1

The History of Obstetric Anesthesia

Donald Caton, MD

For I heard a cry as of a woman in travail, anguish as of one bringing forth her first child, the cry of the daughter of Zion gasping for breath, stretching out her hands, "Woe is me!"

—Jeremiah 4:31

CHAPTER OUTLINE

"The position of woman in any civilization is an index of the advancement of that civilization; the position of woman is gauged best by the care given her at the birth of her child." So wrote Haggard[1] in 1929. If his thesis is true, Western civilization made a giant leap on January 19, 1847, when James Young Simpson used diethyl ether to anesthetize a woman with a deformed pelvis for delivery. This first use of a modern anesthetic for childbirth occurred a scant 3 months after Morton's historic demonstration of the anesthetic properties of ether at the Massachusetts General Hospital in Boston. Strangely enough, Simpson's innovation evoked strong criticism from contemporary obstetricians, who questioned its safety, and from many segments of the lay public, who questioned its wisdom. The debate over these issues lasted more than 5 years and influenced the future of obstetric anesthesia.[2]

JAMES YOUNG SIMPSON

Few people were better equipped than Simpson to deal with controversy. Just 36 years of age, Simpson already had 7 years' tenure as Professor of Midwifery at the University of Edinburgh, one of the most prestigious medical schools of its day (Fig. 1.1). By that time, he had established a reputation as one of the foremost obstetricians in Great Britain, if not the world. On the day he first used ether for childbirth, he also received a letter of appointment as Queen's Physician in Scotland. Etherization for childbirth was only one of Simpson's contributions. He also designed obstetric forceps (which still bear his name), discovered the anesthetic properties of chloroform, made important innovations in hospital architecture, and wrote a textbook on the practice of witchcraft in Scotland that was used by several generations of anthropologists.[3]

An imposing man, Simpson had a large head, a massive mane of hair, and the pudgy body of an adolescent. Contemporaries described his voice as "commanding," with a wide range of volume and intonation. Clearly Simpson had "presence" and "charisma." These attributes were indispensable to someone in his profession, because in the mid-nineteenth century, the role of science in the development of medical theory and practice was minimal; rhetoric resolved more issues than facts. The medical climate in Edinburgh was particularly contentious and vituperative. In this milieu, Simpson had trained, competed for advancement and recognition, and succeeded. The rigor of this preparation served him well. Initially, virtually every prominent obstetrician, including Montgomery of Dublin, Ramsbotham of London, Dubois of Paris, and Meigs of Philadelphia, opposed etherization for childbirth. Simpson called on all of his professional and personal finesse to sway opinion in the ensuing controversy.

MEDICAL OBJECTIONS TO THE USE OF ETHER FOR CHILDBIRTH

Shortly after Simpson administered the first obstetric anesthetic, he wrote, "It will be necessary to ascertain anesthesia's precise effect, both upon the action of the uterus and on the assistant abdominal muscles; its influence, if any, upon the child; whether it has a tendency to hemorrhage or other complications."[4] With this statement, he identified the issues that would most concern obstetricians who succeeded him and thus shaped the subsequent development of the specialty.

Simpson's most articulate, persistent, and persuasive critic was Charles D. Meigs, Professor of Midwifery at Jefferson Medical College in Philadelphia (Fig. 1.2). In character and

stature, Meigs equaled Simpson. Born to a prominent New England family, Meigs' forebears included heroes of the American Revolutionary War, the first governor of the state of Ohio, and the founder of the University of Georgia. His descendants included a prominent pediatrician, an obstetrician, and one son who served the Union Army as Quartermaster General during the Civil War.[5]

