery in the United States and the United Kingdom.[100–102] Intrathecal opioids are commonly administered with a local anesthetic to improve intraoperative anesthesia and postoperative analgesia (Table 27.7).

Morphine

The potency differences between intrathecal and epidural opioids account for the smaller doses of intrathecal opioid used for cesarean delivery. Intrathecal morphine 0.075 to 0.2 mg is equivalent to epidural morphine 2 to 3 mg.[167,168] The analgesic efficacy, duration of action, and side-effect profile of intrathecal morphine are similar to that of epidural morphine (see earlier discussion).[167,168,222]

Onset and duration. Intrathecal morphine administration may result in a faster onset of analgesia than epidural morphine, but 60 to 90 minutes are still required for the drug to achieve a peak effect. The duration of analgesia is similar to the duration after epidural administration (14 to 36 hours).[a] A systematic review and meta-analysis found that the median time to first analgesic request after cesarean delivery was 27 hours (range, 11 to 29 hours) after intrathecal morphine administration.[113] The duration of analgesia is dose-dependent.[113,223,226] A 2016 meta-analysis comparing low-dose (0.05 to 0.1 mg) and high-dose (>0.1 to 0.25 mg) intrathecal morphine found mean time to first analgesic request was longer (mean difference, 4.5 hours; 95% CI, 1.8 to 7.1; $P = .0008$) for the high-dose group compared with the low-dose group.[226]

Dose. Several studies have attempted to determine the optimal dose of intrathecal morphine for postcesarean analgesia. Palmer et al.[227] compared postcesarean intravenous PCA morphine use after doses of intrathecal morphine ranging from 0.025 to 0.5 mg. The investigators found no

TABLE 27.7 Intrathecal Opioids for Cesarean Delivery

Drug	Dose	Onset (min)	Peak Effect (min)	Duration (h)	Advantages	Disadvantages
Morphine	0.05–0.2 mg (50–200 µg)	30–60	60–90	14–36	Long duration	Side-effect profile Potential for delayed respiratory depression
Fentanyl	10–25 µg	5	10	2–3	Rapid onset	Minimal postoperative analgesia Short duration Pruritus
Sufentanil	2.5–5 µg	5	10	2–4	Rapid onset	Minimal postoperative analgesia Short duration Pruritus
Meperidine	10 mg	10–15	15–20	4–5	Rapid onset	Minimal postoperative analgesia Nausea and vomiting

significant difference in PCA morphine use with morphine doses greater than 0.075 mg.[227] They concluded that there was little justification for using a dose of intrathecal morphine higher than 0.1 mg. Milner et al.[228] noted that intrathecal morphine 0.1 mg and 0.2 mg produced comparable analgesia but that the lower dose led to less nausea and vomiting. Yang et al.[229] found that intrathecal morphine 0.1 mg provided similar postcesarean analgesia with fewer side effects in comparison with 0.25 mg. Uchiyama et al.[230] performed a dose-response study with intrathecal morphine 0, 0.05, 0.1, and 0.2 mg. They observed that 0.1 mg and 0.2 mg provided comparable and effective postcesarean analgesia for 28 hours. The 0.05-mg dose was less effective, and the incidence of side effects was greater with the 0.2-mg dose; therefore, the investigators concluded that intrathecal morphine 0.1 mg is the optimal dose for postcesarean analgesia.[230] Berger et al.[231] compared 0.05, 0.1, and 0.15 mg of intrathecal morphine in women who received multimodal analgesia with intravenous ketorolac; all doses provided similar analgesia after cesarean delivery. There were no differences in 24-hour morphine consumption or reported pain or nausea scores, but pruritus scores were lower at 6 and 12 hours in the 0.05-mg group. A retrospective study reported that intrathecal morphine 0.2 mg provided better analgesia than 0.1 mg but with the "trade-off" of increased nausea.[232] Girgin et al.[233] reported no differences in analgesia with intrathecal morphine doses ranging from 0.1 to 0.4 mg; however, pruritus was increased with higher morphine doses.

Sultan et al.[226] completed a meta-analysis to determine whether low-dose (0.05 to 0.1 mg) intrathecal morphine provides comparable duration and quality of analgesia with fewer side effects than a high-dose (greater than 0.1 to 0.25 mg). Pain scores at 12 hours and morphine consumption at 24 hours were not significantly different, but duration of analgesia was longer with the higher doses. The incidence of opioid-related side effects, including nausea or vomiting (OR 0.4; 95% CI, 0.3 to 0.7]) and pruritus (OR 0.3; 95% CI, 0.2 to 0.6) were lower in the low-dose group.[226] Thus, there is a trade-off with incidence of side effects and duration of analgesia.

Studies have compared the analgesic efficacy and side-effect profile of intrathecal morphine with those of PCEA after cesarean delivery. Intrathecal morphine 0.15 mg compared with PCEA with 0.06% bupivacaine and sufentanil 1 μg/mL provided superior analgesia and fewer side effects.[210] Paech et al.[185] compared intrathecal morphine 0.2 mg with PCEA meperidine for postcesarean analgesia. Patients in the morphine group reported lower pain scores offset by a higher incidence of pruritus, nausea, and drowsiness. In another study in which intrathecal morphine (0, 0.05, and 0.1 mg) was combined with CEI (0.2% ropivacaine at 6 mL/h), inclusion of intrathecal morphine improved postcesarean analgesia compared with placebo.[234]

In summary, the intrathecal administration of a small dose of morphine (0.05 to 0.2 mg) provides effective analgesia for 14 to 36 hours after cesarean delivery. Higher doses (greater than 0.1 mg) may slightly increase the *duration* of analgesia but are associated with increasing side effects and limited improvement in analgesic *quality* in the average patient. Because of the variability in patient response to intrathecal morphine, some patients treated with low doses may experience inadequate postoperative analgesia and/or opioid-related side effects. Thus, the use of low-dose intrathecal morphine as a component of multimodal analgesia may provide optimal analgesia with a low risk for side effects.

The relationship between patients' expectations for pain after a cesarean delivery and their analgesic needs requires more study. Carvalho et al.[25] investigated the relationship between patients' choice for their dose of intrathecal morphine and postcesarean pain scores and opioid use. Patients were randomly assigned to a choice of 0.1 or 0.2 mg of intrathecal morphine or no choice. Women assigned a choice were read a standardized script that discussed the trade-off of pain relief with increased risk for the most common intrathecal morphine side effects (nausea, vomiting, and pruritus).[25] Participants who requested the larger dose of intrathecal morphine required more supplemental opioids and reported more pain with movement regardless of the intrathecal morphine dose they actually received.[25] Thus, patients may correctly anticipate a greater postoperative opioid need. Using a higher dose of intrathecal morphine in patients predicted to be at risk for high acute postpartum pain after cesarean delivery may result in less acute postoperative pain.[25,235] Shared decision-making, involvement of both the patient and her anesthesia provider in a sharing of information to build a consensus about preferred dose, and reaching an agreement about which dose to use may result in improved analgesia.[236]

Fentanyl

Intrathecal fentanyl improves intraoperative anesthesia (especially during uterine exteriorization), reduces intraoperative nausea and vomiting, decreases local anesthetic dose requirement, and provides a better postoperative transition to other pain medications during recovery from spinal anesthesia for cesarean delivery.[237–240] However, intrathecal fentanyl provides a limited duration of postoperative analgesia, with a median time to first request for additional analgesia of 4 hours (range, 2 to 13 hours).[113] A study that compared intrathecal morphine 0.1 mg with fentanyl 25 μg found that morphine provided better and longer postoperative analgesia after cesarean delivery.[241]

The analgesic effects, duration of analgesia, and side effects after intrathecal fentanyl are dose-related.[113,237,238] Belzarena[237] found that intrathecal fentanyl provided analgesia for a duration of 305 to 787 minutes (with 0.25 μg/kg and 0.75 μg/kg, respectively). However, patients who received the higher dose experienced decreased respiratory rate and a high incidence of side effects (e.g., pruritus, nausea). Dahlgren et al.[238] reported that intrathecal fentanyl 10 μg added to bupivacaine increased the mean time of effective analgesia from 121 minutes to 181 minutes. Similarly, Wilwerth et al.[242] added intrathecal fentanyl 25 μg to bupivacaine and intrathecal morphine with a resultant median duration of analgesia of

187 minutes (interquartile range [IQR], 151 to 230 minutes). Hunt et al.[243] compared a range of intrathecal fentanyl doses (2.5 to 50 μg) in combination with intrathecal bupivacaine for cesarean delivery. Intrathecal fentanyl doses larger than 6.25 μg were associated with better intraoperative anesthesia and a longer time to first request for additional analgesia than administration of bupivacaine alone (72 minutes versus 192 minutes, respectively).[243] Chu et al.[244] found that fentanyl doses of 12.5 to 15 μg were required to increase the duration of effective analgesia.

In summary, intrathecal fentanyl optimizes intraoperative anesthesia and provides immediate postoperative analgesia. However, intrathecal fentanyl (10 to 25 μg) provides a limited duration of postcesarean analgesia (2 to 4 hours) and does not decrease subsequent postoperative analgesic requirements.

Sufentanil

Sufentanil has a fast onset of action, which may improve intraoperative anesthesia and reduce the dose of local anesthetic required for cesarean anesthesia.[245] However, its pharmacokinetic properties limit the duration of effective postoperative analgesia after intrathecal administration.[113] Courtney et al.[246] found that intrathecal sufentanil 10, 15, or 20 μg resulted in a mean duration of postcesarean analgesia of approximately 3 hours. More than 90% of patients reported pruritus, but only one patient required treatment. Dahlgren et al.[238] compared the safety and efficacy of the coadministration of sufentanil 2.5 or 5 μg, fentanyl 10 μg, or placebo with hyperbaric bupivacaine 12.5 mg for cesarean delivery. The duration of effective analgesia was longer with inclusion of the opioids, particularly in the sufentanil groups; sufentanil 5 μg provided the longest duration of analgesia but also had the highest incidence of pruritus. Patients receiving intrathecal sufentanil had *lower* requirements for intraoperative antiemetics and postoperative intravenous morphine rescue.[238] Intrathecal sufentanil 7.5 μg did not provide more effective postoperative analgesia than that observed in the 5-μg group, and the incidence of pruritus was higher.[247] Karaman et al.[248] found that intrathecal sufentanil 5 μg delayed the time to first analgesic request to 6 hours, compared with 20 hours for intrathecal morphine 0.2 mg. A study that compared intrathecal fentanyl 20 μg and sufentanil 2.5 μg added to bupivacaine for cesarean delivery found no difference in the quality of intraoperative and postoperative analgesia, as well as no difference in the frequency of nausea and pruritus between the two opioid groups.[249] Wilwerth et al.[242] added intrathecal fentanyl 25 μg, sufentanil 2.5 μg, or sufentanil 5 μg to hyperbaric bupivacaine 10 mg. Effective analgesia was defined as time from spinal injection to first intravenous morphine administered. Duration of analgesia was longer with sufentanil 2.5 μg (214 minutes) and 5 μg (236 minutes) compared with fentanyl 25 μg (187 minutes).[242] The incidence of pruritus and PONV was similar among groups. In summary, intrathecal sufentanil, similar to fentanyl, enhances intraoperative anesthesia but has limited postoperative analgesia. It has a ceiling dose of 5 μg, and the likelihood of pruritus increases with higher doses.

Other Intrathecal Opioids

Intrathecal **meperidine** reduces the intensity of pain associated with the regression of spinal anesthesia and provides postoperative analgesia of intermediate duration (4 to 5 hours).[250,251] Yu et al.[252] found that the addition of meperidine 10 mg to hyperbaric bupivacaine 10 mg prolonged the mean duration of postcesarean analgesia (234 minutes in the meperidine group versus 125 minutes in the placebo group). However, the incidence of intraoperative nausea and vomiting was greater in the meperidine group. A dose of 7.5 mg added to bupivacaine 10 mg also prolonged postoperative analgesia for 257 ± 112 minutes (mean ± SD) compared with a saline group (161 ± 65 min).[253]

Unlike other opioids, meperidine possesses local anesthetic qualities in addition to μ-opioid receptor agonism. Some anesthesia providers have administered a higher intrathecal meperidine dose (1 mg/kg) as the sole anesthetic agent for cesarean delivery under spinal anesthesia. However, surgical anesthesia was unreliable, with a short mean (± SD) anesthetic duration of 41 ± 15 minutes.[250,251]

Diamorphine has physicochemical properties that are of value in providing intrathecal analgesia as well as epidural analgesia. A high lipophilicity (octanol-water coefficient, 280) results in a rapid onset of analgesia, and diamorphine's active metabolite (morphine) provides prolonged duration of analgesia. The more rapid onset of diamorphine is an advantage in the provision of intraoperative as well as postoperative analgesia.[254,255] Saravanan et al.[256] concluded that the ED_{95} for intrathecal diamorphine to prevent intraoperative discomfort was 0.4 mg when combined with hyperbaric bupivacaine 12.5 mg.

Kelly et al.[257] compared intrathecal diamorphine 0.125, 0.25, and 0.375 mg for postcesarean analgesia. The 0.25-mg and 0.375-mg doses provided effective analgesia; the incidence of both vomiting and pruritus was dose related. Stacey et al.[258] reported that the duration of analgesia was dose-dependent and found that intrathecal diamorphine 1 mg provided 10 hours of postcesarean analgesia, compared with 7 hours for 0.5 mg. A dose-response study using intrathecal diamorphine 0.1, 0.2, or 0.3 mg reported a dose-dependent enhancement of analgesia and an increase in pruritus.[18] Husaini and Russell[259] observed that intrathecal diamorphine 0.2 mg and intrathecal morphine 0.2 mg provided similar postcesarean analgesia as assessed by rescue postoperative intravenous PCA morphine requirements. However, the patients who received intrathecal morphine had a higher incidence of pruritus and drowsiness. Hallworth et al.[260] reported that *intrathecal* diamorphine 0.25 mg produced the same duration and quality of postcesarean analgesia as *epidural* diamorphine 5 mg, with less nausea and vomiting.

Diamorphine is commonly used in the United Kingdom, but it is not available for clinical use in the United States and Canada. In the United Kingdom, the NICE suggests an intrathecal diamorphine dose of 0.3 to 0.4 mg for postcesarean analgesia.[197]

Intrathecal **hydromorphone** has been used to provide analgesia following cesarean delivery as an alternative to

morphine. The use of intrathecal hydromorphone has increased with shortages of intrathecal morphine in the United States. Two retrospective studies found an analgesic advantage in favor of intrathecal morphine. Marroquin et al.[261] retrospectively compared intrathecal morphine 0.2 mg or epidural morphine 3 mg with intrathecal hydromorphone 60 μg or epidural hydromorphone 0.6 mg. Time to first opioid request was 17 to 21 hours with neuraxial morphine compared with 13 to 15 hours for neuraxial hydromorphone.[261] Beatty et al.[262] compared intrathecal morphine 0.1 mg with intrathecal hydromorphone 40 μg and found 24-hour supplemental opioid use favored intrathecal morphine (8 mg versus 33 mg). The side effects of intrathecal morphine and hydromorphone are similar.[261,262]

The optimal intrathecal hydromorphone dose has not been fully elucidated. Using an up-down sequential allocation method, Lynde[263] estimated that the ED_{50} of intrathecal hydromorphone was 4.6 μg. In a dose-response study, Sviggum et al.[264] randomized 80 participants to intrathecal morphine or intrathecal hydromorphone using a biased-coin, up-down sequential allocation method to assign dose. The effective dose (ED_{90}) for achieving a numeric pain score (0 to 10 scale) less than or equal to 3 for a duration of 12 hours was 75 μg for intrathecal hydromorphone compared with 150 μg for intrathecal morphine.[264] Further research will need to help refine the optimal dose of intrathecal hydromorphone for postcesarean analgesia.

Intrathecal Opioid Combinations

Intrathecal administration of morphine in combination with a lipophilic opioid (e.g., fentanyl, sufentanil) may offer some advantages, similar to their combination in the epidural space. Intrathecal morphine has a delayed onset; therefore, the co-administration of lipophilic opioids may serve to improve intraoperative anesthesia and reduce the intensity of pain associated with the regression of spinal anesthesia in the postanesthesia care unit. Chung et al.[265] found that the combination of intrathecal meperidine 10 mg and morphine 0.15 mg provided better intraoperative analgesia, less need for supplemental analgesia, and greater satisfaction than intrathecal morphine alone following cesarean delivery. Intrathecal sufentanil 5 μg co-administrated with morphine 0.15 mg provided better and longer pain relief than intrathecal sufentanil plus a single injection of subcutaneous morphine; however, a higher incidence of side effects, such as nausea and vomiting, was observed with intrathecal morphine.[266]

Some investigators have suggested that intrathecal morphine may be less effective when concurrently administered with intrathecal fentanyl, suggesting acute spinal opioid tolerance.[267] This claim is controversial, and study results are inconsistent. Cooper et al.[267] reported that patients who received intrathecal fentanyl 25 μg with bupivacaine had higher postoperative intravenous morphine PCA requirements than patients who received bupivacaine alone. By contrast, Sibilla et al.[225] found that the intrathecal combination of fentanyl 25 μg and morphine 0.1 mg provided similar postoperative analgesia to that provided by intrathecal morphine alone. Carvalho et al.[268] found no difference in postoperative analgesia requirements but small increases in postoperative pain scores with the addition of increasing doses of intrathecal fentanyl (5, 10, or 25 μg) to intrathecal morphine 0.2 mg for cesarean delivery. The authors suggested that intrathecal fentanyl may induce subtle acute tolerance to intrathecal morphine. The clinical significance of this finding is unclear, however, especially because of widespread evidence that intrathecal lipid-soluble opioids decrease the incidence of *intraoperative* visceral pain and nausea. Many anesthesia providers currently administer both intrathecal morphine and fentanyl with a local anesthetic for spinal anesthesia for cesarean delivery (see Chapter 26).[101] The co-administration of intrathecal fentanyl does *not* appear to significantly compromise the postoperative analgesia provided by intrathecal morphine.

Despite the administration of neuraxial opioid analgesia, the quality and duration of analgesia after cesarean delivery is often incomplete. Thus, neuraxial opioid analgesia is rarely the sole analgesic technique used for postcesarean analgesia. Rather, neuraxial opioids should be considered as part of a multimodal analgesic approach for the treatment of postcesarean pain.[54,109,118]

Side Effects of Neuraxial Opioids

Careful evaluation of the potential adverse effects of neuraxial pharmacologic agents is important before making the decision to administer these drugs. In obstetric patients, adverse maternal effects as well as potential neonatal effects should be considered.

Maternal Safety

Neurotoxicity (safety) studies suggest that morphine, fentanyl, sufentanil, hydromorphone, meperidine, clonidine, and neostigmine are safe for neuraxial administration.[269–272] Morphine and clonidine are approved by the FDA for neuraxial administration. Although unlicensed for neuraxial administration, fentanyl and sufentanil have been used for many years without evidence of neurotoxicity. Studies in sheep have reported potential neurotoxicity with intrathecal butorphanol.[273] Culebras et al.[274] reported potential toxic interactions with the co-administration of nalbuphine and local anesthetic. However, Rawal et al.[273] evaluated the behavioral and histopathologic effects of butorphanol, sufentanil, and nalbuphine after intrathecal administration in sheep and found that nalbuphine caused the least evidence of neural tissue damage.

Clinicians should avoid neuraxial administration of any agent before adequate evaluation for potential neurotoxicity has been completed.[275–277] Drugs and diluents that are proven safe for parenteral use may have adverse effects when administered intrathecally. Despite these valid concerns, a number of opioid analgesics, including fentanyl and sufentanil, have been administered intrathecally to healthy obstetric patients without prior adequate investigation of their safety profile in animal and clinical volunteer studies.[277]

Preservatives added to many commercial preparations may be hazardous if administered to the neuraxis. Examples are sodium (meta)bisulfite and disodium ethylenediaminetetraacetic acid (EDTA), which are known to incite inflammatory and fibrotic changes in pia-arachnoid and spinal tissue after intrathecal administration. Dezocine has been shown to cause neuropathologic changes in the dog spinal cord.[278] Similarly, glycine, a neurotransmitter, is added as a preservative to **remifentanil** preparations and is specifically contraindicated for neuraxial injection.

Neonatal Effects

All opioids have the potential for placental transfer and neonatal effects. Minimal neonatal effects have been found after the administration of epidural morphine 2 to 7.5 mg for cesarean delivery.[279] This is not surprising given the slow increase in plasma concentration after epidural administration and active transport of morphine out of the blood brain barrier[280] and placenta[281] by P-glycoproteins. Some clinicians prefer to administer neuraxial opioids after umbilical cord clamping to avoid placental transfer, although it is minimal. Lipophilic opioids are associated with faster systemic uptake; if indicated (e.g., for treatment of intraoperative pain before delivery), the smallest necessary dose should be administered. Courtney et al.[246] found that intrathecal sufentanil (10, 15, or 20 μg) did not affect neonatal outcome as assessed by umbilical cord blood gas measurements and Apgar and neurobehavioral scores. Smaller doses of intrathecal opioids are associated with less neonatal drug transfer than epidural or intravenous opioid administration.[282]

Respiratory Depression

Neuraxial opioids can depress the respiratory center in the brainstem via direct and/or indirect mechanisms.[138,140,156,157,283–285] Respiratory depression after neuraxial morphine administration is biphasic.[286] Early respiratory depression can occur 30 to 90 minutes after epidural morphine administration owing to systemic vascular absorption from the epidural space,[157] whereas delayed respiratory depression can occur 6 to 18 hours after epidural or intrathecal morphine administration owing to rostral spread in CSF and slow penetration into the brainstem.[173,287] In contrast, lipophilic opioids do not cause delayed respiratory depression but may cause early respiratory depression, typically within 30 minutes, because of vascular uptake and rostral spread in CSF and, potentially, direct transit in epidural veins.[283,284]

Although rare, perioperative opioid–induced respiratory depression can lead to death or permanent brain damage.[288,289] The incidence of respiratory depression after neuraxial morphine administration in obstetric patients is very low, with reported ranges from 0% to 0.9%.[290] The Serious Complication Repository (SCORE) project of the Society for Obstetric Anesthesia and Perinatology (SOAP) systematically tracked complications related to obstetric anesthesia between 2004 and 2009.[291] Among 90,795 reported cases of neuraxial anesthesia for cesarean delivery, no cases of respiratory arrest secondary to neuraxial opioid administration were reported. No studies in the obstetric setting have reported serious morbidity, although some patients have required naloxone administration for treatment of respiratory depression.[163] Early reports suggested that intrathecal morphine was more likely to cause delayed respiratory depression than epidural morphine.[157] However, this likely reflected the relatively high intrathecal morphine doses (1 to 10 mg) used in early clinical studies.[292] Subsequently, lower doses of intrathecal morphine have been found to provide effective analgesia with a low risk for clinically significant respiratory depression. No maternal deaths attributable to maternal neuraxial opioid administration were reported in the 2013–2015 Confidential Enquiries report from the United Kingdom.[293] In a retrospective study of 5036 postpartum women who received low-dose neuraxial morphine for cesarean delivery, no instances of respiratory depression were identified (defined as clinically relevant episodes of respiratory depression requiring naloxone administration or a rapid-response team call).[294] Thus, clinicians have concluded that the analgesic benefits derived from neuraxial opioids outweigh the risks associated with respiratory depression in most patients. The incidence of respiratory depression associated with systemic (intravenous or intramuscular) opioids is likely to be equivalent or higher than that observed with neuraxial opioids.[38,223,295]

There are very few case reports of respiratory depression after neuraxial administration of a lipophilic agent in the obstetric setting. In one report, respiratory depression occurred 25 minutes after spinal anesthesia with intrathecal fentanyl 15 μg and required reversal with naloxone.[296] Respiratory depression has been described after administration of epidural fentanyl 90 to 100 μg for cesarean delivery.[297,298] Cohen et al.[284] reported that epidural sufentanil 30 to 50 μg depressed the ventilatory response to CO_2 after cesarean delivery. Although overt respiratory depression did not occur, the highest sedation scores and depression of CO_2 response occurred 45 minutes after administration. Another group reported that epidural fentanyl 100 μg or sufentanil 10 to 50 μg added to lidocaine for cesarean delivery caused significant changes in respiratory rate and end-tidal CO_2 but no adverse clinical events.[299]

Historically, respiratory depression was more common because patients received greater doses of neuraxial opioid than those currently used in modern practice. For cesarean delivery, neuraxial morphine appears to have a limit or "ceiling" in analgesic efficacy. More specifically, effective doses of intrathecal and epidural morphine are 0.075 to 0.2 mg and 2 to 4 mg, respectively, in opioid-naïve patients.[113,164,227,300] Sultan et al.[226] performed a systematic review of studies of low-dose compared with high-dose intrathecal morphine administered for postoperative analgesia following elective cesarean delivery; there were no reported episodes of respiratory depression. Thus, avoiding high doses of neuraxial morphine may improve safety without compromising analgesia.[300]

Monitoring and Detection of Respiratory Depression

Guidelines for the prevention, detection, and management of respiratory depression associated with neuraxial opioid

administration have been published by the American Society of Anesthesiologists (ASA) and the American Society of Regional Anesthesia and Pain Medicine (ASRA).[218] These guidelines do not specifically address obstetric patients and are likely overly prescriptive given the low risk for clinically significant neuraxial opioid–induced respiratory depression with conventional dosing in this patient population.[290] The SOAP has commissioned a consensus statement (planned publication in 2019) to provide recommendations specifically for the obstetric population following cesarean delivery.

All patients who receive neuraxial opioids should be monitored for adequacy of ventilation, oxygenation, and level of consciousness. Opioid effects on respiration include reduced minute ventilation (decrease in respiratory rate, tidal volume, or both) and decreased response to hypoxemia and changes in $PaCO_2$.[292,301] Nearly two-thirds of cases of respiratory depression following general anesthesia in the Anesthesia Closed Claims Project database reported somnolence was present, but not addressed, before the respiratory depression event.[302]

Vigilant nursing care and hourly assessments of respiratory effort, respiratory rate, and somnolence are probably adequate for low-risk patients who receive neuraxial opioid analgesia.[163,290,303,304] Continuous pulse oximetry, although appropriate for obstetric patients with risk factors for respiratory depression such as obesity, may be unnecessary in healthy patients receiving low doses of neuraxial opioid (e.g., intrathecal morphine ≤ 0.2 mg, epidural morphine ≤ 4 mg).[290] Greater surveillance and ventilation monitoring (e.g., capnography) may be warranted in patients at high risk for respiratory depression who are receiving supplemental oxygen; the monitoring of patients at high-risk for respiratory depression merits further study.[305]

The duration of respiratory monitoring corresponds to the expected duration of action of the administered opioid. The onset of respiratory depression after neuraxial opioids is variable and has been reported to range from 2 to 12 hours.[295] CO_2 responsiveness is depressed for up to 24 hours after the administration of epidural morphine 5 mg.[306] The ASA recommends that respiratory monitoring after neuraxial administration of morphine should occur at least every hour for the first 12 hours and then every 2 hours for the next 12 hours.[218]

Early-onset respiratory depression associated with lipophilic opioids usually occurs within 30 minutes of administration and is likely to occur in a high-visibility, controlled setting (e.g., operating or labor room). The ASA and ASRA recommend that respiratory monitoring after administration of neuraxial fentanyl should continue for a minimum of 2 hours.[218]

Nausea and Vomiting

Nausea and vomiting are common complaints after cesarean delivery, and the causes are likely multifactorial. Neuraxial opioids increase the risk for PONV after cesarean delivery in a non–dose-dependent manner via rostral spread of opioid in the CSF to the brainstem or from vascular uptake and delivery to the vomiting center and chemoreceptor trigger zone.[307] Palmer et al.[227] found no difference in PONV between intrathecal morphine (0.025 to 0.5 mg) and placebo, nor a relationship between PONV and morphine dose. A similar study by the same group found no difference in the severity of PONV in patients receiving increasing doses of epidural morphine (1.25 to 5 mg).[164] However, neither study was adequately powered to investigate absence of PONV as a primary outcome measure. Many studies have investigated different regimens to reduce PONV in patients receiving neuraxial opioids for cesarean delivery, but these studies did not standardize PONV outcome measures and did not stratify patients according to risk for PONV. In a blinded study assessing PONV as a secondary outcome after intrathecal morphine 0.1 and 0.2 mg, an increased incidence and severity of nausea was identified in the high-dose group.[25]

Single antiemetic agents. Older antiemetics, such as **metoclopramide** and **droperidol,** have been used to prevent or treat neuraxial opioid–induced emesis in the obstetric setting. Metoclopramide antagonizes dopamine receptors in the chemoreceptor trigger zone. It is often administered preoperatively owing to its favorable gut prokinetic properties, and it is associated with a reduction in rates of intraoperative nausea and vomiting (IONV) and PONV in patients receiving spinal anesthesia.[308] In a meta-analysis of studies that assessed efficacy of antiemetic prophylaxis, metoclopramide was associated with a reduced incidence of IONV and early PONV compared with placebo.[309]

The use of a transdermal **scopolamine** patch may also lower the incidence of PONV after cesarean delivery. A transdermal scopolamine patch (1.5 mg) provided efficacy similar to that provided by ondansetron 4 mg in reducing emesis among parturients receiving spinal anesthesia (incidence of 40% and 42%, respectively, versus 59% in the control group).[310] However, transdermal scopolamine has a latency period of 3 to 4 hours, and side effects, including dry mouth, visual disturbances, dizziness, and agitation, are common.

Serotonin ($5\text{-}HT_3$) receptor antagonists have been used for both prophylaxis and treatment of PONV. These drugs bind to $5\text{-}HT_3$ receptors in the chemoreceptor trigger zone and at vagal afferents in the gastrointestinal tract. Prophylactic administration of **ondansetron** 4 to 8 mg has been shown to have a better antiemetic profile in the first 24 hours after intrathecal and epidural opioid administration compared with placebo (Fig. 27.8).[311] A meta-analysis of six trials found that the use of $5\text{-}HT_3$ receptor antagonists reduced the incidence of PONV and the need for rescue antiemetic treatment in women who received intrathecal opioids for cesarean delivery.[312]

Corticosteroid receptors have been identified in areas important to the signal processing of nausea and vomiting, including the nucleus of the solitary tract, the nucleus of raphe, and the area postrema. Tzeng et al.[313] reported that intravenous **dexamethasone** 8 mg and **droperidol** 1.25 mg provided similar efficacy in the prevention of PONV. Wang et al.[314] suggested that dexamethasone 5 mg is the minimum effective dose for preventing PONV. In both studies, patients received epidural morphine 3 mg.[313,314] In a 2012

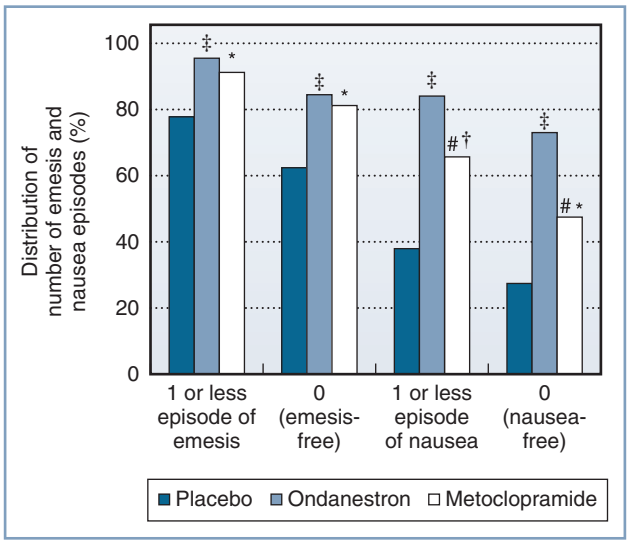

Fig. 27.8 Randomized trial of postoperative nausea and emesis in patients undergoing cesarean delivery with epidural anesthesia (2% lidocaine with epinephrine and fentanyl) who received prophylactic ondansetron, metoclopramide, or placebo. Distribution of nausea and emesis episodes (0 [nausea or emesis free] or 1 or less) in the first 24 hours. Values are given as percentages of each patient group. #Group metoclopramide versus ondansetron; $P < .05$. *Group metoclopramide versus placebo; $P < .05$. †Group metoclopramide versus placebo; $P < .005$. ‡Group ondansetron versus placebo; $P < .005$. (Data from Pan PH, Moore CM. Comparing the efficacy of prophylactic metoclopramide, ondansetron, and placebo in cesarean section patients given epidural anesthesia. *J Clin Anesth.* 2001;13:430–435.)

meta-analysis of studies of obstetric and gynecologic patients who received neuraxial morphine, prophylactic dexamethasone (2.5 to 10 mg) was associated with a reduced risk for PONV and need for antiemetic rescue therapy compared with placebo.[315] Administration of **cyclizine** 50 mg has been reported to be associated with fewer episodes of PONV (0 to 12 hours after cesarean delivery) than administration of dexamethasone 8 mg after intrathecal opioid (fentanyl and morphine) administration.[316]

Combination antiemetic regimens. Administration of drugs acting at two different receptor sites may improve antiemetic efficacy through additivity or synergism.[317] Drug combinations may also facilitate a concomitant reduction in drug doses limiting individual side effects. Wu et al.[318] reported lower rates of PONV after intrathecal morphine administration with use of a combination of dexamethasone 8 mg and droperidol 0.625 mg than with use of dexamethasone 8 mg or droperidol 1.25 mg alone. In a multicenter study, Habib et al.[319] randomized women to one of three groups: placebo, metoclopramide 10 mg plus placebo, or a combination of metoclopramide 10 mg plus ondansetron 4 mg. Spinal anesthesia–induced hypotension was managed prophylactically with a phenylephrine infusion to maintain the systolic blood pressure within 20% of baseline or greater than 90 mm Hg. The combination of metoclopramide and ondansetron reduced IONV and PONV compared with placebo.[319]

Nonpharmacologic techniques. Several studies have investigated the prophylactic use of **acupressure** (using wrist bands with a plastic bead placed bilaterally on the P6 [HG-6] acupoint) for reducing PONV after neuraxial anesthesia for cesarean delivery. A meta-analysis of six studies (649 patients) that assessed the effect of P6 stimulation versus placebo to reduce IONV and PONV revealed inconsistent results, thereby limiting any definitive conclusions regarding the efficacy of this intervention.[320] Based on very limited evidence in patients having cesarean delivery, supplemental oxygen and generous intravenous fluid administration do not appear to reduce IONV or PONV.[321]

Pruritus

Pruritus is a common side effect of neuraxial opioid administration in obstetric patients. In a retrospective review of 4880 patients undergoing cesarean delivery who received epidural morphine 2 to 5 mg, pruritus was reported by 58% of patients.[163] However, a sample of patients who received spinal anesthesia for cesarean delivery ranked pain, nausea, and vomiting as more undesirable than pruritus (see Table 27.1).[15] The incidence and severity of pruritus are likely influenced by the opioid dose, route of administration (more common after intrathecal administration), and method of assessment.[226,322] The incidence of pruritus after intrathecal morphine is as high as 70% to 90%, with approximately 25% to 40% of patients requesting treatment.[163,167,323–326]

Pruritus may manifest in the dermatomal distribution of neuraxial opioid spread as well as nonspecific areas of the head and neck; specific symptoms and severity vary among patients.[327] Opioid-induced histamine release from mast cells does not appear to be the causative mechanism for pruritus after *neuraxial* opioid administration. Plasma opioid and histamine levels are clinically insignificant at the time of symptom presentation (3 to 6 hours after intraspinal morphine administration).[157,173,328] At present, the mechanisms of spinal and epidural opioid–induced pruritus remain unclear. Postulated theories include (1) direct or indirect excitatory effects on central μ-opioid receptors; (2) cephalad migration of the opioid within the CSF to the trigeminal nucleus (which contains the subnucleus caudalis, integrates facial sensory input, and exhibits high opioid receptor density); (3) excitatory effects on dorsal or ventral horn neurons; and (4) other mechanisms (e.g., effects on dopamine-2 [D_2] receptors, prostaglandin system, serotonin 5-HT_3 receptors, and CNS gamma-aminobutyric acid [GABA] and glycine receptors).[328] Pregnant patients may be more susceptible as a result of estrogen interaction with opioid receptors.[329] The incidence of moderate-to-severe pruritus with epidural morphine administered for postcesarean analgesia has been reported to be lower in patients homozygous for the G118G polymorphism in the μ-opioid receptor gene *(OPRM1)* than in patients with the A118G or A118A genotype (incidence 5%, 42%, and 53%, respectively).[330] In a study of 63 women undergoing elective cesarean delivery with spinal anesthesia with morphine 0.1 mg, Pettini et al.[331] reported an incidence of pruritus of 50% in patients homozygous for the G118G polymorphism and 82% in patients with the A118G or A118A genotype.

There is little consensus regarding the prevention and treatment of neuraxial opioid–induced pruritus after cesarean delivery.[332] Further, there are currently no validated or consistent methods for assessing pruritus, which limits the analysis of data from studies investigating the efficacy of antipruritic regimens.

Studies comparing **opioid antagonists** for the treatment of pruritus have demonstrated mixed results. **Nalbuphine** (5 mg) significantly reduced the severity of pruritus after epidural morphine, and fewer patients required additional treatment of persistent pruritus.[325] Smaller doses of nalbuphine (2 to 3 mg) adequately treat moderate-to-severe pruritus after intrathecal morphine administration.[333] Wu et al.[334] found that **butorphanol** 1 mg followed by an infusion of 0.2 mg/h was associated with reduced pruritus compared with a saline-control group in patients who received intrathecal morphine.

Prophylactic treatment with **opioid antagonists** has also been investigated as a method of reducing the incidence of opioid-induced pruritus. Morgan et al.[335] reported that pretreatment with intravenous nalbuphine (20 mg at skin closure) with subsequent postoperative administration (20 mg in divided doses) was ineffective in reducing pruritus in patients receiving epidural morphine. Similarly, pretreatment with subcutaneous **naloxone** (0.4 mg) did not reduce the incidence of pruritus in patients receiving intrathecal fentanyl and morphine for elective cesarean delivery.[336] This is not surprising given the short half-life of naloxone. However, naloxone and nalbuphine administered via patient-controlled bolus doses with a continuous background infusion have been found to reduce the incidence of pruritus after cesarean delivery in patients who received epidural morphine 5 mg.[324] The long-acting oral opioid antagonist **naltrexone** reduced pruritus compared with placebo after cesarean delivery in patients who received epidural or intrathecal morphine.[337,338] Paech et al.[323] compared **methylnaltrexone,** a peripherally acting μ-opioid receptor antagonist developed to antagonize the peripheral side effects of opioids while preserving centrally mediated analgesia, with placebo. Women undergoing elective cesarean delivery under spinal anesthesia with intrathecal morphine 0.1 mg were randomized to receive subcutaneous methylnaltrexone 12 mg or placebo after delivery. The incidence and severity of pruritus were not statistically different between groups, although the study may have been underpowered to identify a small effect. **Pentazocine,** a κ-opioid receptor agonist and partial μ-opioid receptor agonist, may be a useful drug for treating opioid-induced pruritus.[339–341] Hirabayashi et al.[342] randomized women scheduled for cesarean delivery with spinal anesthesia containing fentanyl 10 μg and morphine 0.1 mg to receive pentazocine 15 mg or saline-placebo. Pentazocine reduced the overall incidence of pruritus within the first 24 hours compared with saline.[342]

The effects of neuraxially administered opioid antagonists have also been investigated. Jeon et al.[343] reported less pruritus in patients who received epidural naloxone (1.2 mg over 48 hours) with epidural 0.1% bupivacaine and morphine (6 mg over 48 hours) than in patients in a control group. Similarly, Culebras et al.[274] investigated the effects of three different doses of intrathecal nalbuphine (0.2, 0.8, and 1.6 mg) and found a significantly lower incidence of pruritus in all of the nalbuphine groups compared with a control group that received intrathecal morphine without nalbuphine. However, the duration of analgesia was shorter among patients in the nalbuphine groups.[274] It is not clear whether an optimal dose of μ-opioid receptor antagonists can be found that prevents pruritus without reducing analgesia. These drugs are not approved for administration into the neuraxial canal.

Propofol has been reported to relieve pruritus caused by neuraxial opioids in nonobstetric patients after a single 10-mg bolus dose[344] and after a 10-mg bolus dose followed by a 30 mg/24 h infusion.[345] The mechanism of the antipruritic effect of propofol is unknown, and these results have not been replicated in obstetric patients who received subhypnotic doses of propofol (10 to 20 mg) for treatment of intrathecal morphine–induced pruritus.[346,347] A comparative study demonstrated that intravenous nalbuphine 3 mg is superior to propofol 20 mg for treating pruritus after administration of intrathecal morphine.[348]

Stimulation of 5-HT_3 receptors found in the dorsal horn of the spinal cord and in the nucleus of the spinal tract of the trigeminal nerve in the medulla may occur after subarachnoid opioid administration. A meta-analysis of studies of surgical patients receiving neuraxial opioids concluded that prophylaxis with a **5-HT_3 antagonist** results in a reduced risk for postoperative pruritus compared with placebo (OR, 0.44; 95% CI, 0.29 to 0.68).[349] Intravenous **ondansetron** 4 to 8 mg has been shown to be more effective than placebo for reducing the incidence of postcesarean pruritus after intrathecal administration of morphine 0.15 to 0.2 mg.[350,351] However, other studies that compared ondansetron 8 mg with placebo found no significant reduction in pruritus after intrathecal administration of morphine (0.1 to 0.2 mg) alone[352] or in combination with a lipophilic opioid (sufentanil or fentanyl).[353,354] The lack of antipruritic effect in these studies may be caused by the peak effect of ondansetron occurring sooner (15 minutes after intravenous administration) than that of intrathecal morphine. The antipruritic effects associated with ondansetron may depend on the dose, lipophilicity, and duration of action of the intrathecal opioid.[355] Siddik-Sayyid et al.[352] found no significant differences in the incidence or severity of pruritus among patients who received **granisetron** 3 mg or ondansetron 8 mg or saline. In contrast, Tan et al.[356] observed that the severity of pruritus was reduced at 8 and 24 hours after cesarean delivery in patients who received granisetron 3 mg compared with those who received ondansetron 8 mg.

George et al.[312] reported a meta-analysis of studies of women who received spinal anesthesia with morphine for cesarean delivery; *prophylactic* administration of a 5-HT_3 antagonist did not reduce the risk for pruritus compared with the placebo control group. However, administration of a 5-HT_3 antagonist reduced the severity of pruritus and the need for rescue treatment compared with placebo.

Heterogeneity and small sample sizes in the studies included in this systematic review limited detailed analysis of the efficacy of prophylactic administration of a 5-HT_3 antagonist.

Few studies have assessed the *therapeutic* effect of 5-HT_3 antagonists for managing postcesarean pruritus induced by neuraxial opioids. In one study, ondansetron 4 mg had a high rate of success for the treatment of moderate-to-severe pruritus compared with placebo (80% and 36%, respectively).[357]

Historically, **antihistamines** have been a popular first choice for treatment of pruritus. However, the efficacy of these agents has been questioned in patients receiving neuraxial opioids, as histamine release is not the mechanism of pruritus. Alhashemi et al.[358] demonstrated that diphenhydramine was less effective than nalbuphine (higher itching scores and more treatment failures) after administration of intrathecal morphine 0.2 mg. Yeh et al.[351] found that the incidence of pruritus was comparable among patients receiving diphenhydramine 30 mg and placebo (80% and 85%, respectively); however, both groups had a higher incidence of pruritus than did a group that received ondansetron 0.1 mg/kg (25%). In contrast, Siddik-Sayyid et al.[359] found that the therapeutic success rates for ondansetron 4 mg and diphenhydramine 25 mg were identical (70% for each drug), with similar recurrence rates in successfully treated patients (28% versus 35%, respectively). Differences in study methodology and antihistamine-induced sedation may explain the inconsistent antipruritic effect of diphenhydramine observed in these studies.

Urinary Retention

The mechanisms by which neuraxial opioids affect specific components of micturition (urge sensation, detrusor and sphincter function) are also not fully understood, although spinal and supraspinal sites of action are likely to be involved. Kuipers et al.[360] performed urodynamic studies in healthy male volunteers who received intrathecal sufentanil and morphine. Both opioids caused dose-dependent decreases in detrusor contractility and the urgency to void. Volunteers receiving intrathecal sufentanil had earlier recovery of lower urinary tract function than those receiving intrathecal morphine.[360] Intrathecal local anesthetics (bupivacaine and lidocaine) have also been shown to ablate detrusor contractility and urge sensation until the dermatomal block regresses to S2 to S3, with no partial recovery until this regression has occurred.[361]

Evron et al.[362] performed an observational study investigating the urinary effects of epidural morphine and methadone in 120 women undergoing cesarean delivery. Not surprisingly given the longer duration of action, difficulty in micturition and need for bladder catheterization were greater in the morphine group (58%) compared with the methadone group (3%).[362] A similar study by Liang et al.[363] reported a higher incidence of postcesarean urinary retention and urinary catheterization (22%) among patients receiving epidural morphine compared with other analgesia modalities (PCEA with ropivacaine-fentanyl [7%] and intramuscular meperidine [3%]). In a study of male volunteers, naloxone reversed the impact of neuraxial morphine on urodynamic function.[364]

To avoid impairment of bladder/detrusor function, urinary catheterization should be considered if voiding has not occurred within 6 hours.[365] Risk factors for postcesarean urinary retention include low body mass index, multiparity, emergency cesarean delivery, prolonged operation time, perineal injury, and postoperative analgesia.[366–368] Transient postpartum voiding difficulty is not detrimental to urinary function and does not subsequently lead to voiding difficulties.[367] Reversal with systemic naloxone may be considered in problematic cases.

Neuraxial Nonopioid Analgesic Adjuvants

The addition of neuraxial nonopioid adjuvants to local anesthetic agents may improve the quality of both intraoperative anesthesia and postcesarean analgesia. Nonopioid neuraxial adjuvants have different sites and mechanisms of actions, and interactions between neuraxial opioids and nonopioid adjuvants may be additive or synergistic. Potential advantages of neuraxial drug combinations include a reduction in dose of individual drugs (with subsequent reductions in dose-dependent side effects), in particular a reduction in postoperative opioid requirements and opioid-related side effects.[369]

Alpha$_2$-Adrenergic Receptor Agonists

Alpha$_2$-adrenergic receptor agonists bind to presynaptic and postsynaptic alpha$_2$-adrenergic receptors at peripheral, spinal (dorsal horn), and brainstem sites. Epidural and intrathecal alpha$_2$-adrenergic receptor agonists provide analgesia by activating the descending noradrenergic system.[370,371] This process subsequently leads to norepinephrine release, which in turn modulates pain processing in the dorsal horn by inhibiting the release of substance P and increasing acetylcholine levels to produce analgesia.[372,373] **Clonidine,** an alpha$_2$-adrenergic receptor agonist, provides a more potent analgesic response with fewer side effects when administered neuraxially than systemically. Clonidine also potentiates sensory and motor block when administered with epidural local anesthetics and acts additively or synergistically with intraspinal opioids.[369,373] In combination with an intrathecal local anesthetic, intrathecal clonidine may also prolong the regression of sensory block, improve postoperative analgesia, and decrease intraoperative pain.[374] However, a combination of intrathecal clonidine and local anesthetic may also increase the risk for hypotension in a non–dose-dependent manner.[374] Pregnancy may enhance the analgesic effects of alpha$_2$-adrenergic receptor agonists, thus making them particularly valuable in this setting.[375]

Mendez et al.[376] compared the analgesic efficacy of low-dose epidural clonidine (400-μg bolus) versus high-dose clonidine (800-μg bolus), followed by epidural infusion at 10 or 20 μg/h after cesarean delivery. They observed short-lived, dose-dependent analgesia and sedation, and prolonged motor block, which might lead to delays in the discharge of patients from the postanesthesia care unit. Huntoon et al.[377] reported similar postcesarean analgesia in patients receiving epidural clonidine 400 or 800 μg after epidural bupivacaine anesthesia.