At the heart of the dispute between Meigs and Simpson was a difference in their interpretation of the nature of labor and the significance of labor pain. Simpson maintained that all pain, labor pain included, is without physiologic value. He said that pain only degrades and destroys those who experience it. In contrast, Meigs argued that labor pain has purpose, that uterine pain is inseparable from contractions, and that any drug that abolishes pain will alter contractions. Meigs also believed that pregnancy and labor are normal processes that usually end quite well. He said that physicians should therefore not intervene with powerful, potentially disruptive drugs (Fig. 1.3). We must accept the statements of both men as expressions of natural philosophy, because neither had facts to buttress his position. Indeed, in 1847, physicians had little information of any sort about uterine function, pain, or the relationship between them. Studies of the anatomy and physiology of pain had just begun. It was only during the preceding 20 years that investigators had recognized that specific nerves and areas of the brain have different functions and that specialized peripheral receptors for painful stimuli exist.[2]

In 1850, more physicians expressed support for Meigs's views than for Simpson's. For example, Baron Paul Dubois[6] of the Faculty of Paris wondered whether ether, "after having exerted a stupefying action over the cerebrospinal nerves, could not induce paralysis of the muscular element of the uterus?" Similarly, Ramsbotham[7] of London Hospital said that he believed the "treatment of rendering a patient in labor completely insensible through the agency of anesthetic remedies … is fraught with extreme danger." These physicians' fears gained credence from the report by a special committee of the Royal Medical and Chirurgical Society documenting 123 deaths that "could be positively assigned to the inhalation of chloroform."[8] Although none involved obstetric patients, safety was on the minds of obstetricians.

The reaction to the delivery of Queen Victoria's eighth child in 1853 illustrated the aversion of the medical community to obstetric anesthesia. According to private records, John Snow anesthetized the Queen for the delivery of Prince Leopold at the request of her personal physicians. Although no one made a formal announcement of this fact, rumors surfaced and provoked strong public criticism. Thomas Wakley, the irascible founding editor of *The Lancet,* was particularly incensed. He "could not imagine that anyone had incurred the awful responsibility of advising the administration of chloroform to her Majesty during a perfectly natural labour with a seventh child."[9] (It was her eighth child, but Wakley

had apparently lost count—a forgivable error considering the propensity of the Queen to bear children.) Court physicians did not defend their decision to use ether. Perhaps not wanting a public confrontation, they simply denied that the Queen had received an anesthetic. In fact, they first acknowledged a royal anesthetic 4 years later when the Queen delivered her ninth and last child, Princess Beatrice. By that time, however, the issue was no longer controversial.[9]

PUBLIC REACTION TO ETHERIZATION FOR CHILDBIRTH

The controversy surrounding obstetric anesthesia was not resolved by the medical community. Physicians remained skeptical, but public opinion changed. Women lost their reservations, decided they wanted anesthesia, and virtually forced physicians to offer it to them. The change in the public's attitude in favor of obstetric anesthesia marked the culmination of a more general change in social attitudes that had been developing over several centuries.

Before the nineteenth century, pain meant something quite different from what it does today. Since antiquity, people had believed that all manner of calamities—disease, drought, poverty, and pain—signified divine retribution inflicted as punishment for sin. According to Scripture, childbirth pain originated when God punished Eve and her descendants for Eve's disobedience in the Garden of Eden. Many believed that it was wrong to avoid the pain of divine punishment. This belief was sufficiently prevalent and strong to retard acceptance of even the idea of anesthesia, especially for obstetric patients. Only when this tradition weakened did people seek ways to free themselves from disease and pain. In most Western countries, the transition occurred during the nineteenth century. Disease and pain lost their theologic connotations for many people and became biologic processes subject to study and control by new methods of science and technology. This evolution of thought facilitated the development of modern medicine and stimulated public acceptance of obstetric anesthesia.[10]

The reluctance that physicians felt about the administration of anesthesia for childbirth pain stands in stark contrast to the enthusiasm expressed by early obstetric patients. In 1847, Fanny Longfellow, wife of the American poet Henry Wadsworth Longfellow and the first woman in the United States anesthetized for childbirth, wrote:

> *I am very sorry you all thought me so rash and naughty in trying the ether. Henry's faith gave me courage, and I had heard such a thing had succeeded abroad, where the surgeons extend this great blessing more boldly and universally than our timid doctors. … This is certainly the greatest blessing of this age.*[11]

Queen Victoria, responding to news of the birth of her first grandchild in 1860 and perhaps remembering her own recent confinement, wrote, "What a blessing she [Victoria, her oldest daughter] had chloroform. Perhaps without it her strength would have suffered very much."[9] The new understanding of pain as a controllable biologic process left no room for Meigs's idea that pain might have physiologic value. The eminent nineteenth-century social philosopher John Stuart Mill stated that the "hurtful agencies of nature" promote good only by "inciting rational creatures to rise up and struggle against them."[12]

Simpson prophesied the role of public opinion in the acceptance of obstetric anesthesia, a fact not lost on his adversaries. Early in the controversy he predicted, "Medical men may oppose for a time the superinduction of anaesthesia in parturition but they will oppose it in vain; for certainly our patients themselves will force use of it upon the profession. The whole question is, even now, one merely of time."[13] By 1860, Simpson's prophecy came true; anesthesia for childbirth became part of medical practice by public acclaim, in large part in response to the demands of women.

OPIOIDS AND OBSTETRICS

The next major innovation in obstetric anesthesia came approximately 50 years later. *Dämmerschlaff*, which means "twilight sleep," was a technique developed by von Steinbüchel[14] of Graz and popularized by Gauss[15] of Freiberg. It combined opioids with scopolamine to make women amnestic and somewhat comfortable during labor (Fig. 1.4). Until

that time, opioids had been used sparingly for obstetrics. Although opium had been part of the medical armamentarium since the Roman Empire, it was not used extensively, in part because of the difficulty of obtaining consistent results with the crude extracts available at that time. Therapeutics made a substantial advance in 1809 when Sertürner, a German pharmacologist, isolated codeine and morphine from a crude extract of the poppy seed. Methods for administering the drugs remained unsophisticated. Physicians gave morphine orally or by a method resembling vaccination, in which they placed a drop of solution on the skin and then made multiple small puncture holes with a sharp instrument to facilitate absorption. In 1853, the year Queen Victoria delivered her eighth child, the syringe and hollow metal needle were developed. This technical advance simplified the administration of opioids and facilitated the development of twilight sleep approximately 50 years later.[16]

Although reports of labor pain relief with hypodermic morphine appeared as early as 1868, few physicians favored its use. For example, in an article published in *Transactions of the Obstetrical Society of London*, Sansom[17] listed the following four agents for relief of labor pain: (1) carbon tetrachloride, the use of which he favored; (2) bichloride of methylene, which was under evaluation; (3) nitrous oxide, which had been introduced recently by Klikgowich of Russia; and (4) chloroform. He did not mention opioids, but neither did he mention diethyl ether, which many physicians still favored. Similarly, Gusserow,[18] a prominent German obstetrician, described using salicylic acid but not morphine for labor pain. (Von Baeyer did not introduce acetylsalicylic acid to medical practice until 1899.) In retrospect, von Steinbüchel's and Gauss's descriptions of twilight sleep in the first decade of the century may have been important more for popularizing morphine than for suggesting that scopolamine be given with morphine.

Physicians reacted to twilight sleep as they had reacted to diethyl ether several years earlier. They resisted it, questioning whether the benefits justified the risks. Patients also reacted as they had before. Not aware of, or perhaps not concerned with, the technical considerations that confronted physicians, patients harbored few doubts and persuaded physicians to use it, sometimes against the physicians' better judgment. The confrontation between physicians and patients was particularly strident in the United States. Champions of twilight sleep lectured throughout the country and published articles in popular magazines. Public enthusiasm for the therapy subsided slightly after 1920, when a prominent advocate of the method died during childbirth. She was given twilight sleep, but her physicians said that her death was unrelated to any complication from its use. Whatever anxiety this incident may have created in the minds of patients, it did not seriously diminish their resolve. Confronted by such firm insistence, physicians acquiesced and used twilight sleep with increasing frequency.[19,20]