Several studies have investigated epidural clonidine in combination with epidural opioids for optimizing postcesarean analgesia. An isobolographic evaluation of epidural clonidine (in doses ranging from 50 to 400 μg) with fentanyl (15 to 135 μg) demonstrated additivity but not synergism between clonidine and fentanyl in patients recovering from cesarean delivery.[378] However, marked variability in drug response and failure of high doses to produce complete analgesia limited the validity of dose-response and ED_{50} analyses. Capogna et al.[379] observed that the addition of clonidine 75 to 150 μg to epidural morphine 2 mg lengthened the duration of postcesarean analgesia without increasing the incidence of side effects.

A number of studies have evaluated the potential role of intrathecal clonidine for postcesarean analgesia. Ginosar et al.[380] administered intrathecal clonidine (0 to 100 μg) to healthy volunteers to assess the analgesic effect of doses below 100 μg; analgesia to experimental heat pain was detected for doses greater than 25 μg.[380] Van Tuijl et al.[381] assessed postcesarean analgesia in patients who received intrathecal clonidine 75 μg combined with bupivacaine compared with intrathecal bupivacaine alone. Early postoperative analgesia (for 1 to 2 hours) was improved in patients who received clonidine; however, no difference was found in 24-hour morphine consumption between the groups, likely reflecting the short duration of action of a bolus dose of clonidine.

Interaction studies of intrathecal opioids combined with clonidine have investigated the contribution of each drug to analgesia and side effects. Benhamou et al.[382] evaluated postcesarean analgesic outcomes in patients who received hyperbaric bupivacaine alone, or bupivacaine and clonidine 75 μg, or bupivacaine with clonidine and fentanyl 12.5 μg. Patients who received the bupivacaine-clonidine-fentanyl combination reported less intraoperative pain and more prolonged postcesarean analgesia (time to first analgesia request 215 minutes) than those receiving bupivacaine-clonidine and bupivacaine alone (183 and 137 minutes, respectively). However, higher rates of pruritus and sedation were reported for the bupivacaine-clonidine-fentanyl group. Paech et al.[383] performed a six-arm study assessing postcesarean analgesia after intrathecal bupivacaine 12.5 mg with fentanyl 15 μg and one of the following regimens: clonidine 150 μg; morphine 0.1 mg; and morphine 0.1 mg with clonidine 30, 60, 90, or 150 μg. They concluded that the morphine-clonidine regimens provided optimal analgesia with lower pain scores at rest and with coughing in the first 4 hours. The minimum effective intrathecal dose of clonidine was 30 to 60 μg combined with bupivacaine, fentanyl 15 μg, and morphine 0.1 mg. However, an increase in intraoperative sedation was observed in all groups receiving clonidine.

Lavand'homme et al.[384] compared antihyperalgesic effects in patients receiving intrathecal clonidine 150 μg with bupivacaine, clonidine 75 μg with bupivacaine-sufentanil, or bupivacaine-sufentanil. The bupivacaine-clonidine 150-μg group had a smaller area of peri-incisional hyperalgesia and a lower incidence of hyperalgesia compared with the other study groups. However, no between-group differences were observed in postoperative morphine consumption or in pain scores before and after discharge. Carvalho et al.[385] randomized 195 women to receive intrathecal hyperbaric bupivacaine with morphine 0.05 mg, morphine 0.1 mg, or morphine 0.05 mg combined with clonidine 75 μg for surgical anesthesia. Pain intensity at rest or while coughing did not differ among groups.[385] During recovery, the incidences of hypotension, bradycardia, and sedation were similar among groups.

Crespo et al.[386] performed a systematic review of trials comparing intrathecal clonidine as an adjuvant to local anesthetics with or without additional opioids in women undergoing cesarean delivery. They evaluated outcomes related to efficacy of clonidine as an intrathecal adjuvant, including duration of analgesia and motor block. Clonidine prolonged the duration of sensory block by 128 minutes and motor block by 45 minutes while also increasing sedation compared with intrathecal blocks without clonidine.[386] Allen et al.[387] performed a systematic review and meta-analysis evaluating the effect of neuraxial clonidine on 24-hour morphine consumption and time to first analgesic request in women undergoing elective cesarean delivery. Eighteen studies were included in the analysis (12 intrathecal administration, 6 epidural administration). Neuraxial clonidine reduced 24-hour morphine consumption by 7.2 mg and prolonged time to first analgesic request by 135 minutes compared with the control group.[387] Intraoperative hypotension and intraoperative sedation were more frequent with neuraxial clonidine.

In summary, neuraxial clonidine may offer a small improvement in postcesarean analgesia in addition to that provided by neuraxial morphine. Epidural clonidine (150 to 800 μg) may prolong postcesarean analgesia when given in combination with epidural opioids. Intrathecal clonidine (75 to 450 μg) has modest efficacy and a relatively short duration of action. Ongoing concern about the adverse side-effect profile of epidural and intrathecal clonidine—notably sedation and hypotension—limit the neuraxial administration of this agent in most patients undergoing cesarean delivery. Additionally, in the United States, epidural clonidine has a "black box" warning stating that it is not recommended for obstetric, postpartum, or perioperative pain management because of the risk for hypotension and bradycardia that were identified after high doses. In selected cases, the anesthesia provider may conclude that the potential benefits outweigh the risks.

Dexmedetomidine is a highly selective $alpha_2$-adrenergic receptor agonist that provides some analgesic effects mediated at the spinal level. Its systemic administration is widespread in anesthesia and critical care; however, its use in peripheral nerve blocks and neuraxial anesthesia is off-label.[388] In one of the few studies evaluating neuraxial dexmedetomidine, 80 healthy women were randomly assigned to a control group (intrathecal hyperbaric bupivacaine 5 mg and an epidural mixture of 10-mL plain bupivacaine 0.25% and fentanyl 50 μg) or a study group who received the same drugs with the addition of *epidural* dexmedetomidine (0.5 μg/kg).[389] The dexmedetomidine group required less intraoperative and postoperative fentanyl than the control group (4/40 and 18/40,

respectively). There was no difference between the groups in block characteristics or sedation.[389] In the only study of *intrathecal* dexmedetomidine for cesarean anesthesia, Qi et al.[390] compared bupivacaine 10 mg, bupivacaine 10 mg combined with dexmedetomidine 5 μg, and bupivacaine 10 mg combined with morphine 0.1 mg. Sensory blockade was longer in the dexmedetomidine groups than in other groups. Intrathecal dexmedetomidine provided similar analgesia and less pruritus and shivering compared with morphine.[390]

Epinephrine has a direct analgesic effect by activating alpha$_2$-adrenergic receptors and may potentiate local anesthetics by inducing local vasoconstriction through alpha$_1$-adrenergic activation, resulting in slower drug clearance. A number of clinical studies have investigated epinephrine as a spinal or epidural adjunct. Robertson et al.[141] reported that *epidural* epinephrine 25 μg prolonged the duration of analgesia with epidural fentanyl 100 μg but increased the incidence of pruritus. Similar prolongation of analgesia has been observed when epinephrine (5 to 30 μg/mL) was combined with epidural diamorphine or sufentanil; however, the incidence of side effects (including vomiting that required treatment) was also increased.[195,391] In contrast, McMorland et al.[392] did not replicate this finding, although their study was not powered to demonstrate noninferiority. Importantly, studies of the addition of epidural epinephrine (5 μg/mL) to 2% lidocaine or 0.5% bupivacaine have not demonstrated any detrimental effects of epinephrine on umbilical artery blood-flow velocity waveforms, uteroplacental or fetal vascular resistance, fetal myocardial function, or fetal heart rate or neonatal outcomes.[393,394]

The use of *intrathecal* epinephrine as an adjuvant to local anesthetics, with or without opioids, has been evaluated in several studies. The addition of epinephrine 200 μg to hyperbaric spinal bupivacaine improved perioperative analgesia but was associated with a longer duration of residual sensory and motor block.[395] In a separate study, a combined intrathecal regimen of epinephrine 200 μg with morphine 0.2 mg improved intra- and postoperative analgesia compared with intrathecal morphine 0.2 mg alone.[396] Zakowski et al.[397] found earlier and higher peak plasma bupivacaine concentrations with the addition of spinal epinephrine 200 μg to spinal bupivacaine in patients undergoing cesarean delivery. In contrast, plasma levels of morphine were approximately 66% *lower* in the epinephrine group than in the control group.[397] The investigators concluded that the enhanced efficacy of intrathecal bupivacaine combined with morphine and epinephrine was not caused by vasoconstriction alone.

In summary, the use of epidural epinephrine (2.5 to 30 μg/mL) seems to prolong the duration of analgesia with epidural opioids but may increase side effects. The use of intrathecal epinephrine 200 μg does seem to enhance neuraxial opioid analgesia but is associated with prolonged sensory and motor block.

Neostigmine

By interfering with the breakdown of acetylcholine, neostigmine indirectly stimulates spinal nicotinic and muscarinic receptors and the release of nitric oxide. As both nicotinic and muscarinic receptors are important to central and peripheral pain transmission, the resulting analgesia may be caused by central and/or peripheral alterations in pain modulation and transmission. Initial studies of *intrathecal* neostigmine in animals and human volunteers have demonstrated analgesic effects without neurotoxic effects.[398–400] However, despite producing dose-dependent analgesia, intrathecal neostigmine results in nausea that is particularly resistant to traditional antiemetic treatment, and therefore the use of intrathecal neostigmine is generally not recommended.

Kaya et al.[401] assessed the analgesic efficacy of *epidural* neostigmine administration after cesarean delivery. A CSE technique was employed with intrathecal bupivacaine 8 mg and fentanyl 10 μg, and patients subsequently received epidural neostigmine doses of 75, 150, or 300 μg after delivery. The investigators reported modest, short-lived, and dose-independent reductions in postoperative pain in the neostigmine groups.[401] No differences among groups in 24-hour morphine consumption after surgery were observed.

The use of epidural neostigmine is not currently recommended for routine use until additional studies substantiate clinically significant postcesarean analgesic benefits with fewer side effects compared with alternatives. Data regarding the maternal and fetal safety profile of epidural neostigmine are reassuring.[402]

N-Methyl-D-Aspartate Receptor Antagonists

Ketamine. Limited data exist regarding the role of neuraxial ketamine in the provision of postcesarean analgesia. Anesthetic and subanesthetic doses of ketamine have analgesic properties via noncompetitive antagonism of NMDA receptors. In patients undergoing cesarean delivery randomly assigned to receive intrathecal bupivacaine alone or in combination with S(+) ketamine 0.05 mg/kg or fentanyl 25 μg, significantly prolonged and better quality analgesia was observed in the fentanyl group.[403] It is unclear whether the S(+) or R(−) isomers of ketamine have analgesic advantages over the racemate. No published studies have evaluated perioperative epidural ketamine administration in patients undergoing cesarean delivery. At this time neuraxial use cannot be recommended for patients undergoing cesarean delivery because there is a lack of data regarding the safety of neuraxial administration.

Magnesium. Magnesium is a noncompetitive antagonist of the NMDA receptor and may alter pain signaling by preventing central sensitization after nociceptive stimulation.[404] Magnesium blocks NMDA ion channels in a voltage-dependent manner. Studies investigating intrathecal or epidural magnesium have shown variable analgesic effects after cesarean delivery. Sun et al.[405] compared the postcesarean analgesic profile of four different *epidural* solutions administered in the perioperative period. All patients received 0.1% bupivacaine 10 mL with one of the following: morphine 1.5 mg, magnesium 500 mg, morphine 1.5 mg *and* magnesium 500 mg, or placebo. Patients who received magnesium and morphine had lower postoperative pain scores at

rest and with movement, an increased time to first analgesic request, and increased satisfaction at 24 hours after surgery compared with women who received only one drug or placebo. Albrecht et al.[406] reviewed 18 trials (including some trials in women undergoing cesarean delivery) of the efficacy and safety of neuraxial magnesium sulfate for postoperative analgesia. They observed an overall increase in the interval to first analgesic request (mean difference of 40 minutes after intrathecal administration and 110 minutes after epidural administration). However, only four trials assessed neurologic complications, and the authors concluded that there were not enough patients ($n = 140$) to evaluate the risk for neurologic complications.

Intrathecal magnesium sulfate 50 mg prolonged the duration of spinal anesthesia and improved postoperative analgesia in patients undergoing nonobstetric surgery with bupivacaine and fentanyl spinal anesthesia.[407,408] In women undergoing cesarean delivery, no difference in the first request for postcesarean analgesia was found among patients who were randomized to receive intrathecal magnesium sulfate 50 mg compared with placebo (median time, 100 minutes versus 105 minutes, respectively), and patients who received intrathecal fentanyl 25 μg had a longer time to first request for analgesia (132 minutes) compared with the magnesium group.[409]

In summary, neuraxial administration of magnesium may have a favorable analgesic effect in patients after cesarean delivery. However, more research, including dose-response studies and comparison with systemic administration, are needed to more formally assess the analgesic efficacy of epidural and intrathecal magnesium.

Experimental Agents

In the future, newer agents and adjuvants may enhance postoperative pain management strategies in patients receiving neuraxial anesthesia for cesarean delivery. **Adenosine** (and adenosine analogues) have been proposed to have antinociceptive activity related to activation of spinal adenosine A_1 receptors.[410] However, studies have not demonstrated improved analgesia with intrathecal adenosine administration in patients undergoing hysterectomy[411,412] or for labor analgesia.[413]

A direct relationship may exist between central potassium channel activity and antinociception. Several animal studies have investigated **potassium channel activators (nicorandil, sildenafil)** administered by the intrathecal[414] or epidural[415] route. Neuraxial administration of these drugs has not been studied in humans.

A meta-analysis of studies that assessed the clinical benefit and side effects of intrathecal **midazolam** in obstetric and nonobstetric patients suggested a favorable pharmacologic profile.[416] Intrathecal midazolam was associated with improved analgesia and a reduced risk for PONV. After cesarean delivery, patients who received intrathecal midazolam 2 mg (without neuraxial opioids) had prolonged postoperative analgesia, reduced requirement for rescue analgesic, and lower pain scores for 6 hours after surgery compared with patients who received either intrathecal midazolam 1 mg or no midazolam.[417] Dodawad et al.[418] randomly assigned 60 women with pregnancy-induced hypertension undergoing cesarean delivery to receive intrathecal bupivacaine 10 mg (control group) or bupivacaine combined with midazolam 2 mg (study group). Postoperative analgesia was longer in the midazolam group than in the control group (202 minutes and 358 minutes, respectively). It is unknown whether intrathecal midazolam has any benefit compared with intrathecal morphine or in addition to morphine.

Several neuraxially administered drugs have been shown to produce antinociceptive effects by altering calcium channel conductance in the spinal cord. Intrathecal **gabapentin** reduced incision-induced allodynia in rats,[419,420] and epidural **verapamil** lowered postoperative opioid consumption after lower abdominal surgery.[421] **Ziconotide,** a neuronal N-type-selective voltage-sensitive calcium entry–blocking agent, has been shown to have analgesic effects after intrathecal administration in chronic pain patients.[422]

Before recommendations can be made about the potential use of new adjunct agents, neurotoxicity studies are necessary to ensure these agents' safety for neuraxial administration. In addition, studies assessing analgesic efficacy, side effects, and toxicity must demonstrate that these agents result in significant improvement over the neuraxial local anesthetic and opioid regimens currently used in clinical practice.

NON-NEURAXIAL REGIONAL ANALGESIC TECHNIQUES

Abdominal Fascial Sheath Blocks

The transversus abdominis plane (TAP) block and quadratus lumborum block (QLB) are regional anesthetic techniques in which local anesthetic is injected between fascial sheaths of the abdominal musculature. In clinical practice, the blocks are usually performed using ultrasonography to verify correct needle position and site of injection. In the TAP block, infiltration is between the internal oblique and the transversus abdominis muscle layers (Fig. 27.9), and in the QLB (Fig. 27.10), infiltration is adjacent to the anterolateral aspect of the quadratus lumborum muscle. Both techniques block the plexus of nerves supplying the anterior abdominal wall. Some have suggested the possibility that the QLB may have greater efficacy than the TAP block because of spread of the local anesthetic solution beyond the muscle fascia into an interfascial plane close to the paravertebral space.[423] Chin et al.[424] provide a detailed review of the anatomy of abdominal wall blocks.

Three systematic reviews and meta-analyses of TAP blocks for postcesarean analgesia have been completed. Mishriky et al.[107] reviewed the efficacy of TAP blocks after cesarean delivery with primary outcomes of pain intensity scores and opioid consumption at 24 hours. Nine studies compared TAP blocks with inactive controls, seven of them done in combination with spinal anesthesia for cesarean delivery. In women who did not receive intrathecal morphine, TAP blocks

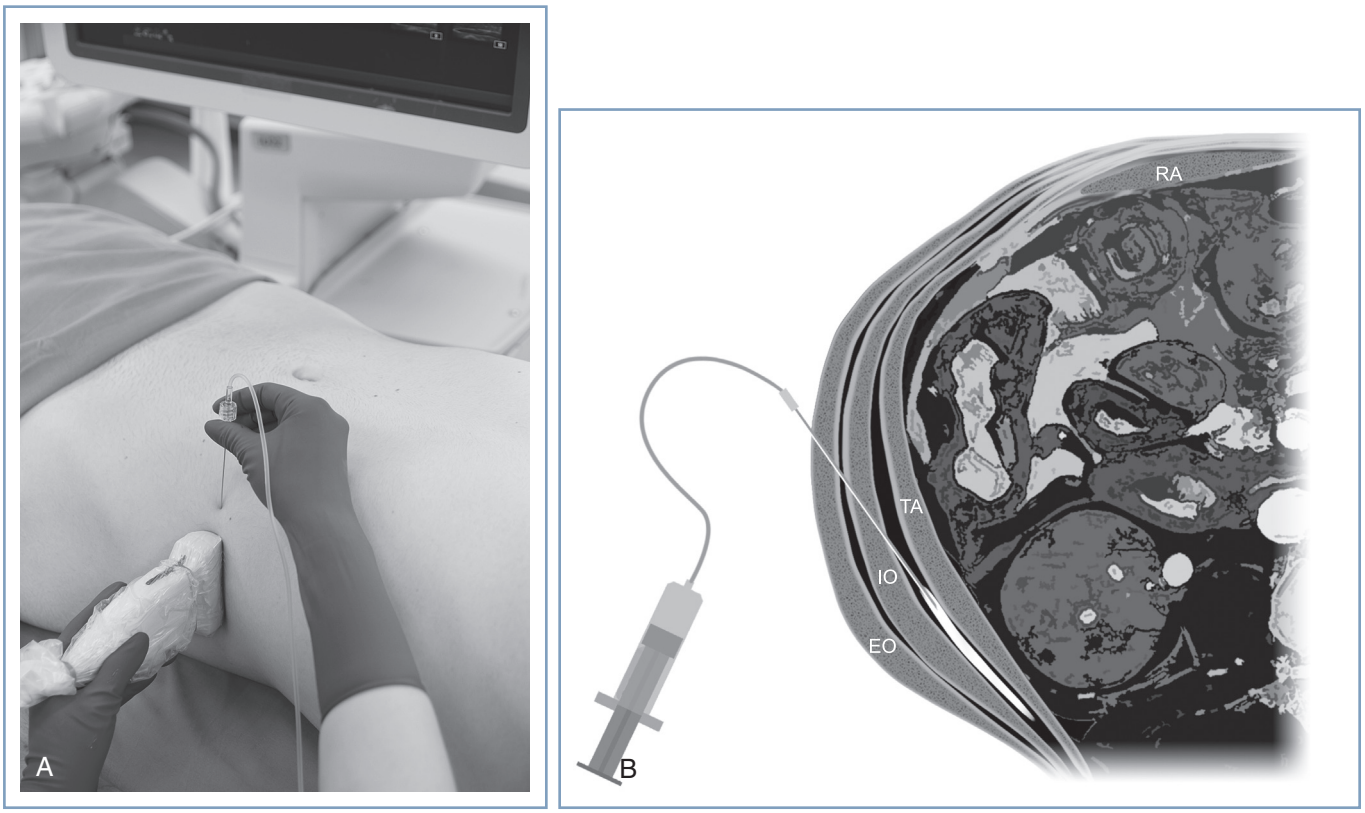

Fig. 27.9 Mid-axillary transversus abdominis plane (TAP) block. (A) With the patient in the supine position, the transducer is placed near the mid-axillary line between the costal margin and pelvic brim for a transverse imaging plane. (B) Line drawing of a transverse section through the abdominal wall with local anesthetic injected in the transversus abdominis plane. *EO,* Exernal oblique; *IO,* internal oblique; *RA,* rectus abdominis; *TA,* transversus abdominis. The transversus abdominis plane lies between the internal oblique and transversus abdominis muscles. Visualization of an elliptical distribution of the local anesthetic with well-defined margins provides evidence for the proper injection of the solution into the plane between the internal oblique and transversus abdominis muscles. (**A,** From Gray AT. *Atlas of Ultrasound-Guided Regional Anesthesia.* 2nd ed. Philadelphia, PA: Elsevier; 2013.)

reduced opioid consumption (mean difference, –20.2 mg morphine equivalents [95% CI, –33.7 to –6.8]) and opioid-related side effects.[107] In patients who received intrathecal morphine, there was no difference between TAP blocks and inactive controls in pain scores at 24 hours, and the impact on opioid consumption was inconclusive. Three studies directly compared TAP blocks with intrathecal morphine, two with 0.1 mg[425,426] and one with 0.2 mg.[427] Intrathecal morphine provided lower pain scores on movement (mean difference, 0.98 [95% CI, 0.06 to 1.91]) and reduced 24-hour opioid consumption (mean difference, –8.4 mg morphine equivalents [95% CI, 1.7 to 15.1]). A limitation of the meta-analysis was the significant heterogeneity among studies. Champaneria et al.[428] completed a subsequent meta-analysis with additional studies; they confirmed the conclusion that TAP blocks are effective but do not confer additional analgesia when intrathecal morphine is included as part of a multimodal analgesia regimen.

The QLB is an abdominal fascial block similar to the TAP block, but with potential for more diffuse analgesia because the point of injection is more posterior. QLB 1, 2, and 3 are all described based on location of local anesthetic administration relative to the quadratum lumborum muscle; consensus on the best approach is lacking.[424] Local anesthetic is infiltrated into the space between the quadratus lumborum muscle and the medial layer of the thoracolumbar fascia[429]; the solution may spread to the paravertebral space. Blanco et al.[430] reported a randomized placebo-controlled trial of QLB after cesarean delivery; 25 women who did not receive neuraxial morphine received a QLB with 0.125% bupivacaine 0.2 mL/kg, and outcomes were compared with 25 women who received a placebo block with saline. Patients in the QLB group used less morphine at 6 and 12 hours postoperatively; the difference was not significant at 24 hours (median dose, 11 mg [IQR 5 to 18] and 19 mg [IQR 11 to 36], respectively; $P = .11$).[430] Similarly, Blanco et al.[423] compared the QLB and the TAP block in women scheduled for elective cesarean delivery under spinal anesthesia with bupivacaine and fentanyl. Women in the QLB group used less morphine than those in the TAP block group with no difference in pain scores between groups. Future research will likely shed light on whether the QLB adds benefit to current multimodal analgesia practices and whether the analgesia it provides is superior to that of intrathecal morphine after cesarean delivery.

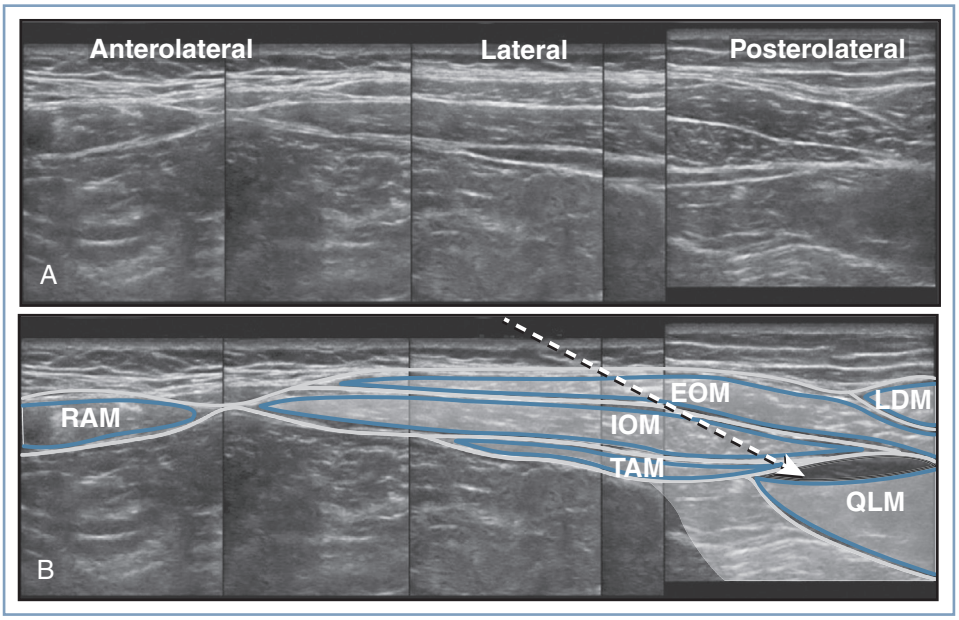

Fig. 27.10 Ultrasonographic image of the quadratus lumborum block-1 (QLB-1). (A) With the patient in the supine position, the three muscle layers of the abdomen and the quadratus lumborum muscle are visualized with a high-frequency linear probe. (B) The outlines the abdominal fascial planes and the infiltration site for the QLB-1 between the quadratus lumborum muscle and the medial layer of the thoracolumbar fascia are clearly outlined. The *broken arrow* shows the needle path and point of injection. *EOM,* External oblique muscle; *IOM,* internal oblique muscle; *LDM,* latissimus dorsi muscle; *QLM,* quadratus lumborum muscle; *RAM,* rectus abdominus muscle; *TAM,* transversus abdominus muscle. (Modified from Murouchi T, Iwasaki S, Yamakage M. Quadratus lumborum block: analgesic effects and chronological ropivacaine concentrations after laparoscopic surgery. *Reg Anesth Pain Med.* 2016;41:146–150.)

Current data support the conclusion that abdominal fascial sheath blocks may represent a reasonable alternative for patients who are unable to receive neuraxial morphine, and they may serve as a rescue technique in special cases.[107,428,431] However, they are not superior to neuraxial opioid analgesia–based multimodal techniques, which remain the gold standard for postcesarean analgesia. Additionally, because analgesia from TAP blocks may be comparable to that provided by simple wound infiltration or a continuous wound infiltration catheter (see later discussion), the value of TAP blocks in postcesarean analgesia remains unclear.

Complications of the blocks are infrequent and include local anesthetic systemic toxicity (LAST) from systemic absorption of local anesthetic or intravascular injection, and bowel perforation. The described potential benefit of the QLB, spread to the paravertebral space, may also result in unintended motor blockade. Wikner[432] described a patient with hip flexion and knee extension weakness leading to unplanned overnight admission following QLB with 20 mL of 0.25% levobupivacaine for a laparoscopic gynecologic procedure. Presumably, paravertebral spread to the lumbar spinal nerves led to weakness of the psoas and quadriceps muscles.

The relationships between local anesthetic dose, volume, concentration, and response have not been well studied, and consensus on the optimal volume and concentration of local anesthetic for single-shot abdominal fascial plane blocks is lacking. Griffiths et al.[433] performed bilateral TAP blocks with a total ropivacaine dose of 2.5 mg/kg (diluted with 0.9% saline to a total volume of 40 mL) in women who had spinal anesthesia for elective cesarean delivery (this dose corresponds to 20 mL of 0.5% ropivacaine on each side for an 80-kg patient). The mean (± SD) peak plasma ropivacaine concentration 30 minutes after injection was 1.82 ± 0.69 μg/mL. Although this concentration is below the reported threshold for LAST (2.2 μg/mL), 12 of 30 patients had peak concentration measurements above this threshold (maximum, 3.76 μg/mL), and 3 patients had symptoms of mild LAST (perioral tingling, metallic taste).[433] Similarly, Trabelsi et al.[434] demonstrated that bilateral TAP blocks with bupivacaine 100 mg (total dose) led to plasma concentrations above the reported toxic threshold in 3 of 17 women; plasma bupivacaine concentration above the threshold value persisted for as long as 90 minutes. The addition of epinephrine to the local anesthetic solution decreases local anesthetic peak plasma concentration.[435] Clinically significant LAST (seizures) has been reported following TAP block in obstetric patients.[436–438]

The concentration of local anesthetic (ropivacaine, bupivacaine, levobupivacaine) has ranged from 0.125% to 0.5% for QLB and TAP blocks. A 2018 meta-analysis comparing high (greater than 50 mg) versus low doses (less than or equal to 50-mg bupivacaine equivalents per side) for TAP block in women undergoing cesarean delivery found no difference in opioid consumption, time to first analgesia, pain scores, or satisfaction between doses.[439] Given current reports, we suggest that a local anesthetic dose less than 2.5 mg/kg should be used and that patients should be observed for LAST for at least 30 minutes after these blocks are performed.[440]

Wound Infusion Catheters

Wound infusion of local anesthetic provides effective analgesia after cesarean delivery. However, whether wound infusion provides additional analgesia beyond that provided by neuraxial morphine is not clear. In a study comparing pain control provided by wound infusion or epidural levobupivacaine, the epidural group had less pain in the first 4 hours, but pain control did not differ between groups thereafter.[441] There was no difference between groups in opioid consumption.[441] In another study comparing intrathecal morphine analgesia and wound infusion with ropivacaine or saline, more oxycodone was required in the ropivacaine wound infusion group than in the intrathecal morphine group during the first 24 hours (48 mg versus 26 mg; $P = .004$); there was no difference in oxycodone use between the ropivacaine wound infusion and saline-control groups.[442] Carvalho et al.[443] compared wound infusion with bupivacaine alone to bupivacaine combined with ketorolac in patients who had received intrathecal morphine. The addition of ketorolac was associated with a decrease in pain scores and opioid consumption, and lower concentrations of inflammatory mediators were collected from the wound.[443] Lalmand et al.[444] randomly allocated patients undergoing elective cesarean delivery into three groups: control, intrathecal morphine, and wound catheter infusion. All patients received spinal anesthesia with bupivacaine and sufentanil, and a multiorifice catheter was inserted into the wound. The control group received saline intrathecally and through the catheter, the morphine group received intrathecal morphine 0.1 mg and saline infusion through the wound catheter, and the catheter group received intrathecal saline and 0.2% ropivacaine infused through the catheter (15-mL bolus followed by a 10-mL/h infusion). Intrathecal morphine and 0.2% ropivacaine wound infusion increased the time to the first oral morphine request and reduced morphine consumption compared with placebo. The wound infusion was not superior to intrathecal morphine 0.1 mg for analgesia and had a similar side-effect profile.[444]

Some of the differences in outcomes among these studies may be because of differences in catheter-insertion technique, local anesthetic concentration, and rate of infusion. Taken together, current evidence does not support the superiority of local anesthetic wound infusion over neuraxial opioid administration, although there may be additive benefit in some circumstances.

Continuous wound infusion below the fascia has been shown to be more effective in reducing postcesarean morphine consumption compared with infusion above the fascia.[445] Klasen et al.[446] evaluated a multimodal analgesic regimen for cesarean delivery and found no difference between a TAP block and continuous subfascial wound infiltration. Although some centers use wound-infusion catheters, the additional cost of the pump and some minor inconveniences, such as wound leakage, may have discouraged widespread use.

Ilioinguinal-Iliohypogastric Block

Ilioinguinal-iliohypogastric nerve block is useful for postoperative analgesia after lower abdominal surgery. Similar to a TAP block, the block can be performed with ultrasonographic guidance. Evidence is inconsistent as to whether ilioinguinal-iliohypogastric blocks improve analgesia provided by neuraxial morphine.[447,448] In a study in women who did not receive neuraxial morphine, women who received multilevel ilioinguinal-iliohypogastric blocks used less systemic opioid, although no difference in opioid-related side effects was observed.[449]

Subcutaneous Infiltration of Local Anesthetics

Subcutaneous local wound infiltration is a relatively simple component of multimodal postoperative analgesia. In a study of patients who did not receive neuraxial morphine for postcesarean analgesia, infiltration of 0.25% bupivacaine with epinephrine (40 mL) before wound closure was associated with decreased opioid requirements in the first 12 hours compared with saline placebo.[450] In the absence of intrathecal morphine, wound infiltration may confer similar analgesia to bilateral TAP blocks following cesarean delivery with spinal anesthesia.[451,452] Simavli et al.[453] randomized patients who had general anesthesia for cesarean delivery to receive bupivacaine-soaked absorbable gelatin sponges or placebo, placed in the wound. Pain scores were lower in the sponge group compared with the control group, and fewer patients required rescue opioid. Adesope et al.[454] conducted a systematic review of randomized trials to assess the efficacy of local anesthetic wound infiltration in women undergoing cesarean delivery. Wound infiltration reduced opioid consumption at 24 hours (morphine equivalent −9.7 mg) but had no clinical effect on pain scores and did not reduce opioid-related side effects.[454]

KEY POINTS

- Cesarean deliveries account for nearly one-third of all deliveries in the United States; therefore, strategies for reducing adverse postcesarean maternal outcomes, including postoperative pain, have important clinical and public health implications.
- Effective postoperative analgesia confers many physiologic and psychological benefits and may improve maternal and neonatal outcomes after cesarean delivery.
- Optimal postcesarean analgesia consists of a multidisciplinary approach that should involve physicians, nurses, pharmacists, and other health care providers.
- Multimodal techniques provide efficient postcesarean analgesia by acting on different pain pathways to maximize analgesia while limiting side effects.
- Neuraxial morphine administration currently represents the "gold standard" for providing effective postcesarean

analgesia and is the most important component of multimodal analgesia.
- Morphine has the longest duration of action among available neuraxial opioids, and neuraxial administration of opioids provides better postoperative pain relief than systemic administration.
- In clinical practice, single-dose epidural (2 to 4 mg) or intrathecal (0.075 to 0.2 mg) morphine administration is most commonly administered for postcesarean analgesia. Higher doses may increase opioid-related side effects without improving analgesia.
- Nonopioid neuraxial adjuncts (e.g., alpha$_2$-adrenergic receptor agonists, anticholinesterases) may be considered as alternatives to, or combined with, neuraxial opioids. However, these adjuncts are associated with modest analgesic benefits, and the risk for spinal neurotoxicity associated with many of these drugs remains to be determined.
- Opioids are the most common systemic medications administered for postcesarean analgesia. Adverse effects associated with opioids, which often limit their use, include respiratory depression, sedation, constipation, nausea and vomiting, urinary retention, and pruritus.
- Oral analgesic adjuvants (acetaminophen, NSAIDs) should be prescribed at a fixed interval, rather than on patient request.
- Abdominal fascial sheath blocks may represent a reasonable alternative for patients who are unable to receive neuraxial morphine, or they may be used as a rescue technique in selected cases.
- Local wound instillation may be considered in addition to neuraxial morphine, acetaminophen, and NSAIDs to provide further multimodal analgesia.

Aspiration: Risk, Prophylaxis, and Treatment

Michaela K. Farber, MD, MS

CHAPTER OUTLINE

HISTORY

In 1848, Sir James Simpson first suggested aspiration as a cause of death during anesthesia. Hannah Greener, a 15-year-old given chloroform for a toenail extraction, became cyanotic and "sputtered" during the anesthetic. A "rattling in her throat" then developed, and she soon died. Her physician administered water and brandy by mouth. Simpson[1] contended that it was the aspiration of water and brandy, and not the adverse effects from the chloroform, that caused her death. In 1940, Hall published a report of 15 cases of aspiration, 14 of which occurred in mothers receiving inhalation anesthesia for a vaginal or cesarean delivery.[2] Among the 14 obstetric cases, 5 mothers died.

Subsequently, Curtis Mendelson, in a landmark paper, reported a series of animal experiments that clearly described the clinical course and pathology of pulmonary acid aspiration.[3] In the same paper, Mendelson audited 44,016 deliveries at the New York Lying-In Hospital between 1932 and 1945. He identified 66 (0.15%) cases of aspiration, of which the aspirated material was recorded in 45 cases; 40 mothers aspirated liquid, and 5 aspirated solid food. Importantly, no mothers died from aspirated liquid, but 2 mothers died from asphyxiation caused by the aspiration of solid food. At this time general anesthesia usually involved the inhalation of ether, often as Mendelson observed, by "a new and inexperienced intern." Mendelson therefore advocated (1) the withholding of food during labor, (2) the greater use of regional anesthesia, (3) the administration of antacids, (4) the emptying of the stomach before administration of general anesthesia, and (5) the competent administration of general anesthesia. This advice became the foundation of obstetric anesthesia practice during subsequent decades.

INCIDENCE, MORBIDITY, AND MORTALITY

Maternal mortality from pulmonary aspiration of gastric contents has declined to almost negligible levels in the past 3 decades (Fig. 28.1).[4,5] This decline can probably be attributed to the following factors: (1) the greater use of neuraxial anesthesia; (2) the use of antacids, histamine-2 (H_2) receptor antagonists, and/or proton-pump inhibitors; (3) the use of rapid-sequence induction of general anesthesia; (4) an improvement in the training of anesthesia providers; and (5) the establishment and enforcement of *nil per os* (NPO) policies. Arguably, the common use of neuraxial analgesic/anesthetic techniques, both during labor and for cesarean delivery, is the single most important factor in this

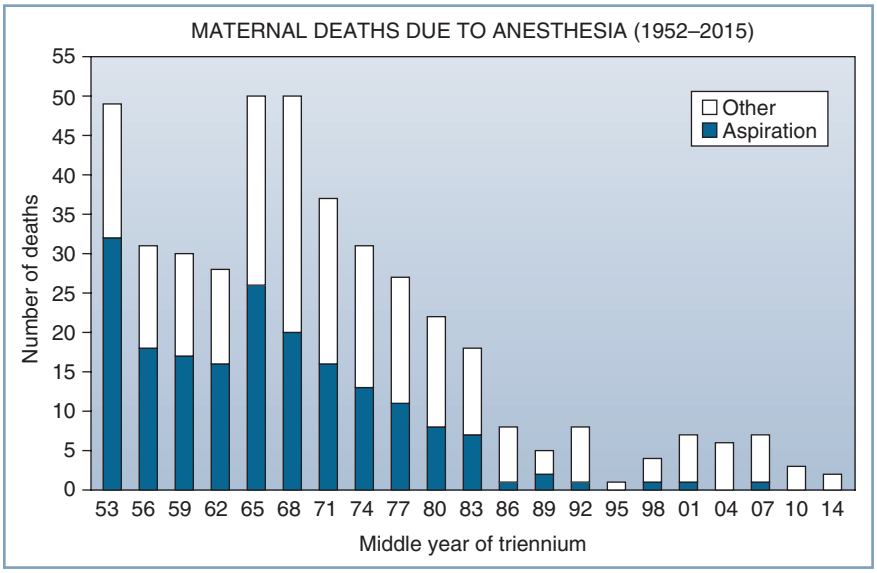

Fig. 28.1 Maternal mortality from anesthesia and pulmonary aspiration in the United Kingdom, 1952–2015 (each year on the *y*-axis represents the middle year of triennial data). remarkable decline in maternal mortality from pulmonary aspiration.

The reported incidence of aspiration pneumonitis depends on the criteria used for making the diagnosis. The relative risk for aspiration in pregnant versus nonpregnant women can best be estimated from comparisons within single-study populations. Olsson et al.[6] reported an overall incidence of aspiration of 1 in 2131 in the general population undergoing anesthesia and 1 in 661 in women undergoing cesarean delivery (i.e., a threefold higher aspiration risk). In two other surveys related to aspiration (one a retrospective review of 172,334 consecutive patients undergoing general anesthesia and the other a review of 133 cases of aspiration from the Australian Anaesthetic Incident Monitoring Study [AIMS]), there were no cases of pulmonary aspiration in women undergoing either elective or emergency cesarean delivery.[7,8] However, in the latter two studies, emergency surgery was a significant predisposing factor for aspiration; this finding may be relevant for the practice of obstetric anesthesia, given that many obstetric surgical procedures are performed on an urgent or emergency basis. The AIMS study also implicated obesity as a significant risk factor for aspiration.

Morbidity and mortality associated with aspiration vary according to (1) the physical status of the patient, (2) the type and volume of aspirate, (3) the therapy administered, and (4) the criteria used for making the diagnosis. Since 1952, organizations in the United Kingdom have published detailed triennial reports on all maternal deaths. Data from these reports, now administered by the body *Mothers and Babies—Reducing Risk through Audits and Confidential Enquiries across the UK* (MBRRACE-UK), indicate that death from pulmonary aspiration in obstetrics is vanishingly rare (see Fig. 28.1).[4,5] In the MBRRACE-UK reports from 2009 to 2015, there were no reported maternal deaths from aspiration. Prior reports from 1994 to 2008 identified three maternal deaths from aspiration[9]; one was an obese parturient, the second was a mother anesthetized 3 days after delivery, and the third was a woman with a placenta previa who required an emergency cesarean delivery after eating a full meal and aspirated on emergence from general anesthesia. Although the number of general anesthetics administered to parturients during this 20-year period (1994 to 2014) is not known, there were approximately 13.8 million deliveries, indicating that the mortality rate from aspiration was less than 1 in 4.6 million deliveries.

Data on pulmonary aspiration in obstetrics in the United States are less comprehensive. The Serious Complication Registry (SCORE) from the Society for Obstetric Anesthesia and Perinatology review of 307,000 deliveries from 30 U.S. centers between 2004 and 2009 reported a failed tracheal intubation rate of 1 in 533, but no related cases of pulmonary aspiration.[10] Data from the U.S. Centers for Disease Control and Prevention's Pregnancy Mortality Surveillance System suggest that before 1990, aspiration was the most common cause of anesthesia-related maternal death in the United States. It was calculated that at that time there were 17 deaths related to general anesthesia for every 1 death related to regional anesthesia, although it is not clear from these data what proportion of deaths are attributable to aspiration.[11] By the early 1990s, this ratio had improved to 6 to 1. By 2002, death rates for both general and regional anesthesia were similar, likely due in part to a decrease in the risk for aspiration in cases in which general anesthesia was employed.[12] However, mortality statistics are generally a poor predictor of maternal morbidity; several studies have indicated that perioperative aspiration is associated with important morbidity in obstetric patients[13–15]; thus all possible measures must be taken to prevent pulmonary aspiration in obstetric patients.

GASTROESOPHAGEAL ANATOMY AND PHYSIOLOGY

Esophagus

In adults, the esophagus is approximately 25 cm long and the esophagogastric junction is approximately 40 cm from

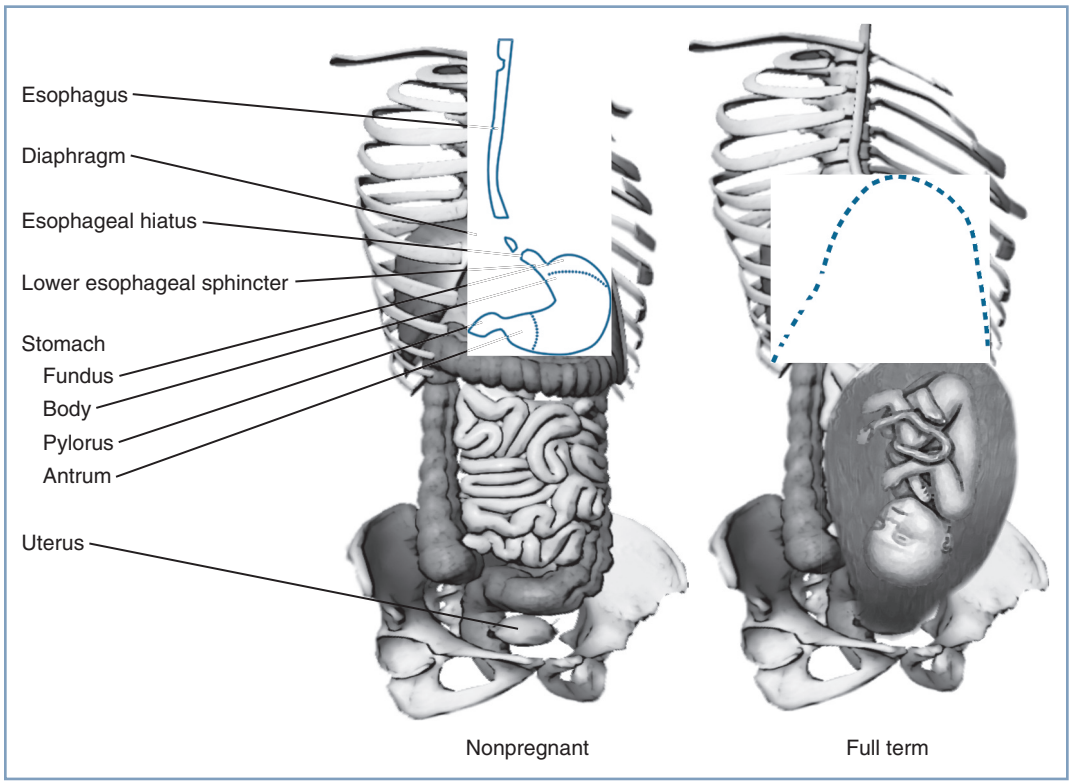

Fig. 28.2 The stomach and its relationship to the diaphragm in nonpregnancy *(left)* and pregnancy *(right)*. The stomach consists of a fundus, body, antrum, and pylorus. The function of the lower esophageal sphincter depends on the chronic contraction of circular muscle fibers, the wrapping of the esophagus by the crus of the diaphragm at the esophageal hiatus, and the length of the esophagus exposed to intra-abdominal pressure. The gravid uterus may encroach on the stomach and alter the effectiveness of the lower esophageal sphincter. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

the incisor teeth. In humans, the proximal one-third of the esophagus is composed of striated muscle, but the distal end contains only smooth muscle. Muscular sphincters at both ends are normally closed. The cricopharyngeal or upper esophageal sphincter prevents the entry of air into the esophagus during respiration, and the gastroesophageal or lower esophageal sphincter prevents the reflux of gastric contents. The lower esophageal sphincter is characterized anatomically and manometrically as a 3-cm zone of specialized muscle that maintains tonic activity. The end-expiratory pressure in the sphincter is 8 to 20 mm Hg above the end-expiratory gastric pressure. The lower esophageal sphincter is kept in place by the phrenoesophageal ligament, which inserts into the esophagus approximately 3 cm above the diaphragmatic opening (Fig. 28.2). The lower esophageal sphincter is not always closed; transient relaxations occur that account for the gastroesophageal reflux that healthy subjects experience.