Although the reaction of physicians to twilight sleep resembled their reaction to etherization, the medical milieu in which the debate over twilight sleep developed was quite different from that in which etherization was deliberated. Between 1850 and 1900, medicine had changed, particularly in Europe. Physiology, chemistry, anatomy, and bacteriology became part of medical theory and practice. Bright students from America traveled to leading clinics in Germany, England, and France. They returned with new facts and methods that they used to examine problems and critique ideas. These developments became the basis for the revolution in American medical education and practice launched by the Flexner report published in 1914.[21]

Obstetrics also changed. During the years preceding World War I, it had earned a reputation as one of the most exciting and scientifically advanced specialties. Obstetricians experimented with new drugs and techniques. They recognized that change entails risk, and they examined each innovation more critically. In addition, they turned to science for information and methods to help them solve problems of medical management. Developments in obstetric anesthesia reflected this change in strategy. New methods introduced during this time stimulated physicians to reexamine two important but unresolved issues, the effects of drugs on the child, and the relationship between pain and labor.

THE EFFECTS OF ANESTHESIA ON THE NEWBORN

Many physicians, Simpson included, worried that anesthetic drugs might cross the placenta and harm the newborn. Available information justified their concern. The idea that gases cross the placenta appeared long before the discovery of oxygen and carbon dioxide. In the sixteenth century, English physiologist John Mayow[22] suggested that "nitro-aerial" particles from the mother nourish the fetus. By 1847, physiologists had corroborative evidence. Clinical experience gave more support. John Snow[23] observed depressed neonatal breathing and motor activity and smelled ether on the breath of neonates delivered from mothers who had been given ether. In an early paper, he surmised that anesthetic gases cross the placenta. Regardless, some advocates of obstetric anesthesia discounted the possibility. For example, Harvard

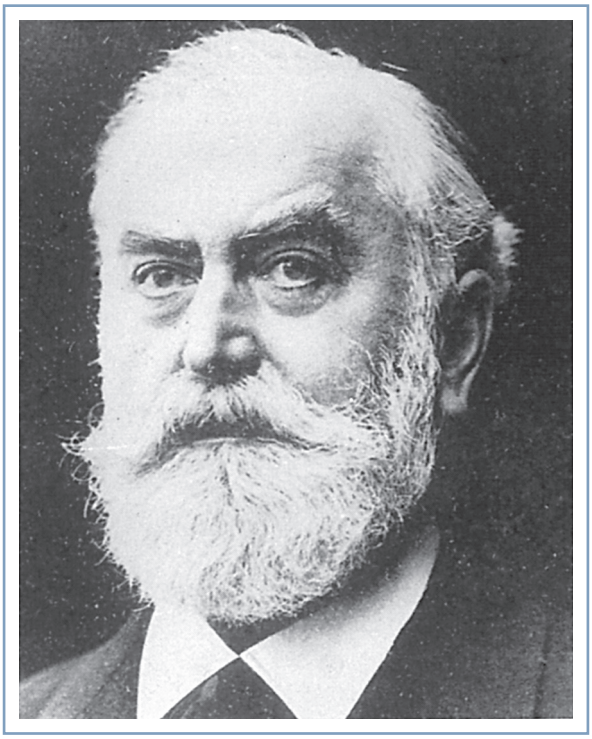

Fig. 1.5 Paul Zweifel, the Swiss-born obstetrician who performed the first experiments that chemically demonstrated the presence of chloroform in the umbilical blood and urine of infants delivered by women who had been anesthetized during labor. (Courtesy of J.F. Bergmann-Verlag, München, Germany.)

professor Walter Channing denied that ether crossed the placenta because he could not detect its odor in the cut ends of the umbilical cord. Oddly enough, he did not attempt to smell ether on the child's exhalations as John Snow had done.[24]

In 1874, Swiss obstetrician Paul Zweifel[25] published an account of work that finally resolved the debate about the placental transfer of drugs (Fig. 1.5). He used a chemical reaction to demonstrate the presence of chloroform in the umbilical blood of neonates. In a separate paper, Zweifel[26] used a light-absorption technique to demonstrate a difference in oxygen content between umbilical arterial and venous blood, thereby establishing the placental transfer of oxygen. Although clinicians recognized the importance of these data, they accepted the implications slowly. Some clinicians pointed to several decades of clinical use "without problems." For example, Otto Spiegelberg,[27] Professor of Obstetrics at the University of Breslau, wrote in 1887, "as far as the fetus is concerned no unimpeachable clinical observation has yet been published in which a fetus was injured by chloroform administered to its mother." Experience lulled them into complacency, which may explain their failure to appreciate the threat posed by twilight sleep.

Dangers from twilight sleep probably developed insidiously. The originators of the method, von Steinbterial and Gauss, recommended conservative doses of drugs. They suggested that 0.3 mg of scopolamine be given every 2 to 3 hours to induce amnesia and that no more than 10 mg of morphine be administered subcutaneously for the whole labor. Gauss, who was especially meticulous, even advised physicians to administer a "memory test" to women in labor to evaluate the need for additional scopolamine. However, as other physicians used the technique, they changed it. Some gave larger doses of opioid—as much as 40 or 50 mg of morphine during labor. Others gave additional drugs (e.g., as much as 600 mg of pentobarbital during labor and inhalation agents for delivery). Despite administering these large doses to their patients, some physicians said they had seen no adverse effects on the infants.[28] They probably spoke the truth, but this probability says more about their powers of observation than the safety of the method.

Two situations eventually made physicians confront problems associated with placental transmission of anesthetic drugs. The first was the changing use of morphine.[29] In the latter part of the nineteenth century (before the enactment of laws governing the use of addictive drugs), morphine was a popular ingredient of patent medicines and a drug frequently prescribed by physicians. As addiction became more common, obstetricians saw many pregnant women who were taking large amounts of morphine daily. When they tried to decrease their patients' opioid use, several obstetricians noted unexpected problems (e.g., violent fetal movements, sudden fetal death), which they correctly identified as signs of withdrawal. Second, physiologists and anatomists began extensive studies of placental structure and function. By the turn of the century, they had identified many of the physical and chemical factors that affect rates of drug transfer. Thus, even before twilight sleep became popular, physicians had clinical and laboratory evidence to justify caution. As early as 1877, Gillette[30] described 15 instances of neonatal depression that he attributed to morphine given during labor. Similarly, in a review article published in 1914, Knipe[31] identified stillbirths and neonatal oligopnea and asphyxia as complications of twilight sleep and gave the incidence of each problem as reported by other writers.

When the studies of obstetric anesthesia published between 1880 and 1950 are considered, four characteristics stand out. First, few of them described effects of anesthesia on the newborn. Second, those that did report newborn apnea, oligopnea, or asphyxia seldom defined these words. Third, few used controls or compared one mode of treatment with another. Finally, few writers used their data to evaluate the safety of the practice that they described. In other words, by today's standards, even the best of these papers lacked substance. They did, however, demonstrate a growing concern among physicians about the effects of anesthetic drugs on neonates. Perhaps even more important, their work prepared clinicians for the work of Virginia Apgar (Fig. 1.6).

Apgar became an anesthesiologist when the chairman of the Department of Surgery at the Columbia University College of Physicians and Surgeons dissuaded her from becoming a surgeon. After training in anesthesia with Ralph Waters at the University of Wisconsin and with E.A. Rovenstine at Bellevue Hospital, she returned to Columbia Presbyterian Hospital as Director of the Division of Anesthesia. In 1949, she was appointed professor, the first woman to attain that rank at Columbia University.[32]

FIVE HUNDRED AND EIGHTY-ONE CASES.