Gastrointestinal Motility

Differences in fasting and fed patterns of gut motility are firmly established. During fasting, the main component of peristalsis is the migrating motor complex (MMC).[16] Each MMC cycle lasts 90 to 120 minutes and comprises four phases: Phase I has little or no electrical spike activity and thus no measurable contractions; phase II has intermittent spike activity; phase III has spikes of large amplitude and is associated with strong contractile activity; and phase IV is a brief period of intermittent activity leading back to phase I. The MMC first appears in the lower esophageal sphincter and stomach, followed by the duodenum, and finally the terminal ileum, at which time a new cycle begins in the lower esophageal sphincter and stomach. The phase of the MMC at the time of administration of certain drugs can affect absorption and thereby the onset of therapeutic effect.[17] Eating abolishes the MMC and induces a pattern of intermittent spike activity that appears similar to that in phase II. The duration of the fed pattern is determined both by the calorie content and the type of nutrients in the meal.

The stomach, through the processes of receptive relaxation and gastric accommodation, can accept 1.0 to 1.5 L of food before intragastric pressure begins to increase. The contraction waves that propel food into the small intestine begin in the antrum. The pylorus closes midway through the contraction wave, allowing some fluid to exit into the duodenum but causing the remaining fluid to move retrograde toward the body of the stomach.[18] The jet of fluid that exits the pylorus contains primarily liquid and fine particles. Large particles that lag behind are caught in the retrograde flow of fluid, which assists in their disintegration. Therefore, the manner by which individual components of a meal pass through the

stomach depends on the particle size and the viscosity of the suspension. Small particles and fluids exit the stomach faster than larger particles.[18] The outlet of the stomach—the pylorus—limits outflow by means of both its chronic tone and its anatomic position. The pylorus is higher than the most dependent portion of the stomach in both the supine and standing positions.[18]

Gastric Secretion

In one day, the stomach produces as much as 1500 mL of highly acidic fluid containing the proteolytic enzyme pepsin.[19] Normal individuals can produce a peak acid output of 38 mmol/h.[20] Acid is secreted at a low basal rate of approximately 10% of maximal output, even when the stomach is empty.[20] There is diurnal variation in this basal rate of gastric acid secretion, with the lowest and highest outputs occurring in the morning and evening, respectively.

The stomach lining has two types of glands: pyloric and oxyntic. The **pyloric glands** contain chief cells, which secrete pepsinogen, the precursor for pepsin. The **oxyntic glands** contain the oxyntic cells, which secrete hydrochloric acid. Water molecules and carbon dioxide in the oxyntic cells combine to form carbonic acid, which dissociates into hydrogen ions and bicarbonate. The bicarbonate leaves the cell for the bloodstream, and the hydrogen ions are actively exchanged for potassium ions in the canaliculi connecting with the lumen of the oxyntic gland. The secretions of the oxyntic cell can contain a hydrochloric acid concentration as great as 160 mmol/L (pH 0.8).[19] **Proton-pump inhibitors (PPIs)** block the hydrogen ion pump on the canaliculi to decrease acid production.[21]

The pylorus contains G cells, which secrete **gastrin** into the bloodstream when stimulated by the vagus nerve, stomach distention, tactile stimuli, or chemical stimuli (e.g., amino acids, certain peptides). Gastrin binds to gastrin receptors on the oxyntic cell to stimulate the secretion of hydrochloric acid. **Acetylcholine** binds to muscarinic (M_1) receptors on the oxyntic cell to cause an increase in intracellular calcium ion concentration, which results in hydrochloric acid secretion. **Histamine** potentiates the effects of both acetylcholine and gastrin by combining with H_2 receptors on the oxyntic cell to increase the intracellular cyclic adenosine monophosphate concentration, leading to a dramatic increase in the production of acid.[19] **H_2-receptor antagonists** (e.g., ranitidine, famotidine) prevent histamine's potentiation of acid production (Fig. 28.3).

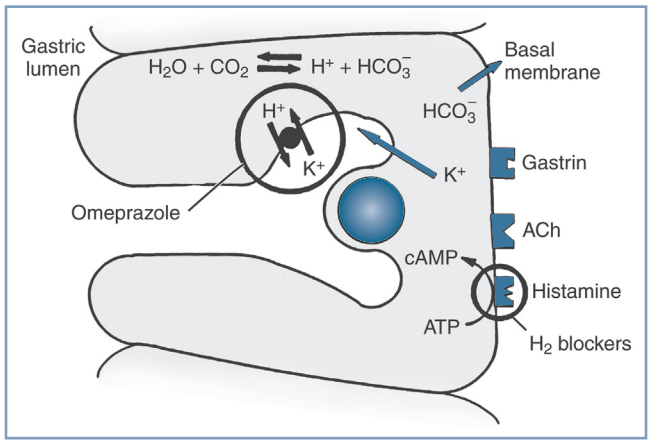

Fig. 28.3 The oxyntic cell produces hydrogen ions that are secreted into the gastric lumen and bicarbonate ions that are secreted into the bloodstream. H_2-receptor antagonists (e.g., ranitidine, famotidine) and proton-pump inhibitors (e.g., omeprazole) act on the oxyntic cell to reduce gastric acid secretion. H_2-receptor antagonists block the histamine receptor on the basal membrane to decrease hydrogen ion production in the oxyntic cell. Omeprazole blocks the active transport of the hydrogen ions into the gastric lumen. *ACh,* acetylcholine; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; CO_2, carbon dioxide; H^+, hydrogen ion; HCO_3^-, bicarbonate; H_2O, water; K^+, potassium.

Ingestion of Food

When a meal is eaten, the mechanisms that control the secretion of gastric juice and the motility and emptying of the stomach interact in a complex manner to coordinate the functions of the stomach. The response to eating is divided into three phases: cephalic, gastric, and intestinal. Chewing, tasting, and smelling cause an increase in the vagal stimulation of the stomach, which in turn increases gastric acid production. This represents the **cephalic phase** of digestion.[19] In this phase, gastric acid output increases to approximately 55% of peak output.[22] The **gastric phase** begins with the release of gastrin. Gastric acid secretion depends on antral distention, vagal activity, gastrin concentration, and the composition of the meal.[22,23] Gastric acid secretion during a mixed-composition meal increases to approximately 80% of peak acid output.[20] The **intestinal phase** begins with the movement of food into the small intestine and is largely inhibitory. Hormones (e.g., gastrin, cholecystokinin, secretin) and an enterogastric reflex further modulate gastric acid secretion and motility depending on the composition and volume of the food in the duodenum.[19,24] This inhibition of gastric emptying by food in the duodenum enables the duodenal contents to be processed before more material is delivered from the stomach.

After the ingestion of a meal, gastric emptying depends on (1) the premeal volume, (2) the volume ingested, (3) the composition of the meal, (4) the size of the solids, (5) the amount of gastric secretion, (6) the physical characteristics of the stomach contents entering the duodenum, and (7) patient position.[24–26] A mixture of liquids and solids passes through the stomach much more slowly than liquids alone. Gastric emptying is slowed by high lipid content, high caloric load, and large particle size.[27,28] Thus, predicting an exact time for the passage of liquids and solids through the stomach is very difficult. For non-nutrient liquids (e.g., normal saline), the gastric volume decreases exponentially with respect to time.[26] In one study, 90% of a 150-mL saline meal given to fasting adults in the sitting position passed through the stomach in a median time of 14 minutes; however, in adults in the left lateral position, the median time for gastric emptying was 28 minutes.[25] In a subject eating a 400-mL meal of steak, bread, and vanilla ice cream, 800 mL of gastric juice was

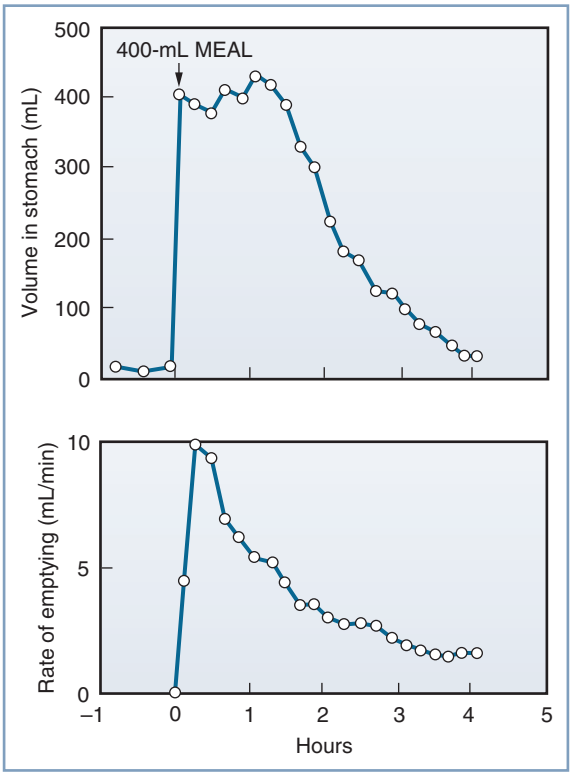

Fig. 28.4 Volume of gastric contents and rate of gastric emptying in a subject eating a 400-mL meal of steak, bread, and vanilla ice cream. (From Malagelada JR, Longstreth GF, Summerskill WHJ, et al. Measurements of gastric functions during digestion of ordinary solid meals in man. *Gastroenterology*. 1976;70:203–210.)

secreted (Fig. 28.4). Consequently, the volume in the stomach remained high for almost 2 hours despite early, rapid emptying.[29] These studies indicate that the volume and composition of the test meal, the resulting gastric secretions, and even patient positioning can impact gastric emptying and residual gastric content.

Effects of Pregnancy on Gastric Function

Gastroesophageal reflux, resulting in heartburn, is a common complication of late pregnancy. Pregnancy compromises the integrity of the lower esophageal sphincter; it alters the anatomic relationship of the esophagus to the diaphragm and stomach, raises intragastric pressure, and in some women limits the ability of the lower esophageal sphincter to increase its tone.[30–33] Progesterone, which relaxes smooth muscle, probably accounts for the inability of the lower esophageal sphincter to increase its tone.[34] Lower esophageal pH monitoring has shown a higher incidence of reflux in pregnant women at term, even in those who are asymptomatic, than in nonpregnant controls. Therefore, at term gestation the pregnant woman who requires anesthesia should be regarded as having an **incompetent lower esophageal sphincter.** These physiologic changes return to their prepregnancy levels by 48 hours after delivery.[33]

Serial studies assessing **gastric acidity** during pregnancy have proved difficult to perform because they require repeated placement of nasogastric tubes. However, in the most comprehensive study of gastric acid secretion during pregnancy, basal and histamine-augmented gastric acid secretion was measured in 10 controls and 30 pregnant women equally distributed throughout the three trimesters of pregnancy.[35] No significant differences in basal gastric acid secretion were seen between the pregnant and nonpregnant women.

A variety of techniques have been used to study **gastric emptying** during pregnancy and labor (Table 28.1).[36–60] Overall, the data suggest that pregnancy does not significantly alter the rate of gastric emptying.[39] In addition, gastric emptying has not been found to be delayed in either obese or nonobese term pregnant women who ingested 300 mL of water after an overnight fast.[56,57] However, management of obese parturients should take into account the possible presence of other associated problems in this group of patients (e.g., hiatal hernia or difficult airway). Gastric emptying appears to be normal in early labor but becomes delayed as labor advances[49]; the cause is uncertain. Pain is known to delay gastric emptying, but even when labor pain is abolished with epidural analgesia using a local anesthetic alone, the delay still occurs.[60] Parenteral opioids cause a significant delay in gastric emptying, as do bolus doses of epidural and intrathecal opioids.[40,45,49,51,58] Continuous epidural infusion of low-dose local anesthetic with fentanyl does not appear to delay gastric emptying until the total dose of fentanyl exceeds 100 μg.[51]

The plasma concentration of the gastrointestinal hormone motilin is decreased during pregnancy.[61] Studies have shown either no change[30,32,62] or an increase[63] in the plasma concentration of gastrin.

RISK FACTORS FOR ASPIRATION PNEUMONITIS

Mendelson[3] divided aspiration pneumonitis into two types: liquid and solid. Whereas the aspiration of solids could result in asphyxiation, Mendelson demonstrated that the sequelae from the aspiration of liquids were more severe clinically and pathologically when the liquid was highly acidic. His observations, together with the results from other investigations,[64–69] suggest that the morbidity and mortality of aspiration depend on the following three variables: (1) the chemical nature of the aspirate, (2) the physical nature of the aspirate, and (3) the volume of the aspirate. Aspirates with a pH less than 2.5 cause a granulocytic reaction that continues beyond the acute phase.[69] Aspiration of particulate material can yield a clinical picture with severity equal to or greater than that caused by the aspiration of acidic liquid.[68] Aspiration of small volumes of neutral liquid results in a very low rate of mortality. However, aspiration of large volumes of neutral liquid results in a high mortality rate, presumably as a result of the disruption of surfactant by the large volume of liquid or from a mechanism similar to that seen in "near drowning."[65]

Historically, anesthesia providers have considered a nonparticulate gastric fluid with a pH less than 2.5 and a gastric volume greater than 25 mL (i.e., 0.4 mL/kg) as risk factors for aspiration pneumonitis.[64,66,67] No human study has directly

TABLE 28.1 Studies of Gastric Emptying during Pregnancy and Labor

Method of Assessment	Study	Study Period and Subjects	Gastric Emptying
Radiographic	Hirsheimer et al. (1938)[43]	Labor (10 subjects)	Delay in 2 subjects

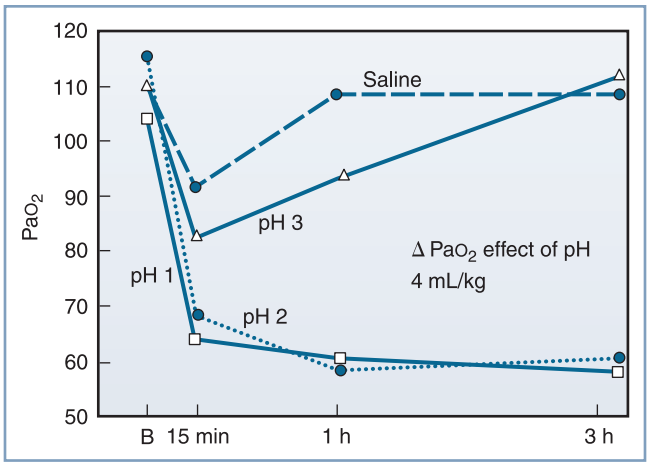

Fig. 28.5 Relationship between acidity and PaO_2. In this study, 4 mL/kg of fluid of varying pH was instilled into the tracheas of dogs. The severity of the hypoxemia correlated with the pH of the aspirate. A maximal decrease in PaO_2 occurred with aspirates with a pH of less than 2.5. *B,* baseline. (From Awe WC, Fletcher WS, Jacob SW. The pathophysiology of aspiration pneumonitis. *Surgery.* 1966;60: 232–239.)

addressed the relationship between preoperative fasting, gastric acidity and volume, and the risk for pulmonary aspiration during anesthesia.[70,71] There appears to be a reasonable scientific basis using a gastric pH cutoff value of less than 2.5 as a risk factor. In animal experiments, the risk for aspiration pneumonitis clearly increased with decreasing pH of the tracheal aspirate[64,65] (Fig. 28.5).

Animal studies have also demonstrated that an increase in the volume of tracheal aspirate is associated with a higher risk for aspiration pneumonitis.[65] However, the volume of aspirated material associated with risk has been disputed. The commonly accepted volume of 0.4 mL/kg (approximately 25 mL in a 70-kg adult) originated from an experiment in a single rhesus monkey in which 0.4 mL/kg of an acidic liquid was administered into the right mainstem bronchus and resulted in the animal's death.[67] The investigators made the assumption that this entire volume, if contained in the stomach, could be aspirated. However, Raidoo et al.[72] demonstrated variability in the response of juvenile monkeys to different volumes of an acidic tracheal aspirate. Death was seen with aspirate volumes of 0.8 mL/kg and 1.0 mL/kg but not with volumes of 0.4 mL/kg and 0.6 mL/kg. Similarly, Plourde and Hardy[73] refuted the assumption that all the gastric contents would be aspirated and demonstrated that gastric volumes of 0.4 mL/kg did not increase the risk for aspiration. Hence the gastric volume that puts a patient at risk for aspiration pneumonitis has not been determined. However, a reasonable goal of prophylactic therapy would be a gastric pH greater than 2.5 and a gastric volume as low as possible.

PATHOPHYSIOLOGY

Aspiration pneumonitis (Mendelson's syndrome) describes a chemical injury to the tracheobronchial tree and alveoli caused by the inhalation of sterile acidic gastric contents, whereas **aspiration pneumonia** may be regarded as an infectious process of the respiratory tract caused by the inhalation of oropharyngeal secretions that are colonized by pathogenic bacteria. Aspiration of gastric contents could therefore result in acid injury to the lung with or without bacterial and particulate matter–related effects.

Aspiration of acidic liquid injures the alveolar epithelium and results in an alveolar exudate composed of edema, albumin, fibrin, cellular debris, and red blood cells,[3,66,68,69] whereas the aspiration of neutral, nonparticulate liquid leads to an alveolar exudate with minimal damage to the alveoli. The phospholipid and apoprotein composition of surfactant changes, exerting a negative effect on its surface-active properties.[74] This effect leads to an increase in intra-alveolar water and protein content and a loss of lung volume, resulting in a decrease in pulmonary compliance and intrapulmonary shunting of blood. The cellular debris and bronchial denuding cause bronchial obstruction. The exudative pulmonary edema, bronchial obstruction, reduced lung compliance, and shunting result in hypoxemia, increased pulmonary vascular resistance, and increased work of breathing. After the direct acid-mediated injury of the respiratory tract, an intense inflammatory response ensues from macrophage activation and secretion of cytokines (e.g., interleukins [IL]-1, IL-6,

IL-8, and IL-10, and tumor necrosis factor-alpha [TNF-α]).[75] These inflammatory mediators lead to the chemotaxis, accumulation, and activation of neutrophils in the alveolar exudate, up-regulation of adhesion molecules within the pulmonary vasculature, and activation of the complement pathways. The neutrophils subsequently release oxidants, proteases, leukotrienes, and other proinflammatory molecules.[75] Amplification of these inflammatory processes may result in the development of acute lung injury or acute respiratory distress syndrome (ARDS) (Fig. 28.6).[74–76]

The acidic contents of the stomach prevent the growth of bacteria under normal conditions. However, gastric contents may become colonized with pathogenic gram-negative bacteria in patients receiving antacid therapy (e.g., proton-pump inhibitor or H_2-receptor antagonist) or patients with gastroparesis or intestinal obstruction. The bacterial content adds to the inflammatory response to acid aspiration.[77]

Aspiration of particulate matter in the supine position most commonly involves injury to the posterior segments of the upper lobes and the apical segments of the lower lobes, whereas aspiration in the semirecumbent or upright position typically leads to injury to the lower lobes. The right lower lobe is the most common site of aspiration injury because the right mainstem bronchus has larger and more vertical architecture compared with the left mainstem bronchus. Obstruction of the bronchus or bronchioles results in bronchial denudation and collapse of the bronchopulmonary segments. Persistent or unresolved collapse can lead to lung abscesses and cavitation.[77]

After the acute period, the process resolves through the proliferation and differentiation of surviving type II pneumocytes in the alveolar epithelial cells.[75,76] The type II pneumocytes actively transport sodium out of the alveolus, and water follows passively. Soluble proteins are removed by paracellular diffusion and endocytosis, and insoluble proteins are removed by macrophages. Neutrophils are removed by programmed cell death and subsequent phagocytosis by macrophages. Type II pneumocytes gradually restore the normal composition of the surfactant. In a subset of patients with ARDS, the injury progresses to a fibrosing alveolitis—an accumulation of mesenchymal cells, their products, and new blood vessels.

Bronchospasm and disruption of surfactant likely account for the slight decrease in Pa_{O_2} and increase in shunting that are observed.[69] Aspiration of large solid particles may cause atelectasis by obstructing large airways.[3] Aspiration of smaller particulate matter causes an exudative neutrophilic response at the level of the bronchioles and alveolar ducts; the clinical picture is similar after the aspiration of acidic liquid.[68,69]

CLINICAL COURSE

In most cases of aspiration during anesthesia, the anesthesia provider witnesses regurgitation of gastric contents into the hypopharynx.[3] Patients who aspirate while breathing spontaneously have a brief period of breath-holding followed by tachypnea, tachycardia, and a slight respiratory acidosis. Significant aspiration always results in some hypoxemia caused by greater shunting and, frequently, bronchospasm.

An abnormality on a chest radiograph can be seen in 85% to 90% of patients who aspirate gastric contents.[78] Because these chest radiographic findings may lag behind clinical signs by as much as 12 to 24 hours, the initial radiograph may appear normal.[78] In mild cases, alveolar infiltrates are seen in the dependent portions of the lungs. Severe aspiration results in diffuse bilateral infiltrates without signs of heart failure (i.e., without engorged pulmonary vasculature and/or enlarged cardiac silhouette) (Fig. 28.7).

These symptoms and signs may progress to satisfy the Berlin Definition for ARDS; the criteria are as follows[79]:

- *Clinical:* within 1 week of known clinical insult
- *Chest imaging:* bilateral opacities not explained by effusions
- *Biochemical:* Pa_{O_2}/F_{IO_2} ratio less than 300 with continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) greater than 5 cm H_2O
- *Origin of pulmonary edema:* not explained by cardiac failure or fluid overload

TREATMENT

Management of Aspiration

Management principles include (1) tracheal suction; (2) rigid bronchoscopy in cases of aspiration of large, solid particles; and (3) management of hypoxemia with CPAP in nonintubated patients. Treatments that lack evidence to support their use are the administration of corticosteroids, routine use of prophylactic antibiotics, and lung lavage with saline and bicarbonate.[77]

Initial Management

Suction of the upper airway followed by tracheal intubation and suction of the primary bronchi with a soft suction catheter is indicated for the initial management. Fiberoptic bronchoscopy can be useful for evaluating the extent of aspiration and whether solid particles are present, and for the removal of liquid contents. Rigid bronchoscopy is useful for removing large food particles that cause airway obstruction. Lung lavage with saline or bicarbonate does *not* reduce the parenchymal damage caused by acid aspiration and can worsen preexisting hypoxemia.[77]

Antibiotics

Prophylactic antibiotics are *not* efficacious for aspiration and may lead to the development of infection with resistant organisms. Infection is not a component of acute pulmonary aspiration of sterile gastric contents.[77] Antibiotics should be administered only in the presence of clinical findings that suggest infection (e.g., fever, worsening infiltrates on chest radiographs, leukocytosis, positive result of Gram stain of sputum, clinical deterioration).

In patients who are intubated, a nonbronchoscopic bronchoalveolar lavage sample can be sent for laboratory analysis. Tracheal sputum samples may be insufficient to identify a

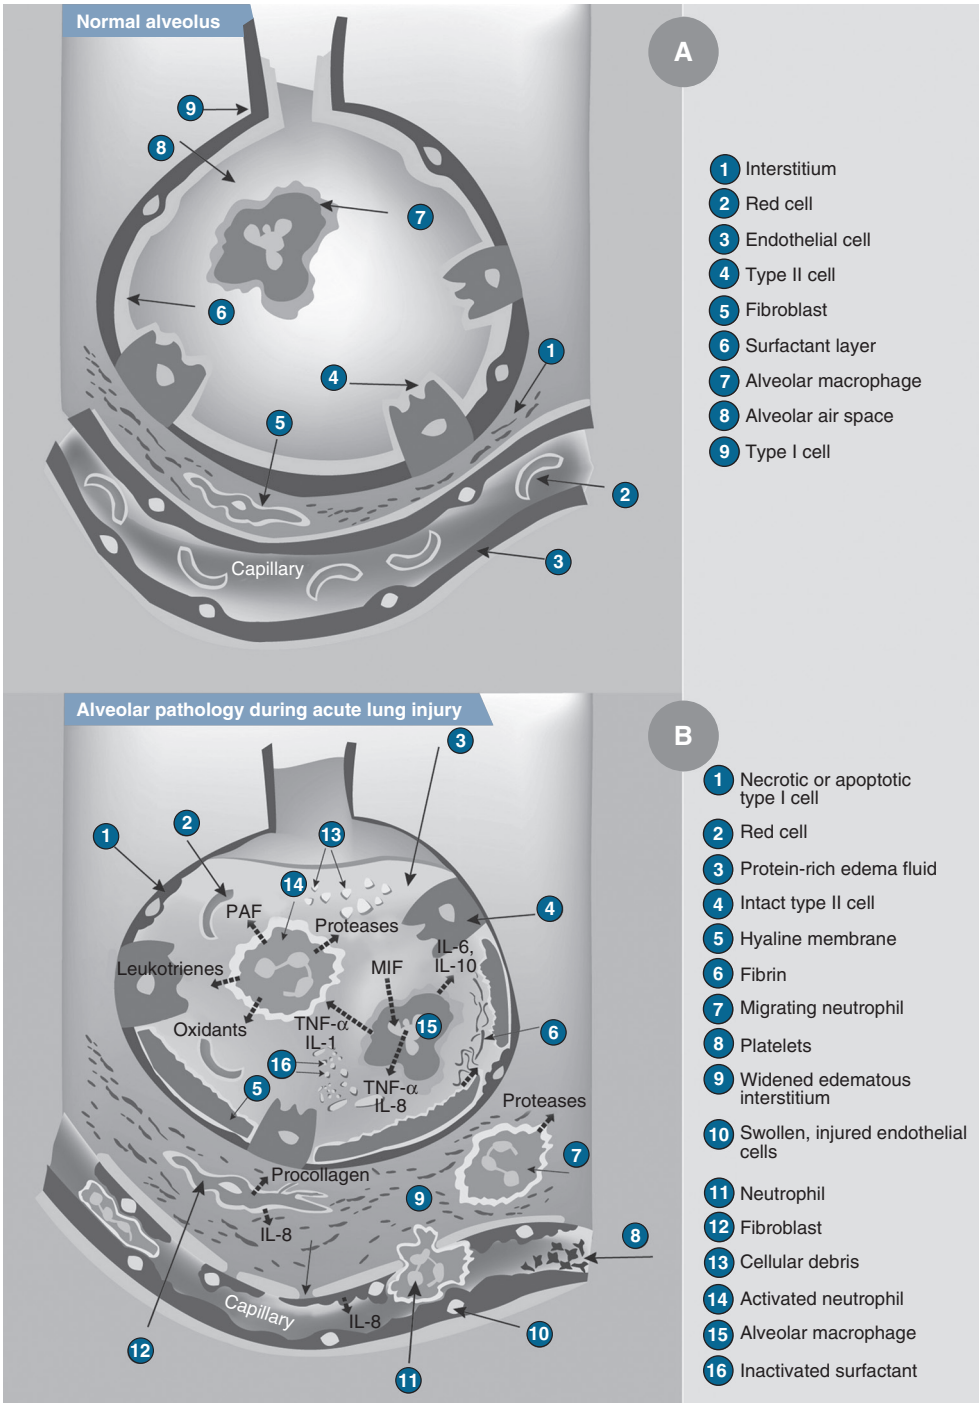

Fig. 28.6 Illustration showing the normal alveolus (A) and the injured alveolus (B) during acute lung injury. In the acute phase of acute lung injury, there is formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are marginating through the interstitium into the air space. Alveolar macrophages secrete interleukin (*IL*)-1, 6, 8, and 10, as well as tumor necrosis factor-alpha (*TNF*-α), which stimulate and activate neutrophils. Neutrophils release proinflammatory molecules (oxidants, proteases, leukotrienes, platelet-activating factor [*PAF*]). The influx of protein-rich edema fluid into the alveolus has led to the inactivation of surfactant and, together with unresolved fibrin depositions, fibrin-rich hyaline membranes are formed. *MIF,* müllerian inhibiting factor. Fig. 28.7 Radiographic changes after pulmonary aspiration of gastric contents in pregnancy.

bacterial pathogen, and some authorities recommend sampling of the lower respiratory tract with a protected specimen brush.[77]

Empirical antibiotic therapy is appropriate in patients with suspected bacterial colonization of gastric contents. The "at risk" group (see earlier discussion) includes patients who have gastroparesis or bowel obstruction and those who are receiving antacid therapy. The use of PPIs and H_2-receptor antagonists is common in late pregnancy, given the prevalence of gastroesophageal reflux disease. Reduced gastric acidity from long-term antacid therapy increases the incidence of community-acquired and ventilation-associated pneumonia,[80,81] but it is uncertain whether parturients on long-term acid-suppression therapy are at higher risk for developing bacterial pneumonia after aspiration. Nonetheless, empirical antibiotic therapy is also appropriate for parturients on long-term antacid therapy and for those with aspiration pneumonitis that fails to resolve within 48 hours. The choice of antibiotic depends on the observed local patterns of antibiotic resistance. The target pathogens are gram-positive organisms (e.g., *Streptococcus pneumoniae, Staphylococcus aureus*) and some gram-negative organisms (e.g., *Haemophilus influenzae, Escherichia coli,* Enterobacteriaceae) when the diagnosis is made less than 48 hours after hospital admission (i.e., community-acquired pneumonia). *Pseudomonas aeruginosa* is a common pathogen in cases of nosocomial (hospital-acquired) aspiration pneumonia. Anaerobes are no longer believed to be present in the majority of cases.[77] Pharmacologic therapy should be altered when specific pathogens and their antibiotic sensitivities are determined.

Treatment of Hypoxemia

Exudation of fluid into the alveoli, decreased surface activity of surfactant, and atelectasis all result in intrapulmonary shunting and hypoxemia. The administration of CPAP in patients breathing spontaneously or the administration of PEEP in patients undergoing mechanical ventilation restores functional residual capacity, reduces pulmonary shunting, and reverses hypoxemia. Supplemental oxygen should be given as required.

Corticosteroids

Despite decades-long use of corticosteroids in the management of aspiration pneumonitis, animal and human studies have failed to demonstrate a beneficial effect on pulmonary function, lung injury, alveolar-capillary permeability, or clinical outcomes after acid aspiration.[77] Thus, the administration of corticosteroids for aspiration pneumonitis is not recommended.

Management of Respiratory Failure

Aspiration of gastric contents can result in activation of inflammatory intrapulmonary pathways[77] consistent with the pathophysiology observed in ARDS.[76,79] The basic tenets of management of ARDS include the use of "lung-protective" ventilation strategies, the judicious management of fluids, and the application of basic critical care algorithms. The management of severe ARDS and hypoxemia resistant to conventional management involves the use of rescue therapies (e.g., prone positioning, high-frequency oscillatory ventilation, extracorporeal membrane oxygenation) usually used in the critical care setting[82] and thus will not form part of this overview. The following section outlines the basic principles in immediate management and stabilization. Readers are referred to extensive reviews of management of ARDS for further information.[82,83]

Mechanical Ventilation

The key principles governing mechanical ventilation in ARDS involve limiting the inspiratory plateau pressure to 30 cm H_2O and providing the lowest effective tidal volume to prevent alveolar overdistention and tidal (cyclic) recruitment-derecruitment. Such lung-protective strategies correlated with improved outcomes in a prospective multicenter trial of the management of ARDS in which the use of low tidal volumes and plateau pressure (6 mL/kg and 30 cm H_2O or less) was compared with traditional ventilation strategy (12 mL/kg and 50 cm H_2O or less).[84] Patients in the lower tidal volume group had a 22% reduction in mortality and an increase in ventilator-free days. Current recommendations for the treatment of ARDS include mechanical ventilation that minimizes ventilator-induced lung injury (low target tidal volume [6 mL/kg], plateau pressure less than 30 cm H_2O, prone positioning for severe ARDS, and higher PEEP in moderate and severe ARDS).[83] In addition, guidelines from new evidence support the use of high-frequency oscillatory ventilation for those with severe hypoxemia and limiting extracorporeal membrane oxygenation to a subset of patients who have defined dead space and static lung compliance values.[82,83]

Positive End-Expiratory Pressure

PEEP is a recommended component of the initial ventilatory support in the setting of ARDS. A randomized clinical trial of

ARDS (n = 549) compared the effects of low and intermediate PEEP levels set according to predetermined combinations of PEEP and F_{IO_2} in the setting of a lung-protective mechanical ventilation strategy.[85] There were no significant differences in hospital mortality (24.9% versus 27.5%, respectively) or days to unassisted breathing (14.5 days versus 13.8 days, respectively) between the two groups. However, the role of comparatively higher levels of PEEP in protective ventilation strategies for ARDS is far from clear.[86–88] An experimental model for acute lung injury from acid aspiration demonstrated that the titration of PEEP improved arterial oxygenation but was associated with lung inflammation as evidenced by histopathologic evaluation.[89] This study supports the concept of best PEEP as a compromise between alveolar recruitment, lung inflammation, and hyperinflation. Current PEEP strategies focus on degree of recruitability of the lungs, given the finding that higher PEEP benefits patients with high recruitability (severe lung injury), while the injurious effects of high PEEP outweigh the benefit in those with low recruitability (mild lung injury).[90]

Fluid Management

In a 2 × 2 factorial trial design, the ARDS Clinical Trials Network Research Group evaluated the use of a conservative versus liberal fluid strategy and the value of guiding this intervention with central venous pressure or pulmonary artery occlusion pressure measurements.[91] The group that received conservative fluid management, whether guided by central venous pressure and/or pulmonary capillary occlusion pressure measurements, had much lower net fluid balance, better lung function, and a shorter duration of mechanical ventilation and intensive care unit stay. Further, there appeared to be no increase in the incidence or duration of shock or need for dialysis in the conservative fluid management arm of the trial. A 2017 meta-analysis comparing conservative and liberal fluid resuscitation strategies found increased ventilator-free days and decreased intensive care unit stay among patients managed with conservative fluid strategies.[92] Thus, early management of ARDS (after initial resuscitation) focuses on limiting iatrogenic insult with conservative fluid management.

Basic Critical Care Algorithms

To minimize the risk for sepsis, central venous catheters and other invasive hemodynamic monitors should be removed as early as is clinically feasible. Aseptic precautions should be used during care, and infections should be treated with antibiotics specific to the bacterial pathogen. Whether tight and rigorous glycemic control should be employed is controversial. Occasional withdrawal of sedation and the use of prophylaxis for gastrointestinal bleeding and thromboembolic events are currently considered the standard of care in any critically ill patient (see Chapter 54).[93]

Corticosteroids

Recovery from ARDS depends on the functional resolution of the underlying pulmonary disorder, which may follow one of two courses: (1) rapid improvement in lung function with an uncomplicated recovery or (2) slow improvements in lung function, oxygenation, and ventilation with prolonged weaning and recovery.

The corticosteroid controversy in ARDS in the context of aspiration is still unresolved.[77] Although a 2009 systematic review suggested potential benefit from corticosteroids,[94] their use did *not* appear to improve lung function or recovery in patients with ARDS in two of the well-conducted randomized clinical trials[95,96] and may be associated with longer-term side effects. To further add to the controversy, a 2007 randomized controlled trial reported an improvement in outcomes in patients with ARDS randomized to receive a methylprednisolone infusion versus placebo.[97] Most recently, a 2014 meta-analysis including 1474 patients in 18 studies showed no impact of corticosteroid therapy on mortality. While there was no specific analysis of cases of ARDS from aspiration-related lung injury, corticosteroid therapy increased mortality in a subgroup of patients with influenza-related ARDS. At the current time, data do not support the routine use of corticosteroids in ARDS for the attenuation of lung injury after pulmonary aspiration.[98]

PROPHYLAXIS

The risk for aspiration is extremely low when gastric emptying is normal and patients, including parturients, are appropriately fasted. Factors predisposing to regurgitation, particularly in obstetrics, include emergency surgery, difficult/failed tracheal intubation, light anesthesia, and gastroesophageal reflux. The risk for failed intubation is 3 to 11 times greater in pregnant patients than in nonpregnant patients, reported as 1 in 250 at the end of a 17-year audit in the United Kingdom (1978 to 1994)[99] and as 1 in 232 in an 8-year audit in the United States (2006 to 2013)[100] (see Chapter 29). Airway edema, breast enlargement, obesity, and the high rate of emergency surgery can all contribute to the risk for failed tracheal intubation in pregnant women. Aspiration pneumonitis is often associated with difficult or failed intubation during the induction of general anesthesia. In a survey conducted by the Society for Obstetric Anesthesia and Perinatology, intubation was recorded as difficult in 14 of 19 cases of aspiration in which tracheal intubation was required.[101] Moreover, Warner et al.[8] reported that the risk for aspiration during emergence from anesthesia was almost as high as that during induction of anesthesia. Thus, prophylactic regimens must provide protection during both induction of, and emergence from, general anesthesia. Although the risk for aspiration during elective, as opposed to emergency, surgery under general anesthesia is very low, parturients undergoing cesarean delivery or other surgical procedures should receive pharmacologic prophylaxis.

Because the incidence of aspiration pneumonitis is low, the efficacy of prophylactic regimens is measured by their ability to alter gastric pH and volume. In 30% to 43% of pregnant women, the fasting gastric volume is greater than 25 mL and the gastric fluid pH is less than 2.5.[102,103] However,

TABLE 28.2 Prevalence of Fasting Gastric Findings in Various Populations (%)

Population	pH < 2.5	Volume > 25 mL	pH < 2.5 and Volume > 25 mL
Pregnant[101–103]	57–80	51–54	31–43
Nonpregnant[104,106]	75–95	45–67	45–60
Postpartum[104,105,108]	54–93	61	60
Children[107]	93–100	64–78	64–77
Obese, nonpregnant[109]	88	86	75

the percentage of term parturients at risk may not differ from that of patients undergoing elective abortion, postpartum sterilization, or gynecologic surgery (Table 28.2).[104–106] Gastric volume and acidity at term gestation are similar to gastric volume and acidity during early pregnancy, during the postpartum period, and in nonpregnant patients.[102–109] Decreased lower esophageal sphincter tone and a higher risk for difficult tracheal intubation are the primary factors that increase the risk for aspiration during pregnancy and the immediate postpartum period, and these are the factors that mandate the need for pharmacologic prophylaxis.

Preoperative Oral Fluid Administration

Multiple studies have described no increase in gastric volume or acidity after the oral administration of 150 mL of fluid (e.g., coffee, tea, water, other clear liquids, orange juice without pulp) in nonpregnant adults 2 hours before elective surgery.[71] The patients in these studies all fasted overnight and were expected to have a low gastric volume when the test meal was given. Lewis and Crawford[110] noted that allowing women undergoing elective cesarean delivery to consume a meal of both tea and toast 2 to 4 hours preoperatively increased gastric volume and decreased gastric pH compared with a fasted control group. Consumption of tea without toast resulted in an increase in gastric volume, but it did not alter gastric pH. Particulate material was aspirated from the stomachs of 2 of the 11 patients who consumed both tea and toast. The investigators did not state the volume of tea consumed by these patients.

When gastric emptying of both 50 mL and 300 mL of water was assessed in nonlaboring term parturients, the gastric emptying half-time for 300 mL was significantly shorter than that for 50 mL.[56] When a similar study was conducted in obese nonlaboring term parturients (mean [±SD] prepregnancy body mass index 41 ± 9 kg/m^2), the gastric emptying time for 300 mL was not longer than that for 50 mL.[57] The latter finding suggests that the American Society of Anesthesiologists (ASA) Guidelines for Obstetric Anesthesia,[70] which state that "the uncomplicated patient undergoing elective cesarean delivery may have modest amounts of clear liquids up to 2 h before induction of anesthesia" could also be applied to healthy, *obese* pregnant women presenting for elective surgery. However, factors other than the rate of gastric emptying can influence the rate of pulmonary aspiration, particularly in obese subjects. Obesity is associated with a higher incidence of gastroesophageal reflux and difficult airway management (both intraoperatively and postoperatively) (see Chapter 49). Moreover, the cesarean delivery rate is higher and the success rate of trial of labor after cesarean delivery is lower in obese parturients.[111,112]

Choice of Anesthesia

The Obstetric Anesthesia Work Force Survey demonstrated that general anesthesia was used for less than 5% of elective cesarean procedures by 2011.[113] Two sequential analyses performed at a large tertiary care obstetric facility showed that the use of general anesthesia for cesarean delivery decreased from 7.2% to 3.6% from 1990 to 1995,[114] with a further decline from 1% to 0.8% from 2000 to 2005.[115] One maternal death resulted from a failed tracheal intubation in the first cohort, with no reported anesthesia-related mortality during the second study period. Hawkins et al.[11] reported 67 maternal deaths resulting from complications of general anesthesia and 33 maternal deaths resulting from complications of neuraxial anesthesia in the United States during the years 1979 to 1990. Approximately 73% of general anesthesia–related maternal deaths were caused by airway difficulty, primarily failed intubation and/or aspiration. In contrast, data from the more recent period spanning the years 1997 to 2002 indicate that the mortality rates for cesarean delivery are similar for general and regional anesthesia.[12] Studies reviewing failed tracheal intubation during the periods 1993 to 1998 and 1999 to 2003 in the United Kingdom showed that, while the rate of failed intubation during this period had not declined, there were no deaths from this potentially fatal complication.[116,117] Although this relative change in maternal mortality from the complications of general anesthesia is very encouraging, other factors such as the worldwide obesity epidemic have increased the challenges presented to anesthesia providers, particularly with respect to emergency operative deliveries. Therefore, techniques for preventing pulmonary aspiration of gastric contents will remain or even become increasingly pertinent to clinical practice.

Antacids

The ASA Practice Guidelines for Obstetric Anesthesia state: "Before surgical procedures (e.g., cesarean delivery and postpartum tubal ligation), consider timely administration of nonparticulate antacids, H_2-receptor antagonist, and/or metoclopramide for aspiration prophylaxis."[70] Particulate antacids should not be used as prophylaxis because when aspirated they cause pulmonary shunting and hypoxemia of magnitude similar to that caused by acid aspiration and

greater than that caused by saline, alkalinized saline, or sodium citrate.[118] Therefore, nonparticulate antacids (e.g., 0.3 M sodium citrate, Bicitra, Alka-Seltzer effervescent) should be used; their efficacy depends on the baseline gastric volume and acidity.[119,120] A volume of 30 mL of sodium citrate neutralizes 255 mL of hydrochloric acid with a pH of 1.0. The effective duration of action of sodium citrate is variable and depends on the rate of gastric emptying.[121,122] O'Sullivan and Bullingham[121,122] used radiotelemetry pH pills to perform noninvasive assessments of the efficacy of sodium citrate in pregnant women. After the administration of 15 mL of sodium citrate to women in the third trimester of pregnancy, the time that the pH remained greater than 3.0 was less than 30 minutes.[121] When the same study was repeated in laboring women,[122] the mean time that the pH remained greater than 3.0 was 57 minutes in subjects who had received no analgesia and 166 minutes in those who had received meperidine. Nonparticulate antacids should be administered within 20 minutes of the induction of general anesthesia, particularly if the procedure is an emergency and there is insufficient time for a co-administered H_2-receptor antagonist to be effective.

Histamine-2 Receptor Antagonists

The ASA Task Force on Obstetric Anesthesia concluded that H_2-receptor antagonists are efficacious in reducing gastric acidity and volume.[70] H_2-receptor antagonists block histamine receptors on the oxyntic cell and thus diminish gastric acid production, leading to a slight reduction in gastric volume in the fasting patient. When given intravenously, an H_2-receptor antagonist begins to take effect in as little as 30 minutes, but 60 to 90 minutes are required for maximal effect.[103] After oral administration, gastric pH is higher than 2.5 in approximately 60% of patients at 60 minutes and in 90% at 90 minutes.[123] The duration of action is sufficiently long to cover emergence from general anesthesia for a cesarean delivery.

Cimetidine (given in doses of 200 to 400 mg intravenously or orally) reduces gastric acidity within 60 to 90 minutes.[103,123] Therapeutic plasma concentrations are sustained for approximately 4 hours. Cimetidine may decrease the rate of plasma clearance of certain drugs, including some local anesthetics (e.g., lidocaine), by binding to the cytochrome P450 system in the hepatocyte and by reducing hepatic blood flow.[124] Cimetidine crosses the placenta, but this does not appear to have harmful effects.[125] Because arrhythmias and cardiac arrest have been reported with the rapid intravenous administration of cimetidine,[126] a slow rate of intravenous administration or the oral route of administration is recommended. The use of cimetidine in obstetric anesthesia has largely been replaced by the use of other H_2-receptor antagonists.

Ranitidine, a chemically substituted amino-alkyl furan, has been evaluated after the administration of an intravenous or intramuscular dose of 50 to 100 mg or an oral dose of 150 mg.[127–129] These studies have noted that the administration of ranitidine results in a gastric pH greater than 2.5 within 1 hour and sustained therapeutic concentrations for approximately 8 hours.[127–129] Ranitidine does not have any major interaction with the cytochrome P450 system[130] and does not alter plasma concentrations of lidocaine or bupivacaine after their epidural administration.[131]

Nizatidine (given in doses of 150 to 300 mg orally) and **famotidine** (given in doses of 20 to 40 mg orally or intravenously) are alternative H_2-receptor antagonists.[132] Both have a duration of action greater than 10 hours and do not interfere with the metabolism of other drugs by the cytochrome P450 system.[132]

Proton-Pump Inhibitors

Omeprazole (20 to 40 mg orally) and **lansoprazole** (15 to 30 mg orally) are substituted benzimidazoles that inhibit the hydrogen ion pump on the gastric surface of the oxyntic cell. Purported advantages of PPIs are a long duration of action, low toxicity, and the potential for low maternal and fetal blood concentrations at the time of delivery.[21,133] However, a meta-analysis has indicated that premedication with ranitidine is more effective than PPIs in reducing the volume of gastric secretion and increasing gastric pH.[134]

Metoclopramide

Metoclopramide is a procainamide derivative that is a peripheral cholinergic agonist and a central dopamine receptor antagonist. An intravenous dose of metoclopramide 10 mg increases lower esophageal sphincter tone and reduces gastric volume by increasing gastric peristalsis. Metoclopramide can have a significant effect on gastric volume in as little as 15 minutes.[102] Unfortunately, prior administration of an opioid or atropine antagonizes the effect of metoclopramide.[135] Extrapyramidal effects are a major potential side effect of metoclopramide. Metoclopramide crosses the placenta, but no significant effects on the fetus or neonate have been reported.[136]

A systematic review of antacid prophylaxis concluded that there was no evidence to support the routine administration of drugs to women in normal labor to reduce the incidence of pulmonary aspiration or Mendelson's syndrome.[137] This conclusion reflects the low incidence of pulmonary aspiration of gastric contents and the absence of high-quality studies of antacid prophylaxis, rather than the presence of studies demonstrating negative results; the review cited only three studies, published in 1971, 1980, and 1984.[137] One study assessed the use of metoclopramide and perphenazine in women receiving meperidine in labor, and the other two studies focused on the use of particulate antacids. An audit of acid aspiration prophylaxis during labor in the United Kingdom showed a decreasing number of institutions with policies to administer routine antacid prophylaxis to all laboring women.[138] However, many institutions attempted to identify women at high risk for an emergency cesarean delivery, to whom they gave oral ranitidine 150 mg at 6-hour intervals throughout labor. An audit of French obstetric units revealed that at least one medication to prevent gastric content aspiration was used in every patient in 93% of institutions before cesarean delivery, but the frequency of

prophylaxis administration for laboring parturients was not assessed.[139]

Combination Prophylaxis Therapy

A systematic review of interventions for reducing the risk for aspiration pneumonitis in women who received general anesthesia for cesarean delivery (22 studies) showed that each assessed therapy, including antacids, H_2-receptor antagonists, and PPIs, achieved significant reduction of intragastric pH below 2.5.[140] H_2-receptor antagonists showed superior gastric acid pH reduction compared with PPIs at the time of tracheal intubation. Compared with placebo or with antacids alone, the combined use of antacids and H_2-receptor antagonists yielded a significantly greater reduction in intragastric pH.

Sellick Maneuver and Induction of Anesthesia

Sellick demonstrated that the occlusion of the esophagus by cricoid pressure in cadavers prevented the flow of barium from the stomach to the pharynx.[141] He also reported the successful use of this maneuver in 26 cases to prevent the passive regurgitation of gastric contents into the airway. For proper application of cricoid pressure, the head should be fully extended; it may help to have a trained assistant place a hand behind the patient's neck, so that the cervical vertebrae and esophagus are brought forward, making it easier to occlude the latter. The trained assistant should place the thumb and middle finger on either side of the cricoid cartilage; no more than light pressure should be applied while the patient is awake, to prevent coughing, straining, retching, and esophageal rupture. After denitrogenation (preoxygenation) and administration of induction drugs, an increasingly firm downward pressure is applied to the cricoid cartilage as loss of consciousness occurs. Full application of cricoid pressure requires a force of 30 newtons (N), 1 N being the force required to accelerate a mass of 1 kg by 1 m/s^2. As a practical clinical guide to the amount of force to apply, 10 N is approximately equivalent to the downward force exerted by a mass of 1 kg. Vanner and Pryle[142] demonstrated that 30 N of cricoid force prevented regurgitation of saline in cadavers with esophageal pressures as high as 40 mm Hg. The research team recommended a modest cricoid force (10 N) before loss of consciousness, increasing to 30 N after loss of consciousness; their data suggested that such pressure should be sufficient to prevent passive regurgitation of esophageal contents during induction of general anesthesia in most patients.[143] Cricoid pressure is maintained until the endotracheal tube cuff is inflated and correct endotracheal tube position is confirmed.

The value of cricoid pressure has been questioned. A study employing magnetic resonance imaging of 22 healthy volunteers of both genders noted that the resting position of the esophagus was lateral relative to the cricoid cartilage in 53% of the subjects without cricoid pressure and in 91% with cricoid pressure.[144] In addition, cricoid pressure displaced the esophagus relative to its initial resting position to the left and right in 68% and 21% of the subjects, respectively. The authors suggested that cricoid pressure may lead to airway displacement and an inability to reliably produce midline esophageal compression; these factors could limit the protective effect of the maneuver against passive reflux and make the intubation process more difficult. However, Rice at al.[145] challenged these conclusions in a subsequent magnetic resonance imaging study investigating the efficacy of cricoid pressure. They demonstrated that the hypopharynx, rather than the esophagus, lies behind the cricoid cartilage (Fig. 28.8). The relationship of the cricoid and laryngeal cartilages is constant and is maintained by their connecting ligaments and muscles. Because the cricoid cartilage and postcricoid hypopharynx are constantly related, they will behave as a unit when compressed against the cervical spine. The investigators contended that the sealing of the hypopharynx is therefore independent of the position of the esophagus, and the actual position of the esophagus is irrelevant to the successful application of cricoid pressure.

When the technique of rapid-sequence induction of anesthesia with tracheal intubation was first described in detail, it was recommended that the trunk be elevated 30 degrees to prevent reflux and aspiration.[146] Hignett et al.[147] demonstrated that the functional residual capacity of healthy term parturients was increased in the 30-degree head-up position compared with the supine position. Moreover, in the 30-degree head-up position, the esophageal pressure is lower and thus the force applied to the cricoid could be reduced to 20 N[148]; this reduction in force may reduce the incidence of airway problems, because these problems are often proportional to the force applied.[149] Further work is required to determine whether the increase in functional residual capacity in the 30-degree head-up position prolongs the time to oxyhemoglobin desaturation during the apnea phase of rapid-sequence induction and whether this position should be routinely adopted for induction of general anesthesia in obstetric patients.

Should the incorrect application of cricoid pressure distort the laryngeal inlet and cause difficulty with laryngoscopy and/or intubation, the cricoid pressure should be promptly released.

RECOMMENDATIONS FOR CESAREAN DELIVERY

When possible, all mothers should be encouraged to have neuraxial anesthesia for cesarean delivery. Awake fiberoptic intubation should be considered for parturients with a potentially difficult airway who require general anesthesia. For **elective cesarean delivery,** a suitable antacid regimen may include the oral or intravenous administration of an H_2-receptor antagonist (e.g., famotidine 20 mg) 60 to 120 minutes before the induction of anesthesia and oral sodium citrate 30 mL within 30 minutes before surgery. Some practitioners also give metoclopramide 10 mg orally at the same time as the H_2-receptor antagonist or intravenously at least 15 minutes before the induction of anesthesia.

For **emergency cesarean delivery under general anesthesia,** 30 mL of sodium citrate should be administered

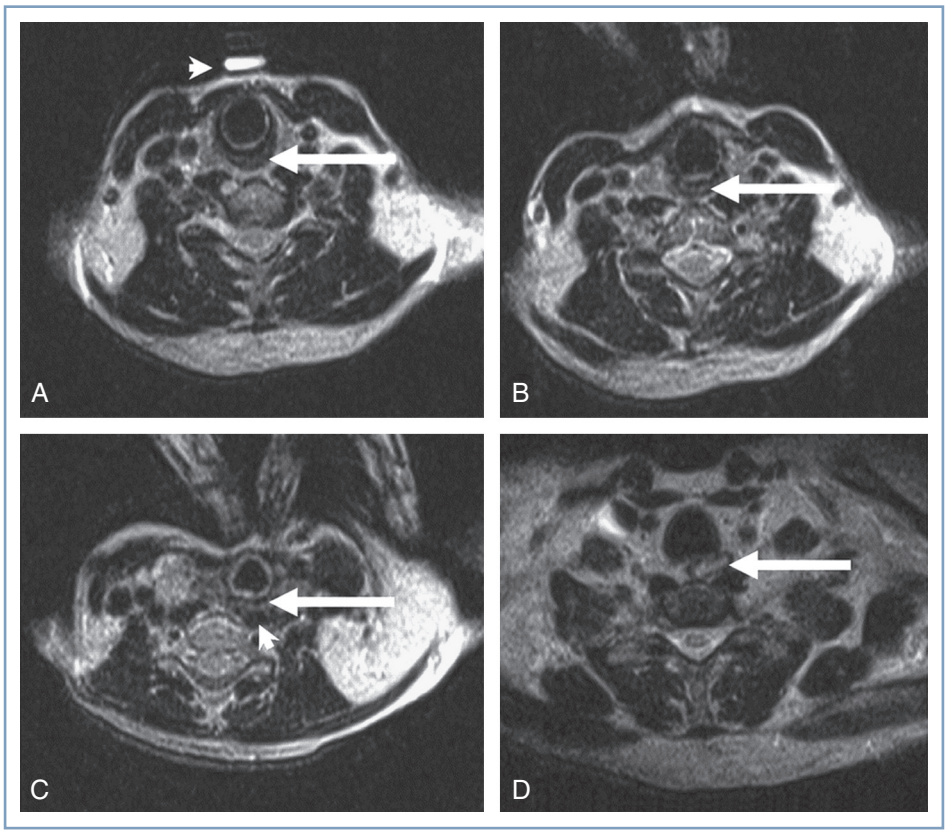

Fig. 28.8 Axial magnetic resonance images in the sniffing position, without (A) and with (B) cricoid pressure. (A) Postcricoid hypopharynx *(arrow)* and the cricoid cartilage skin marker *(arrowhead)* placed by the anesthesiologist before imaging. (C) Example of postcricoid hypopharynx compression *(arrow)* lateral to the vertebral body with cricoid pressure. In this image, the postcricoid hypopharynx is compressed against the longus colli muscle group *(arrowhead)*. (D) Image 2 cm inferior to the cricoid ring distinctly shows the cervical esophagus *(arrow)* lateral to the vertebral body. In (B) and (C) the anesthesiologist's thumb and index finger can be seen pushing on the cricoid cartilage. The axial image chosen for each study (A to C) was the image at the most inferior level of the cricoid cartilage. (From Rice MJ, Mancuso AA, Gibbs C, et al. Cricoid pressure results in compression of the postcricoid hypopharynx: the esophageal position is irrelevant. *Anesth Analg.* 2009;109:1546–1552.)

just after transfer of the patient to the operating room. This timing is important because sodium citrate has a relatively short duration of action, except in those mothers in whom gastric emptying has been delayed by the administration of an opioid. In addition, ranitidine 50 mg (or famotidine 20 mg or omeprazole 40 mg) and metoclopramide 10 mg should be given intravenously when time allows. Administration of these drugs may not reduce gastric volume or acidity at the time of tracheal intubation but will decrease the risk for aspiration at the time of extubation. For further protection against aspiration upon emergence from general anesthesia, an orogastric tube can be utilized to empty the stomach contents before extubation. Some units administer an H_2-receptor antagonist orally every 6 hours during labor to all mothers considered to be at risk for an operative delivery.

The evidence that H_2-receptor antagonists or PPIs reduce maternal morbidity and mortality has not been conclusively demonstrated; however, increasing the pH and reducing the volume of gastric contents should assist in limiting damage if pulmonary aspiration occurs. The use of cricoid pressure as part of a rapid-sequence induction technique remains standard practice.

Gastric Ultrasonography

Real-time assessment of gastric contents through the use of gastric ultrasonography may have clinical utility for cases in which nonfasted parturients require urgent cesarean delivery. The use of gastric ultrasonography to assess peripartum aspiration risk and guide anesthetic management has evolved since its first reported use in studies of gastric emptying during pregnancy.[36,37,56,57] The gastric antrum can be visualized in a saggital plane between the liver anteriorly and the pancreas posteriorly and the antral cross-sectional area (CSA) can be measured.[150] Two mathematical models have been reported to predict gastric volume based on antral CSA.[151,152] Additionally, a qualitative 3-point grading system, which assesses gastric antrum contents in both the supine and right lateral decubitus (RLD) positions, has been described[153]; grade 0 antrum is defined as the absence of fluid content in

both the supine and RLD positions, grade 1 antrum is defined as the observation of fluid in only the RLD position, and grade 2 antrum if fluid is observed in both positions. The upper 95th percentile limit of antral CSA for fasting term, nonlaboring pregnant women in this study was 10.3 cm^2 in the RLD position. In a randomized controlled trial with blinded assessors, fasted third-trimester pregnant women ingested apple juice, 0 mL, 50 mL, 100 mL, 200 mL, 300 mL, or 400 mL; antral CSA measures correlated well with ingested volume.[154] Further studies are warranted to validate the use of gastric ultrasonography for assessment of aspiration risk and anesthetic management for obstetric patients. Ultrasonographic detection of delayed gastric emptying or full stomach may serve as a trigger to avoid the use of general anesthesia or prompt administration of prophylactic neutralizing and promotility agents.

ORAL INTAKE DURING LABOR

Women in the third trimester of pregnancy exhibit a state of "accelerated starvation" if denied food and drink.[155] Fasting results in the production of ketones, primarily beta-hydroxybutyrate and acetoacetic acid, and the nonesterified fatty acids from which they are derived. These changes are exacerbated by the metabolic demands of labor and delivery. Consequently, some obstetricians and nurse-midwives have suggested that maternal oral intake policies should be liberalized during labor.[156] It is argued that allowing mothers to eat and drink during labor prevents ketosis and dehydration and subsequently improves obstetric outcome. The widespread use of neuraxial analgesia has resulted in a reduction in the use of systemic opioids for labor analgesia[113]; thus, fewer women may be at risk for opioid-induced delays in gastric emptying (with its inherent potential for aspiration). This trend has increased the demand to liberalize NPO policies during labor.[157]

A randomized study examined the effect of a light diet on the maternal metabolic profile, the residual gastric volume, and the outcome of labor.[158] Women presenting in early, uncomplicated labor at term were stratified by parity and randomized to receive a light diet or water only. Women who consumed a light diet did not have the increase in beta-hydroxybutyrate and nonesterified acid levels seen in the mothers who consumed water only. However, the gastric volumes as measured by ultrasonography were significantly larger in those who had eaten. Thus, mothers who consume a light diet during labor could be at greater risk for aspiration if general anesthesia is required. The same study design was used in another group of women, but isotonic "sports drinks" were administered instead of solid food[159]; these drinks reduced ketosis without increasing intragastric volume.

O'Sullivan et al.[160] evaluated the effect of food intake during labor on obstetric outcomes in a randomized controlled study. A total of 2443 low-risk nulliparous women in labor were randomly assigned to either an "eating" or a "water only" group. Intention-to-treat analysis was performed. No

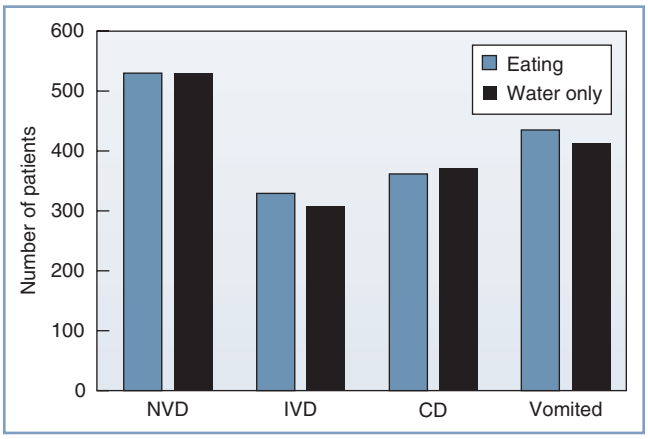

Fig. 28.9 The effect of eating during labor on maternal obstetric outcome. *CD,* cesarean delivery; *IVD,* instrumental vaginal delivery; *NVD,* normal vaginal delivery. (Based on data from O'Sullivan G, Liu B, Hart D, et al. Effect of food intake during labour on obstetric outcome: randomised controlled trial. *BMJ.* 2009;338:b784.)

significant differences were found in (1) the normal vaginal delivery rate, (2) the instrumental vaginal delivery rate, (3) the cesarean delivery rate, or (4) the incidence of vomiting (Fig. 28.9). Similarly, there was no difference between groups in the duration of labor; the geometric mean (GM) labor duration was 597 minutes in the "eating" group and 612 minutes in the "water only" group (ratio of GM, 0.975; 95% confidence interval, 0.927 to 1.025).

Maternal death from Mendelson's syndrome is now extremely rare, and its decline probably owes more to the widespread use of neuraxial anesthesia than to NPO policies. Rigid NPO policies are therefore no longer appropriate on the labor and delivery unit, and women should be allowed to alleviate thirst during labor by consuming ice chips and clear fluids (e.g., isotonic sports drinks, fruit juices without pulp, black tea, and coffee). In some high-risk pregnancies, it will remain appropriate to maintain hydration by the intravenous route, and such cases must be managed individually. The American College of Obstetricians and Gynecologists (ACOG) has stated that adherence to a predetermined fasting period before nonelective surgical procedures (i.e., cesarean delivery) is not possible.[161] They therefore conclude, along with the American Society of Anesthesiologists (ASA) and the Society for Obstetric Anesthesia and Perinatology, that *solid food should be avoided in laboring patients.*[70,161] European guidelines also discourage women from eating solid food during labor. However the European guidelines acknowledge the low incidence of aspiration in obstetrics and therefore state that *low-risk women could consume low residue foods (biscuits, toast, cereals) during labor.*[162] To date, countries with a more liberal attitude to eating during labor (e.g., the Netherlands, the United Kingdom, Australia) have not witnessed a higher incidence of maternal deaths from pulmonary aspiration. Further audit, research, and observation are required to fully inform the guidelines for oral intake during labor.

KEY POINTS

- Airway problems associated with the use of general anesthesia are a common cause of anesthesia-related maternal deaths.
- Reduced lower esophageal sphincter tone and a higher risk for difficult tracheal intubation are the primary factors that increase the risk for aspiration during pregnancy and the immediate postpartum period.
- Although pulmonary aspiration of gastric contents is rare in contemporary obstetric anesthesia practice, fatal aspiration may occur during cesarean delivery, during difficult or failed tracheal intubation, or after extubation.
- The most effective way to decrease the risk for aspiration is to avoid the administration of general anesthesia.
- The mother undergoing elective cesarean delivery should fast from solid food. Preoperative antacid prophylaxis may include an H_2-receptor antagonist.
- Preoperative prophylaxis before emergency cesarean delivery under general anesthesia should include a nonparticulate antacid. A clear antacid is preferred because aspiration of a particulate antacid results in pulmonary parenchymal damage similar to the damage that occurs after the aspiration of gastric acid. Strong consideration should also be given to administration of an H_2-receptor antagonist (or a proton pump inhibitor) and metoclopramide. These drugs may be administered after the induction of anesthesia if time does not permit their administration before induction.
- Hypoxemia is the hallmark of aspiration pneumonitis. Mechanical ventilation with positive end-expiratory pressure is the most effective treatment for severe hypoxemia. "Lung-protective" ventilation strategies (i.e., lower tidal volumes and inspiratory pressures) should be employed.
- The oral intake of clear fluids may be allowed during labor.
- Eating during labor results in larger residual gastric volumes. Eating during labor does not improve obstetric outcomes.

The Difficult Airway: Risk, Assessment, Prophylaxis, and Management

Robin Russell, MBBS, MD, FRCA

CHAPTER OUTLINE

RISK

Definitions

A **difficult airway** can be defined in several ways. A practitioner may be said to encounter a difficult airway when he or she experiences difficulty providing adequate maintenance or protection of the airway that leads to hypoxemia or soiling of the tracheobronchial tree.[1] This definition includes difficulty in providing ventilation via a face mask or supraglottic airway (e.g., laryngeal mask airway [LMA]) or tracheal intubation. The American Society of Anesthesiologists (ASA) Task Force on Management of a Difficult Airway defines a difficult airway as the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with face mask ventilation of the upper airway, difficulty with tracheal intubation, or both.[2]

The prevalence of **difficult face mask ventilation** is dependent on the definition. In one study,[3] 5% of 1502 nonpregnant patients experienced difficulty in face mask ventilation, which was defined as an oxyhemoglobin saturation value less than 92%. A multivariate analysis identified five independent risk factors for difficult face mask ventilation: (1) age older than 55 years, (2) body mass index (BMI) greater than 26 kg/m^2, (3) presence of a beard, (4) lack of teeth, and (5) a history of snoring. **Impossible face mask ventilation,** defined as an inability to exchange air during bag-and-mask ventilation despite multiple providers, airway adjuncts, and neuromuscular blockade, was reported in 77 of 50,000 (0.15%) nonobstetric anesthetic procedures.[4] Independent predictors of impossible face mask ventilation were previous neck irradiation, male sex, diagnosis of sleep apnea, and a Mallampati class III or IV (see later discussion).[4] **Difficult laryngeal mask ventilation** may be defined as the inability within three attempts of device insertion to produce expired tidal volumes more than 7 mL/kg (leak pressure greater than 15 to 20 cm H_2O).[1] In a study of 11,910 nonobstetric patients,[5] the incidence of difficult laryngeal mask ventilation was 0.19%.

Although **failed tracheal intubation** may appear to be a tangible endpoint, its definition is not standardized. Various

definitions have been used, ranging from tracheal intubation not accomplished with a single dose of succinylcholine to simply an inability to intubate during general anesthesia. Such variation inevitably leads to a difference in the reported rate of failed intubation.[6] Defining **difficult tracheal intubation** is even more complex. Difficulty may be encountered because of failure to visualize the glottis (difficult laryngoscopy) or due to an anatomic laryngeal or tracheal abnormality. Difficulty has been variously defined by (1) the time taken to intubate, (2) the number of attempts, (3) the view at laryngoscopy, and (4) the requirement for special equipment.

Although a dramatic decrease in the number of anesthesia-related deaths has been reported in the UK Confidential Enquiries into Maternal Deaths over the past 40 years,[7] complications from general anesthesia, primarily complications of airway management, continue to be a leading cause of anesthesia-related maternal mortality. Similarly, data from the United States have demonstrated a higher case-fatality rate with general anesthesia compared with neuraxial anesthesia.[8] Although the development of national guidelines[2,9,10] has resulted in a more systematic approach to the management of the difficult airway, deaths directly resulting from anesthesia still occur owing to failures in ventilation, tracheal intubation, or airway management following extubation. Despite widespread use of neuraxial anesthesia for operative delivery, general anesthesia may still be required in emergency situations, if neuraxial anesthesia is contraindicated or patients refuse it, or, most commonly, if neuraxial anesthesia fails to provide adequate anesthesia.

Incidence and Epidemiology

The incidence of failed intubation in obstetrics has long been considered to be approximately 1 in 250 to 300 (Table 29.1).[11-23] A 2015 systematic review including data from published studies, abstracts, and databases reported a failed intubation rate at cesarean delivery of 1 in 433.[6] The incidence of failed intubation for all obstetric procedures was slightly higher at 1 in 390, which likely reflects intubation difficulties resulting from airway swelling following crystalloid resuscitation in postpartum hemorrhage. The authors noted no increase in incidence from 1985 to 2014. However, there was significant heterogeneity among reports. Importantly, the authors highlighted the perceived emphasis on the need to achieve tracheal intubation. This emphasis (see later discussion) may encourage repeated efforts with their accompanying risk for morbidity.[6]

TABLE 29.1 The Incidence of Failed Intubation in Obstetrics

Study	Year	Country	Number	Incidence
Lyons[11]	1985	UK	2331	1 : 291
Samsoon[16]	1987	UK	1980	1 : 280
Rocke[12]	1992	South Africa	1500	1 : 750
Hawthorne[17]	1996	UK	5802	1 : 250

Bullough[22]	2009	UK	19,762	1 : 309
McKeen[15]	2011	Canada	2633	1 : 1300
Quinn[21]	2013	UK	12,800	1 : 224
D'Angelo[23]	2014	US	5332	1 : 533

Regardless, the failed intubation rate in obstetric patients is approximately 8 times higher than estimates of the rate in nonobstetric surgical populations.[16] A number of reasons have been proposed to explain the increased difficulty with obstetric airway management. Significant physiologic and anatomic changes of pregnancy (see later discussion) affect the airway, oxygenation, and metabolism. The majority of obstetric general anesthetics are administered for emergency deliveries, often during off-hours[24]; these anesthetic procedures may be conducted by inexperienced anesthesia providers with less proficiency in difficult airway management. Excessive cricoid pressure applied by a poorly trained assistant can worsen the glottic view at laryngoscopy,[25] as can positioning the parturient with left lateral tilt. With a decrease in the number of cesarean deliveries performed under general anesthesia, trainees have fewer opportunities to become familiar with challenges of the obstetric difficult airway.[26–28] Changes in anesthesia training, notably the reduction in trainee working hours and the advent of supraglottic airway (SGA) devices, mean that laryngoscopy and intubation are now less commonly performed than previously. Therefore, the skills required to manage a challenging tracheal intubation are less likely to have been gained before working on the labor and delivery unit without direct supervision.

Changes in maternal demographics, most notably an increase in the prevalence of maternal obesity, may increase the risk for complications from general anesthesia, especially when performed for emergency procedures. Obese women are at increased risk for obstetric interventions requiring anesthesia[29] and are at increased risk for failed neuraxial anesthesia,[30] necessitating the use of general anesthesia for emergency delivery (see Chapter 49). Difficulty with intubation has been reported to occur in 15.5% of the nonobstetric obese population.[31] A large Danish cohort study of more than 90,000 nonobstetric patients found that a BMI greater than 35 kg/m^2 was a significant risk factor for difficult intubation (odds ratio [OR], 1.34)[32]; BMI was a more accurate predictor of difficult intubation than weight alone. Data collected from one UK region from 1993 to 1998 identified 26 parturients with failed intubation at cesarean delivery; the mean BMI was 33.1 kg/m^2.[18] Poor head and neck positioning at induction of anesthesia, inappropriately applied cricoid pressure, macromastia, shorter interval from start of apnea until significant oxygen desaturation,[33,34] and operator anxiety may be responsible for a higher incidence of difficult airway management in obese patients.[13]

In contrast to some experts, others have questioned whether the rate of difficult and failed intubation is increasing

in obstetric anesthesia practice.[12,14,15] A more liberal attitude toward the use of general anesthesia has been suggested to lead to greater familiarity with maternal airway management and subsequent reduced rates of difficulty.[14] Other explanations include increased use of neuraxial blocks in those with predicted airway difficulty, focused training with a bougie as a tracheal tube guide, senior specialist–level involvement, and increasing use of video laryngoscopy and fiberoptic intubation.

Certainly the presence of experienced anesthesia staff during induction of general anesthesia is recommended and should reduce the morbidity and mortality, and perhaps the frequency, of difficulty with airway management.[24] It is hoped that the introduction and widespread acceptance of simulation training in obstetrics[35] will lead to improvement in staff performance during critical events such as difficult airway management (see Chapter 11). A need for situational awareness and recognition of the risk for fixation error, especially when dealing with emergency airway issues, was highlighted in a recent edition of the UK Confidential Enquiries into Maternal Deaths.[36]

Maternal Morbidity and Mortality

For many years the UK Confidential Enquiries into Maternal Deaths have reported thromboembolism, hypertensive disease, hemorrhage, and infection as the leading direct causes of maternal mortality. In the report covering the 2012 to 2014 triennium, pregnancy-related mortality from anesthetic causes was the 11th most common cause, accounting for 1% of maternal deaths.[7] In the United States between 1991 and 2002, 1.6% of maternal deaths were related to complications of anesthesia care, representing a 59% reduction in anesthesia-related mortality compared with data from 1979 to 1990.[8] Experience from both countries demonstrates dramatic improvements in anesthesia-related maternal mortality in the past three decades. This improvement likely reflects the tremendous efforts by national anesthesia organizations in defining standards of care that lead to improved maternal safety.

Compared with neuraxial anesthesia, general anesthesia is associated with a greater risk for maternal mortality (Table 29.2; see also Chapter 39).[8] Using data from the Centers for Disease Control and Prevention (CDC), the estimated case-fatality risk ratio for general anesthesia compared with neuraxial anesthesia was 16.7 between 1985 and 1990.[37] However, the estimated risk ratio for the period between 1997 and 2002 was only 1.7 (95% CI, 0.6 to 4.6, $P = 0.2$).[8] Improvements in monitoring and rescue airway equipment, and the publication of algorithms for difficult airway management may account for the reduction in mortality from general anesthesia.[38] The case-fatality risk for general anesthesia from the earlier period may have overstated the relative risk because the accuracy of data was questionable and it is likely that general anesthesia was used for more complex cases for which mortality was expected to be greater.[39] Unfortunately, maternal deaths directly attributable to general anesthesia are still reported.[36,40] Although protocols for the management of a difficult airway are now ubiquitous, they are not always followed.[18,41]

Hypoventilation and airway obstruction *after* extubation are now increasingly recognized as causes of maternal mortality.[7,42] In Michigan between 1985 and 2003, eight maternal deaths were believed to be related to anesthesia care; all deaths occurred during emergence from general anesthesia or the recovery period, and six of the eight patients were obese. System errors in which the care of the patient did not meet recognized standards were identified in five of the eight cases.[42] These errors included inadequate supervision by an anesthesiologist and lapses in postoperative monitoring.

TABLE 29.2 Case-Fatality Rates and Risk Ratios of Anesthesia-Related Mortality during Cesarean Delivery in the United States: 1979 to 2002

	CASE-FATALITY RATES[a]		
Year Range	General Anesthesia	Neuraxial Anesthesia	Risk Ratio
1979–1984	20.0	8.6	2.3 (95% CI, 1.9–2.9)
1985–1990	32.3	1.9	16.7 (95% CI, 12.9–21.8)
1991–1996	16.8	2.5	6.7 (95% CI, 3.0–14.9)
1997–2002	6.5	3.8	1.7 (95% CI, 0.6–4.6)

CI, confidence interval.
[a]Deaths per million anesthetics.

BOX 29.1 Anatomic and Physiologic Risk Factors for Airway Complications during Pregnancy

- Airway edema
- Decreased functional residual capacity
- Increased oxygen consumption
- Weight gain
- Breast enlargement
- Full dentition
- Decreased lower esophageal sphincter tone
- Delayed gastric emptying in labor

Physiologic and Anatomic Changes in Pregnancy

Of the multitude of anatomic and physiologic changes that occur in pregnancy (see Chapter 2), some have a significant effect on the degree of difficulty of laryngoscopy and tracheal intubation (Box 29.1).

Airway Edema

Fluid retention makes the tissues of the head and neck less compliant and may lead to narrowing of the upper airway,

especially in the supine position. Nasal congestion, snoring, and voice changes all occur more frequently in advanced pregnancy.[43] A 34% increase in Mallampati class IV scores[44] from the first to the third trimester of pregnancy has been observed (see later discussion).[45] Difficulty with intubation has been shown to be more than 11 times more common in pregnant and postpartum women with Mallampati class IV than class I scores.[12]

Although changes in the airway develop gradually during pregnancy, more acute changes may be observed during labor. Mallampati class scores deteriorate during labor.[46,47] Decreases in upper airway volume during labor have been demonstrated by acoustic reflectometry.[46] The volume of both the oral component of the airway (from the incisors to the oropharyngeal junction) and the pharyngeal component (from the oropharyngeal junction to the glottis) are decreased, presumably as a result of increasing soft tissue edema. Airway narrowing may be more significant in women with preeclampsia. The airway edema that has been observed during labor may be exacerbated by expulsive efforts during the second stage of labor,[48] after extubation after cesarean delivery,[12] or by fluid resuscitation for obstetric hemorrhage. It is therefore prudent to reevaluate the airway before induction of general anesthesia rather than rely solely on a prelabor assessment.[46]

Nasal capillary engorgement during pregnancy increases the risk for epistaxis after nasal instrumentation and has led many practitioners to believe that nasal intubation is relatively contraindicated in pregnancy. In a 2011 review, Arendt et al.[49] challenged this opinion, suggesting that nasal fiberoptic intubation is acceptable after careful and appropriate preparation of the nasal mucosa with topical vasoconstrictors. However, the effects of topical agents on both the prevention of epistaxis and maternal hemodynamic parameters and uteroplacental perfusion must be evaluated, and the relative risk associated with this procedure should be assessed on an individual basis.

Respiratory and Metabolic Changes

As pregnancy progresses, the gravid uterus increasingly encroaches on the diaphragm and lung volumes are reduced. By term, expiratory reserve volume decreases by 25% and residual volume decreases by 15%, resulting in a 20% reduction in functional residual capacity (FRC). This decrease is more marked in the supine than in the upright position, and in the obese than in the lean patient. Closing volume is unchanged in pregnancy, but the decrease in FRC results in airway closure in 50% of women in the supine position.[50] Metabolic requirements for oxygen increase by nearly 60% during pregnancy, predominantly because of fetal demands. Oxygen requirement is further increased during labor (see Chapter 2). These changes make pregnant women more likely to become hypoxemic during periods of apnea such as during the induction of general anesthesia.[51] Therefore, adequate denitrogenation (so-called preoxygenation—replacing nitrogen in the FRC with oxygen) is vital to delay the onset of hypoxemia during periods of apnea (see later discussion).

Preoxygenation and the rate of hemoglobin desaturation have been investigated by computer modeling.[34,52,53] In these models, labor, morbid obesity, and sepsis all hasten preoxygenation; however, desaturation also occurs more rapidly in the moderately ill and the obese (Fig. 29.1). Importantly, the time to life-threatening hypoxemia is significantly shorter

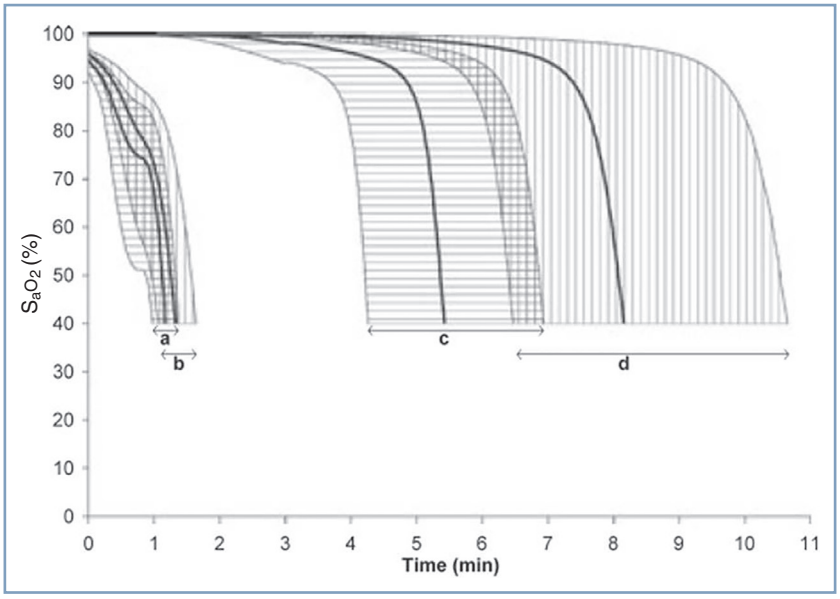

Fig. 29.1 Time course of Sa_{O_2} during apnea in pregnant (horizontal hatching) and nonpregnant (vertical hatching) virtual subjects predicted to tolerate short, average, and long periods of apnea. Heavy lines represent average subjects. (a) Pregnant subjects, no preoxygenation; (b) nonpregnant subjects, no preoxygenation; (c) pregnant subjects, 99% complete denitrogenation; (d) nonpregnant subjects, 99% complete denitrigenation. (From McClelland SH, Bogod DG, Hardman JG. Apnoea in pregnancy: an investigation using physiological modelling. *Anaesthesia*. 2008;63:264–269.)

than that for recovery from paralysis from succinylcholine.[52] Therefore, should ventilation be impossible, it cannot be assumed that the patient will recommence breathing before dangerously low levels of oxygen saturation have been reached. Alternatively, if rocuronium is used instead of succinylcholine and ventilation and oxygenation are impossible, emergency reversal of neuromuscular blockade with sugammadex 16 mg/kg is recommended. Using physiologic simulations in 40-year-old male patients in three BMI categories, Naguib et al.[54] demonstrated that sugammadex reversal of neuromuscular function with rocuronium 1.2 mg/kg was faster than spontaneous recovery of ventilation after succinylcholine 1 mg/kg. However, ventilatory depression leading to a significant fall in oxygen saturation was more likely in obese subjects. Studies of emergency sugammadex reversal in obstetric patients are currently lacking.

Weight Gain

During pregnancy, most women gain 10 to 15 kg (22 to 33 lb) or more due to increases in fat deposition, blood and interstitial fluid volume, and uterine and fetal mass. High BMI is associated with difficulty in mask ventilation and tracheal intubation[4,13] and with a greater risk for requiring emergency cesarean delivery.[29] Increasing BMI is associated with more rapid oxygen desaturation during apnea during the induction of general anesthesia.

Breast Enlargement

Breast enlargement during pregnancy may impede intubation by interfering with correct placement of the laryngoscope blade and laryngoscopic manipulation to improve visualization of the larynx. Various strategies can minimize this problem, the most important of which is optimizing the patient's position. With both arms abducted, breast tissue falls away from the chest. Ensuring that the patient is in the ideal intubating position (see later discussion and Chapter 49) further facilitates laryngoscope blade insertion; a short-handled laryngoscope is recommended. The handle can be directed toward the shoulder on insertion of the blade and then redirected once the blade is in the oropharynx.

Full Dentition

Full dentition is typically present in young pregnant women and can interfere with direct laryngoscopy, particularly if the maxillary incisors are protruding or the thyromental distance is small.[12]

Gastroesophageal Changes

Pregnancy-induced changes in the gastroesophageal system do not *per se* make laryngoscopy and intubation more difficult. However, owing to the increased risk for regurgitation and aspiration from the second trimester onward (see Chapters 2 and 28), rapid-sequence induction of general anesthesia is advocated for almost all parturients, thus potentially increasing the risk for difficult airway management. Antacid prophylaxis is therefore mandatory if surgical intervention is required.

AIRWAY ASSESSMENT

Preanesthetic assessment of the airway is necessary before both general and neuraxial anesthesia, so that plans for airway management can be made in advance. A variety of bedside tests have been used, either singularly or in combination, to predict the airway difficulty. The validity of many tests has been questioned, and it is useful to consider how these assessments have been investigated.[55] First, *airway difficulty,* the outcome, must be defined. A number of definitions have been used (see earlier discussion), including difficulty or failure with ventilation (with or without an SGA) or intubation. Second, various predictive factors that are associated with difficult airway management have been tested on different sample populations of patients.

For an assessment to be useful, it must be both sensitive (i.e., correctly identify those whose tracheas are difficult to intubate) and specific (i.e., correctly identify those whose tracheas are easy to intubate). Despite having both reasonably high sensitivity and specificity, many predictive tests have limited use in the clinical environment because failed intubation is rare; the number of false-positive tests (those predicted to be difficult that are not) will always be significantly higher than the number of true-positive tests (those predicted to be difficult that are).[55] The positive predictive value (ratio of true-positive tests to the total number of positive tests) for individual difficult airway tests is typically less than 50%; that is, fewer than one-half of the procedures predicted to be difficult will actually be difficult.[55] Despite these shortcomings in difficult airway prediction, airway assessment is a vital part of anesthetic management. Combining difficult airway tests can raise the index of suspicion for difficulty with airway management. Preanesthetic assessment allows the consideration of potential airway problems and the creation of a stepwise plan for dealing with difficulties should they arise.

Cormack and Lehane Grade

Cormack and Lehane[56] devised a glottic view grading system in 1984. The purpose of the system was to grade the glottic view obtained with direct laryngoscopy and use the grade as a means of training for general anesthesia in the obstetric patient. Therefore, the Cormack and Lehane grade is not a preoperative assessment tool but rather a classification method to describe the relative difficulty with subsequent tracheal intubation. The original description includes four grades of laryngoscopy (Fig. 29.2):

- Grade 1: Full view of glottis
- Grade 2: Partial view of glottis or arytenoids
- Grade 3: Only epiglottis visible
- Grade 4: Neither glottis nor epiglottis visible

Subsequent modifications have been proposed. Grade 2 may be divided into 2A (part of vocal cords visible) and 2B (only arytenoids or very posterior origin of vocal cords visible).[57,58] Further, Grade 3 may be divided into those in whom the epiglottis is visible and is able to be lifted, such as with a gum elastic bougie (Grade 3A), and those in which the epiglottis is visible but not able to be lifted (Grade

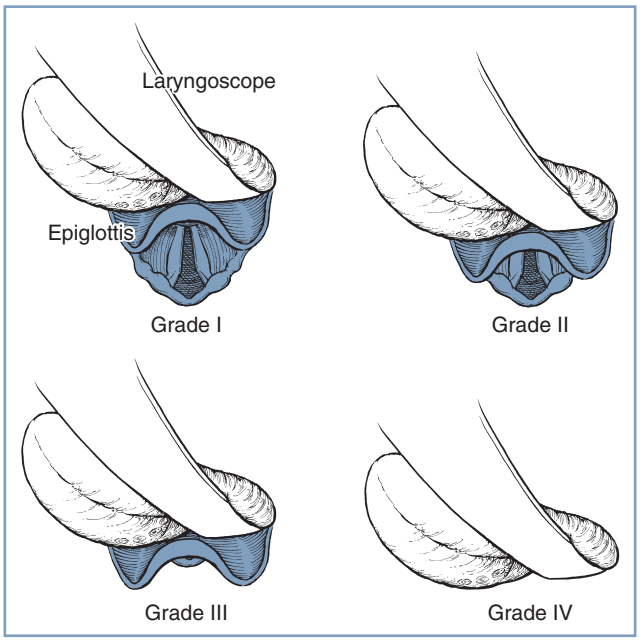

Fig. 29.2 Cormack and Lehane laryngoscopic view grades. Grade I is visualization of the entire laryngeal aperture. Grade II is visualization of only the posterior portion of the laryngeal aperture. Grade III is visualization of only the epiglottis. Grade IV is visualization of only the soft palate. (From Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia.* 1984;39:1105–1111.)

3B).[58,59] Increasing difficulty with intubation is to be expected with each progressive grade of the Cormack and Lehane classification.

Because of the widespread acceptance of the Cormack and Lehane grading system, some useful information can be gained by reviewing the anesthetic records of patients who have a previous history of direct laryngoscopy; the Cormack and Lehane glottic view grade is often documented. However, prior reports should be treated with caution because grades given in the nonpregnant state will likely differ from those determined during pregnancy, and the potential for interobserver and intraobserver variability exists.

Mallampati Class

In 1985 Mallampati et al.[44] described a three-point scale of the oropharyngeal view of the open mouth based on concealment of the faucal pillars, soft palate, and uvula by the base of the tongue; the more the view was obscured, the greater the difficulty with laryngoscopy and intubation. Samsoon and Young[16] later modified the scoring system into a four-point scale (Fig. 29.3):

- Class I: visualization of soft palate, uvula, and tonsillar pillars
- Class II: visualization of soft palate and base of uvula
- Class III: visualization of soft palate only
- Class IV: visualization of hard palate only

The test should be performed with the patient sitting upright with her head in the neutral position. The patient is instructed to open her mouth as wide as possible and protrude her tongue as far as possible *without* phonation. Increasing difficulty with laryngoscopy and tracheal intubation has been demonstrated with greater Mallampati scores in both obstetric[12] and nonobstetric populations.[44]

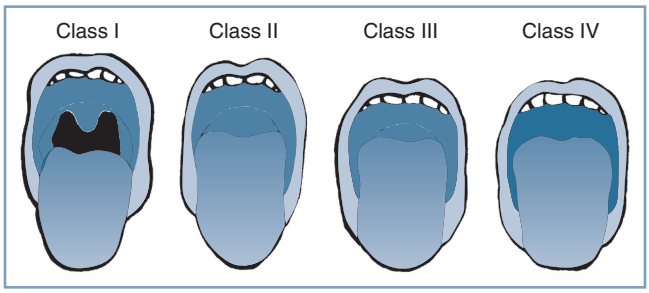

Fig. 29.3 Modified Mallampati classification of the oropharynx. Classification of the upper airway in terms of the size of the tongue and the pharyngeal structures that are visible with the mouth open. In class I, the soft palate, uvula, and anterior and posterior tonsillar pillars can be seen. In class II, the soft palate and uvula can be seen; the tonsillar pillars are hidden by the tongue. In class III, the soft palate and the base of the uvula can be seen. In class IV, only the hard palate can be seen. (From Mallampati SR, Gatt SP, Gugino LD, et al. A clinical sign to predict difficult tracheal intubation: a prospective study. *Can Anaesth Soc J.* 1985;32:429–434.)

Mallampati scores are frequently used as part of an assessment to predict difficult intubation. It is important to remember that scores change during pregnancy[45] and during labor.[46,47] When used as the sole predictor of a difficult airway, the incidence of both significant false-positive and false-negative results is high.[60] This poor predictive value may be explained by the use of phonation, poor patient positioning, involuntary arching of the tongue, and interobserver variability in interpretation. A meta-analysis of the Mallampati score concluded that the test had limited accuracy for predicting a difficult airway and was not a useful screening test.[61] Consequently, the Mallampati score is best used in combination with other tests.

Thyromental Distance

During laryngoscopy, the tongue is normally pushed into the mandibular space. The thyromental distance, the distance from the tip of the chin to the notch of the thyroid cartilage, can be used to estimate the size of this space and, therefore, whether the tongue can easily be displaced to facilitate laryngoscopy.[62] In the absence of other abnormalities, if the thyromental distance is more than 6.5 cm and the horizontal mandibular length more than 9 cm, intubation should proceed without difficulty. A thyromental distance of less than 6 cm suggests an increased risk for difficulty.[60] However, lack of detail in various studies regarding precisely how the thyromental distance was measured (whether it was performed from the inner or outer border of the mandible) make interpretation of this test difficult.

Anatomically, if the mandibular space is small and unable to accommodate the tissues displaced by the laryngoscope blade, few alterations will improve the line of vision during direct laryngoscopy.[62] When the mandibular space is small, the larynx lies relatively anterior and the tongue must be pulled forward maximally and compressed to expose the larynx.

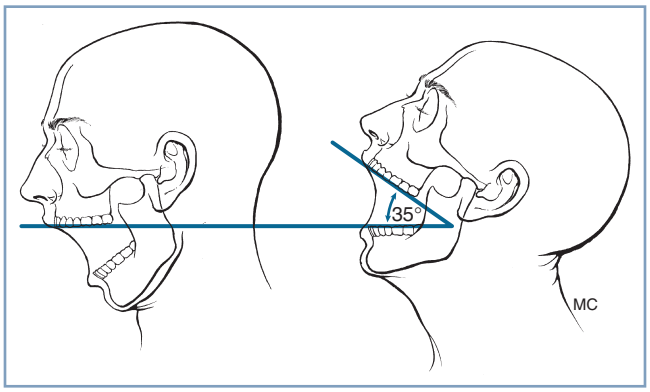

Fig. 29.4 Clinical method for quantifying atlanto-occipital joint extension. When the head is held erect and faces forward, the plane of the occlusal surface of the upper teeth is horizontal and parallel to the floor. When the atlanto-occipital joint is extended, the occlusal surface of the upper teeth form an angle with the plane parallel to the floor. The angle between the erect and the extended planes of the occlusal surface of the upper teeth quantifies the atlanto-occipital joint extension. A normal person can produce 35 degrees of atlanto-occipital joint extension. (From Bellhouse CP, Dore C. Criteria for estimating likelihood of difficulty of endotracheal intubation with Macintosh laryngoscope. *Anaesth Intensive Care*. 1988;16: 329–337.)