BY WALTER CHANNING, M.D.

PROFESSOR OF MIDWIFERY AND MEDICAL JURISPRUDENCE IN THE UNIVERSITY AT CAMBRIDGE.

"Give me the facts, said my Lord Judge: your reasonings are the mere guess-work of the imagination." — OLD PLAY.

BOSTON:

WILLIAM D. TICKNOR AND COMPANY,

CORNER OF WASHINGTON AND SCHOOL STREETS.

M.DCCC.XLVIII.

Fig. 1.8 Frontispiece from Walter Channing's book on the use of etherization for childbirth. Channing favored the use of etherization, and he persuaded others to use it, although evidence ensuring its safety was scant.

In 1953, Apgar[33] described a simple, reliable system for evaluating newborns and showed that it was sufficiently sensitive to detect differences among neonates whose mothers had been anesthetized for cesarean delivery by different techniques (Fig. 1.7). Infants delivered of women with spinal anesthesia had higher scores than those delivered with general anesthesia. The Apgar score had three important effects. First, it replaced simple observation of neonates with a reproducible measurement—that is, it substituted a numerical score for the ambiguities of words such as oligopnea and asphyxia. Thus it established the possibility of the systematic comparison of different treatments. Second, it provided objective criteria for the initiation of neonatal resuscitation. Third, and most important, it helped change the focus of obstetric care. Until that time, the primary criterion for success or failure had been the survival and well-being of the mother, a natural goal considering the maternal risks of childbirth until that time. After 1900, as maternal risks diminished, the well-being of the mother no longer served as a sensitive measure of outcome. The Apgar score called attention to the child and made its condition the new standard for evaluating obstetric management.

THE EFFECTS OF ANESTHESIA ON LABOR

The effects of anesthesia on labor also worried physicians. Again, their fears were well-founded. Diethyl ether and chloroform depress uterine contractions. If given in sufficient amounts, they also abolish reflex pushing with the abdominal muscles during the second stage of labor. These effects are not difficult to detect, even with moderate doses of either inhalation agent.

Simpson's method of obstetric anesthesia used significant amounts of drugs. He started the anesthetic early, and sometimes he rendered patients unconscious during the first stage of labor. In addition, he increased the depth of anesthesia for the delivery.[34] As many people copied his technique, they presumably had ample opportunity to observe uterine atony and postpartum hemorrhage.

Some physicians noticed the effects of anesthetics on uterine function. For example, Meigs[35] said unequivocally that etherization suppressed uterine function, and he described occasions in which he had had to suspend

etherization to allow labor to resume. Other physicians waffled, however. For example, Walter Channing,[36] Professor of Midwifery and Medical Jurisprudence at Harvard (seemingly a strange combination of disciplines, but at that time neither of the two was thought sufficiently important to warrant a separate chair), published a book about the use of ether for obstetrics (Fig. 1.8). He endorsed etherization and influenced many others to use it. However, his book contained blatant contradictions. On different pages Channing contended that ether had no effect, that it increased uterine contractility, and that it suspended contractions entirely. Then, in a pronouncement smacking more of panache than reason, Channing swept aside his inconsistencies and said that whatever effect ether may have on the uterus he "welcomes it." Noting similar contradictions among other writers, W.F.H. Montgomery,[37] Professor of Midwifery at the King and Queen's College of Physicians in Ireland, wrote, "By one writer we are told that, if uterine action is excessive, chloroform will abate it; by another that if feeble, it will strengthen it and add new vigor to each parturient effort."