Atlanto-Occipital Joint Extension

Extension of the atlanto-occipital joint is necessary for the patient to be in the ideal intubating position in which the oral, pharyngeal, and laryngeal axes are aligned (see later discussion). Movement can be assessed with the patient seated with the head and neck in the neutral position facing forward and then with the joint maximally extended (Fig. 29.4). Normal extension should be 35 degrees or more; difficulty with intubation can be expected when joint movement is decreased.[62] The accuracy of this assessment is subject to interobserver variability, making its role in routine airway assessment questionable.

Mandibular Protrusion

The patient's ability to extend the mandibular teeth anteriorly beyond the line of the maxillary teeth may predict adequate visualization of the larynx during direct laryngoscopy. In the mandibular protrusion test, patients are asked to protrude their mandible as far as possible (Fig. 29.5); one of three classes is assigned:[63,64]

- Class A: The lower incisors can protrude anterior to the upper incisors
- Class B: The lower incisors can be brought edge to edge with the upper incisors
- Class C: The lower incisors cannot be brought edge to edge with the upper incisors

Class A is a good predictor of a good glottic view with direct laryngoscopy, whereas class C is associated with poor glottic view.[63]

The **upper lip bite test** (ULBT) is similar to mandibular protrusion. In class I, the lower incisors can bite the upper lip above the vermillion border (i.e., the normally sharp demarcation between the lip and the adjacent normal skin); in class II, the lower incisors can bite the upper lip below the vermillion border; and in class III, the lower incisors cannot bite the upper lip.[65] The ULBT has been shown to be a better predictor than a Mallampati score for predicting ease with laryngoscopy and intubation.[65] The ULBT cannot be assessed in edentulous patients.

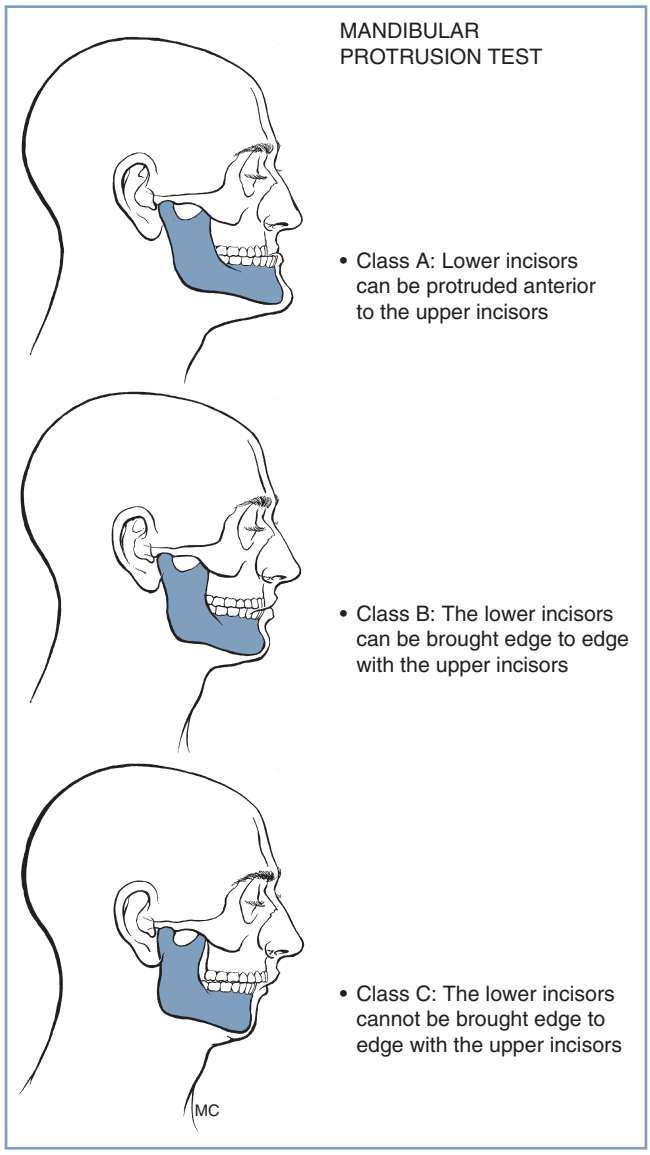

Fig. 29.5 Mandibular protrusion test. Three classifications are based on the test, which is also referred to as the upper lip bite test. (Redrawn from Munnur U, de Boisblanc B, Suresh MS. Airway problems in pregnancy. *Crit Care Med*. 2005;33:S259–S268.)

Other Assessments

Sternomental distance has been suggested to predict difficult laryngoscopy. This distance is measured between the chin and sternum with the head fully extended on the neck and the mouth closed. Unfortunately, the assessment has extremely weak predictive power, and consequently it has largely been abandoned.

Limited mouth opening impedes the introduction of a laryngoscope blade as well as other airway devices; an interincisor distance of less than 5 cm may predict difficult intubation. Mouth opening of less than two fingerbreadths has been shown to reduce the prevalence of easy intubation from 95% to 62%.[66] Mouth opening also is influenced by cervical spine movement; if movement is limited, mouth opening may also be restricted.[67] Protruding maxillary incisors, a single maxillary incisor, and missing maxillary incisors have been shown to be predictive of difficult intubation in obstetric patients.[12]

Comorbidities, including those not related to pregnancy, may influence airway management and should be considered before anticipated airway management. Most notably, maternal obesity is associated with an increased incidence of airway problems (see earlier discussion).[13,29–31] Similarly, difficulties in airway management should be anticipated in patients with severe preeclampsia.

Multivariable Assessments

Individual tests are poorly predictive of airway difficulty; therefore, investigators have combined assessments in an effort to improve specificity. Wilson et al.[68] assessed five risk factors (weight, head and neck movement, jaw movement, presence or absence of a receding mandible, prominent teeth). Each variable was scored from 0 to 2, giving a Wilson risk sum. Although 75% of cases of difficult laryngoscopy could be predicted, 12% were falsely predicted to be difficult.[68] Subsequent work using the Wilson risk sum found a positive predictive value of only 9%, and consequently it is now rarely used in clinical practice.[69]

Frerk[70] demonstrated that a combination of the Mallampati score and thyromental distance was more predictive than either test alone; the combined assessment had a sensitivity of 81% and a specificity of 98% in predicting a difficult airway. However, owing to the rarity of difficult intubation, the positive predictive value was only 64%.[70] Realizing that there was an absence of a clear description and agreement as to the method of performing individual tests, Lewis et al.[71] assessed different methods of grading the oropharyngeal view and the mandibular space as predictors of difficult laryngoscopy. Twenty-four different oropharyngeal assessments were considered using two body positions, three head positions, and two tongue positions, each with and without phonation. Similarly, the mandibular space was measured in 24 ways using two body positions, three head positions, and two distal and two proximal endpoints. The results were subject to logistic regression analysis. Although most difficult intubations could be predicted, one-half of those that were anticipated to be difficult were ultimately found to be easy, even with the most predictive combination of tests.[71]

Tse et al.[72] combined the angle at full head extension (in an upright position, the angle made by a line joining the ear tragus [apex] and the corner of the mouth to a line parallel to the floor [horizontal]), thyromental distance, and Mallampati classification in an attempt to predict difficult intubation in a general surgery population. Although these tests were likely to identify easy intubations, they had low sensitivity for predicting those in whom intubation was difficult.[72]

In a study of 400 pregnant women scheduled for elective cesarean delivery, Honarmand and Safavi[73] evaluated Mallampati class score, ratio of height to thyromental distance, and the ULBT, both in isolation and combination. A total of 8.75% of patients had a Cormack and Lehane grade 3 or 4 laryngoscopic view; the ratio of height to thyromental distance was the best predictor of this outcome.[73]

Recommendations

The thoroughness of the airway assessment often depends on the urgency with which surgery needs to be performed. For emergency procedures, relatively little time is available; thus it is prudent to assess all women in the labor and delivery suite soon after their arrival, focusing on those with the greatest risk for intervention.[74] However, changes in assessment during the course of labor must be anticipated, and reevaluation before inducing anesthesia is vital to the safe care of these patients.

The assessment should attempt to identify the patients who will be difficult to ventilate and whose tracheas will be difficult to intubate. It should start with a history to detect factors that may indicate the presence of a difficult airway, as well as the potential risk for pulmonary aspiration. Examination of previous anesthetic records, if available, may indicate problems with ventilation or intubation. The presence of comorbidities such as obesity and preeclampsia should be considered. The ASA Practice Guidelines for Management of the Difficult Airway[2] list 11 airway examination components that can be assessed (Table 29.3), acknowledging the absence of a single test that can reliably predict who is likely to present difficulty with airway management. Consequently, a combination of assessments is generally considered preferable.

Performing and documenting mouth opening, the Mallampati class, atlanto-occipital mobility, thyromental distance, and mandibular protrusion may be performed relatively quickly and should identify most patients who will present difficulties with airway management. The preanesthesia evaluation should seek to identify risk factors for difficulty with mask ventilation, laryngoscopy, airway device insertion (including intubation), and performance of a surgical airway. When risk factors are identified, appropriate plans for airway management, such as the ready availability of additional equipment and personnel (e.g., individuals experienced with airway management and the creation of a surgical airway) should be made. The proposed plan should consider that the administration of a neuraxial anesthetic technique may be the safest option for both mother and infant, even in the presence of nonreassuring fetal status. The plan must also include alternatives for situations in which the initial plan is not possible. The use of ultrasonography to identify the cricothyroid membrane before the induction of general anesthesia may improve landmark identification should emergency surgical (front-of-neck) access be required to rescue failed intubation.[75] The risks and benefits of various alternatives should be discussed with the patient and the obstetric, neonatal,

TABLE 29.3 Components of Preoperative Airway Examination

Airway Examination Component	Nonreassuring Findings
1. Length of upper incisors	Relatively long
2. Relation of maxillary and mandibular incisors during normal jaw closure	Prominent overbite (maxillary incisors anterior to mandibular incisors)
3. Relation of maxillary and mandibular incisors during voluntary protrusion	Patient cannot bring mandibular incisors anterior to maxillary incisors
4. Interincisor distance	Less than 3 cm
5. Visibility of uvula	Not visible when tongue protruded with patient sitting (e.g., Mallampati class > II)
6. Shape of palate	Highly arched or very narrow
7. Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
8. Thyromental distance	Less than three ordinary fingerbreadths
9. Length of neck	Short
10. Thickness of neck	Thick
11. Range of motion of head and neck	Patient cannot touch tip of chin to chest or cannot extend neck

Modified from American Society of Anesthesiologists. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2013;118:251–270.

and nursing teams and documented in the patient's medical record.

PROPHYLAXIS

Neuraxial Labor Analgesia

The widespread acceptance and use of neuraxial analgesic and anesthetic techniques for obstetric patients has significantly reduced the need for general anesthesia and airway manipulation. In obstetric patients in whom difficulty in airway management or neuraxial technique administration is anticipated or when risk factors for an urgent or emergent cesarean delivery are present, early or prophylactic placement of an epidural catheter should be encouraged. A *prophylactic* epidural catheter is one that is placed and tested with a small dose of local anesthetic; analgesia is not established until active labor begins, the patient requests analgesia, and/or an operative delivery is required. Such a catheter provides a readily available conduit for providing neuraxial analgesia or anesthesia, especially if rapid onset (e.g., an emergency cesarean delivery) is desirable. Early epidural catheter placement also allows the procedure to take place in a controlled setting and allows time for catheter manipulation and replacement, if necessary, before further pathophysiologic changes (e.g., decreased platelet count, worsening airway edema) occur. The correct placement of the epidural catheter in the epidural space should be tested with the injection of a local anesthetic test dose and careful bilateral sensory testing to confirm the presence of bilateral neural blockade. It should, however, be remembered that these catheters can dislodge, leading to delays in analgesia when activation is required. Starting a low-dose local anesthetic infusion after insertion of a prophylactic epidural catheter serves to verify that the catheter remains in position in the epidural space, facilitating timely extension of anesthesia if necessary.

Unfortunately, labor *analgesia* cannot always be successfully converted to surgical *anesthesia* for an operative delivery; reported failure rates are as high as 8%.[76] A 2012 meta-analysis demonstrated the need for conversion to general anesthesia in 5% of women who receive epidural analgesia in labor[77]; higher failure rates are observed among women requiring more provider interventions for inadequate epidural labor analgesia, in settings of need for urgent delivery, and when an anesthesiologist without specialty training or experience in obstetric anesthesia is providing care. Consequently, women receiving labor epidural analgesia must be evaluated at regular intervals; if analgesia is inadequate, re-siting the epidural catheter must be considered. A meta-analysis of studies comparing different local anesthetics for conversion of epidural analgesia to anesthesia found that lidocaine with epinephrine has a faster onset than bupivacaine, levobupivacaine, or ropivacaine.[78] The addition of bicarbonate to chloroprocaine or lidocaine with epinephrine further hastens the onset of local anesthetic action (see Chapter 26).

In situations in which conversion of epidural analgesia to anesthesia is not possible, general anesthesia may still be avoided if time permits the initiation of spinal or combined spinal-epidural anesthesia. However, care should be taken when administering a spinal anesthetic after a failed epidural top-up dose of local anesthetic, because cases of high and total spinal anesthesia have been reported in this setting (see Chapter 26). An airway management plan must always be in place, even if the primary plan is for the administration of neuraxial anesthesia.

Fasting and Antacid Prophylaxis

All obstetric patients requiring surgical anesthesia are at risk for pulmonary aspiration of gastric contents, particularly if airway difficulties are encountered (see Chapter 28). Because conversion from neuraxial to general anesthesia may be required either before or during surgery, strategies must be adopted to minimize this risk. The ASA and the American College of Obstetricians and Gynecologists (ACOG) recommendations allow modest amounts of clear liquid with uncomplicated labor, but they recommend the avoidance of solid foods in laboring women.[79] Clear liquids and solids are allowed up to 2 hours and 6 to 8 hours, respectively, before an elective operative procedure.[79,80] However, more liberal policies on oral intake in labor have become increasingly widespread as maternal death from aspiration becomes less

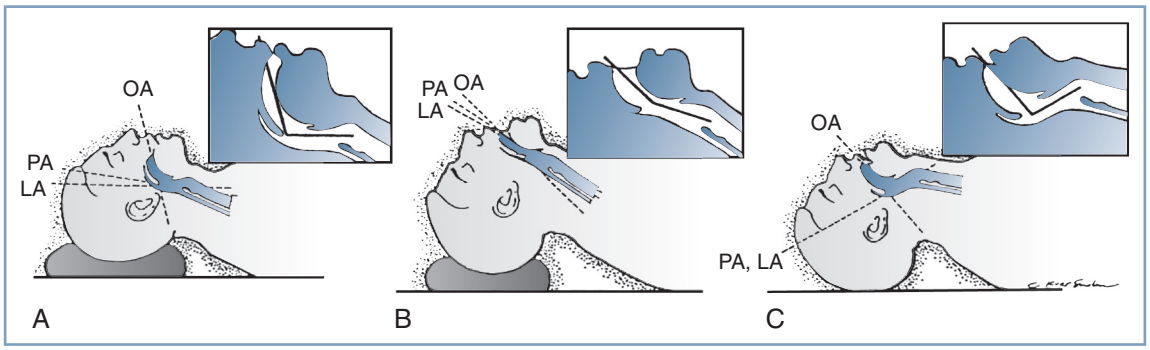

Fig. 29.6 Head and neck position during laryngoscopy. As the head position changes from neutral, the alignment of the oral axis (OA), pharyngeal axis (PA), and laryngeal axis (LA) changes within the upper airway. (A) The head is resting on a large pad that flexes the neck on the chest and aligns the LA with the PA (the neutral position). (B) The head is resting on a pad (which flexes the neck on the chest) and concomitant extension of the head on the neck can be seen, which brings all three axes into alignment (the sniffing position). (C) Extension of the head on the neck without concomitant elevation of the head on a pad, which results in nonalignment of the PA and LA with the OA. (From Benumof JL. Conventional [laryngoscopic] orotracheal and nasotracheal intubation [single-lumen type]. In Benumof JL, ed. *Clinical Procedures in Anesthesia and Intensive Care*. Philadelphia, PA: JB Lippincott; 1991:115–148.)

common. The UK National Institute for Health and Clinical Excellence suggests that women be allowed to drink isotonic fluids in labor and eat a light diet unless they develop risk factors that make general anesthesia more likely.[81] Consequently, all laboring women should be assessed and oral intake restricted if surgical intervention appears likely.

Once surgical intervention is required, antacids such as intravenous histamine-2 (H_2)-receptor antagonists or proton-pump inhibitors should be administered, if not already given, in case general anesthesia is necessary. However, these drugs take up to 30 minutes to become effective. If emergency general anesthesia is required, oral administration of a nonparticulate antacid such as sodium citrate is used to increase the pH of gastric contents. A dose of sodium citrate (0.3 molar) 30 mL is effective for approximately 30 minutes and should be administered shortly before the induction of general anesthesia.[82]

Metoclopramide promotes gastric emptying and increases lower esophageal sphincter tone, although its efficacy is decreased by concurrent use of opioids. It may be given orally in labor or intravenously before general anesthesia.

A number of deaths from presumed aspiration after tracheal extubation have been reported in the UK Confidential Enquiries into Maternal Deaths.[36] Previous reports have recommended that when general anesthesia is administered to a woman with a potentially full stomach, consideration should be given to passing an "in and out" orogastric tube before extubation.

Patient Positioning

The optimal view during laryngoscopy, which yields the best chance for successful intubation, requires appropriate patient positioning. The sniffing position, with 35 degrees of neck flexion and 15 degrees of head extension, has been considered the ideal position for facilitating a view of the glottis by aligning the oral, pharyngeal, and laryngeal axes (Fig. 29.6).[83] Although use of the sniffing position has recently been questioned, most studies find it superior to other positions. The correct use of the sniffing position requires that the external auditory meatus and sternum are in horizontal alignment. Some video laryngoscopes (see later discussion) do not require the patient's head and neck to be in the sniffing position for successful device use.

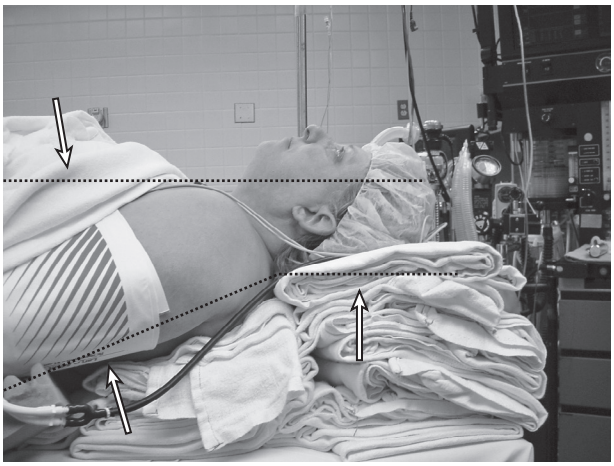

Fig. 29.7 A morbidly obese patient is in an optimal position for direct laryngoscopy when an imaginary horizontal line can be drawn from the sternal notch through (or slightly anterior to) the external auditory meatus. To achieve this, the upper back and shoulders should be significantly elevated with pads or blankets (or a commercial elevation wedge/pillow) to allow the head to be extended at the atlantooccipital joint. Additional blankets should be used to support the head in this position.

For obese patients, a ramped position is preferable (Fig. 29.7). The anteroposterior chest diameter is increased in obese patients, making 35 degrees of neck flexion unachievable in the supine position. Consequently, the shoulders and upper torso need to be raised; this position can be achieved with the use of blankets or pillows, or one of the many commercially available, wedge-shaped positioning cushions.

Optimal elevation is verified by checking that the external auditory meatus and sternoclavicular joint are in horizontal alignment. Elevating the back of the operating table by 25 degrees may make laryngoscopy easier and also aids preoxygenation (see later discussion). The operating room table should be elevated to a height at which the laryngoscopist is most comfortable, with space at the head of the bed to accommodate access for the anesthesia team and necessary equipment.

Left uterine displacement to minimize aortocaval compression should be maintained during preparation for, and induction of, general anesthesia. This may be achieved by tilting the operating table or by placing a wedge under the right hip.

Denitrogenation (Preoxygenation)

In pregnancy, the decrease in FRC and increase in oxygen requirement result in rapid oxygen desaturation during periods of apnea (e.g., during induction of general anesthesia). The FRC is the primary reservoir for oxygen during apnea. Therefore, effective denitrogenation, or preoxygenation, of the FRC is vital to delay the onset of hypoxemia.

The standard technique for preoxygenation has been to breathe 100% oxygen through a tight-fitting face mask at normal tidal volumes for 3 to 5 minutes. Given the urgent nature of obstetric general anesthesia, attention has focused on whether several maximal deep breaths over a shorter period can be as effective. Chiron et al.[84] compared a traditional 3-minute technique with either eight deep breaths over 1 minute (8 DB/1 min) or four deep breaths over 30 seconds (4 DB/30 sec). By monitoring with end-tidal fractional oxygen concentration ($F_{ET}O_2$), which is probably the best marker of lung denitrogenation, the authors found that 3 minutes of tidal volumes and the 8 DB/1 min technique were more effective than the 4 DB/30 sec technique. They suggested using the 8 DB/1 min technique in the setting of emergency obstetric anesthesia.

The use of maximal deep breaths to achieve denitrogenation may cause maternal hypocarbia and, therefore, should be limited to situations in which time does not allow normal tidal volume breathing of 100% oxygen to maximize oxygen storage in tissue and vascular body compartments. Indeed, during apnea, the time to desaturation depends on (1) the amount of oxygen stored in the lungs, tissue, and blood; (2) the mixed venous oxyhemoglobin saturation; and (3) the presence of intrapulmonary shunting.

A tight-fitting face mask is necessary to prevent air entrainment, which reduces the efficiency of preoxygenation. With normal tidal volume breathing, preoxygenation is best achieved with oxygen flow rates in excess of 10 L/min for 3 minutes,[85] although this may still be inadequate due to air entrainment; some authors suggest $F_{ET}O_2$ should be greater than 0.8 before anesthesia is induced.[86] A 20-degree to 30-degree head-up tilt increases the FRC[87] and delays the time to desaturation, especially in obese patients.[88]

There has been recent interest in the use of the transnasal humidified rapid-insufflation ventilator exchange (THRIVE) technique.[89] Using flow rates of up to 70 L/min of oxygen, desaturation was not observed despite a mean apnea time of 248 seconds in nonobstetric patients undergoing rapid-sequence induction.[90] Computer modeling of the effects of high-flow nasal oxygen in the pregnant patient has shown that with an F_IO_2 of 1.0 and a patent airway, apnea times in excess of 30 minutes can be achieved without maternal desaturation to less than 90%.[91] However, the authors cautioned against long apnea times due to a significant increase in P_aCO_2 and a fall in pH. Further work is required to determine the role of THRIVE in obstetric airway management.

Rapid-Sequence Induction and Cricoid Pressure

In an attempt to minimize the risk for aspiration, rapid-sequence induction has become the standard technique for induction of obstetric general anesthesia. It usually consists of preoxygenation, rapid intravenous injection of a predetermined dose of induction agent followed immediately by succinylcholine administration, application of cricoid pressure, and avoidance of positive-pressure ventilation before tracheal intubation with a cuffed endotracheal tube (ETT). The relative urgency of intubation, in a patient in whom ventilation is avoided, may increase the likelihood of failure.

Although in widespread use, the conduct of rapid-sequence induction is not uniform. Induction agents should provide rapid loss of consciousness with minimal hemodynamic instability while improving the quality of intubating conditions.[92] Although no longer available in the United States, thiopental has traditionally been the induction agent of choice for obstetric general anesthesia.[93] When used with succinylcholine, it provides intubating conditions that are as good or better than other agents. An additional advantage is that it can be reconstituted and stored for future use. Furthermore, some evidence suggests that, compared with propofol, thiopental leads to less maternal hypotension and fewer detrimental effects on the neonate.[93] Propofol, however, appears to offer better intubating conditions when combined with rocuronium; compared with thiopental in nonobstetric patients, visualization of the vocal cords was significantly more likely with propofol.[94] Its superiority to thiopental is most likely related to its greater ability to suppress pharyngeal and laryngeal reflexes. However, when succinylcholine is used, the choice of induction agent has no significant effect on intubating conditions.[92] With thiopental increasingly difficult to obtain, the popularity of propofol continues to increase (see Chapter 26).

Opioids have traditionally not been part of rapid-sequence induction because of concerns about respiratory depression should intubation fail. Moreover, in the obstetric population, the potential for neonatal depression is greater if opioids are used because of rapid placental transfer of these drugs.[95] In nonobstetric patients, the addition of opioids produces better intubating conditions when combined with rocuronium; this improvement has not been demonstrated with succinylcholine.[92]

Succinylcholine is associated with a number of undesirable side effects, most notably a prolonged duration of action

in patients with cholinesterase deficiency and a trigger for malignant hyperthermia and anaphylaxis. However, because of its rapid onset, succinylcholine has traditionally been the muscle relaxant of choice for rapid-sequence induction of anesthesia in obstetric patients. Despite reduced levels of plasma pseudocholinesterase in pregnancy, the duration of action of succinylcholine remains clinically unchanged in the obstetric patient.[96] The ideal dose of succinylcholine, traditionally 1 mg/kg, remains controversial[97]; when combined with opioids in nonobstetric patients, succinylcholine 1 mg/kg fails to produce good intubating conditions at 1 minute in up to 8% of cases.[98] Naguib et al.[98] found that succinylcholine doses as high as 2 mg/kg still do not guarantee excellent intubating conditions in all patients; however, the authors found little extra benefit from using doses above 1.5 mg/kg. In a study of succinylcholine in nonobstetric obese patients,[99] a dose of 1 mg/kg total body weight was found to provide more predictable laryngoscopic conditions than 1 mg/kg ideal or lean body weight.

The potential disadvantage of increasing the succinylcholine dose is delayed return of spontaneous respiration; return of spontaneous ventilation is vital should intubation not be achieved. Reducing the succinylcholine dose to 0.5 mg/kg does not appear to compromise intubating conditions, at least when administered in the nonobstetric population with propofol and fentanyl; the lower dose slightly shortens the recovery time.[100] In pregnancy, however, the reduced maternal FRC and greater oxygen demands make significant desaturation likely before the return of spontaneous respiration, no matter the succinylcholine dose. Because opioids are not commonly administered at induction, continued use of succinylcholine 1 to 1.5 mg/kg is recommended.

The side-effect profile of succinylcholine has resulted in consideration of alternative muscle relaxants for the rapid-sequence technique. **Rocuronium** is often used when succinylcholine is contraindicated. In a study of 240 women undergoing rapid-sequence induction of general anesthesia for cesarean delivery,[101] rocuronium did not prolong time to tracheal intubation, and provided less resistance to laryngoscopy and a lower incidence of postoperative myalgia than succinylcholine. However, its prolonged duration of action is a significant concern when failure to ventilate or intubate occurs. **Sugammadex,** with its ability to rapidly reverse the effects of rocuronium, may address this concern (see earlier discussion). When used with propofol for rapid-sequence induction, results of a 2015 meta-analysis[102] indicated that succinylcholine (1 mg/kg or greater) produced superior intubating conditions than rocuronium (0.6 to 0.7 mg/kg) (relative risk [RR], 0.86; 95% CI, 0.81 to 0.92). No significant difference was observed between the two agents when a larger dose of rocuronium (1.2 mg/kg) was used.[102] Therefore, succinylcholine currently remains the preferred muscle relaxant for use in rapid-sequence induction of anesthesia.

Cricoid pressure as a method to decrease pulmonary aspiration during induction of anesthesia was first described in 1961.[103] Interest in the technique was promoted by the reports of deaths due to aspiration under general anesthesia.[104] Although the effectiveness of cricoid pressure in preventing pulmonary aspiration of gastric contents has recently been challenged,[105,106] it is frequently used during the induction of obstetric general anesthesia (see Chapters 26 and 28). However, the use of cricoid pressure can adversely affect the ease of ventilation, laryngoscopy, and intubation. In a comparison of cricoid pressure with 20 N, 30 N, and 44 N of force, increasing pressure was more likely to lead to cricoid deformity and esophageal occlusion, particularly in women.[107] Difficulty with ventilation is less likely when 30 N is applied (currently accepted practice) than with 44 N (the previously suggested optimum value).[108] When correctly applied, with an increase in force from 10 N to 30 N with the induction of general anesthesia, there is little evidence of harm. However, when difficulty with intubation or ventilation arises, pressure may need to be reduced or released (see later discussion).

Although the cricoid pressure technique originally described by Sellick[103] was a one-handed technique, the placement of a second hand behind the patient's neck to prevent excessive neck flexion has been observed to provide a superior laryngoscopic view.[109] However, it should also be remembered that the two-handed cricoid pressure technique does not allow the anesthetic assistant to assist with other procedures, such as holding additional equipment necessary for difficult airway management.

MANAGEMENT

Planning

The approach to the difficult airway in the obstetric patient depends on the situation as well as the skill set of the anesthesia provider. A suggested approach for management of obstetric patients with an anticipated difficult airway is outlined in Fig. 29.8. After an initial assessment of the patient, an airway management plan should be created and shared with the patient and other members of the multidisciplinary team. In extreme cases, anesthesia considerations may influence the mode and timing of delivery. Despite a thorough airway assessment and management plan, unanticipated or unrecognized airway issues and complications may arise; alternative algorithms and equipment should be readily available to ensure oxygenation and ventilation. Emergence and extubation should also be planned in advance. Lack of forethought and planning can lead to poor decision-making in crisis situations.

Neuraxial Anesthesia

The value of establishing and confirming a functional epidural catheter during labor in patients with an anticipated difficult airway has been described (see earlier discussion). A neuraxial anesthetic technique may also be preferable in patients with an anticipated difficult airway undergoing urgent or elective cesarean delivery. The choice of anesthetic technique (e.g., single-shot spinal, combined spinal-epidural, epidural, continuous spinal techniques) depends on the circumstances and preferences of the anesthesia provider.

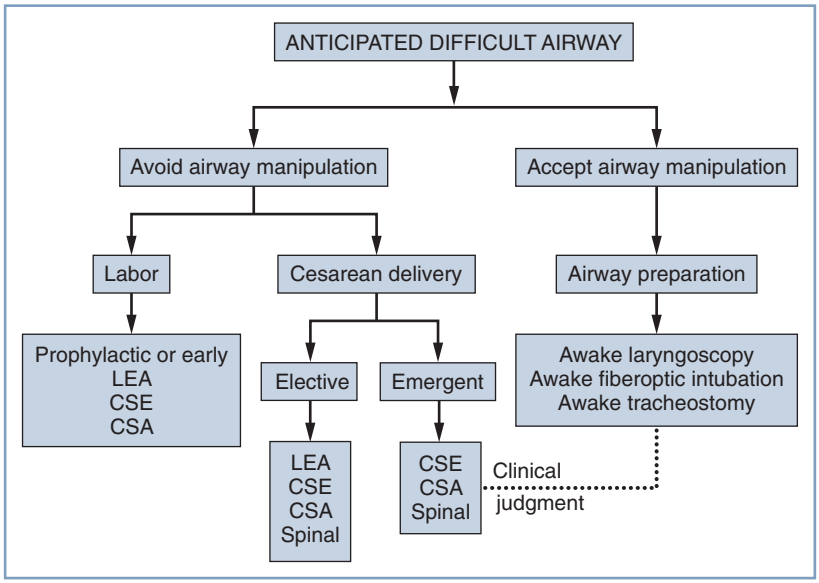

Fig. 29.8 Algorithm for anticipated difficult airway. This algorithm is not intended to provide comprehensive guidance that addresses every contingency. Rather, it should help anesthesia providers consider the various options that are available. Management should be individualized, and the anesthesia provider's clinical skills and judgment should guide decision-making. For additional information, the reader is referred to the American Society of Anesthesiologists practice guidelines.[2] *CSA,* continuous spinal anesthesia technique; *CSE,* combined spinal-epidural technique; *LEA,* lumbar epidural analgesia or anesthesia technique; *spinal,* spinal anesthesia technique.

Neuraxial techniques do not obviate the necessity of planning airway management. High spinal anesthesia necessitating urgent airway intervention is a complication of all neuraxial techniques. Epidural anesthesia may be complicated by unintentional intravascular or intrathecal injection. Despite optimal planning and execution, a neuraxial anesthetic technique may fail to provide a surgical blockade of adequate density or duration. Therefore, plans for securing the airway must always be preformulated, and standard and alternative airway equipment should be readily available.

Awake Intubation before General Anesthesia

Performing an awake intubation may be the safest option for the patient with an anticipated difficult airway, particularly if very difficult or impossible face mask ventilation is anticipated or if neuraxial anesthesia is contraindicated or fails. Even patients with an advanced upper airway pathologic process have the ability to breathe when awake. However, induction of general anesthesia with paralysis can distort airway anatomy by allowing soft tissue relaxation and movement of the larynx in an anterior direction; this distortion can make attempts at direct laryngoscopy more difficult. Therefore, an appropriate sequence of events includes securing the airway of these patients while they are awake and spontaneously breathing, before induction of general anesthesia.[110] There is a perceived notion, particularly among practitioners with limited experience with the technique, that an awake intubation is time-consuming, results in patient discomfort and anxiety, and is often difficult. In skilled hands, the technique can be accomplished quickly and comfortably with a high success rate.[111]

BOX 29.2 Advantages of a Flexible Fiberoptic Bronchoscope for Tracheal Intubation

- Flexibility and continuous visualization allows negotiation of even the most difficult anatomy
- Can be used for oral and nasal intubation
- Can be used with other devices (e.g., LMA/ILMA) to aid intubation
- Ability to instill local anesthetic through working channel is unique
- Immediate definitive endotracheal tube position check
- Excellent patient acceptability
- High success rate

ILMA, Intubating laryngeal mask airway; *LMA,* laryngeal mask airway.

Awake intubation can be performed with a number of airway management devices, but the flexible fiberoptic bronchoscope offers unique advantages (Box 29.2). Proper planning and execution, with attention to detail, are key to patient cooperation and a high success rate. Appropriate equipment must be readily available, and experienced assistance is desirable. It is useful to have two anesthesia providers: one to perform the endoscopy and another to monitor the patient.[112] Pulse oximetry, capnography, continuous electrocardiography, and blood pressure monitoring are mandatory. The level of conscious sedation must be constantly monitored to obtain the desired level for the procedure (see later discussion). Supplemental oxygen should be administered.

An unhurried, thorough explanation of the technique to the patient helps allay anxiety. Pharmacologic premedication should include prophylaxis for pulmonary aspiration and an **antisialagogue** such as intravenous glycopyrrolate 0.2 mg. A dry mouth improves topical oral anesthesia by ensuring better contact between the local anesthetic and the mucosa.[113] Secretions may also cause internal reflection from the light source and distort the fiberoptic view. Performing the procedure with the patient in the upright, rather than supine, position minimizes airway obstruction and aortocaval occlusion, enhances drainage of secretions, and allows better acceptance of topical anesthesia by the patient.

Conscious Sedation

The term *awake intubation* is a misnomer because in practice most patients receive some form of sedation to relieve anxiety, produce amnesia, and reduce pain and discomfort during the procedure. Moderate sedation/analgesia, also termed *conscious sedation,* is a drug-induced depression of consciousness during which the patient can respond purposefully to verbal or tactile stimulation.[114] No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate.[114] An overdose of the sedative/hypnotic or analgesic drugs can result in airway obstruction, hypoxemia, and cardiorespiratory depression; maintenance of continuous verbal contact is the optimal method for avoiding oversedation.[115]

The choice of drugs to produce conscious sedation depends on the preference and experience of the anesthesia provider. Small boluses of intravenous midazolam (0.5 to 1 mg) and fentanyl (25 to 50 µg) are usually adequate[116]; the use of a propofol infusion has also been described.[110] Remifentanil may confer some advantages over fentanyl in providing rapid onset, more precise titration with the ability to use an infusion, and rapid metabolism and dissipation of effects; decreased respiratory rate or apnea may be quickly reversed by stopping the infusion. Remifentanil infusion rates between 0.05 and 0.175 µg/kg/min have been used for awake fiberoptic intubation in nonobstetric patients[117]; target-controlled infusions of remifentanil, with or without propofol, can also provide ideal conditions.[118] The use of intravenous dexmedetomidine infusion to facilitate awake fiberoptic intubation at cesarean delivery has also been described.[119,120] Neonatal effects of the drugs used for sedation are usually minimal; however, the neonatologist should be informed of the drugs administered to the mother before delivery.

Topical Anesthesia

Providing adequate topical anesthesia of the upper respiratory tract is one of the most critical elements of successful awake fiberoptic intubation. Local anesthetic agents can be used in two basic ways to provide topical upper airway anesthesia: direct application to the mucosa or the injection for laryngeal nerve blocks. Topical application of local anesthetic is the most commonly used technique owing to its ease and effectiveness. There are a number of techniques. For example, the patient can be asked to gargle and slowly swallow viscous lidocaine (2% or 4%), or lidocaine (2%, 4%, or 10%) can be aerosolized and sprayed onto the tongue and oropharynx.

A number of commercially available devices, which are produced in a variety of shapes and sizes, can aerosolize and spray local anesthetic solutions in a jetlike stream. The Mackenzie technique uses an intravenous cannula with an injection port (e.g., 20- or 18-gauge) connected to oxygen tubing via a three-way connector (Fig. 29.9). Administration of local

Fig. 29.9 Topical airway anesthesia. The MacKenzie technique[121] uses a 20-gauge intravenous cannula with an injection port connected to oxygen tubing via a three-way tap to produce a jetlike spray of local anesthetic administered from a syringe connected to the cannula with the oxygen flowing at 2 L/min.

anesthetic from a syringe through the connector, with the oxygen flowing at 2 L/min, creates a jetlike spray.[121] An additional method uses a nebulizer mask or mouthpiece, with 4% lidocaine (4 to 6 mL) placed in the nebulizer bowl and connected to an oxygen source at a flow rate of 8 L/min. This method is easy to administer, noninvasive, and comfortable for the patient, with minimal or absent coughing. Each of these techniques may be insufficient as a single entity and may be combined with other methods, including instillation of local anesthetic through the working channel of the fiberoptic bronchoscope channel.

The "spray as you go" (SAYGO) technique uses the working channel of the fiberoptic bronchoscope to instill local anesthetic onto the mucous membranes of the airway. The working channel of an intubating fiberoptic bronchoscope, such as the Olympus LF-2 (Olympus America Inc., Centre Valley, PA), is 600 mm long and 1.5 mm in diameter. If a small syringe is directly attached to the working channel port and the solution is merely injected, the local anesthetic is likely to stay in the channel rather than be sprayed onto the mucosa. This problem can be overcome by placing an epidural catheter through the working channel; using a Luer-Lok connector for the epidural catheter allows a direct and tight connection with the local anesthetic syringe and avoids leakage. The local anesthetic agent is drawn up in a 2-mL syringe and "dripped" on the mucus membranes; this instillation can be better targeted if the distal tip of the epidural catheter is allowed to protrude approximately 1 cm from the tip of the fiberoptic bronchoscope.

Nerve Blocks

The nerve supply to the upper airway is derived from branches of cranial nerves V, VII, IX, and X. The lingual branch of the glossopharyngeal nerve (IX), which innervates the submucosal pressure receptors at the base of the tongue, can be blocked with the bilateral administration of 1% lidocaine (2 mL) just under the mucosa at the base of the anterior tonsillar pillars. The value or necessity of this block during performance of awake intubation in obstetric patients is controversial.[122] Laryngeal and tracheal sensation can be minimized with blockade of the internal branch of the superior laryngeal nerve and transtracheal administration of lidocaine, respectively. Blockade of the superior laryngeal nerve may be performed by locating the greater cornu of the hyoid bone, advancing a small-bore needle until the bone is contacted, walking the needle off the edge of the bone into the thyrohyoid membrane, and injecting 1% lidocaine, approximately 3 mL. The injection is then repeated on the other side of the neck.

Historically, nerve blocks were an essential part of preparing the upper airway; today, meticulous topical application is easier to perform, less invasive, and provides effective intubating conditions. A technique for topical anesthesia for oral awake fiberoptic intubation is described in Box 29.3.

Airway Anesthesia and Risk for Aspiration

Some anesthesia providers are concerned that local anesthesia of the larynx might obtund the reflexes for protecting the airway. An early study found that an unprotected glottis might result from translaryngeal block.[123] Local anesthetic solutions can spread to the superior aspect of the vocal cords after a translaryngeal block.[124] However, in a series of 129 patients, both the translaryngeal injection and SAYGO techniques were effective and safe, with no evidence of regurgitation or aspiration in any patient.[125] It has been suggested that topical anesthesia of the larynx does not impair voluntary motor function of the vocal cords, such as coughing on request,[126] thus allowing the patient to protect her airway. The SAYGO technique may be preferred because the interval between topical anesthesia and endoscopy is minimal and if gastric reflux occurs during endoscopy it can be visualized and the gastric juice aspirated through the fiberoptic bronchoscope. The key to minimizing the risk for aspiration, however, is avoidance of oversedation. Nonetheless, administration of aspiration prophylaxis is advised, and the patient should be monitored for possible reflux or emesis.

BOX 29.3 Suggested Airway Anesthesia for Awake Fiberoptic Intubation

Topical Anesthesia

- Tongue and oropharynx: 2% lidocaine gargle (5 to 10 mL) plus 4% lidocaine (3 to 4 mL) sprayed using the Mackenzie technique[a]
- Supraglottic region: SAYGO through an epidural catheter,[b] 4% lidocaine (1 to 2 mL)
- Glottic/infraglottic: SAYGO through an epidural catheter,[b] 4% lidocaine (1 to 2 mL)

Supplemental Anesthesia

- The gag reflex is tested before endoscopy with gentle suction; if it is not obtunded, transtracheal anesthesia is performed (cricothyroid puncture and injection of 4% lidocaine [3 to 4 mL])

SAYGO, spray as you go (see text).
[a]See Fig. 29.9.
[b]An epidural catheter is inserted through the working channel of the fiberoptic scope. A syringe with local anesthetic is attached to the proximal end (see text).

Fiberoptic Intubation

Fiberoptic laryngoscopy can be performed orally or nasally, but the oral route is more common because of the engorgement of the nasal mucosa and the potential for epistaxis. However, in very specific situations (i.e., when the oral aperture is insufficient to allow fiberoptic bronchoscope passage), the nasal route can be successfully used in the obstetric patient with careful topical preparation of the nasal mucosa with agents that provide anesthesia and vasoconstriction.[49]

A common impediment to successful fiberoptic laryngoscopy is being able to easily advance the ETT into the correct position. Guiding the ETT over the fiberoptic bronchoscope is a "blind" procedure. The ETT most commonly arrests at the right arytenoid cartilage.[127] In a review of the causes, incidence, and solutions to this issue, Asai and Shingu[128]

Fig. 29.10 Endotracheal tube tips. *Left,* The tip of a conventional endotracheal tube. *Right,* The tip of an endotracheal tube used with an intubating laryngeal mask airway (LMA). The Huber tip of the intubating LMA endotracheal tube is less likely to impinge on other structures, thus increasing the success of advancement and correct placement in the trachea.

noted that impingement can be minimized by selecting the appropriate size and type of ETT and by using proper advancement technique. Smaller-diameter tracheal tubes (6 to 7 mm internal diameter [ID]) that fit more snugly onto the bronchoscope generally advance more easily. The design and flexibility of the tube and tip may also determine success; for example, the intubating LMA ETT with its Huber tip is easier to advance than a flexometallic ETT during nasal fiberoptic intubation, probably owing to the acute angle of the Huber tip (Fig. 29.10).[129]

The lubricated ETT is loaded over the fiberoptic bronchoscope in its normal position (curve facing anterior, leading edge [tip] on the right, bevel facing left) and the fiberoptic bronchoscope is advanced into the airway. After the tip of the fiberoptic bronchoscope is positioned above the carina, the ETT is advanced over the fiberoptic bronchoscope into the airway. If impingement occurs, the ETT is withdrawn approximately 1 cm and rotated 90 degrees counterclockwise to bring the tip of the ETT anteriorly, and the ETT is reinserted. If this does not work, the ETT is rotated a further 90 degrees counterclockwise, and advancement is reattempted. Alternatively, the tube can be loaded on the fiberoptic bronchoscope with the tip facing anteriorly or other maneuvers may be employed, such as keeping the airway patent with jaw thrust and application of pressure on the neck to shift the vocal cords posteriorly.

Awake direct laryngoscopy results in more noxious stimulation than fiberoptic laryngoscopy, but a well-prepared and highly motivated patient may tolerate the procedure surprisingly well. Awake intubation also has been described using indirect or video laryngoscopes (see later discussion), but their role in awake intubation in the obstetric setting has yet to be determined. Other techniques for awake intubation, such as blind-nasal intubation and retrograde intubation, are performed infrequently in obstetric patients.

BOX 29.4 Advantages and Disadvantages of Video Laryngoscopes

Advantages
- Improvement in Cormack and Lehane grade 1–2 view
- Fewer failed intubations in anticipated and simulated difficult airways
- Reduced requirement for bougie and external laryngeal manipulation
- Utility as a rescue technique in patients with a difficult airway
- Assistant can view glottis and facilitate view with external glottic manipulation
- Useful teaching tool
- Possible advantage in patients with cervical spine pathology because of less need to manipulate neck
- Reduced risk for dental trauma because less force is required to align axes
- Increased rates of successful tracheal intubation for inexperienced providers

Disadvantages
- Various models with different characteristics requiring different positioning
- Limited data comparing efficacy of different models
- Learning required to become familiar with technique
- Difficulty passing endotracheal tube despite good glottic view
- Increased rate of successful intubation only in those familiar with technique
- Adequate mouth opening required
- Possibly increased time to achieve intubation

Modified from Scott-Brown S, Russell R. Video laryngoscopes and the obstetric airway. *Int J Obstet Anesth.* 2015;24:137–146.

Video Laryngoscopy

Since the introduction of the Bullard laryngoscope in the late 1980s, a number of rigid indirect-optical laryngoscopes have been developed. Frequently referred to as video laryngoscopes because of a video camera eye positioned near the tip of the blade, these devices capture an image of the glottis in real time and transmit it to a video screen.[130] Video laryngoscopes offer several advantages over conventional direct laryngoscopy (Box 29.4). To obtain a good view of the glottis with a direct laryngoscope, a line of sight from the oral opening to the glottis must be obtained by neck flexion and head extension (see earlier discussion). With video laryngoscopes, a direct line of sight to the glottis is unnecessary. In patients with an anteriorly positioned larynx, an assistant is frequently required to apply pressure on the thyroid cartilage to move the larynx posteriorly and improve the view; with the use of a

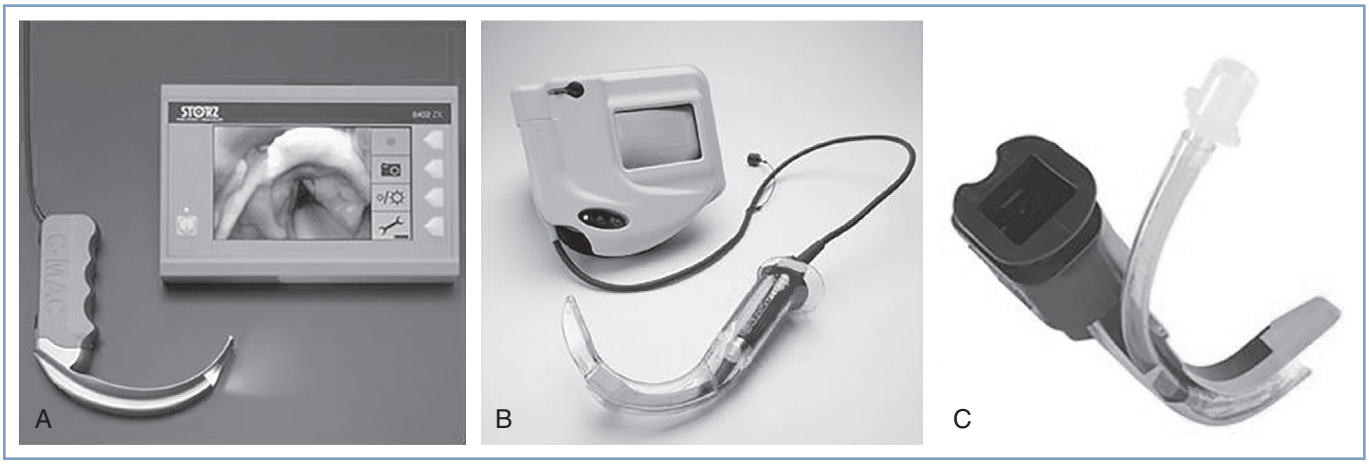

Fig. 29.11 The three categories of video laryngoscope. (A) The C-MAC video laryngoscope with a Macintosh type blade. (B) The Glidescope video laryngoscope with an anatomically shaped blade without a tube guide. (C) The Airtraq video laryngoscope with an anatomically shaped blade and a tube guide. (**A,** courtesy of Karl Storz Endoscopy, Tuttlingen, Germany; **B** and **C,** courtesy of Verathon Inc., Bothell, WA.)

video laryngoscope, the assistant may watch the screen image to directly witness the effect of the pressure.

A 2016 systematic review,[131] which included more than 7000 adult patients, found significantly fewer failed intubations when a video laryngoscope was used (OR 0.35) compared with direct laryngoscopy, and fewer failed intubations in both anticipated (OR 0.28) and simulated (OR 0.18) difficult airways. However, in patients not predicted to have a difficult airway, no significant reduction in failed intubation rate was observed. Of note, laryngeal or airway trauma was reduced when a video laryngoscope was used. Due to the high level of statistical heterogeneity, the authors did not present data on the time taken to achieve tracheal intubation.

Video laryngoscopes may be classified into three categories (Fig. 29.11)[132]:

1. *Macintosh type* (e.g., C-MAC, Karl Storz Endoscopy, Tuttlingen, Germany). These devices have a Macintosh-type blade and an insertion method similar to that used with conventional laryngoscopy. The glottis is visualized either directly or on the video screen. In the setting of anticipated difficult airway, the success rate is generally higher with these devices than with direct laryngoscopy, but external pressure and an ETT introducer are more frequently required.[133]
2. *Anatomically shaped without a tube guide* (e.g., GlideScope video laryngoscope, Verathon Inc., Bothell, WA; McGrath video laryngoscope, LMA North America, San Diego, CA). The curved shape of the blade allows a view of the glottis without flexing or extending the head and neck; however, directing the ETT toward the glottis may be difficult, resulting in trauma. Several reports have described pharyngeal and palatal injury with use of the GlideScope.[134,135] Injury is more likely when the GlideScope or ETT is inserted blindly through the mouth, when a rigid stylet is used, and when undue force is employed during ETT insertion.
3. *Anatomically shaped blade with tube guide* (e.g., Airtraq, King Systems Corporation, Noblesville, IN; The Airway Scope AWS-S100, Hoya-Pentax, Tokyo, Japan). The tip of the tube is captured on the video screen even before the device is inserted, and hence its location can be continuously confirmed during the entire course of intubation. Palatal injury has also been reported with the Pentax Airway Scope.[136]

Although there are a number of studies comparing different video laryngoscopes in normal airways,[137–139] there are few studies that compare the use of different video laryngoscopes in patients with an anticipated difficult airway.[140,141] Furthermore, it is not known whether the preoperative assessments used to predict difficult direct laryngoscopy are valid predictors of difficult video laryngoscopy. Additional investigation is necessary to compare various devices and to ascertain whether specific devices or device types are better for specific airway conditions.

Evidence of benefit of video laryngoscopy in the obstetric population is limited.[132] Arici et al.[142] performed a randomized study comparing the McGrath Series 5 with a Macintosh blade in 80 women undergoing cesarean delivery with general anesthesia. Video laryngoscopy resulted in a significantly better view of the glottic opening but a longer apnea interval. All intubation attempts were successful on the first attempt. Dhonneur et al.[143] reported the successful use of a difficult airway algorithm in which the Airtraq device was used in parturients as a rescue device if tracheal intubation failed after 2 minutes of direct laryngoscopy. During a 6-month period, 69 parturients underwent emergency cesarean delivery with general anesthesia; 2 morbidly obese parturients required the Airtraq device for successful tracheal intubation. The investigators suggested that the device might be an acceptable primary airway management tool in cases of emergency cesarean delivery in parturients with an anticipated difficult airway. Aziz et al.[144] retrospectively analyzed 180 tracheal intubations over a 3-year period in their obstetric unit. Traditional direct laryngoscopy resulted in 157 of 163 successful intubations on first attempt, with one failed

intubation (95% CI, 92% to 99%). Video laryngoscopy with a GlideScope resulted in 18 of 18 successful intubations on the first attempt (95% CI, 81% to 100%) and a successful intubation in the patient with the failed direct laryngoscopy. Of note, the patients whose tracheas were intubated with the video laryngoscope were more likely to require urgent or emergency surgery and/or have predictors of difficult direct laryngoscopy than the patients whose tracheas were intubated using direct laryngoscopy.

Video laryngoscopy has become increasing popular in anesthesia care,[145] as evidence demonstrating their potential advantages continues to be published. Literature in the obstetric population is, however, relatively sparse, although extrapolation of studies in nonpregnant patients, especially the obese, would suggest use of video laryngoscopy is of benefit. Moreover, the 2015 Obstetric Anaesthetists' Association (OAA)/Difficult Airway Society (DAS) guidelines for the management of failed intubation state that a video laryngoscope should be immediately available for all obstetric general anesthetics.[9]

Awake Tracheostomy or Surgery Standby

It is possible to perform an awake tracheostomy with local anesthesia, a technique that may be required in some situations in which airway management is anticipated to be extremely difficult and dangerous.[146] In some cases, particularly if there is a known airway pathologic process, it is prudent to request that a surgical team proficient in emergency surgical airway management be immediately available before the induction of anesthesia for cesarean delivery.

Local Anesthesia for Cesarean Delivery

Rarely, the infiltration of local anesthesia may be used as a *primary* anesthetic technique for emergency cesarean delivery in the patient with an anticipated difficult airway. This technique, which has been well described, is most often used in developing countries, where contemporary anesthetic techniques may not be readily available (see Chapter 26).[147] Few obstetricians today are familiar or proficient with this technique, but some resident training programs still provide instruction on its use.[64] A large volume (i.e., 75 to 100 mL) of a dilute local anesthetic solution, such as 0.5% lidocaine or 1% prilocaine, is often required.[148] Administration of such a large volume entails a risk for systemic local anesthetic toxicity. Mei et al.[149] described four cases in which cesarean delivery was performed with bilateral transversus abdominis plane (TAP) block and ilioinguinal-iliohypogastric (IIIH) nerve blocks using 0.5% ropivacaine 40 mL.

In some cases, it is possible to perform the entire surgical procedure with local infiltration, provided the obstetrician makes a midline abdominal incision, makes minimal use of retractors, and does not exteriorize the uterus. Alternatively, the obstetrician might begin surgery and deliver the infant with the aid of local infiltration. Temporary hemostasis may be achieved until the airway is secured and then surgery completed after the induction of general anesthesia.[147]

Cesarean delivery performed with local infiltration, if successful, has the advantages of preserving maternal hemodynamic stability and a patent airway while allowing emergency delivery of the infant. However, the technique requires a skilled and patient obstetrician; it may not be suitable when emergency delivery is necessary. Maternal anesthesia is typically incomplete and often inadequate, a fact that subsequently presents significant management issues, given that the abdomen has been opened, positioning options are limited, and the consequences of the surgical procedure such as hemorrhage may require immediate attention.

THE UNANTICIPATED DIFFICULT AIRWAY

Obstetric Anesthesia Failed Intubation Guidelines

Despite attempts to adequately assess parturients preoperatively, cases of unanticipated difficulty with airway management do occur. Therefore, the anesthesia provider and the entire operating team should have a plan to manage unanticipated difficulties in airway management *before* administering general anesthesia to obstetric patients. Until recently, guidelines on difficult airway management specifically for the obstetric patient have not been available. New guidelines have been developed that reflect the unique and often difficult conflict in which safe management of the mother may threaten the life of the fetus and vice versa. In 2013, Law et al.[150] published recommendations on difficult airway management which contained a section on the obstetric patient. Subsequently, in 2015, the OAA and DAS published guidelines on the management of difficult and failed intubation in obstetrics.[9] These guidelines are divided into three algorithms and two tables: the master algorithm is shown in Fig. 29.12.

Algorithm 1 covers safe obstetric general anesthesia practice, emphasizing the need for planning and preparation. The algorithm includes preoperative assessment of mother and fetus, multidisciplinary team planning, performance of a rapid-sequence induction, and up to three attempts at laryngoscopy. Before induction of anesthesia, the anesthesia provider and obstetrician should discuss whether to awaken the woman or continue with surgery if tracheal intubation is not possible. Patient position should be optimized, effective preoxygenation performed (see earlier discussion), and appropriate doses of drugs administered. If the first attempt at laryngoscopy produces a poor view of the larynx, consideration should be given to reducing or removing cricoid pressure, external laryngeal manipulation, head repositioning, and the use of a bougie. If this fails to improve the view, the guidelines recommend gentle face mask ventilation. For a second attempt at laryngoscopy, consideration should be given to using an alternative laryngoscope and removing cricoid pressure. If this is also unsuccessful, a third attempt should only be attempted by an experienced colleague.

Algorithm 2 summarizes the initial management of an obstetric failed intubation. Failure to intubate is communicated to the operating room team who should summon help. The priority at this stage is to maintain maternal oxygenation. This may be achieved by insertion of an SGA, preferably a

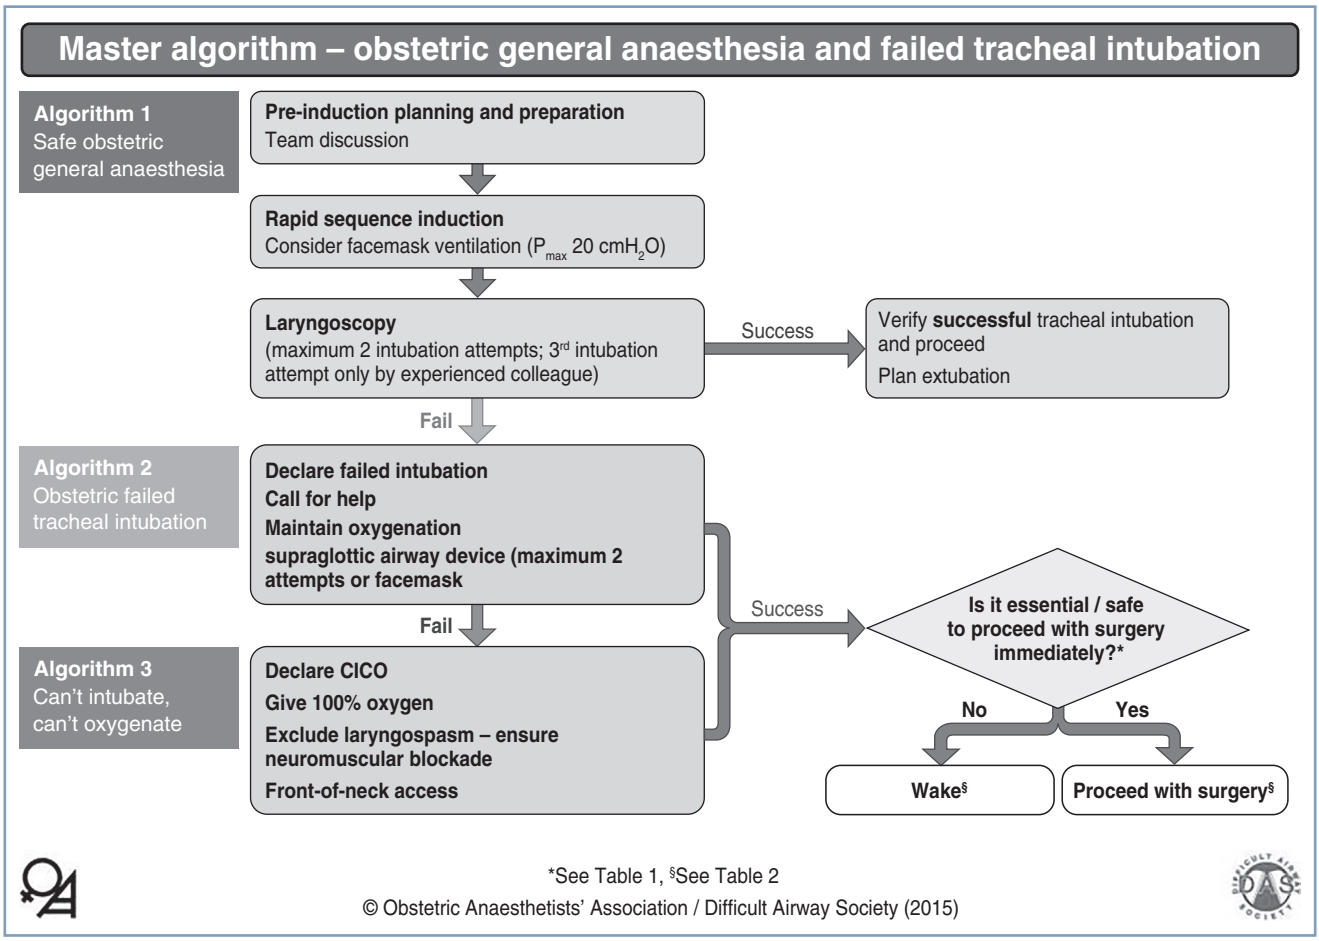

Fig. 29.12 Obstetric Anaesthetists' Association and Difficult Airway Society master algorithm for the management of difficult and failed tracheal intubation in obstetrics. *CICO,* Can't intubate, can't oxygenate; *Pmax,* maximal inflation pressure. (From Mushambi MC, Kinsella SM, Popat M, et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed tracheal intubation in obstetrics. *Anaesthesia.* 2015;70:1286–1306, with permission from Obstetric Anaesthetists' Association/Difficult Airway Society.)

second-generation device with a gastric drain (see later discussion) with cricoid pressure removed during insertion; or by face mask, with or without an oropharyngeal airway. If oxygenation is possible, a decision must then be made regarding whether to proceed with surgery. However, if oxygenation is not possible, **Algorithm 3** should be followed. This final algorithm provides details of management of a "*can't intubate, can't oxygenate*" scenario. The situation should be declared to all members of the operating room team, and specialist help (e.g., otolaryngologist, trauma surgeon, intensivist) should be summoned. Laryngospasm should be excluded and neuromuscular block ensured; 100% oxygen should be administered. Front-of-neck access (see later discussion), with either a needle or surgical cricothyroidotomy may be necessary. If successful, a decision is made on whether to proceed with cesarean delivery. If front-of-neck access fails to restore oxygenation, maternal advanced life support and perimortem cesarean delivery may be required.

Table 1 of the OAA/DAS algorithm (Fig. 29.13) provides a structure of individual factors that should aid in the decision of whether to proceed with surgery. Several factors (maternal and fetal condition, experience of the anesthesia provider, maternal obesity, anticipated surgical difficulty, aspiration risk, and possible alternative anesthetic techniques) should be addressed before induction of anesthesia. Two factors (availability of airway devices, presence of ventilation and airway hazards) are assessed after failed intubation. Although some criteria may suggest proceeding and others waking, the final decision depends on the anesthesia provider's judgment. If the mother and fetus are not in immediate jeopardy, the safest course is to awaken the mother. Once this is accomplished, other anesthetic options, such as an awake intubation or a neuraxial anesthetic technique, should be considered. The risk associated with proceeding with surgery in this scenario represents an elective commitment to the possibility of mask airway failure, the requirement of additional airway manipulation, risk for aspiration, and progression to a "*cannot oxygenate*" scenario.

If the situation is immediately life-threatening to the mother secondary to hemorrhage (e.g., uterine rupture, placental abruption), it may be necessary to proceed with cesarean delivery to optimize outcome for both the mother and

Table 1 – proceed with surgery?

	Factors to consider	WAKE			PROCEED
Before induction	**Maternal condition**	• No compromise	• Mild acute compromise	• Haemorrhage responsive to resuscitation	• Hypovolaemia requiring corrective surgery • Critical cardiac or respiratory compromise, cardiac arrest
	Fetal condition	• No compromise	• Compromise corrected with intrauterine resuscitation, pH < 7.2 but > 7.15	• Continuing fetal heart rate abnormality despite intrauterine resuscitation, pH < 7.15	• Sustained bradycardia • Fetal haemorrhage • Suspected uterine rupture
	Anaesthetist	• Novice	• Junior trainee	• Senior trainee	• Consultant / specialist
	Obesity	• Supermorbid	• Morbid	• Obese	• Normal
	Surgical factors	• Conplex surgery or major haemorrhage anticipated	• Multiple uterine scars • Some surgical difficulties expected	• Single uterine scar	• No risk factors
	Aspiration risk	• Recent food	• No recent food • In labour • Opioids given • Antacids not given	• No recent food • In labour • Opioids not given • Antacids given	• Fasted • Not in labour • Antacids given
	Alternative anaesthesia **• regional** **• securing airway awake**	• No anticipated difficulty	• Predicted difficulty	• Relatively contraindicated	• Absolutely contraindicated or has failed • Surgery started
After failed intubation	**Airway device / ventilation**	• Difficult facemask ventilation • Front-of-neck	• Adequate facemask ventilation	• First generation supraglottic airway device	• Second generation supraglottic airway device
	Airway hazards	• Laryngeal oedema • Stridor	• Bleeding • Trauma	• Secretions	• None evident

Criteria to be used in the decision to wake or proceed following failed tracheal intubation. In any individual patient, some factors may suggest waking and others proceeding. The final decision will depend on the anaesthetist's clinical judgement.

Fig. 29.13 Obstetric Anaesthetists' Association and Difficult Airway Society guidance for the management of difficult and failed tracheal intubation in obstetrics: Table 1—proceed with surgery? (From Mushambi MC, Kinsella SM, Popat M, et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed tracheal intubation in obstetrics. *Anaesthesia.* 2015;70:1286–1306, with permission from Obstetric Anaesthetists' Association/Difficult Airway Society.)

infant. Significant angst and controversy often accompany decision-making in the management of a stable mother with evidence of life-threatening fetal compromise, such as fetal bradycardia as a result of a prolapsed umbilical cord. In such cases, if mask ventilation is easy and adequate, the risk-benefit ratio of proceeding with an unsecured airway and an increased risk for aspiration should be weighed against the benefits of prompt delivery of the infant. In cases in which the maternal risk for aspiration is considered low and mask ventilation is easy, it may be reasonable to continue mask ventilation and avoid further intubation attempts. It is unclear whether continued mask ventilation or repeated intubation attempts represent the greater risk to the mother; even insertion of an SGA may further traumatize the airway or precipitate regurgitation.

The anesthesia provider should carefully consider the maternal risks of proceeding with cesarean delivery in a mother with an unsecured and unprotected airway, especially if no urgency exists and/or mask ventilation is difficult. Some obstetric anesthesiologists argue that even a nonreassuring (but not life-threatening) fetal heart rate tracing does not always justify proceeding with cesarean delivery under general anesthesia in a patient with an unsecured airway. Alternatively, in some of these cases, proceeding with cesarean delivery via mask ventilation or with an SGA may be a better option than awakening the patient, especially in those in whom neuraxial techniques are contraindicated. In these cases, the importance of communication between the obstetric and anesthesia teams cannot be overemphasized.

Table 2 from the OAA/DAS guidelines (Fig. 29.14) provides information on management after a failed intubation with information on awakening the patient and proceeding with surgery. If the patient is to be awakened, oxygenation should be maintained and cricoid pressure continued unless it impedes ventilation. The patient is positioned head-up or in the left-lateral position, and, if necessary, neuromuscular blockade is reversed. Further airway difficulty should be anticipated. Once awake, the urgency for delivery should be reviewed and alternative anesthetic options considered. In situations in which surgery is to proceed, anesthesia needs to be maintained with consideration of controlled or spontaneous ventilation. Aspiration risk should be minimized by maintaining cricoid pressure, emptying the stomach, minimizing fundal pressure, and administering antacids. Surgery

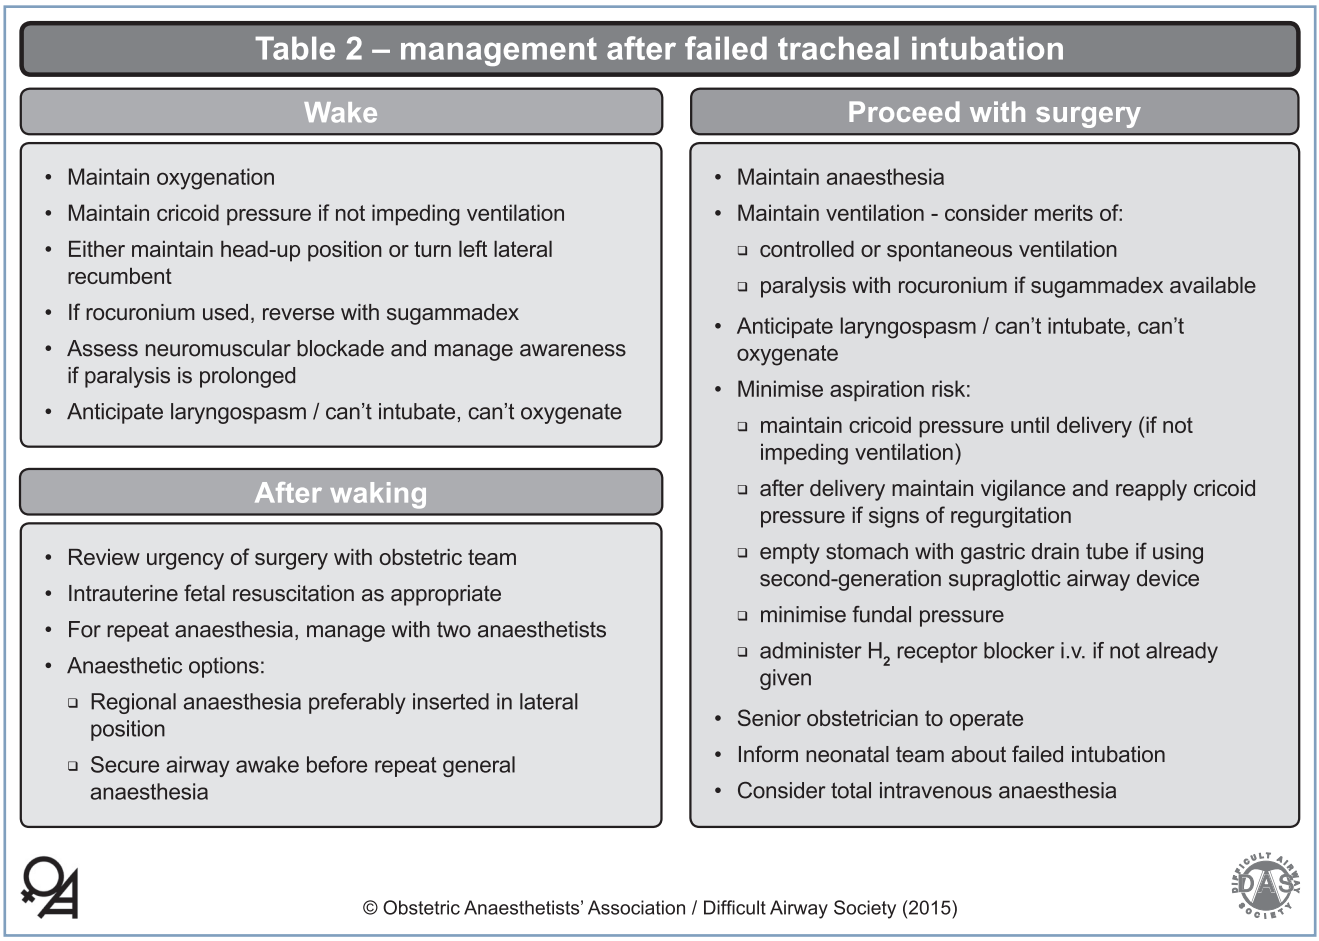

Fig. 29.14 Obstetric Anaesthetists' Association and Difficult Airway Society guidance for the management of difficult and failed tracheal intubation in obstetrics: Table 2—management after failed tracheal intubation. *i.v.,* Intravenous. (From Mushambi MC, Kinsella SM, Popat M, et al. Obstetric Anaesthetists' Association and Difficult Airway Society guidelines for the management of difficult and failed tracheal intubation in obstetrics. *Anaesthesia.* 2015;70:1286–1306, with permission from Obstetric Anaesthetists' Association/Difficult Airway Society.)

should be performed by the senior obstetrician and the neonatal team informed of the failed tracheal intubation attempt. If uterine tone is poor, propofol may be substituted for volatile agents to maintain anesthesia. Throughout surgery, the anesthetist must anticipate further airway problems.

The publication of the OAA/DAS guidelines[9] and the associated narrative review[6] are welcome additions to the armamentarium of the obstetric anesthesia provider. These important documents address problems specific to the obstetric patient; an accompanying editorial by Preston[151] highlights some important management features. The emphasis is now on *oxygenation* rather than *ventilation,* with bag-and-mask ventilation no longer forbidden. The decision to awaken the patient and perform another technique is often a difficult one. Kinsella et al.[6] concluded that there has been increasing willingness to continue with general anesthesia rather than awakening the patient over the last 40 years. Hopefully, with routine preinduction discussion and with the guidance offered in Table 1 of the OAA/DAS guidelines, this decision will be more informed. Finally, front-of-neck access (attaining a surgical airway) is not an easy rescue technique and one that is unfamiliar to many obstetric anesthesia providers. If it is to be recommended, obstetric anesthesia providers will need to master this skill.

Laryngeal Mask Airway

The LMA is arguably the SGA with which anesthesia providers are most familiar. The introduction of the LMA into anesthetic practice was a significant advance in airway management that resulted in major alterations to the difficult airway algorithms of the ASA and other societies.[2] Insertion of an LMA in an obstetric patient who can easily be ventilated by face mask is controversial, because little additional ventilation benefit is obtained and placement can induce vomiting and aspiration in this setting. However, in any situation in which conventional face mask ventilation is difficult or impossible, an SGA is the rescue device of choice.

The LMA has many advantages, most notably its ease of use and a very high initial success rate.[152] Moreover, the LMA need not be perfectly positioned over the larynx to allow adequate ventilation. When assessed by flexible fiberoptic endoscopy, radiography, and magnetic resonance imaging,

placement of the LMA around the larynx is variable[152]; however, 94% to 99% of patients with an LMA have little or no difficulty with ventilation.

In a prospective study, an LMA was inserted by experienced users in 1067 healthy parturients undergoing *elective* cesarean delivery under general anesthesia.[153] The investigators demonstrated that a clinically effective and acceptable airway was obtained on the first attempt in 98% of patients and on the second or third attempt in an additional 1%. Fewer than 1% of patients required tracheal intubation for failure to obtain satisfactory LMA placement within 90 seconds, or for an Spo_2 less than 94%, or an end-tidal CO_2 greater than 45 mm Hg. Moreover, the airway management (which was accomplished with the LMA, maintenance of cricoid pressure until delivery, and mechanical tidal-volume ventilation of 8 to 12 mL/kg) was associated with no episodes of hypoxemia (Spo_2 less than 90%), regurgitation, aspiration, laryngospasm, bronchospasm, or gastric insufflation. The investigators concluded that, in experienced hands, an LMA is effective and "probably safe" for ventilation and the administration of a volatile anesthetic agent for general anesthesia in selected healthy patients undergoing elective cesarean delivery.

Many case reports have described the use of an LMA as a rescue device for obstetric patients in whom conventional methods of securing the airway have failed. In a national case control study performed in the UK from 2007 to 2009, 39 of 57 patients with a failed intubation were managed with a classic LMA.[21]

An LMA may also act as a conduit for intubation; however, passage of an ETT without visualization has a low success rate.[154] By contrast, fiberoptic-guided intubation through the LMA has a success rate that has approached 100% in some studies.[152]

Despite these benefits, the LMA has been associated with the following disadvantages: (1) placement can induce vomiting; (2) aspiration of gastric contents is not prevented; (3) improper positioning can lead to gastric insufflation; (4) multiple insertion attempts may be required for correct placement, which may result in airway trauma; and (5) use of positive-pressure ventilation may be limited. In 0.4% to 0.6% of patients with normal airway findings, the placement of an LMA leads to inadequate ventilation[152]; reasons for this outcome have been reported to include (1) backfolding of the distal cuff, (2) occlusion of the glottis by the distal cuff, (3) complete downfolding of the epiglottis, and (4) 90- to 180-degree rotation of the mask around its long axis.

Most of the data just cited pertain to the use of the original classic LMA; several variations in LMA design have since become available. Updated designs that have been found to be useful in difficult airway management of parturients are the ProSeal LMA (LMA North America, San Diego, CA, USA) and the Fastrach LMA (LMA North America, San Diego, CA, USA). The ProSeal LMA has a specialized high-volume/low-pressure cuff that allows the device to achieve a better fit over the glottis than a classic LMA (Fig. 29.15).[155] This design allows the use of higher ventilation pressures (up to 30 to 40 cm H_2O) with less air leakage around the cuff and a lower risk for air entry into the stomach. The ProSeal LMA also contains a specialized drainage conduit that bypasses the bowl of the LMA to minimize the entry of gastric fluid into the glottis. The drainage conduit has been shown to be effective in venting both passive and active regurgitation[156,157] and can accommodate the passage of a gastric tube, which can assist in decompressing or emptying the stomach.

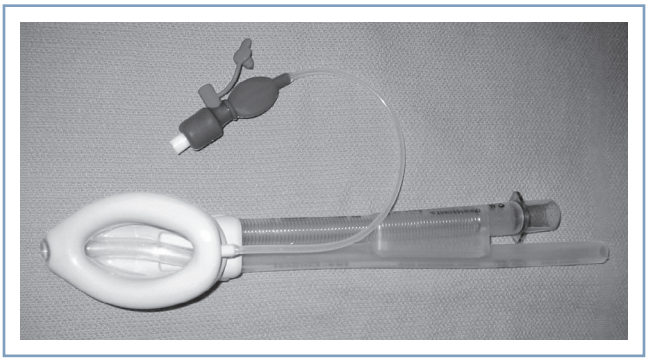

Fig. 29.15 The ProSeal LMA (laryngeal mask airway). This LMA device has a specialized high-volume/low-pressure cuff, which allows glottis coverage that enables the use of higher ventilation pressures (up to 30 to 40 cm H_2O) with less air leakage around the cuff and a lower risk for entry of air into the stomach than a conventional LMA. The ProSeal LMA also contains a specialized drainage tube that bypasses the bowl of the LMA and prevents gastric fluid from entering the glottic area. A gastric tube can be passed down this drainage lumen to assist in emptying the stomach contents.

Cook et al.[158] randomly assigned 180 nonparalyzed, nonpregnant anesthetized patients to airway management with a ProSeal or classic LMA. The ProSeal more reliably allowed positive-pressure ventilation than the classic LMA. Halaseh et al.[159] described the use of the ProSeal LMA in 3000 patients undergoing cesarean delivery who had fasted for more than 4 hours and were not thought to have a difficult airway. They established an "effective" airway on the first attempt in 2992 (99.7%) women, with only 8 patients (0.3%) requiring a change to a different LMA size. None of the patients required tracheal intubation, and only one patient experienced regurgitation of gastric contents into the mouth.[159] Minor side effects such as sore throat occurred in 21 patients (0.7%). Case reports have described the successful use of the ProSeal LMA after failed intubation in obstetric patients.[160–162]

A disadvantage of use of the ProSeal LMA in an emergency is that it requires practice and experience to use correctly. High rates of successful first-pass insertion can be achieved by loading the drainage conduit with a lubricated gum elastic bougie[163] or orogastric tube[164] and using direct laryngoscopy to position the conduit in the esophagus, and then railroading the ProSeal LMA into position. Given its complexity, this technique may not be appropriate when inserting an LMA to rescue failed intubation. A disposable, single-use version of the ProSeal LMA—the LMA Supreme—has a rigid design that facilitates high rates of successful first-pass insertion. Yao et al.[165] described the successful use of the LMA Supreme in 700 nonobese women undergoing cesarean delivery under

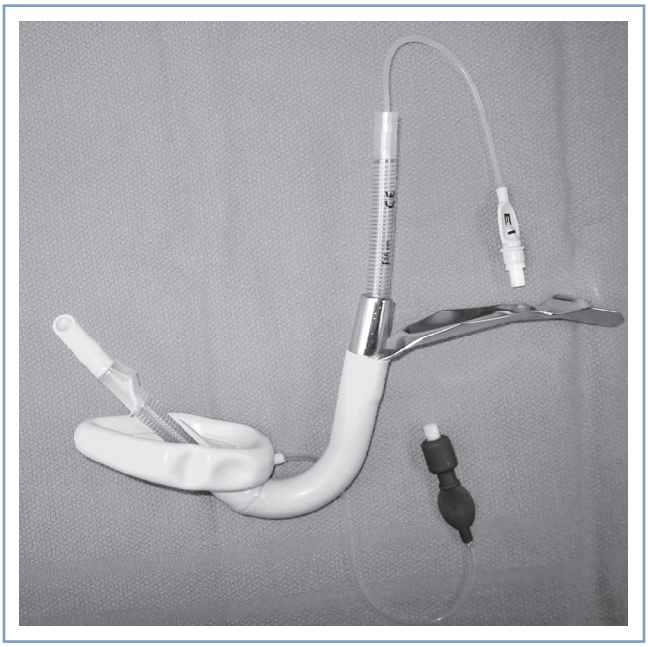

Fig. 29.16 Intubating laryngeal mask airway (LMA). This device features a more rigid *J*-shaped design than the conventional LMA to facilitate the alignment of the mask over the glottic opening and better accommodate a special soft-tipped tracheal tube for blind intubation (see Fig. 29.10).

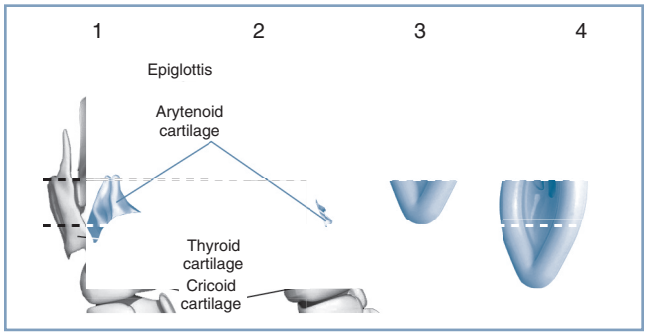

Fig. 29.17 The position of the laryngeal mask airway (LMA) with and without cricoid pressure. The blue-shaded area indicates the distal part of the LMA that occupies the hypopharynx. The dashed lines indicate anatomic correlation. *1,* Posterior view of the larynx. *2,* Lateral view of the larynx. *3,* Position of the tip of the LMA when cricoid pressure is applied. When cricoid pressure is applied before placement, the LMA, in theory, might be wedged in the hypopharynx but is more likely to occupy the space behind the arytenoid cartilages. The LMA is positioned at least 2 cm more proximal than usual. *4,* Position of the LMA when no cricoid pressure is applied. When the LMA is placed correctly, the distal tip is at the distal end of C5 (fifth cervical vertebra), and the distal part of the LMA should fully occupy the hypopharynx and the pharyngeal space behind both the arytenoid and cricoid cartilages. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

general anesthesia. Both the ProSeal LMA and LMA Supreme have a large esophageal drain that decreases the size of the airway conduit, and thereby impedes direct passage of an ETT. Further, intubating conduits (e.g., fiberoptic scope) are difficult to insert through the LMA Supreme due to its rigid design.

Although designed specifically to facilitate blind tracheal intubation, the Fastrach or intubating LMA can also be combined with fiberoptic bronchoscopy (Fig. 29.16).[166] Both reusable and disposable versions are available; unlike the Proseal LMA and LMA Supreme, neither has a gastric drainage conduit. When properly placed, the intubating LMA allows ventilation similar to that of the original LMA; however, a more rigid *J*-shaped design improves the alignment of the mask over the glottic opening and better accommodates a special soft-tipped tracheal tube for blind intubation (see Fig. 29.10). This special silicone ETT minimizes the risk for airway trauma and is available in diameter sizes 6.0 to 8.0 mm. In addition, the intubating LMA has an epiglottis elevator bar at its distal end that acts to lift the epiglottis anteriorly as the ETT exits the intubating LMA into the glottis. When a fiberoptic bronchoscope is used with an intubating LMA, the ETT should be advanced far enough to partially elevate the epiglottis elevator bar to assist the passage of the fiberoptic bronchoscope into the trachea. The successful use of the intubating LMA during a failed intubation at emergency cesarean delivery has been reported.[167]

Laryngeal Mask Airway and Cricoid Pressure

With the possible exception of the ProSeal, an LMA does not protect against pulmonary aspiration of gastric contents, and its placement may precipitate regurgitation in a lightly anesthetized patient.[168] Therefore, it is generally recommended that continuous cricoid pressure be maintained after the placement of an LMA in obstetric patients. Although a correctly placed LMA does not appear to compromise the effectiveness of cricoid pressure,[169] the use of cricoid pressure can inhibit proper insertion of the LMA and, in some cases, may make correct insertion impossible (Fig. 29.17).[170–173] The application of cricoid pressure can prevent the tip of the LMA from fully occupying the hypopharynx behind the arytenoid and cricoid cartilages. Therefore, if difficulty with insertion of an LMA is encountered during an obstetric airway emergency, consideration should be given to releasing cricoid pressure temporarily while a second attempt is made at insertion.[172] The risk for hypoxemia after failed LMA placement is most likely greater than the small risk for aspiration due to the temporary release of cricoid pressure. Once the LMA is in place, cricoid pressure can be reapplied.[169] However, in some patients, reapplication of cricoid pressure may decrease tidal volumes during positive-pressure ventilation through an LMA.[174] In such cases, a reduction in cricoid pressure typically allows adequate ventilation.

Laryngeal Mask Airway as a Conduit for Intubation

Intubation through an LMA can be achieved blindly, especially with an intubating LMA, or with the assistance of a fiberoptic bronchoscope. Before starting this maneuver, the risks and benefits of an intubation attempt must be weighed.[175] Intubation attempts should never supersede or compromise active ventilation; however, in certain situations, such as a patient at significant risk for aspiration or if ventilation is

marginal, securing the airway with an ETT may take precedence. The use of a fiberoptic bronchoscope through an LMA has been reported to be nearly 100% successful in achieving intubation.[175] A 6-mm ID cuffed ETT may be passed over the fiberoptic bronchoscope and through the shaft of a size 3 or 4 classic or intubating LMA; of note, a nasal RAE tube (Nellcor, Boulder, CO) is a suitable match for this purpose, owing to its adequate length and widespread availability.[176] A 7-mm ID cuffed ETT may be passed in a similar manner through the shaft of a size 5 classic or intubating LMA.

When a fiberoptic bronchoscope is passed through an LMA, the bronchoscope should be introduced through the self-sealing diaphragm of an elbow adapter attached to the ETT and the airway circuit to allow continuous ventilation. The space available for ventilation around a 4-mm outer diameter (OD) fiberoptic bronchoscope placed within a 6-mm ID ETT is equivalent to that available with a 4.5-mm ID tube. Alternatively, a two-stage method can be employed, in which a fiberoptic bronchoscope is placed through the lumen of an Aintree Intubation Catheter (Cook Critical Care, Bloomington, IN) and the stem of a size 3 or 4 LMA. With the LMA in the oropharynx, the fiberoptic bronchoscope and Aintree Catheter are advanced through the vocal cords, the fiberoptic bronchoscope withdrawn, and then an ETT is guided over the Aintree Catheter.[177] There are no studies assessing the success rate of these advanced techniques that use the LMA as a conduit for tracheal intubation; however, these techniques take time and skill and should be performed by anesthesia providers experienced in their use.

Laryngeal Tube and Esophageal-Tracheal Combitube

The laryngeal tube (VBM Medizintechnik GmbH, Sulz, Germany) is another SGA device.[178,179] Laryngeal tubes are manufactured from either silicone or polyvinylchloride (PVC) and have ventilation apertures between a proximal oropharyngeal cuff and a distal esophageal cuff. The laryngeal tube is inserted into the oropharynx until resistance is met, which should result in positioning of the ventilation apertures directly above the glottic opening. These devices are reported to provide seal pressures similar to those with the ProSeal LMA (40 cm H_2O) and insertion times and success rates comparable to those of the LMA.[180] The Laryngeal Tube-S (LTS) contains a second lumen that can be used for drainage of the stomach.[181] The LTS has been used successfully after a failed intubation and ventilation in a patient undergoing emergency cesarean delivery.[182]

The esophageal-tracheal Combitube (ETC) (Sheridan Catheter Corporation, Argyle, NY) is a twin-lumen plastic tube with an outer diameter of 13 mm. One lumen has an open distal end and thus resembles a tracheal tube (i.e. the tracheal lumen), and the other (esophageal) lumen has a closed distal end. The ETC has a 100-mL proximal pharyngeal balloon; when the ETC is correctly positioned, the pharyngeal balloon fills the space between the tongue base and soft palate. When inflated, the proximal balloon seals the oral and nasal cavities. Distal to the pharyngeal balloon, but proximal to the level of the larynx, are eight perforations in the esophageal lumen. A smaller 15-mL distal cuff, similar to that on an ETT, seals either the esophagus or trachea when inflated. The ETC is inserted, with or without the aid of a laryngoscope, but its insertion does not require visualization of the larynx. Indeed, in the usual clinical context, the larynx cannot be visualized. The ETC enters the esophagus 96% of the time, allowing ventilation through the esophageal lumen perforations.[183] If the ETC enters the trachea, the patient's lungs can be ventilated directly through the tracheal lumen. Therefore, regardless of whether the distal end of the ETC enters the trachea or esophagus, the anesthesia provider can ventilate the lungs, assuming correct identification of which lumen should be used for ventilation.

The ETC allows adequate ventilation while preventing aspiration of gastric contents. If the distal end of the ETC enters the esophagus, the ETC can assist in removing gastric fluids through suction applied to the "tracheal" lumen. When long-term ventilation is anticipated or required, the ETC should be exchanged for an ETT.

Use of the ETC in the out-of-hospital setting has been associated with a notable incidence of serious complications, including upper airway bleeding, esophageal laceration and perforation, and mediastinitis.[184] Although a lower incidence of serious complications would be expected in the more controlled operating room environment with an anesthesia provider using a laryngoscope to facilitate placement, the stiffness and the anterior curvature of the ETC, as well as the potential for balloon overinflation, still represent potential sources of airway and esophageal injury.

Cannula and Surgical Cricothyrotomy

The anesthesia provider must diagnose the failure of face mask and alternative devices to oxygenate and ventilate the patient and decide that direct tracheal access is necessary. A delay in performing cricothyrotomy results in greater morbidity and mortality than complications resulting from the attempt.[41,185] Three techniques for cricothyrotomy are available[186]:

1. Narrow-bore cricothyrotomy using a purpose-designed cannula less than 2-mm ID (e.g., Ravussin; VBM Medizintechnik GmbH, Sulz, Germany)
2. Wide-bore cricothyrotomy using a purpose-designed cannula greater than 4-mm ID (e.g., QuickTrach; VBM Medizintechnik GmbH, Sulz, Germany)
3. Surgical cricothyrotomy using a scalpel to enable placement of a small (less than 6-mm ID) standard tracheal or tracheostomy tube

Narrow-bore cannula cricothyrotomy requires the use of a high-pressure ventilation source (e.g., Manujet) for transtracheal jet ventilation (TTJV). The other two techniques use standard ventilation circuits. Most TTJV systems have an in-line regulator that allows the delivery pressure between 0 and 50 psi. A minimum pressure of 20 to 30 psi is required in the majority of patients to inflate the chest and provide appropriate tidal volumes and minute ventilation.[187] During TTJV, it is critical that the operator allow time for exhalation

of inspired gas to avoid hyperinflation of the lungs, potential air trapping, and barotrauma.[188–190] Exhalation can be facilitated by keeping the airway patent by some means (e.g., nasal/oral airway, jaw thrust, LMA). There are numerous reports of the use of TTJV as a means to prevent hypoxemia during life-threatening airway emergencies[190–192] and as a temporizing measure before a more definitive surgical airway can be established.

Although cannula cricothyrotomy is faster and carries significantly fewer risks, its success rate is much lower than that of surgical cricothyrotomy.[112,186] Frerk and Cook reported failure in 12 of 19 emergency narrow-bore cricothyroidotomies and three failures out of seven with wide-bore cricothyroidotomies. Skill fade associated with increased length of time since training is likely to have a more significant impact on outcome than choice of device.[186] The choice of technique can therefore be determined by local protocols. As highlighted by Preston,[151] the anesthesia provider should evaluate and practice various airway techniques to maximize success during an emergency. The role of ultrasound in locating the cricothyroid membrane has recently received attention[193]; further research is required to assess its benefit in emergency front-of-neck access.