John Snow[23] gave a more balanced review of the effects of anesthesia on labor. Originally a surgeon, Snow became the first physician to restrict his practice to anesthesia. He experimented with ether and chloroform and wrote many insightful papers and books describing his work (Fig. 1.9). Snow's technique differed from Simpson's. Snow withheld anesthesia until the second stage of labor, limited administration to brief periods during contractions, and attempted to keep his patients comfortable but responsive. To achieve better control of the depth of anesthesia, he recommended using the vaporizing apparatus that he had developed for surgical cases. Snow[23] spoke disparagingly of Simpson's technique and the tendency of people to use it simply because of Simpson's reputation:

> *The high position of Dr. Simpson and his previous services in this department, more particularly in being the first to administer ether in labour, gave his recommendations very great influence; the consequence of which is that the practice of anesthesia is presently probably in a much less satisfactory state than it would have been if chloroform had never been introduced.*

Snow's method, which was the same one he had used to anesthetize Queen Victoria, eventually prevailed over Simpson's. Physicians became more cautious with anesthesia, reserving it for special problems such as cephalic version, the application of forceps, abnormal presentation, and eclampsia. They also became more conservative with dosage, often giving anesthesia only during the second stage of labor. Snow's methods were applied to each new inhalation agent—including nitrous oxide, ethylene, cyclopropane, trichloroethylene, and methoxyflurane—as it was introduced to obstetric anesthesia.

Early physicians modified their use of anesthesia from experience, not from study of normal labor or from learning more about the pharmacology of the drugs. Moreover, they had not yet defined the relationship between uterine pain and contractions. As physicians turned more to science during the latter part of the century, however, their strategies began to change. For example, in 1893 the English physiologist Henry Head[38] published his classic studies of the innervation of abdominal viscera. His work stimulated others to investigate the role of the nervous system in the control of labor. Subsequently, clinical and laboratory studies of pregnancy after spinal cord transection established the independence of labor from nervous control.[39] When regional anesthesia appeared during the first decades of the twentieth century, physicians therefore had a conceptual basis from which to explore its effects on labor.

Carl Koller[40] introduced regional anesthesia when he used cocaine for eye surgery in 1884. Recognizing the potential of Koller's innovation, surgeons developed techniques for other procedures. Obstetricians quickly adopted many of these techniques for their own use. The first papers describing obstetric applications of spinal, lumbar epidural, caudal, paravertebral, parasacral, and pudendal nerve blocks appeared between 1900 and 1930 (see Fig. 1.4).[41–43] Recognition of the potential effects of regional anesthesia on labor developed more slowly, primarily because obstetricians seldom used it. They continued to rely on inhalation agents and opioids, partly because few drugs and materials were available for regional anesthesia at that time, but also because obstetricians did not appreciate the chief advantage of regional over general anesthesia—the relative absence of drug effects on the infant. Moreover, they rarely used regional

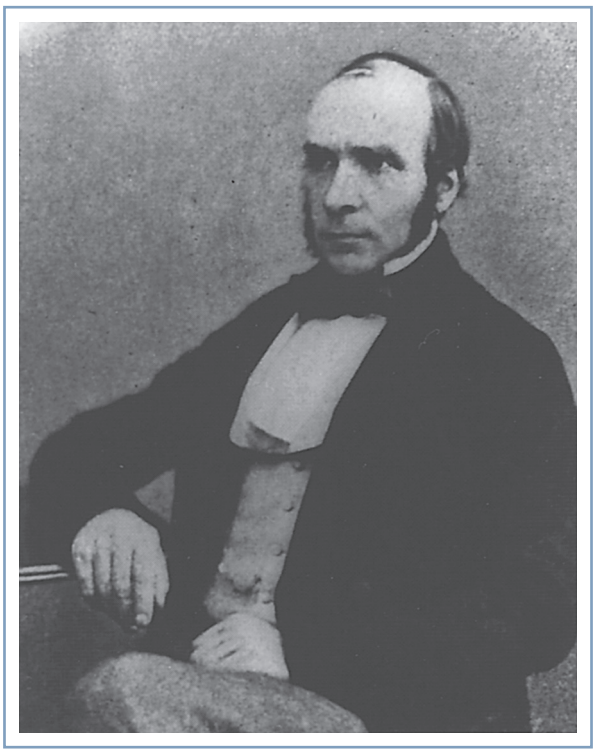

Fig. 1.9 John Snow, a London surgeon who gave up his surgical practice to become the first physician to devote all his time to anesthesia. He wrote many monographs and papers, some of which accurately describe the effects of anesthesia on the infant and mother. (Courtesy of Wood-Library Museum.)

anesthesia except for delivery, and then they often used elective forceps anyway. This set of circumstances limited their opportunity and motivation to study the effects of regional anesthesia on labor.