EXTUBATION OF THE PATIENT WITH A DIFFICULT AIRWAY

General Principles

Tracheal extubation is a critical step during emergence from general anesthesia. Airway condition at the time of tracheal extubation may be less favorable than at induction of anesthesia. The patient's disease process (e.g., preeclampsia) may contribute to worsening airway edema, as do fluid and blood products that have been administered during the procedure. Comorbidities, such as obesity and obstructive sleep apnea, may contribute to an increased risk for airway compromise after extubation of the trachea. Although the majority of extubations occur without incident, a number of serious adverse events, including hypoxic brain injury, can occur during emergence from general anesthesia and tracheal extubation or in the postoperative period.[42,194]

After publication of the ASA guidelines for management of the difficult airway,[2] a statistically significant reduction in airway claims arising from injury at *induction* of anesthesia was observed.[195] However, the number of claims arising from intraoperative events and those at extubation and during recovery has not changed. Death and brain injury occur more commonly after extubation and during recovery than during induction of anesthesia.[195] Not surprisingly, extubation problems are more common in obese patients and in those with obstructive sleep apnea.[195] In the fourth National Audit Project (NAP4) of the Royal College of Anaesthetists and DAS, major airway complications in patients receiving anesthesia occurred during emergence or recovery in approximately one-third of the reported cases.[112]

Extubation is an elective procedure that should always have a management strategy.[196–198] The goals of extubation management are to ensure uninterrupted oxygen delivery, avoid airway stimulation, and allow ventilation and possibly reintubation with minimum difficulty and delay should extubation fail. The DAS Extubation Guidelines[10] describe a four-step approach to the safe management of tracheal extubation:

- Step 1: Plan extubation
- Step 2: Prepare for extubation
- Step 3: Perform extubation
- Step 4: Postextubation care: recovery and follow-up

The planning and preparation steps allow the anesthesia provider to stratify risk and categorize the patient as either at *low risk* or *at risk* for extubation complications. A fasted patient with an uncomplicated airway is at *low risk,* whereas a patient at risk for aspiration in whom the ability to oxygenate and reintubate is potentially difficult is *at risk*.[10] By definition, all obstetric patients fall into the "at-risk" group owing to the risk for pulmonary aspiration.[10] A crucial decision is to determine whether it is safe to extubate the trachea or to postpone the extubation. Unfortunately, studies attempting to identify risk factors that can reliably predict difficulty with extubation, performed almost entirely in the critical care population, have been inconclusive.[199] The leak test, in which the ETT cuff is deflated, the proximal end of the tube is occluded, and the patient is evaluated to determine if she can spontaneously ventilate around the tube, has not been uniformly demonstrated to predict success with extubation.[200]

If the surgical procedure was long, or massive bleeding and significant fluid replacement has occurred, consideration should be given to transferring the patient to the intensive care unit and delaying tracheal extubation. The decision to remove the ETT should follow a full assessment of the patient (i.e., ability to follow commands, appropriate level of consciousness, recovery from neuromuscular blockade). The head of the bed can be elevated or the patient positioned on her left side. Patients for whom oxygenation and/or reintubation is predicted to be difficult may benefit from the insertion of an airway exchange catheter before tracheal extubation (see later discussion).

Airway Exchange Catheters

In situations in which the patient appears ready for extubation but concerns exist regarding potential difficulty with—and/or need for—reintubation (e.g., difficult intubation), establishing continuous airway access may be of benefit; such access can be achieved with an airway-exchange catheter (AEC) inserted through the ETT before extubation.[201–204] There are many commercially available AECs: the Cook AEC (Cook Critical Care, Bloomington, IN) is a long, thin, hollow tube made from semirigid thermostable polyurethane. It has a blunt end with distal terminal and side holes; it is radiopaque and has length markings on its outer surface. The catheter is supplied with a removable 15-mm connector that is compatible with anesthetic circuits for oxygenation and Luer-Lok connectors for use with high-pressure source (jet) ventilation. AECs are available in various sizes; the most appropriate sizes for extubation are of sufficient length

(e.g., 83 cm) and diameter (e.g., 11- to 14-gauge) to remain between the vocal cords while removing and/or reinserting an ETT. These catheters are compatible with tracheal tubes of internal diameters greater than 5 and 4 mm, respectively. Successful reintubation can be enhanced by the use of a smaller tracheal tube and rotation of the ETT 90 degrees during insertion to facilitate passage of the bevel through the vocal cords.[128]

Mort[203] evaluated 354 patients with potentially difficult airways who were extubated over an AEC; 51 required reintubation. The reintubation success rate was greater than 90%. Complications during airway management, including low oxygen saturation, bradycardia, hypotension, esophageal intubation, and the need for accessory airway adjuncts, were less common when an AEC was used to assist reintubation than without. Successful outcomes have been reported in other similar studies.[201,205] Visualization of the larynx, either by direct or video laryngoscopy, during AEC use can also increase the success of reintubation and reduce the incidence of complications.[206]

Morbidity associated with AEC use is predominantly a result of inappropriate positioning and failure of oxygenation. The distal tip of the AEC is ideally positioned in the mid-trachea; oxygen insufflation and jet ventilation through an AEC should only be undertaken with extreme caution; barotrauma and death have been reported.[202,207,208]

KEY POINTS

- Morbidity and mortality associated with airway management are key concerns for obstetric anesthesia providers.
- Difficulties with airway management occur with both intubation and extubation of the trachea.
- Physiologic and anatomic changes of pregnancy, such as airway edema, respiratory and metabolic changes, weight gain, breast enlargement, and the risk for gastroesophageal reflux, contribute to difficult airway management.
- All parturients receiving either general or neuraxial anesthesia must undergo airway assessment; plans should be devised for airway management.
- Airway difficulty is best predicted using a combination of assessments, including Mallampati class, thyromental distance, atlanto-occipital extension, and protrusion of the mandible.
- Early administration of neuraxial labor analgesia is recommended in those with an anticipated difficult airway.
- Antacid prophylaxis should be given to all parturients who require general or neuraxial anesthesia.
- Correct positioning of the parturient on the operating table is necessary to maximize the chance of successful tracheal intubation, especially in the obese parturient.
- Securing the airway before inducing general anesthesia may be the safest option in patients in whom airway management is expected to be difficult.
- Maintenance of maternal and fetal oxygenation is the primary objective in the management of an unanticipated difficult airway.
- If conventional mask ventilation is difficult or impossible, a supraglottic airway (e.g., laryngeal mask airway) is the rescue device of choice.
- Needle cricothyrotomy with transtracheal jet ventilation can be life sustaining when other means to achieve adequate oxygenation have failed.
- In parturients known to be difficult to intubate or with risk factors for a difficult airway, caution must be employed with both intubation and extubation of the trachea.
- Potential or actual airway difficulties should be discussed with obstetricians, and management decisions should incorporate multidisciplinary communication and cooperation.

Postpartum Headache

Feyce Peralta, MD, Alison Macarthur, BMSc, MD, FRCPC, MSc

CHAPTER OUTLINE

Postpartum headache is the complaint of cephalic, neck, or shoulder pain occurring during the first 6 weeks after delivery. The incidence of postpartum headache throughout the 6-week postpartum period has not been followed in a prospective manner. However, information is available from several sources, including an evaluation of women during the first week postpartum,[1] from a database that recorded symptoms during pregnancy and in the first week after delivery,[2] from a secondary analysis of parturients followed for postpartum pain,[3] and from a survey of women at 5 months and 1 year postpartum.[4] Goldszmidt et al.[1] evaluated 985 women during the first week postpartum and found a 38.7% incidence of headache. The median time to onset of symptoms was 2 days, and the median duration of headache was 4 hours. Benhamou et al.[2] examined information collected on pregnant women who delivered at their institution during a 2-year period; exclusion criteria included recognized dural punctures, preterm deliveries, multiple gestation, and/or elective cesarean delivery. Headache was reported by 12% of 1058 patients who had epidural analgesia without recognized dural puncture and by 15% of 140 patients who delivered without epidural analgesia. Turner et al.[3] evaluated patients at four university hospitals in the United States and Europe and found that 10% reported headache during pregnancy, 3.7% within 72 hours after delivery, and 3.6% at 8 weeks postpartum. A history of headache before pregnancy was predictive of headache during pregnancy and at 8 weeks postpartum but not at 72 hours. A history of intrapartum headaches was independently associated with headaches at 72 hours. Saurel-Cubizolles et al.[4] surveyed 1286 women on their general health following their first or second delivery and found the incidence of headache was 22% and 42% at 5 and 12 months, respectively.

Post–dural puncture headache (PDPH) is one of the most common postpartum complications of neuraxial anesthesia. However, physicians and nurses should be aware that a dural puncture is only one of many causes of postpartum headache (Table 30.1). Most headaches are benign or do not require immediate attention; however, the timely diagnosis of some headaches (e.g., cortical vein thrombosis, subdural hematoma) is critical to good outcomes. Knowledge of both benign and nonbenign headaches is important for the anesthesiologist who is frequently the first physician to evaluate the patient with postpartum headache. Difficult diagnostic problems may require a consultation with a neurologist or imaging studies. The purpose of this chapter is to discuss the differential diagnosis of postpartum headache and PDPH in particular.

DIFFERENTIAL DIAGNOSIS OF POSTPARTUM HEADACHE

The classification of headaches follows the International Classification of Headache Disorders (ICHD), created in 1988 by the Headache Classification Committee of the International Headache Society. This classification system, which was updated in 2018 (3rd edition), identifies two broad categories of headaches: primary and secondary (Box 30.1).[5] Primary headaches are classified as migraine, tension-type headache, trigeminal autonomic cephalalgia, or other primary headache disorders associated with recurring activities (e.g., coughing, strenuous exertion, sexual activity). Secondary headaches are attributable to a specific underlying pathologic process. Primary headaches are 20 times more common than secondary headaches among women in the first week postpartum.[1] In a study of 95 women identified

TABLE 30.1 Differential Diagnosis of Postpartum Headache

Headache Etiology	Primary Symptoms/Signs	Diagnostic Modality
Tension headache	Mild to moderate headache, lasting 30 minutes to 7 days Often bilateral, nonpulsating, and not aggravated by physical activity	History and physical examination
Migraine	Recurrent moderate to severe headache, lasting 4 to 72 hours Often unilateral, pulsating, and aggravated by physical activity Associated with nausea, photophobia, and phonophobia	History and physical examination
Musculoskeletal	Mild to moderate headache accompanied by neck and/or shoulder pain	History and physical examination
Preeclampsia/eclampsia	Hypertension and/or HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome Headache often bilateral, pulsating, and aggravated by physical activity	History and physical examination Laboratory evaluation (alanine aminotransferase [ALT], aspartate transaminase [AST], uric acid, platelet count, urine protein)
Posterior reversible (leuko) encephalopathy syndrome (PRES)	Severe and diffuse headache with an acute or gradual onset Possible focal neurologic deficits and seizures	History and physical examination MRI
Stroke	Ischemic or hemorrhagic. *Cerebral infarction/ischemia:* new headache that is overshadowed by focal signs and/or disorders of consciousness. *Subarachnoid hemorrhage*: abrupt onset of an intense and incapacitating headache. Often unilateral accompanied by nausea, nuchal rigidity, and altered consciousness.	History and physical examination CT without contrast or MRI (FLAIR sequence)
Subdural hematoma	Headache usually without typical features Often overshadowed by focal neurologic signs and/or altered consciousness	History and physical examination CT or MRI
Carotid artery dissection	Late developing headache that is constant in nature Bilateral or unilateral location	History and physical examination. Carotid ultrasonography or MRA
Cerebral venous and sinus thrombosis	Nonspecific headache that may have a postural component. Often accompanied by focal neurologic signs and seizures	History and physical examination MRV Possible angiography
Brain tumor	Progressive and often localized headache Often worse in the morning Aggravated by coughing/straining	History and physical examination CT or MRI
Idiopathic intracranial hypertension (pseudotumor cerebri/benign intracranial hypertension)	Progressive nonpulsating headache Aggravated by coughing/straining Associated with increased CSF pressure and normal CSF chemistry	History and physical examination Lumbar puncture
Spontaneous intracranial hypotension	No history of dural trauma Diffuse, dull headache worsening within 15 minutes of sitting or standing Associated with neck stiffness, nausea, tinnitus, and photophobia CSF opening pressure < 60 mm H_2O in the sitting position	History and physical examination Lumbar puncture Radioisotope cisternography CT myelography
Pneumocephalus	Frontal headache Often an abrupt onset immediately after dural puncture Symptoms can worsen with upright posture	History and physical examination CT or MRI
Meningitis	Headache is most frequent symptom Often diffuse Intensity increases with time Associated with nausea, photophobia, phonophobia, general malaise, and fever	History and physical examination Lumbar puncture

Continued

TABLE 30.1 Differential Diagnosis of Postpartum Headache—cont'd

Headache Etiology	Primary Symptoms/Signs	Diagnostic Modality
Sinusitis	Frontal headache with accompanying facial pain Development of headache coincides with nasal obstruction Purulent nasal discharge, anosmia, and fever	History and physical examination Nasal endoscopy CT or MRI
Caffeine withdrawal	Onset of headache within 24 hours of cessation of regular caffeine consumption[a] Often bilateral and pulsating Relieved within 1 hour of ingestion of caffeine 100 mg	History and physical examination
Lactation headache	Mild to moderate headache associated temporally with onset of breast-feeding or with breast engorgement	History and physical examination
Ondansetron headache	Mild to moderate headache associated with ondansetron intake	History and physical examination
Post–dural puncture headache	Headache within 5 days of dural puncture Worsens within 15 minutes of sitting or standing Associated with neck stiffness, tinnitus, photophobia, and nausea	History and physical examination Possible MRI

CSF, cerebrospinal fluid; *CT,* computed tomography; *FLAIR,* fluid-attenuated inversion recovery; *MRA,* magnetic resonance angiogram; *MRI,* magnetic resonance imaging; *MRV,* magnetic resonance venography.

[a]The International Classification of Headache Disorders criterion states that caffeine-withdrawal headache occurs on cessation of ≥ 200 mg daily caffeine consumption for more than 2 weeks.[5] However, others have suggested that caffeine-withdrawal headache may occur after as little as 3 days' exposure to 300 mg/day or 7 days' exposure to 100 mg/day.[38]

BOX 30.1 International Classification of Headache Disorders, 3rd Edition (ICHD-3)

Primary
- Migraine
- Tension-type headache
- Trigeminal autonomic cephalagias
  - Cluster headache
- Other primary headaches

Secondary
- Headache attributed to:
  - Head and/or neck trauma
  - Cranial or cervical vascular disorder
  - Nonvascular intracranial disorder
  - A substance or its withdrawal
  - Infection
  - Disorder of homeostasis
  - Disorder of the cranial structures (e.g., eyes, ears, nose, sinuses, teeth, mouth)
  - Psychiatric disorder
- Lesions of cranial neuralgias and other facial pain
- Other headache disorders

Modified from Headache Classification Committee of the International Headache Society (IHS). The international classification of headache disorders. 3rd ed. *Cephalalgia.* 2018;38:1–211.

with postpartum headache at a single center, Stella et al.[6] noted that tension-type/migraine headache was the most common cause (47%) of postpartum headache. Preeclampsia/eclampsia and PDPH comprised 24% and 16% of cases, respectively.

Primary Headaches

The postpartum patient can present with a recurrence of her known primary disorder or with the first manifestation of a primary condition. Patients with a history of headache disorders typically are diagnosed with one of the four major types of primary headaches. The most common postpartum headaches are tension-type and migraine headaches, which account for almost two-thirds of headaches during this period.[1,2,6] **Tension-type headaches** are often circumferential and constricting, can be associated with scalp tenderness, and are usually of mild to moderate severity.

Migraine

Migraine headaches are defined as recurring cranial pain lasting 4 to 72 hours, often with typical features such as pulsating pain in a unilateral location, nausea, and photophobia.[5] In the United States, the estimated overall age-adjusted 3-month prevalence of migraine is 19% in females and 9% in males, and is more common between 18 and 44 years of age.[7] Pregnancy has an ameliorating effect on migraine frequency in the majority of sufferers. However, symptoms may recur soon after delivery, with reports of 34% within the first week postpartum and 55% within the first month.[8] Generally, the symptoms are similar to their typical pattern, although often milder and less often unilateral. It is rare for a migraine to manifest for the first time during the postpartum period. Pregnant women with severe migraine experience higher rates of adverse labor and delivery outcomes (e.g., preterm delivery, preeclampsia, low birth weight) but a lower rate of cesarean delivery than the general population.[9] The higher rates of preeclampsia may reflect an underlying predisposition to cerebral ischemic injury.

Secondary Headaches

A common secondary headache in the postpartum period is the **musculoskeletal headache,** exacerbated by the maternal physical exertion of labor and associated sleep deprivation. This headache has accompanying neck and shoulder pain without a history of dural puncture. Approximately 11% to 14% of postpartum headaches are diagnosed as musculoskeletal.[1] Other causes of secondary headache are discussed in the following paragraphs.

Hypertension

Hypertensive disorders of pregnancy, including preeclampsia, are commonly associated with headaches. Eclampsia is a form of hypertensive encephalopathy that includes headache, visual disturbances, nausea, vomiting, seizures, stupor, and coma. Seizures may occur in the absence of severe hypertension. Headache is a serious premonitory sign, present in more than 50% of women in whom eclampsia develops.[10] About one-half of the cases of postpartum eclampsia occur within 48 hours after delivery, and the remainder occur between 2 days and 4 weeks after delivery. Occipital or frontal thunderclap headache, blurred vision, scotomas, photophobia, and altered mental status are some of the potential presenting symptoms. Other hypertensive disorders, with or without superimposed preeclampsia, are also associated with headaches both antepartum and postpartum and may lead to encephalopathy.

Posterior Reversible Leukoencephalopathy Syndrome

Posterior reversible (leuko)encephalopathy syndrome (PRES) was described in 1996 after recognition of consistent symptom presentation and brain magnetic resonance imaging (MRI) findings in a diverse group of patients. Conditions associated with PRES include preeclampsia, uremia, hemolytic-uremic syndrome, infection, malignancy, and exposure to immunosuppressant drugs.[11] Approximately 25% of cases of PRES occur during pregnancy or in the immediate postpartum period. Mayama et al.[12] conducted a retrospective cohort study to assess the incidence of PRES in women with eclampsia and preeclampsia with neurologic symptoms. PRES occurred in 92.3% of women with eclampsia and in 19.2% of women with preeclampsia with neurologic symptoms. PRES symptoms include headache, seizures, altered mental status, visual changes, and, occasionally, focal neurologic deficits.[13]

The pathophysiology of PRES is believed to be similar to that of hypertensive encephalopathy in that altered cerebrovascular regulation causes loss of blood-brain barrier integrity. The accompanying vasogenic edema can be reversed by prompt recognition and supportive therapy (e.g., cessation of provocative medications, aggressive treatment of hypertension, seizure prophylaxis) in 70% to 90% of cases.[14] However, irreversible cytotoxic edema with permanent neurologic damage can occur if the initial disorder is not diagnosed early.[15]

The neuroradiologic features of PRES typically include symmetric areas of cerebral edema, predominantly involving the white matter regions of the posterior circulation (occipital lobes, posterior parietal and temporal lobes) (Fig. 30.1). MRI is the "gold standard" for diagnosing PRES because it can provide information about cerebral involvement earlier than computed tomography (CT).[16]

Stroke

The physiologic changes that occur during pregnancy (e.g., venous stasis, edema, hypercoagulability) render these patients susceptible to stroke, and headache is a common presenting symptom. Approximately 50% of strokes occur within the first 6 weeks postpartum.[17] Strokes can be ischemic or hemorrhagic.

The evaluation and treatment of stroke during pregnancy should mimic that performed for nonpregnant patients. Treatment will depend on the etiology. In addition to supportive care, acute reperfusion therapy with fibrinolytic agents (recombinant tissue plasminogen activator) and intra-arterial mechanical thrombectomy should be considered in pregnant women with qualifying strokes.[17–19]

Ischemic strokes account for approximately 87% of all strokes.[20] Causes of ischemic stroke include cerebral venous sinus thrombosis, preeclampsia/eclampsia, thromboembolism related to valvular heart disease, and profound and persistent hypotension (e.g. cervical arterial dissection, amniotic fluid embolism).[17] The clinical presentation often comprises new onset headache that is overshadowed by focal neurologic signs and/or disorders of consciousness.

Hemorrhagic strokes can be subclassified into intracerebral hemorrhage (ICH) or subarachnoid hemorrhage (SAH), with a 10% and 3% incidence, respectively.[20] Hemorrhagic stroke in pregnancy and the postpartum period is relatively more common than in the nonpregnant state. Conditions associated with hemorrhagic stroke include preeclampsia/eclampsia, aneurysms, and arterio-venous malformations.[17]

Subarachnoid Hemorrhage

Subarachnoid hemorrhage usually occurs secondary to ruptured aneurysms or arterio-venous malformations. The classic presentation is sudden onset of a severe headache that is unlike any previous headache ("worst headache of my life"). Associated symptoms may include neck stiffness, nausea, vomiting, decreased level of consciousness, and focal neurologic deficits. Suspicion of SAH necessitates urgent investigation by CT imaging; nonsurgical therapies (e.g., endovascular ablation) are available, and long-term sequelae can be minimized with early therapy.

Subdural Hematoma

Although usually associated with head trauma, subdural hematomas can occur spontaneously during pregnancy or can be associated with dural puncture (see later discussion). In several case reports, identification of the subdural hematoma was preceded by symptoms of PDPH.[21] Dural puncture results in leakage of cerebrospinal fluid (CSF) and decreased intracranial pressure (ICP). Presumably, the reduction in ICP causes stress on bridging cerebral vessels, which precipitates

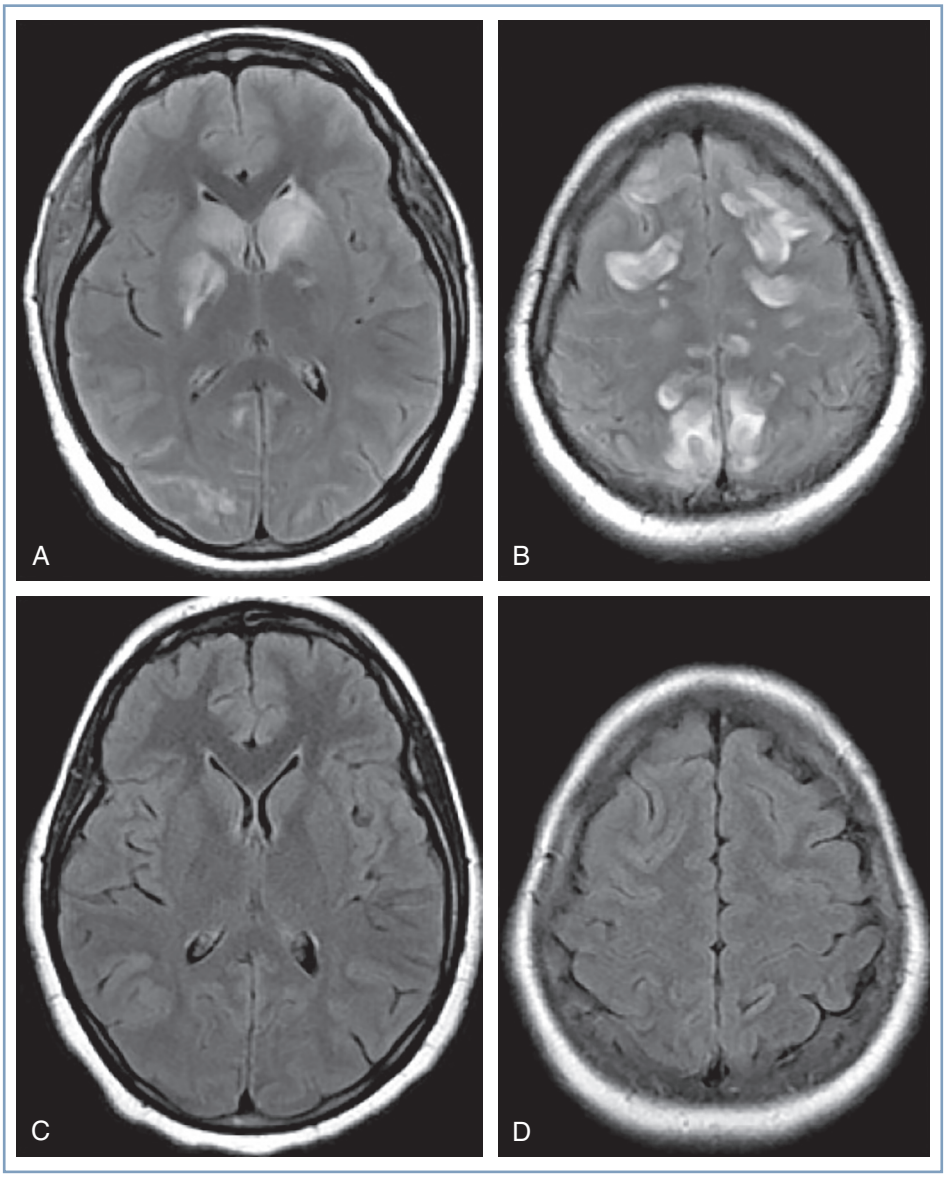

Fig. 30.1 Posterior reversible (leuko)encephalopathy syndrome (PRES). MR images of a 19-year-old pregnant woman at 31 weeks' gestation who presented with a urinary tract infection. She developed eclampsia, hemolysis–elevated liver enzymes–low platelet count (HELLP) syndrome, confusion, seizures, and a blood pressure of 190/140 mm Hg. Axial T2 fluid-attenuated inversion recovery (FLAIR) images demonstrate cortical/subcortical vasogenic edema in the frontal lobes (the superior frontal sulci), parietal lobes, and occipital lobes as well as deep gray structures such as caudate nuclei and lentiform nuclei (A, B). With magnesium sulfate, blood pressure control, and cesarean delivery, the patient had complete resolution of imaging findings (C, D) and symptoms. (From Brady E, Parikh NS, Navi BB, et al. The imaging spectrum of posterior reversible encephalopathy syndrome: A pictorial review. *Clin Imaging*. 2018;47:80–89.)

tearing and bleeding. Spontaneous subdural hematomas have been reported in parturients with diseases associated with angiopathy, such as preeclampsia and fatty liver disease of pregnancy.[22] Neurologic signs of subdural hematoma are variable but include evidence of increased ICP (e.g., headache, somnolence, vomiting, confusion) and focal abnormalities.

Carotid Artery Dissection

A rare, vascular cause of postpartum headache is spontaneous carotid artery dissection. Borelli et al.[23] reviewed the 19 known published cases of postpartum carotid artery dissection in 2011. The mean interval from delivery to headache onset was 9.3 days. The headaches were constant in character and both unilateral and bilateral. Stricken women appeared older (mean age, 35 years) than the average parturient. Diagnosis was made after carotid vessel ultrasonography or magnetic resonance angiography.

Cerebral Venous and Sinus Thrombosis

Cerebral venous and sinus thrombosis (CVST) is an uncommon cause of stroke (less than 1% of all strokes) that results from thrombosis of the cerebral venous system, including

dural venous sinuses, and deep and superficial cerebral veins.[24] Approximately 2% of pregnancy-associated strokes are attributable to CVST.[25] The most frequent symptoms in women with CVST are headache (86.1%) and epileptic seizures (26.8%). Diagnosis is best confirmed by MRI in combination with magnetic resonance venography; CT imaging identifies only one-third of cases. Treatment of cortical vein thrombosis includes anticoagulation and treatment of seizures and increased ICP.[25] Anticoagulation therapy is recommended for patients with acute CVST, even in selected patients with intracranial hemorrhage. Thrombolysis may be a therapeutic option in a select group of patients with small hemorrhagic infarct and continued neurologic deterioration. Steroid therapy is not recommended.[25]

Brain Tumor

Intracranial tumors may manifest as postpartum headache. Headache that is dull rather than throbbing may be an early feature of a brain tumor. Nausea, vomiting, seizures, and/or focal neurologic signs may be present. Neurologic examination may reveal evidence of increased ICP.

Idiopathic Intracranial Hypertension

Parturients with idiopathic intracranial hypertension (i.e., increased ICP in the absence of a mass lesion, also known as pseudotumor cerebri or benign intracranial hypertension) have headache and visual disturbances, usually in the antepartum period (see Chapter 48). The features of postpartum pseudotumor cerebri mimic the usual chronic headache symptoms experienced by the patient (i.e., nonspecific and varying in type, location, and frequency) and associated symptoms (e.g., visual loss, diplopia, nausea, vomiting, pulsatile tinnitus). The diagnosis largely is one of exclusion. Treatment involves reduction of CSF pressure, either with glucocorticoids, carbonic anhydrase inhibitors, diuretics, or surgical interventions (e.g., optic nerve sheath fenestration, cerebrospinal fluid diversion via lumboperitoneal or ventriculoperitoneal shunt, or intracranial venous sinus stenting). Since CSF volume is rapidly replaced, serial lumbar punctures are of limited value and should be reserved for patients who refuse or cannot undergo conventional medical or surgical therapy. Case reports describe the use of an intrathecal catheter for labor analgesia[26] and administration of epidural blood patch for PDPH in patients with idiopathic intracranial hypertension.[27]

Spontaneous Intracranial Hypotension

Spontaneous intracranial hypotension is an uncommon cause of headache that develops following CSF leakage secondary to dural tears. The tears usually occur at the thoracic spinal level and are not associated with prior spinal intervention.[28] MRI of the brain with contrast will confirm the diagnosis of intracranial hypotension. MRI of the spine, CT cisternography, or CT myelography with contrast or radioisotope can help identify the exact location of CSF leak. Presentation of this disorder is identical to that of PDPH, because the pathophysiology is the same. The only difference is the lack of a prior neuraxial procedure. Spontaneous intracranial hypotension has been reported during pregnancy and in the postpartum period.[29]

Pneumocephalus

The subdural or subarachnoid injection of air used for identification of the epidural space may be associated with the sudden onset of severe frontotemporal headache, sometimes accompanied by neck pain, back pain, or changes in mental status.[30] Headache is caused by meningeal irritation by air, and symptoms can mimic those of PDPH in that they are worse in the sitting position and may be relieved by lying down. Roderick et al.[31] noted that 2 mL of air injected into the subarachnoid space was sufficient to provoke a symptomatic pneumocephalus. CT is more sensitive than MRI to confirm the presence of air density areas within the cranial cavity. The headache typically occurs soon after air entrance into the intrathecal space and resolves within 3 to 5 days with reabsorption of the air.[32] Treatment is symptomatic. Administration of oxygen by nasal cannula or face mask may hasten resorption of the air and speed recovery, although this therapy has yet to be proven for pneumocephalus after neuraxial anesthesia.[33]

Meningitis

Meningitis is a complication of neuraxial procedures, and the associated severe headache typically manifests within 12 hours to several days following the procedure (see Chapter 31). Headache is accompanied by fever, nuchal rigidity, and the presence of Kernig and Brudzinski signs. Lethargy, confusion, vomiting, seizures, and a rash also may occur. Various strains of *Streptococcus,* organisms typically found in the upper airway and vagina, have been linked to bacterial meningitis after neuraxial procedures.[34,35] In several cluster cases, the involved organisms in the patients' CSF were matched with the proceduralists' nasopharyngeal swabs, confirming that these cases of post–dural puncture bacterial meningitis were the result of droplet contamination.[36] Aseptic technique during the neuraxial procedure, including donning of a face mask by the proceduralist, is of paramount importance. The diagnosis of meningitis is confirmed by examination and CSF culture, and warrants immediate treatment.

Sinusitis

Headache caused by inflamed paranasal sinuses is associated with purulent nasal discharge and, occasionally, fever. Pain may be unilateral or bilateral, depending on the extent of the disease, and the skin over the affected sinus may be tender. The sinuses fill overnight, and pain typically is worse on awakening. Pain improves in the upright position, which assists drainage.[37]

Caffeine Withdrawal

The withdrawal of caffeine may lead to headache, increased fatigue, and anxiety. Caffeine withdrawal headaches may occur after just 3 days' exposure to 300 mg/day or 7 days' exposure to 100 mg/day of caffeine.[38] Normal-sized caffeinated drinks usually contain 50 to 100 mg of caffeine per

serving. Although caffeine-withdrawal headache has not been documented as a cause of postpartum headache, the diagnosis should be considered if the parturient has been drinking caffeinated beverages during the pregnancy.

Lactation Headache

Askmark and Lundberg[39] reported episodes of intense headache during periods of breast-feeding in a woman known to suffer from migraine. Onset of headaches occurred within the first few minutes of breast-feeding, and the headaches resolved after cessation of nursing. The headaches were associated with an increase in plasma vasopressin concentration. Headaches have also been described in women with breast engorgement who either have elected not to breast-feed or have reduced the frequency of breast-feeding.[40]

Ondansetron

Sharma and Panda[41] reported a case in which a woman received ondansetron for nausea and vomiting after uneventful spinal anesthesia for cesarean delivery. Several hours later, she developed a severe frontal headache that was worse in the upright position and in the morning and evening hours. The symptoms abruptly stopped after the discontinuation of ondansetron. Headache is a common side effect of ondansetron (incidence, 3% to 17%), owing to its antagonism of serotonin 5-HT_3 receptors, and should be considered in the differential diagnosis of postpartum headache.

POST–DURAL PUNCTURE HEADACHE

Incidence

PDPH may occur after intentional dural puncture with a spinal needle or unintentional dural puncture with an epidural or other needle. A meta-analysis of studies of PDPH in obstetric patients (n = 328,769) calculated a pooled risk for unintentional dural puncture with any epidural needle of 1.5% (95% confidence interval [CI], 1.5% to 1.5%).[42] After a dural puncture with an epidural needle, the risk for PDPH was 52.1% (95% CI, 51.4% to 52.8%) (Fig. 30.2). The rate of PDPH after dural puncture with spinal needles ranged between 1.5% and 11.2%, depending on the needle size and type of needle (see later discussion) (Table 30.2).[42–46] Although PDPH is often considered a "minor" complication of dural puncture, it was the cause of 12% of obstetric claims in the American Society of Anesthesiologists (ASA) Closed-Claims Project database.[47]

Symptoms

The ICHD-3 beta classification defines PDPH as a headache occurring within 5 days of a lumbar puncture, caused by

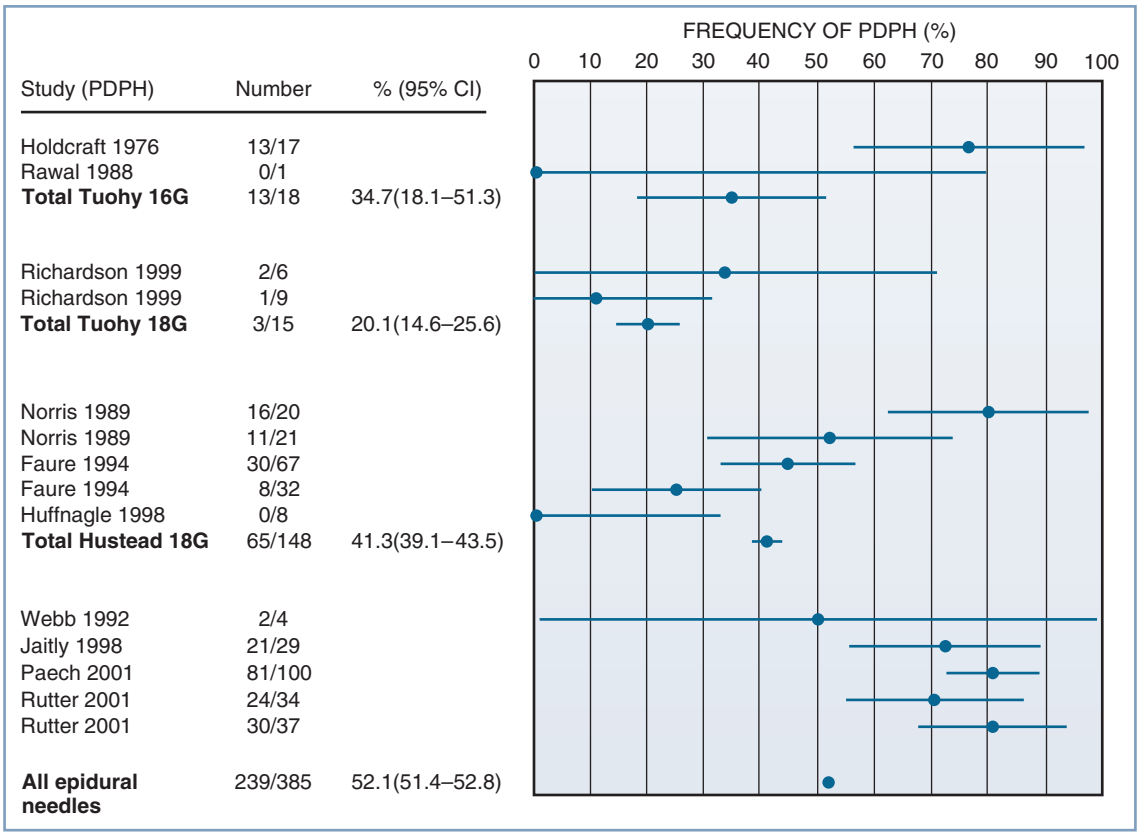

Fig. 30.2 Meta-analysis of post–dural puncture headache (PDPH) frequency for epidural needles in the obstetric population. The dots represent the percentages of patients experiencing the event. The horizontal lines represent the 95% confidence interval (CI). (From Choi PT, Galinski SE, Takeuchi L, et al. PDPH is a common complication of neuraxial blockade in parturients: a meta-analysis of obstetric studies. *Can J Anaesth.* 2003;50:460–469.)

TABLE 30.2 Frequency of Post–Dural Puncture Headache in Obstetric Patients According to Spinal Needle Design

Needle Design	Gauge	*n/N*	Frequency of PDPH (%)[a]	95% Confidence Interval[b]
Quincke	24	15/238	11.2	10.2–12.2[42,46]
	25	114/1792	6.4	5.3–7.6[42,46]

TABLE 30.3 Symptoms Associated with Post–Dural Puncture Headache

Symptom	Incidence (%)
Nausea	60
Vomiting	24
Neck stiffness	43
Ocular[a]	13
Auditory[b]	12

[a]Ocular symptoms include photophobia, diplopia, and difficulty in accommodation.
[b]Auditory symptoms include hearing loss, hypacusis, and tinnitus.
Data from Lybecker H, Djernes M, Schmidt JF. Postdural puncture headache (PDPH): onset, duration, severity, and associated symptoms. An analysis of 75 consecutive patients with PDPH. *Acta Anaesthesiol Scand*. 1995;39:605–612.

cerebrospinal fluid (CSF) leakage through the dural puncture. It is usually accompanied by neck stiffness and/or subjective hearing symptoms. PDPH usually remits spontaneously within 2 weeks, or after sealing of the leak with an autologous epidural blood patch. The headache is invariably orthostatic, but this is not a diagnostic criterion. Usually headache symptoms occur immediately or within seconds of assuming an upright position and resolve quickly (within 1 minute) after lying horizontally. Alternatively, the symptoms may exhibit delayed response to postural change, worsening after minutes or hours of being upright and improving, but not necessarily resolving, after minutes or hours of being horizontal.[5]

Van de Velde et al.[48] published a 10-year retrospective review of unintentional dural puncture and PDPH in obstetric patients. Of 65 patients diagnosed with PDPH, 55% reported associated symptoms such as nausea, photophobia, tinnitus, and vertigo. Headache was frontal in 34 patients, occipital in 9 patients, and combined frontal and occipital in 15 patients. In 7 patients, headache was not localized to a specific area. In a retrospective review of 75 patients with PDPH after spinal anesthesia, symptoms associated with headache included nausea, vomiting, neck stiffness, and ocular and auditory symptoms (Table 30.3).[49]

Cranial nerve palsy, thought to be secondary to nerve traction caused by low CSF volume, is associated with PDPH. The sixth cranial nerve (abducens) is most susceptible to traction during its long and tortuous intracranial course. Injuries to this nerve constitute 92% to 95% of cranial nerve injuries associated with intracranial hypotension.[50] The traction results in failure of the involved eye to abduct, and patients may have diplopia or extraocular muscle paralysis. In a literature review, Hofer and Scavone[50] concluded that early administration of an epidural blood patch may decrease morbidity or prevent progression of ocular symptoms if PDPH is present with symptoms of nerve palsy. Corrective surgery may be necessary in persistent or permanent cases.

Hearing loss is also associated with PDPH. The deficit is usually in the low-frequency range and may be secondary to endolymph and perilymph imbalance and alteration of hair cell position in the inner ear.[51] Therapeutic epidural blood patch improves hearing within 1 hour in most patients with severe PDPH.[52]

Other rare symptoms associated with PDPH include seizures,[53] vertigo,[54] bilateral forearm pain,[55] abdominal pain, and diarrhea.[56] In these rare case reports, the headache and associated symptoms resolved after therapy with an epidural blood patch.

Onset and Duration

In a prospective study of 75 nonobstetric patients with PDPH, 65% developed symptoms within 24 hours of the lumbar puncture and 92% developed symptoms within 48 hours.[49] By ICHD-3 beta criteria, headache must appear within 5 days of dural puncture.[5] However, a systematic review of PDPH in obstetric patients reported that onset of headache can occur up to 7 days after dural puncture,[42] and one case report described a woman who developed a PDPH 12 days after labor neuraxial analgesia.[57] Headaches caused by dural puncture with a spinal needle ranged in duration from 1 to 7 days.[42] The duration of headache after dural puncture with an epidural needle has not been well studied, but is likely longer than that for a spinal needle.[42,58] Webb et al.[59] found that 18% of women who sustained a dural puncture with a 17-gauge Tuohy needle suffered from chronic headaches compared with 5% of women in a matched cohort who did not sustain dural puncture with an epidural needle.

Imaging

Imaging investigations are not routinely recommended for the postpartum patient with a PDPH unless the symptoms suggest other diagnoses or the diagnosis of PDPH is in doubt. Contrast-enhanced MRI is the method of choice to

study the meninges and has revealed characteristic findings of PDPH.[60,61] These findings include (1) marked, diffuse pachymeningeal thickening and enhancement; (2) compression of the ventricles; (3) caudal displacement of the brain, brainstem, and optic chiasm; (4) cerebellar ectopia; (5) pituitary enlargement and enhancement; and (6) expansion of the superior sagittal sinus. The enlarged venous sinus may represent compensatory venous expansion in response to low CSF pressure. At times, imaging is needed to differentiate a PDPH from other causes of headache.

Pathophysiology

Debate continues regarding the precise etiology of PDPH symptoms. The original theory was that pain-sensitive nerve fibers were stimulated by a downward shift of the brain secondary to a loss of CSF volume. German surgeon August Bier[62] is credited with the first description of successful spinal anesthesia and PDPH after his pioneering work on spinal anesthesia with cocaine. Bier and his assistant, Hildebrandt, performed spinal anesthesia on each other; using blows to the shin with an iron hammer and application of a burning cigar to the skin, they demonstrated dense sensory blockade.[62] Both experienced severe PDPH. The assistant forced himself to work the next day, but Bier stayed home for 9 days. Bier suggested the PDPH might be caused by CSF loss. Today there is no doubt that leakage of CSF initiates the syndrome. Kunkle et al.[63] consistently produced PDPH by draining 20 mL of CSF from volunteers. Symptoms were immediately relieved by subarachnoid injection of saline to restore initial CSF pressure.

Total CSF volume is approximately 150 mL, and the production rate is approximately 0.35 mL/min or a daily rate of 500 mL. The rate of CSF leakage through a dural hole may exceed the rate of CSF production. If this occurs, low CSF pressure results in a loss of the cushioning effect provided by intracranial fluid.

CSF pressure during labor is normal between contractions but increases significantly during painful contractions and expulsive efforts. Effective epidural analgesia attenuates this increase in CSF pressure.[64] In a study of five women with unintentional dural puncture, epidural pressures were normal preceding the development of headache.[65] However, with development of headache symptoms, the mean epidural pressure measurements were found to decrease significantly.

Not all patients with PDPH symptoms have decreased CSF pressure, and not all patients with a significant CSF leak experience symptoms. The pain of PDPH may be caused, in part, by an increase in cerebral blood flow (and cerebral vasodilation) as a consequence of low CSF pressure or volume. This phenomenon has been observed in animals.[66,67] The inverse relationship between intracranial blood volume and CSF volume reflects the body's effort to maintain a constant intracranial volume.[68] The lumbar CSF compartment is a dynamic structure and acts as a reservoir for intracranial CSF volume adjustment.[69] In a descriptive study of cerebral blood flow measured by middle cerebral artery transcranial Doppler in 15 postpartum women with unintentional dural punctures following labor epidural analgesia, the authors demonstrated that women with PDPH symptoms had lower pulsatility indices compared with women without headaches.[70] Pulsatility index is inversely related to cerebral blood flow. The occurrence of cerebral vasodilation may explain the relief of headache symptoms with treatment with vasoconstrictors such as caffeine, theophylline, and sumatriptan.

Risk Factors

In a classic study of 10,098 spinal anesthetics published in 1956, Vandam and Dripps[71] noted that three patient factors influenced the incidence of PDPH: age, gender, and pregnancy. The analysis did not allow determination of whether these factors were independent risk factors. Subsequently, other risk factors for development of PDPH have been identified.

Age

Extensive evidence supports the observation that PDPH is uncommon in patients older than 60 years of age and is most common in patients younger than 40 years of age.[72] In the elderly, the dura may be inelastic and less likely to gape after puncture. CSF leakage may be impeded by adhesions and calcification. The cerebrovascular system also may be less reactive in older patients. Further, this group is less active physically, and older patients may be less likely to complain.

Gender

Amorim et al.[72] observed a gender difference with respect to the incidence of PDPH after spinal anesthesia (11.1% female versus 3.6% male). This difference may be related to differences in cerebrovascular reactivity; it is well known that migraine headaches occur predominantly in females and are influenced by hormonal changes. Women may have enhanced vascular reactivity, or perhaps changes in cerebral blood flow are more likely to produce pain in women than in men. A meta-analysis of randomized clinical trials identified a twofold higher risk for PDPH in nonpregnant females than in males.[73]

Vaginal Delivery

In a retrospective review of 235 parturients who suffered an unintentional dural puncture during epidural catheter placement, the rate of PDPH was lower in women who delivered via cesarean compared with those that delivered vaginally (53% versus 74%).[74] This difference may be a result of the mechanical consequences of expulsive efforts during the second stage of labor and/or postpartum hormonal changes in cerebrovascular reactivity. Expulsive efforts in the second stage may increase CSF leakage. This possibility has prompted some physicians to restrict maternal pushing after dural puncture and to use forceps to shorten the second stage of labor. The evidence supporting this practice, however, is conflicting.[75,76]

Morbid Obesity

The results of studies assessing the relationship between body mass index (BMI) and risk for PDPH after dural puncture are

inconsistent. No association between BMI and PDPH was found in two retrospective studies.[77,78] However, in the largest retrospective study of women with unintentional dural puncture ($n = 518$), Peralta et al.[76] demonstrated that higher BMI was associated with a lower rate of PDPH. Using a threshold BMI of 31.5 kg/m^2, the incidence of PDPH was 39% and 56% in those with BMI greater than and less than the threshold, respectively. However, pain intensity at headache presentation and the highest reported pain score were similar between high and low BMI groups. Possible but unproven explanations of a lower incidence of PDPH in obese patients include increased abdominal pressure (which may reduce the extent of CSF leakage) and/or reduced physical activity in these patients. Other confounding factors, such as differences in the mode of delivery (higher rate of cesarean delivery) and neuraxial opioid administration, may also play a role.

History of Previous Post–Dural Puncture Headache

A history of PDPH after previous spinal anesthesia is associated with the development of PDPH with subsequent spinal anesthesia. In a cross-sectional study of nonobstetric patients who underwent spinal anesthesia for elective surgery, those with a previous history of PDPH were 4.3 times more likely (95% CI, 1.99 to 9.31) to have a second PDPH than patients without a history of PDPH (26.4% versus 6.2%, respectively).[72] This finding suggests that certain individuals are predisposed to the development of PDPH.

Multiple Dural Punctures

Seeberger et al.[79] found that multiple dural punctures significantly increased the risk for PDPH. Surgical patients who received a second spinal injection owing to failure of the initial spinal puncture had a 4.2% incidence of PDPH compared with a 1.6% incidence among patients who had a single dural puncture.

Neuraxial Anesthetic Technique

Technical factors related to the neuraxial technique influence the incidence of PDPH.

Spinal needle design. Historically, the beveled Quincke needle, a needle with a cutting bevel (Fig. 30.3) was widely used for dural puncture for both diagnostic and anesthetic purposes (see Chapter 12). In 1951, Hart and Whitacre[80] introduced a solid-tipped, pencil-point spinal needle with a lateral injection port, which is now known as the Whitacre design. They believed that the new needle tip would stretch and separate rather than cut the dural fibers and result in a lower incidence of PDPH. Studies have confirmed the anticipated lower incidence of PDPH with the pencil-point tip (see Table 30.2).[42,81] *In vitro* data suggest that fluid leak through the dural puncture site is slower with a pencil-point needle compared with a beveled needle.[82] With the recognition that pencil-point spinal needle tips reduce the incidence of PDPH, other tip designs have appeared. In 1987, Sprotte et al.[83] reported experience with the use of a new needle that has a solid oval tip and a longer orifice than the Whitacre needle. The incidence of PDPH was 0.02% with its use in a heterogeneous patient population of almost 35,000 patients.[83] Subsequent studies have shown the incidence of PDPH with the Sprotte needle is lower than that with Quincke needles of smaller gauge.[42] A 2017 meta-analysis of 8 randomized clinical trials including 1324 women undergoing cesarean delivery confirmed that spinal needles with cutting bevels were more likely to cause PDPH than pencil-point needles (relative risk (RR) 3.12; 95% CI, 1.60 to 6.10).[84]

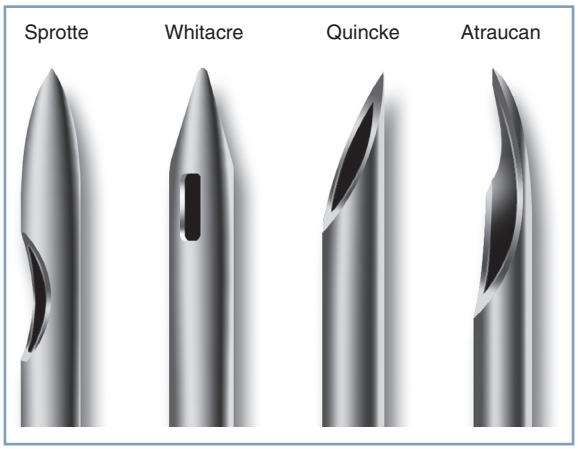

Fig. 30.3 Designs of spinal needle tips (not to scale). (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

A modification of the Quincke needle, the Atraucan needle, has a cutting tip and a double bevel, which is intended to cut a small dural hole and then dilate it.[43] Studies suggest that the use of this needle is associated with a higher risk for PDPH than the use of a noncutting, pencil-point needle.[45]

Spinal needle size. With the Quincke needle, the incidence and severity of PDPH are directly related to the size of the needle. The incidence of PDPH is lower with a 27-gauge needle than with 25- and 26-gauge needles (see Table 30.2). A similar relationship may exist with pencil-point needles. The current popularity of spinal anesthesia in obstetric patients is largely a result of an improvement in needle technology, which has led to a reduction in the incidence of PDPH. Because of the morbidity associated with PDPH, every effort should be made to use a needle associated with a low incidence of PDPH (e.g., a small-gauge, noncutting needle).

Direction of bevel of the Quincke needle. Studies have confirmed that puncturing the dura mater with a Quincke needle bevel parallel to the long axis of the spine reduces the incidence of PDPH by 70% compared with a perpendicular orientation.[85] It was originally thought that the dural fibers ran in a longitudinal direction and therefore inserting the needle parallel to the long axis of the spine caused less trauma to the dura. However, electron microscopy has revealed that the dura consists of multidirectional interlacing collagen fibers with both transverse and longitudinal elastic fibers.[86] Some authors have suggested that the insertion of the needle with the bevel parallel to the long axis of the spine most likely results in less tension on the dural hole and, therefore, a smaller aperture with less CSF leak. *In vitro* studies of bevel orientation and fluid leak have provided conflicting

results.[87–89] However, despite confusing anatomic evidence, clinical experience strongly supports insertion of the Quincke needle with the bevel parallel to the long axis of the spine.[85]

Epidural needle size/design. The high rate of PDPH after unintentional dural puncture with an epidural needle has led investigators to alter the epidural needle design and size in an attempt to reduce headache incidence and severity. Data on the success of this endeavor are conflicting. In an *in vitro* study using cadaver dura, no differences were found in fluid leak rate among punctures made with Hustead, Tuohy, Crawford, and Sprotte epidural needles.[90] In contrast, in an *in vivo* study, Morley-Forster et al.[91] observed a risk difference of –0.44 (95% CI, –0.67 to –0.21) in the incidence of PDPH with the use of an 18-gauge Sprotte needle compared with the standard 17-gauge Tuohy needle despite no difference in the unintentional dural puncture rate. However, the Sprotte epidural needle, with its lateral orifice, is not commonly used as an introducer of epidural catheters.

The incidence of PDPH is greater when unintentional dural puncture occurs with a 16-gauge compared with an 18-gauge epidural needle (RR 2.21; 95% CI, 1.4 to 2.6).[92]

Direction of the bevel of the Tuohy needle. Norris et al.[93] examined two groups of women who received epidural anesthesia with a Tuohy needle. In one group, the bevel was advanced with the orifice perpendicular to the long axis of the spine. In the other group, the needle entered the epidural space with the bevel parallel to the long axis and the needle was then rotated 90 degrees before insertion of the catheter. The authors observed a decreased incidence of PDPH in the latter group. However, some anesthesiologists argue that rotation of the needle within the epidural space may increase the risk for unintentional dural puncture. Richardson and Wissler[94] randomized laboring women to a cephalad or lateral orientation of the Tuohy bevel during epidural needle insertion. The needle was not rotated before insertion of the epidural catheter. There was no difference in dural puncture or PDPH rates, but catheter insertion was easier with a cephalad orientation of the bevel.

Midline or paramedian approach. There is conflicting evidence as to whether the spinal needle approach affects the incidence of PDPH. Hatfalvi[95] reported no cases of PDPH in a retrospective survey of 4465 spinal anesthesia procedures. This investigator used a paramedian approach with a 20-gauge Quincke needle, and the skin was punctured 3 cm from the midline. He suggested that tangential dural puncture creates a dural flap and prevents PDPH. In contrast, Viitanen et al.,[96] prospectively monitoring obstetric patients after administration of single-shot spinal analgesia for labor (27-gauge Quincke needle), observed PDPH in 3 of 85 (3.5%) patients in whom the midline approach was used, compared with 15 of 127 (11.8%) patients in whom the paramedian approach was used. Using a rigid paper cylinder model of the dura, Kempen and Mocek[97] studied median and paramedian punctures with a 22-gauge Quincke needle in different orientations. With midline punctures, all entry and exit holes were of uniform size regardless of bevel orientation, and no "dural" flaps were seen. After paramedian punctures, flaps formed when the needle bevel faced the cylinder surface with a near-tangential angle of perforation, suggesting it may be beneficial to insert the needle via the paramedian approach to reduce the incidence of PDPH. Currently, data are insufficient to recommend either the median or paramedian approach.

Air versus saline method of locating the epidural space. The medium (air or saline) used for the loss-of-resistance technique to identify the epidural space has not clearly been shown to influence the incidence of PDPH. Many anesthesia providers have adopted the loss-of-resistance-to-saline technique in the belief that it is associated with a lower incidence of unintentional dural puncture and PDPH than the use of air.[98] However, the data are inconsistent, and not all studies have found a difference.[99]

Segal and Arendt[100] suggested that a randomized study of air versus saline to identify the epidural space may lead to overestimation of the difference between air and saline, should one exist, because it is impossible to blind the anesthesia provider to technique, and the study design forces the provider to use a less preferred technique. In a retrospective study, they found that the rate of unintentional dural puncture was not different between the saline versus air technique.[100] However, among anesthesia providers who had a preference for one technique, use of their preferred technique was associated with fewer unintentional dural punctures than use of the nonpreferred technique. Thus, current data do not support a difference in the incidence of PDPH between the loss-of-resistance-to-air versus the loss-of-resistance-to-saline technique to identify the epidural space, and providers who currently use air to identify the epidural space should not change techniques hoping it may decrease the rate of PDPH.

Choice of local anesthetic drug for spinal anesthesia. Naulty et al.[101] reported that the use of bupivacaine-glucose or lidocaine-glucose for spinal anesthesia was associated with a higher incidence of PDPH than the use of tetracaine-procaine. They postulated that osmotic, cerebral irritant, and/or cerebrovascular effects of the glucose could be responsible for these findings. Whether this finding is applicable to other non–glucose-containing local anesthetic preparations, such as plain bupivacaine, is unknown.

Continuous spinal anesthesia. A multicenter randomized clinical trial compared analgesia and safety of 28-gauge spinal microcatheters to epidural catheters for labor analgesia.[102] There was no difference in the incidence of PDPH (9% versus 4%, respectively) or epidural blood patch (5% versus 2%, respectively) between women randomly assigned to receive an intrathecal catheter and those who received an epidural catheter; however, the study was insufficiently powered to assess these outcomes. Spinal microcatheters are not currently available in North America.

Three case series have evaluated a 23-gauge spinal catheter for labor analgesia or cesarean delivery.[103–105] The PDPH rate ranged from 3% to 29% in these series. This range is greater than that reported in other studies using traditional epidural or combined spinal-epidural techniques.

Combined spinal-epidural anesthesia. The combined spinal-epidural (CSE) technique is widely used for both labor

analgesia and cesarean delivery. Intuitively, it seems that the incidence of PDPH should be identical to, or greater than, that observed after single-shot spinal anesthesia with the same size and type of needle. However, the available evidence, primarily from observational studies, suggests that the risk for PDPH is not increased with the CSE technique.[106–108] PDPH rates with the CSE technique in these three studies were 1.7%, 0.43%, and 1.4%, respectively, compared with 1.6%, 0.45%, and 0.8%, respectively, for the epidural technique. Initial placement of the epidural needle facilitates precise dural puncture, and the subsequent increase in epidural space pressure after the epidural injection of local anesthetic may reduce CSF leakage. If the anesthesia provider is in doubt about correct epidural needle placement, a needle-through-needle dural puncture might resolve the issue and prevent unintentional dural puncture with a large-gauge epidural needle.

Complications

The immediate problems associated with post–dural puncture headaches include (1) the inability to perform activities of daily living, such as providing care for the newborn; (2) an extended duration of hospitalization; and (3) a higher number of emergency department visits. The National Obstetric Anaesthesia Database project of the Obstetric Anaesthetists' Association reported that 75% of 975 women with PDPH had difficulty performing activities of daily living.[109] In a retrospective study, Angle et al.[110] reported that hospital length of stay increased by a mean ± SD of 17 ± 24 hours. Rare but serious complications may occur following dural puncture and PDPH, including subdural hematoma, cerebral venous sinus thrombosis, chronic headache, diplopia, and hearing loss.

Zeidan et al.[111] reviewed the published reports of **subdural hematoma** after dural puncture. They found that subdural hematoma was associated with new neurologic symptoms in addition to changing headache characteristics. The proposed mechanism of subdural hematoma development is ongoing intracranial hypotension leading to caudal movement of the brain and rupture of fragile, bridging subdural veins (see earlier discussion). Lim et al.[112] reported a case series of 11 obstetric patients who developed a subdural hematoma after neuraxial labor analgesia at a tertiary care hospital. The observed rate of subdural hematoma was 0.026% (11 in 42,969, approximately 1:3900), and the rate of subdural hematoma following a recognized dural puncture with an epidural needle was 1.1% (5 in 437, approximately 1:87). Ten of 11 patients with subdural hematoma had signs consistent with PDPH before the diagnosis of subdural hematoma; five had a recognized unintentional dural puncture. Subdural hematoma was diagnosed within 7 days of the neuraxial procedure (mean 4.1 days) in 10 patients; in one case the diagnosis was made 25 days later. Ten patients required a second hospital stay, and one patient required a decompressive hemicraniectomy.

Cerebral venous and sinus thrombosis has been documented after unintentional dural puncture and treatment of PDPH with an epidural blood patch.[113] Contributing factors may include cerebral venous dilation (associated with decreased ICP) and the hypercoagulability of pregnancy. Anticoagulation therapy is recommended for patients with acute CVST, even in selected patients with intracranial hemorrhage (see earlier discussion).[25]

Diplopia or **hearing loss** after dural puncture, secondary to cranial nerve dysfunction, may be permanent, even after successful treatment of the PDPH with an epidural blood patch.[52] A review of 95 cases of neurapraxia or axonotmesis of the ocular cranial nerves (oculomotor, trochlear, and abducens nerves) concluded that symptoms may last from 2 weeks to 8 months but that almost 90% of patients recover.[114]

Several studies have described the **persistence of headache, backache, or cranial nerve symptoms** after PDPH.[59,115,116] Ranganathan et al.[115] conducted a retrospective case-control study over a 5-year period in which parturients with an unintentional dural puncture were contacted by telephone to assess acute and long-term residual symptoms. Compared with a control group, patients with an unintentional dural puncture were more prone to acute headache (87% versus 8.7%) and chronic headache (34.9% versus 2.2%) as well as backache and neck ache. These findings reinforce the concept that long-term sequelae from dural puncture can occur.

Prevention

Many practices and maneuvers have been used in an attempt to reduce the incidence of PDPH after unintentional dural puncture, most with limited success. A 2005 survey of British obstetric anesthesiologists quantified the frequency of such practices.[117] These included encouraging postpartum fluid intake (91%), regular analgesia (83%), caffeine administration (30%), and using an intrathecal catheter (15%) at the time of unintentional dural puncture. Older practices, such as avoiding pushing during the second stage, restricting postpartum mobility, abdominal binders, and prophylactic epidural administration of saline or autologous blood, appear to be declining in use. A 2010 systematic review of prevention strategies summarized the evidence from comparative studies and concluded that studies were heterogeneous and that "no clinical recommendation can be made until the superiority of one preventative intervention over another has been unequivocally proven in a definitive multicenter RCT [randomized controlled trial]."[118]

Bed Rest

In a 2016 systematic review, Arevalo-Rodriguez et al.[119] reviewed the evidence for prolonged bed rest combined with different body and head positions, as well as supplementary fluid administration, for the prevention of PDPH after dural puncture. The review included 24 trials with 2996 patients; 26% of study participants randomized to bed rest experienced PDPH compared with 21% in women who were allowed to mobilize immediately after dural puncture. Given these data, and the knowledge that pregnant women are hypercoagulable and at increased risk for deep vein thrombosis and pulmonary embolism, immobility should not be used as a maneuver to prevent PDPH (see Chapter 38).

Hydration

Despite the widespread practice of encouraging women to increase oral fluid intake after unintentional dural puncture, there is little evidence that greater hydration prevents PDPH. A 2016 systematic review identified only one randomized trial in 100 nonobstetric patients. There was no difference in the incidence of PDPH in patients randomized to receive 3 L or 1.5 L of fluid per day.[119]

Caffeine

Two clinical trials in nonobstetric patients have evaluated the efficacy of oral or intravenous caffeine to prevent PDPH, but neither study showed a reduction in the incidence of headache.[120,121] Based on these results, prophylactic caffeine is not advocated for prevention of PDPH.

Cosyntropin

Hakim[122] evaluated whether cosyntropin, an adrenocorticotropic hormone (ACTH) analogue, was effective in reducing the incidence of PDPH after unintentional dural puncture in parturients. Patients were randomized to receive intravenous cosyntropin 1 mg or placebo 30 minutes after delivery. The incidence of PDPH was significantly lower in the cosyntropin group (33% versus 69%). The mechanism is unknown but may be related to an aldosterone-stimulating effect on volume expansion, modulation of pain perception via central endorphin-like action, or increased CSF production by enhanced sodium ion transport. The study has not been replicated, and adequate dose-response and safety studies have yet to be performed.

Neuraxial Opioids

Early studies suggested that prophylactic neuraxial administration of a hydrophilic or lipophilic opioid does not reduce the incidence of PDPH after spinal anesthesia or unintentional dural puncture.[123,124] However, in a randomized, blinded trial published in 2008, 50 parturients with unintentional dural puncture and subsequent epidural analgesia were randomized to receive epidural morphine 3 mg or saline-placebo after delivery and again 24 hours later, before removal of the epidural catheter.[125] The incidence of PDPH was 48% in the saline-placebo group and 12% in the morphine group. Although no complications were reported, we would caution against routine administration of epidural morphine in these circumstances until this finding is confirmed and further safety studies are undertaken. The movement of morphine across the dura is increased by the presence of a large-gauge needle puncture, possibly increasing the risk for respiratory depression.[126]

Intrathecal Catheters

Placing a 19- or 20-gauge epidural catheter into the intrathecal space after an unintentional dural puncture with an epidural needle has become an increasingly popular technique.[127–129] The immediate benefits of an intrathecal catheter are continuous labor analgesia using low doses of local anesthetic and opioid, and rapid-onset surgical anesthesia should it be required. Some experts have speculated that the intrathecal catheter might reduce the immediate CSF leak into the epidural space by mechanical obstruction as well as inducing an inflammatory fibrous reaction in the dura rent, thus facilitating closure of the puncture after removal of the catheter. Most studies are retrospective and observational and lack rigorous outcome definitions and follow-up. Data from these studies are conflicting but suggest that intrathecal catheters do not significantly reduce the incidence of PDPH unless they are left in place for at least 24 hours after delivery (Table 30.4).[74,92,127–134] Russell[92] conducted a prospective, nonblinded, quasi-randomized multicenter study in parturients who had an unintentional dural puncture during epidural needle placement. Participating institutions were randomized in 6-month blocks to either repeating the epidural procedure with placement of an epidural catheter, or placement of a spinal catheter through the dural puncture if unintentional dural puncture occurred during initiation of epidural labor analgesia. Spinal catheters were left *in situ* for 24 to 36 hours. The incidence of PDPH was not significantly different between women in the epidural (62%) and spinal (72%) catheter groups.

Some studies have evaluated the effect of intrathecal catheter placement on the severity of PDPH. Heesen et al.[135] conducted a meta-analysis that included nine studies of various quality. The authors concluded that placement of an intrathecal catheter did not significantly reduce the incidence of PDPH compared with placement of an epidural catheter.[135] However, they did observe a significant reduction in the need for epidural blood patch (RR, 0.64; 95% CI, 0.49 to 0.84) after intrathecal catheter placement. Similar results were reported in a more recently published retrospective study that compared laboring patients with unintentional dural puncture who had the epidural resited or had an intrathecal catheter placed.[134] There was no difference in the incidence of PDPH between groups, but there was a significant increase in the number of women who received an epidural blood patch in the epidural compared with the intrathecal catheter group (52% versus 20.3%, respectively).[134]

The current evidence suggests that advancing a traditional epidural catheter into the intrathecal space after unintentional dural puncture does *not* appear to reduce the incidence of PDPH but may reduce its severity or the need for an epidural blood patch. Although one retrospective study suggested that leaving the spinal catheter in place for 24 hours resulted in a lower incident of PDPH than removing the catheter shortly after delivery,[127] the effect of spinal catheter dwell time has not been rigorously studied. Leaving the spinal catheter *in situ* after the patient leaves the birthing unit may increase the risk for drug error or infection. Further studies are required before a definitive conclusion can be reached about the benefits and safety of this technique.

Prophylactic Epidural/Intrathecal Saline

Trivedi et al.[136] randomly assigned patients with unintentional dural puncture to receive either a prophylactic epidural saline bolus (40 to 60 mL) or blood patch (15 mL) just before epidural catheter removal, or conservative therapy without a

saline bolus or blood patch. The incidence of PDPH was not different between the saline and control groups (88% versus 67%, respectively). Shah[65] studied 17 patients who received an epidural saline infusion (at a rate of approximately 40 mL/h) for 24 to 36 hours after unintentional dural puncture. Four patients complained of severe intrascapular pain, which resolved when the infusion rate was reduced. Severe PDPH developed in 47% of patients after the infusion was stopped. In contrast, in a nonrandomized, nonblinded study of patients with unintentional dural puncture, Charsley and Abram[137] reported that *intrathecal* injection of 10 mL of saline immediately before needle or catheter withdrawal resulted in a lower incidence of PDPH (32%) than in a control group who did not receive the saline (62%), as well as a less frequent need for an epidural blood patch. The intrathecal injection of saline after unintentional dural puncture deserves further study. Intrathecal saline should not be administered until residual local anesthetic effects have resolved.

Prophylactic Blood Patch

Interest in the use of prophylactic epidural blood patch before the removal of a labor epidural catheter arose after early observational studies suggested that the incidence of PDPH was lower with such treatment.[138] A 2010 systematic review[139] identified five studies in 221 obstetric patients; four studies found a reduction in the headache rate, and one did not.[140] Scavone et al.,[140] in the largest study included in the review, reported a double-blind trial in which 64 parturients with unintentional dural puncture were randomly assigned to receive 20 mL of autologous blood (prophylactic epidural blood patch) or a sham procedure. Both groups had a 56% incidence of PDPH; however, the duration of headache was shorter in the prophylactic blood patch group. The systematic review highlighted the difficulty in estimating the risks and benefits of prophylactic epidural blood patch. Because of the low incidence of unintentional dural puncture, studies are small; therefore, reliable conclusions about the technique cannot be made based on current evidence.[139]

Because unintentional dural puncture with a 16- or 18-gauge epidural needle results in a high incidence of PDPH, some anesthesiologists believe that prophylactic blood patch is always justified. Others argue that with such an approach, a significant number of patients will receive unnecessary treatment and that a blood patch is not devoid of complications. These latter anesthesiologists call attention to the potential for epidural catheters to become contaminated after prolonged use. The injection of blood through a contaminated epidural catheter may be associated with a higher risk for infection than injection through an epidural needle placed *de novo* for a therapeutic blood patch. A case report of a parturient who received a prophylactic epidural blood patch and was subsequently diagnosed with streptococcal septicemia highlights the potential risk for maternal infection using this technique.[141]

If performed, a prophylactic blood patch should be delayed until resolution of residual neuroblockade. The occurrence of pain during injection is a signal for the anesthesia provider to stop the injection of blood. Additionally, evidence suggests that lidocaine may inhibit coagulation.[142] Finally, Leivers[143] reported a case of total spinal anesthesia after the epidural injection of 15 mL of blood before epidural anesthesia had regressed. The investigator speculated that residual lidocaine in the lumbar CSF was transferred to the brain as a consequence of an increase in lumbar CSF pressure and reduced CSF volume produced by the patch. (*Editors' note:* One of us [DHC] has observed one case of transient, total blindness after the rapid, bolus injection of 30 mL of epidural saline after vaginal delivery in a patient who had experienced unintentional dural puncture during labor. The blindness resolved after 15 to 20 minutes, and subsequent ophthalmologic and neurologic examinations were normal. The etiology of the transient blindness was unclear. Nonetheless, it seems prudent to delay administration of prophylactic epidural saline or blood until the block has regressed and to avoid rapid epidural administration of blood or saline at any time.)

It is important to avoid the direct intrathecal injection of blood. Aldrete and Brown[144] reported a case of intrathecal hematoma and arachnoiditis with prolonged neurologic sequelae after prophylactic blood patch. Nineteen milliliters of blood were injected through an epidural catheter that, in retrospect, was positioned in the subarachnoid space. There was considerable resistance to injection of the blood, and severe lower back pain with tinnitus accompanied the procedure.

Prophylactic Dextran Patch

Salvador et al.[145] reported the prophylactic epidural injection of 20 mL of dextran-40 in 17 patients who had experienced unintentional dural puncture with a 17- or 18-gauge needle. Three of the patients were parturients, and none of the 17 patients experienced PDPH. This injection was performed before regression of the local anesthetic effect. No additional studies of this technique have been reported; its safety and efficacy remain unclear.

Treatment

Early treatment of PDPH is indicated. Not only does this avert the vicious cycle of immobility, weakness, and depression, but it also may help prevent the rare case of subdural hematoma, chronic headache, or cranial nerve palsy in the patient with persistent PDPH.

Psychological Support

The patient is aware that PDPH is an iatrogenic problem, and she may be angry and resentful as well as depressed and tearful. It is imperative to include disclosure of the risk during the preoperative interview. Headache makes it more difficult to care for the newborn and to interact with other family members. Severe PDPH may delay discharge from the hospital and have economic consequences.[110] Unlike patients who have PDPH after nonobstetric surgery, these patients typically are healthy and do not expect to feel ill. Two patients have eloquently described their own miserable experiences with postpartum PDPH.[146,147] Not surprisingly, a retrospective study of 43 obstetric patients with PDPH showed that this complication leads to a negative attitude toward epidural anesthesia.[148]

It is essential that anesthesia providers visit the patient at least once daily to explain symptoms and prognosis, give support, and offer therapeutic options. If feasible, the patient's partner should attend these discussions. Nurses can help the patient by ensuring adequate analgesics are given on a regular schedule and by teaching alternative breast-feeding techniques, such as the lateral horizontal position.

The anesthesia provider and nurses should write detailed notes in the patient's record. After discharge, follow-up telephone conversations should be documented. Headache associated with neuraxial anesthesia was the third most common reason for litigation among obstetric cases in the ASA Closed-Claims Project database, after maternal death and neonatal brain damage.[47] This fact should dispel any notion that postpartum PDPH is a trivial complaint.

Posture

In most cases, PDPH presents with a postural component. Significant relief should occur when the patient assumes the horizontal position. However, there is no evidence that remaining supine for a prolonged period treats or shortens the duration of the headache. The prone position relieves PDPH in some patients, presumably because increased intra-abdominal pressure results in an increase in CSF pressure. Unfortunately, this position is not comfortable for many patients, especially those who had a cesarean delivery.

Hydration

Enhanced oral hydration remains a popular therapy initiated by most anesthesiologists for parturients with PDPH, but there is no evidence that vigorous hydration has any therapeutic benefit in a patient with normal fluid intake. However, no patient with PDPH should be allowed to become dehydrated, because of the increased fluid demands of breast milk formation and CSF production.

Pharmacologic Treatment

A safe and effective drug therapy for PDPH would be very useful, even if relief is transient. The current gold standard therapy, an epidural blood patch, is not appropriate or effective in all patients. A 2015 systematic review of pharmacologic therapies for treatment of PDPH evaluated studies using caffeine, gabapentin, hydrocortisone, theophylline, sumatriptan, adrenocorticotropic hormone, pregabalin, and cosyntropin.[149] Participants in the studies were not limited to obstetric patients. Of the drugs included in this study, caffeine and theophylline seemed most beneficial for the treatment of PDPH. The evidence was inconclusive for sumatriptan, adrenocorticotropic hormone, pregabalin, and cosyntropin. The authors noted that the results of the analysis should be interpreted with caution because of the inability to assess risk for

bias and the small sample sizes of the studies included in their study.[149]

Caffeine

Caffeine has been used to treat PDPH for many years. In the systematic review,[149] two randomized trials comparing caffeine with placebo with different routes of administration but at equipotent doses were identified. Caffeine transiently reduced the number of participants with PDPH at 4 hours compared with placebo but not beyond, and also decreased the need for a conservative supplementary therapeutic medication.

Caffeine is a cerebral vasoconstrictor, and one study demonstrated a reduction of cerebral blood flow after intravenous administration of caffeine sodium benzoate for the treatment of PDPH.[150] Caffeine also increases CSF production by stimulating sodium-potassium pumps.[151] However, caffeine is also a potent central nervous system stimulant. Published case reports have described seizures after intravenous[152] and oral administration[153] of caffeine for the treatment of PDPH in postpartum patients.

Caffeine appears in breast milk in very small amounts.[154] To our knowledge, there are no reports of adverse effects on the infant after maternal administration of one or two doses of caffeine for the treatment of PDPH. The risk-to-benefit ratio to mother and newborn of multiple doses of caffeine has not been addressed. Until such studies are available, it seems wise to restrict the prescription of oral caffeine to 600 mg in 24 hours. Long-term caffeine therapy cannot be recommended.

Theophylline

Theophylline, a methylxanthine, has also been used for the management of PDPH. Although several studies have demonstrated that theophylline results in lower pain scores than either placebo or acetaminophen, none have included obstetric patients.[149] Additionally, theophylline is not commonly used for the management of PDPH because of its narrow safety profile.

Sumatriptan

Sumatriptan is a serotonin receptor agonist with cerebral vasoconstrictor properties that is administered subcutaneously for the treatment of migraine headaches. Side effects include pain at the injection site and, uncommonly, chest tightness and coronary artery vasospasm. Carp et al.[155] reported that the administration of sumatriptan 6 mg resulted in complete resolution of PDPH in four of six patients. Connelly et al.[156] randomized 10 patients with severe PDPH scheduled for epidural blood patch to receive sumatriptan 6 mg or placebo. After 1 hour, only one patient in each group had significant relief; the authors concluded that sumatriptan was of no value.

Adrenocorticotrophic Hormone and Analogs

The use of ACTH for the treatment of PDPH was first reported in a 1994 letter.[157] Subsequently, anecdotal reports have described different regimens of either intramuscular or intravenously administered ACTH or the synthetic drugs cosyntropin or tetracosactrin acetate. Mood elevation, anti-inflammatory effects, increased endorphin levels, and augmented intravascular volume are postulated as possible mechanisms of action in the relief of headache following ACTH administration. To date, the only randomized clinical trial of ACTH treatment in parturients involved 18 postpartum women who had PDPH after spinal anesthesia or unintentional dural puncture.[158] There was no difference in the severity of headache or the requirement for epidural blood patch between women receiving tetracosactrin acetate 1 mg intramuscularly and those who received saline-placebo.

In a small, prospective, nonblinded, randomized trial of 28 nonpregnant patients with severe PDPH, Hanling et al.[159] evaluated the efficacy of intravenous cosyntropin as an alternative to epidural blood patch for the treatment of refractory or severe PDPH. Epidural blood patch showed a significant reduction of pain and improved function compared with cosyntropin on day 1; however, cosyntropin demonstrated similar efficacy to epidural blood patch immediately after treatment, and at days 3 and 7 after treatment. The number of patients who returned to the emergency department for further treatment was greater in the cosyntropin group compared with the epidural blood patch group (60% versus 8%, respectively).[159] Additional study is needed to assess the safety and efficacy of cosyntropin for the prevention and treatment of PDPH. With current evidence, we do not recommend ACTH therapy as the first-line treatment of PDPH, but it may be considered for cases that are not amenable to epidural blood patch therapy.

Miscellaneous Medications

Other agents evaluated for their effectiveness in reducing PDPH symptoms include pregabalin, methylergonovine, hydrocortisone, and gabapentin. Randomized clinical trials have been conducted with intravenous hydrocortisone[160] and oral pregabalin.[161] In a nonblinded study, Noyan et al.[160] evaluated 60 parturients who developed PDPH after spinal anesthesia and were randomly assigned to receive intravenous hydrocortisone (200 mg loading dose followed by 100 mg three times daily for 2 days) or conventional therapy (bed rest, hydration, and scheduled acetaminophen with meperidine). Patients who received hydrocortisone had a 50% reduction in headache severity as assessed by visual analog scale (VAS) pain scores at 6 to 48 hours. Huseyinoglu et al.[161] randomized 40 patients with PDPH after lumbar puncture to receive pregabalin (150 mg daily for 2 days followed by 300 mg for 3 days) or placebo; pain scores and oral analgesic requirements were lower in the treatment group.

Use of gabapentin or methylergonovine has been reported only in case series.[162] Efficacy and side effects (maternal and neonatal) are unclear. All four drugs require further study before they can be recommended for therapy for PDPH.

Epidural Morphine

Eldor et al.[163] reported six nonobstetric patients whose PDPH headaches were successfully treated with epidural morphine

3.5 to 4.5 mg. Further study is required before conclusions can be reached. However, this therapy should be used with caution because epidural morphine injected in the presence of a large dural puncture site may pass readily into the CSF and predispose to respiratory depression. Additionally, treatment requires that patients remain in the hospital for 24 hours to assess for respiratory depression.

Epidural/Intrathecal Saline

The use of epidural or intrathecal fluids to treat PDPH preceded the use of epidural blood patches. Intrathecal injection of fluid was first described by Jacobaeus et al.[164] in 1923, and epidural injection of saline was reported by Rice and Dabbs in 1950.[165] These first reports were in conjunction with research attempting to understand the pathophysiology of PDPH, and they demonstrated transient elevations of CSF pressure after fluid injection. Subsequently there has been sporadic interest in using injection of fluids (other than blood) into the neuraxial space to treat PDPH.

Usubiaga et al.[166] injected 10 to 30 mL of saline through a lumbar epidural catheter in 11 nonobstetric patients with a PDPH after spinal anesthesia in whom 48 hours of conservative therapy had failed. Immediate relief of headache was observed in 10 patients, and the relief was permanent in 8 patients. However, the investigators did not comment whether other therapies (e.g., supine posture, abdominal binder, analgesics) were continued. In a quasi-randomized trial, 43 parturients with PDPH after unintentional dural puncture during an epidural procedure or after spinal anesthesia with a 25-gauge needle were assigned to receive a 30-mL lumbar epidural saline bolus or a 10-mL lumbar epidural blood patch.[167] Forty-two patients had dramatic relief of their symptoms in the first hour after the intervention; however, 12 of the 21 (57%) patients who had received saline had return of the PDPH in the next 24 hours.

Prolonged epidural saline infusion may provide better therapy for PDPH symptoms than therapy with a single bolus. In a retrospective study that included both obstetric and nonobstetric patients, patients who received a continuous epidural saline infusion for 4 days had a lower incidence of PDPH, and the headache was less severe, than patients who received conservative therapy.[168] This therapy, however, may not be practical in hospital settings in which women are discharged 1 or 2 days after delivery. Two case reports described the use of epidural saline infusion for parturients with an unintentional dural puncture whose PDPH symptoms returned after epidural blood patch therapy.[169,170] The rate of infusion (15 to 25 mL/h) was limited by the onset of pain in the back, legs, and eyes. Although both saline techniques offer only temporary relief, these options might be considered for patients who have a contraindication to epidural blood patch therapy.

Epidural Blood Patch

Efficacy. The epidural blood patch is regarded by many as the gold standard therapy for PDPH. Although reported in third person, Gormley, in 1960, is credited with performing the first successful epidural blood patch.[171] He described relief of PDPH symptoms in seven patients after epidural administration of only 2 to 3 mL of blood. However, this report was largely ignored until 1970, when DiGiovanni and Dunbar[172] described the immediate and permanent cure of PDPH in 41 of 45 patients in whom 10 mL of autologous blood was injected into the epidural space. Their success led to the widespread adoption of this technique for the relief of PDPH.

In early case series, the reported success rate of epidural blood patch therapy for PDPH was between 89% and 91%.[172,173] Safa-Tisseront et al.[174] reviewed their experience with epidural blood patch therapy over a 12-year period (n = 504 patients, including 78 obstetric patients). Complete relief of PDPH was obtained in 75%, partial relief occurred in 18%, and treatment failed in 7% of patients. The investigators noted a significantly higher failure rate of epidural blood patch after large-gauge needle puncture of the dura. The difference in early reports and more modern audits of PDPH and epidural blood patch success may be related to differences in the studied population, timing of epidural blood patch, blood volume injected, or the duration of follow-up after blood patch therapy.

In studies limited to obstetric patients, the published success rates of epidural blood patch have been even less encouraging. Stride and Cooper[75] noted complete and permanent relief of PDPH in 64% of patients after one blood patch procedure. Williams et al.[175] reported only 33% of their patients obtained complete and permanent relief from the first blood patch. Banks et al.[176] prospectively monitored 100 patients with unintentional dural puncture. Fifty-eight received a therapeutic blood patch; the treatment completely failed in 3 patients, and 17 patients had recurrence of moderate or severe headache requiring further therapy. Finally, in a prospective trial in postpartum patients with unintentional dural puncture with an epidural needle, the proportion of patients with complete headache relief was 32% after an epidural blood patch with 20 mL autologous blood.[177]

A 2010 systematic review[139] identified three randomized trials comparing epidural blood patch to either a sham procedure or conservative treatment. All three studies found a reduction in headache rate in the treatment group. Seebacher et al.[178] randomized 12 heterogeneous patients with PDPH to receive an epidural blood patch with 10 to 20 mL of blood or a sham patch procedure. Five of six patients receiving a blood patch had complete relief of headache symptoms at 24 hours, and none of the sham procedure patients did. Sandesc et al.[179] described a randomized trial of 32 obstetric and nonobstetric patients with PDPH symptoms for a minimum of 24 hours; subjects were randomly assigned to receive conservative therapy or an epidural blood patch. The primary outcome was headache VAS pain scores at 2 and 24 hours. At 2 hours, the mean ± SD VAS score for the conservative therapy group was 8.2 ± 1.4 cm compared with 1.0 ± 0.2 cm for the group receiving a blood patch. This difference remained at 24 hours. In the largest trial to date, van Kooten et al.[180] randomized 40 subjects with PDPH for 1 to 7 days to receive either conservative therapy or an epidural blood patch using 15 to 20 mL

of autologous blood. The primary outcome was headache 24 hours after intervention, but patients were observed for 1 week after therapy. The incidence of headache at 24 hours was 58% in the blood patch group compared with 90% in the conservative therapy group. At 1 week the difference widened, with a 16% incidence of headache in the blood patch group compared with 86% in the conservative group. In summary, administration of an autologous epidural blood patch, although not perfect, often dramatically relieves this debilitating condition and, at present, it is the therapy with the greatest likelihood of success.

Volume. The optimal volume of injected blood remains controversial. Szeinfeld et al.[181] used a gamma camera to observe the epidural spread of technetium-labeled red blood cells during and after epidural blood patch. They injected blood until pain occurred in the back, buttocks, or legs. The mean ± SD volume injected was 14.8 ± 1.7 mL of blood, and the mean ± SD spread was 9.0 ± 2.0 spinal segments. Blood spread more readily in the cephalad than in the caudad direction. The blood patch relieved the headache in all 10 patients. The investigators concluded that 12 to 15 mL of blood should be a sufficient patch volume for most patients.

The best evidence to date is an international, multicenter study by Paech et al.,[177] who randomized 121 women after unintentional dural puncture with a Tuohy needle (16- or 18-gauge) to receive an epidural blood patch with 15, 20, or 30 mL of blood. Partial or complete relief of headache (the primary outcome) occurred in 61%, 73%, and 67% of those who received 15, 20, or 30 mL of blood, respectively. However, complete relief of headache was achieved by only 10%, 32%, and 26% of women in these same groups. The rate of complete headache relief was greater in the 20-mL than in the 15-mL group; there was no difference between the 20-mL and 30-mL groups. Thus, the investigators concluded that 20 mL of autologous blood is the optimal volume for an epidural blood patch. This suggestion is supported by a single-institution review of 466 epidural patches performed over 15 years in obstetric patients in which the mean ± SD blood patch volume was 20.5 ± 5.4 mL.[182] A 2011 survey demonstrated that most North American anesthesiologists inject 20 mL of blood.[183]

Beards et al.[184] performed MRI studies after the performance of an epidural blood patch (18 to 20 mL) in five patients. Similar to Szeinfeld et al.,[181] they noted that the injected blood spread over three to five segments in a predominantly cephalad direction. All patients had an extensive hematoma in subcutaneous fat, and some also had displacement of nerve roots and/or evidence of intrathecal blood. A thick layer of mature clot had formed by 7 hours, but the clot had broken up into smaller clots by 18 hours. These findings may help explain the back pain and occasional nerve root pain that occur after blood patch therapy.

In another MRI study, Vakharia et al.[185] noted compression of the thecal sac and a mean spread over 4.6 segments after a lumbar epidural injection of 20 mL of blood. Djurhuus et al.[186] employed CT epidurography in four patients immediately and 24 hours after an 18-mL blood patch. Initial images showed adherence of clot to the dura in three patients as well as dural compression in two patients, but there was no evidence of compression at 24 hours.

Using a goat model, DiGiovanni et al.[187] examined the microscopic appearance of the dura as late as 6 months after dural puncture. Some study animals received a 2-mL blood patch in addition to dural puncture. The investigators concluded that the blood patch acted as a gelatinous tampon that produced no harmful tissue reaction.

Mechanism of action. The mechanism of epidural blood patch for relief of PDPH is unclear. Pain relief is often rapid, but CSF volume is not restored immediately. Thus, there must be another explanation for the immediate relief of headache besides "patching" of the dural puncture. Carrie[188] hypothesized that epidural injection of blood increases lumbar CSF pressure, an action that restores intracranial CSF pressure and decreases symptoms. Increased CSF pressure also may result in reflex cerebral vasoconstriction. Coombs and Hooper[189] demonstrated that epidural blood patch resulted in a threefold increase in lumbar CSF pressure. Further, they noted that 15 minutes later, lumbar CSF pressure was sustained at greater than 70% of the peak pressure observed after the injection of blood. Ultrasonographic examination of the optic nerve sheath diameter (a noninvasive measurement that correlates with intracranial pressure) in 10 patients with PDPH demonstrated increased measurements after epidural blood patch.[190] The sheath diameter increased 10 minutes after an epidural blood patch with 17 to 26 mL of blood and was sustained over the 20-hour study period. The only patient whose blood patch failed to successfully relieve the PDPH did not have the same increase in optic nerve sheath diameter.

MRI and CT studies have shown that the epidural blood is largely resorbed or broken up 18 to 24 hours after the procedure.[184] It is unlikely that the increase in CSF pressure is sustained or that the blood acts as a mechanical plug to block CSF leak for a prolonged duration. The blood applied to the hole in the dura may initiate an inflammatory reaction that facilitates puncture site repair and closure. It is possible, and even likely, that an epidural blood patch ameliorates PDPH by several mechanisms.

Timing. The optimal timing for administration of a blood patch has not been adequately studied. Observational studies suggest that failure is more likely if the blood patch is performed within 24[174] or 48 hours[177] of the dural puncture. Booth et al.[182] demonstrated a strong positive correlation between success of the epidural blood patch and the interval from the dural puncture or onset of PDPH to performance of the blood patch. It is unclear, however, whether this finding is a result of selection bias. Early-onset PDPH (often resulting from dural puncture with a large-gauge needle) is likely to be more severe and more difficult to treat. Alternatively, a large CSF leak may displace the clot. Partial healing of the dura may have already occurred if a blood patch is delayed, a possibility that may explain the better outcome of a delayed patch procedure.

Technique. The anesthesia provider should thoroughly explain the risks and benefits of the blood patch procedure to the patient, and the patient should give consent for the procedure. An epidural blood patch can be accomplished on an outpatient basis. Ideally, the environment for the procedure is one conducive to postpartum patients who may have accompanying family and a newborn. Contraindications to the administration of an epidural blood patch are related to complications of placing a needle in the central neuraxis or the injection of blood into the epidural space; they include (1) known coagulopathy (e.g., concurrent pharmacologic anticoagulation), (2) local cutaneous infection or untreated systemic infection, (3) increased ICP caused by a space-occupying lesion, and (4) patient refusal. Transient bradycardia has been observed after administration of an epidural blood patch, and some anesthesia providers may choose to establish intravenous access and monitor the electrocardiogram in selected patients.[191]

The blood patch procedure should employ sterile measures equivalent to those used for the administration of any neuraxial procedure. The lateral position is usually more comfortable than the sitting position for patients with severe PDPH. If the anesthesia provider is uncertain about the location of the dural puncture, the more caudad interspace should be chosen. The epidural space is identified in the usual manner. Using meticulous sterile technique (including skin preparation and draping, and donning of a face mask and sterile gloves), an assistant withdraws the desired volume of blood (usually 10 to 25 mL) into a syringe. This autologous blood is injected slowly into the epidural space through the Tuohy needle; the injection is terminated if severe back, leg, or neck pain or pressure occurs. Sometimes slowing the injection rate leads to resolution of the back pain. Jehovah's Witness patients may accept a blood patch procedure if a technique is used that keeps blood in continuity with the circulation.[192]

Occasionally a few drops of CSF are encountered on entering the epidural space, leading to doubt about correct needle placement.[193] One can either repeat the epidural needle placement, or a small test dose of a local anesthetic agent can be administered, sufficient to cause a rapid onset of spinal anesthesia. If no block results, the blood patch can be performed. Real-time ultrasound-guided and fluoroscopically guided epidural blood patch has been described and should be considered when difficulty with epidural needle placement is anticipated.[194,195]

After the procedure, the patient should rest quietly in the supine position for 1 to 2 hours.[196] Subsequently, the patient may resume ambulation, but she should avoid vigorous physical activity for several days. It would be wise for the patient to avoid the Valsalva maneuver and heavy lifting. A stool softener should be considered. Most patients report almost instantaneous relief of headache symptoms, although relief is delayed for 6 to 8 hours in some patients. The patient may continue to have neck and back fullness over the next 24 hours.[177] The back pain can continue up to 5 days after the procedure. Patients should be counseled to immediately report fever, severe back pain, or radiating lower extremity pain. The anesthesia provider should contact the patient after the blood patch procedure.

The blood patch may be repeated if the initial patch fails to relieve pain. Often the second patch is successful. Although not adequately studied, it seems reasonable to wait 24 hours before repeating an epidural blood patch procedure to allow the first procedure adequate time to work. The diagnosis should be reconsidered if headache persists after two failed blood patch procedures. Consultation by a neurologist may be appropriate when a PDPH fails to respond to two blood patches and should definitely be requested if there is any doubt about the diagnosis. Imaging of the head should be considered to exclude other causes of headache.

Complications. Ong et al.[197] reported that the success of neuraxial anesthesia/analgesia was impaired in women with a prior history of unintentional dural puncture with or without epidural blood patch therapy. However, this conclusion has been refuted by follow-up studies in both obstetric patients[198] and nonobstetric patients.[199]

Although epidural blood patch therapy is the most reliable method of relieving PDPH symptoms, adverse outcomes are associated with the procedure. These adverse events can be categorized into two broad groups: infectious/hematologic and neurologic.