Among early papers dealing with regional anesthesia, one written by Cleland[44] stands out. He described his experience with paravertebral anesthesia, but he also wrote a thoughtful analysis of the nerve pathways mediating labor pain, an analysis he based on information he had gleaned from clinical and laboratory studies. Few investigators were as meticulous or insightful as Cleland. Most of those who studied the effects of anesthesia simply timed the length of the first and second stages of labor. Some timed the duration of individual contractions or estimated changes in the strength of contractions by palpation. None of the investigators measured the intrauterine pressures, even though a German physician had described such a method in 1898 and had used it to evaluate the effects of morphine and ether on the contractions of laboring women.[45]

More detailed and accurate studies of the effects of anesthesia started to appear after 1944. Part of the stimulus was a method for continuous caudal anesthesia introduced by Hingson and Edwards,[46] in which a malleable needle remained in the sacral canal throughout labor. Small, flexible plastic catheters eventually replaced malleable needles and made continuous epidural anesthesia even more popular. With the help of these innovations, obstetricians began using anesthesia earlier in labor. Ensuing problems, real and imagined, stimulated more studies. Although good studies were scarce, the strong interest in the problem represented a marked change from the early days of obstetric anesthesia.

Ironically, "natural childbirth" appeared just as regional anesthesia started to become popular and as clinicians began to understand how to use it without disrupting labor. Dick-Read,[47] the originator of the natural method, recognized "no physiological function in the body which gives rise to pain in the normal course of health." He attributed pain in an otherwise uncomplicated labor to an "activation of the sympathetic nervous system by the emotion of fear." He argued that fear made the uterus contract and become ischemic and therefore painful. He said that women could avoid the pain if they simply learned to abolish their fear of labor. Dick-Read never explained why uterine ischemia that results from fear causes pain, whereas ischemia that results from a normal contraction does not. In other words, Dick-Read, like Simpson a century earlier, claimed no necessary or physiologic relationship between labor pain and contractions. Dick-Read's book, written more for the public than for the medical profession, represented a regression of almost a century in medical thought and practice. It is important to note that contemporary methods of childbirth preparation do not maintain that fear alone causes labor pain. However, they do attempt to reduce fear by education and to help patients manage pain by teaching techniques of self-control. This represents a significant difference from and an important advance over Dick-Read's original theory.

SOME LESSONS

History is important in proportion to the lessons it teaches. With respect to obstetric anesthesia, four lessons stand out. First, every new drug and method entails risks. Physicians who first used obstetric anesthesia seemed reluctant to accept this fact, perhaps because of their inexperience with potent drugs (pharmacology was in its infancy) or because they acceded too quickly to patients, who wanted relief from pain and had little understanding of the technical issues confronting physicians. Whatever the reason, this period of denial lasted almost half a century, until 1900. Almost another half-century passed before obstetricians learned to modify their practice to limit the effects of anesthetics on the child and the labor process.

Second, new drugs or therapies often cause problems in completely unexpected ways. For example, in 1900, physicians noted a rising rate of puerperal fever.[48] The timing was odd. Several decades had passed since Robert Koch had suggested the germ theory of disease and since Semmelweis had recognized that physicians often transmit infection from one woman to the next with their unclean hands. With the adoption of aseptic methods, deaths from puerperal fever had diminished dramatically. During the waning years of the nineteenth century, however, they increased again. Some physicians attributed this resurgence of puerperal fever to anesthesia. In a presidential address to the Obstetrical Society of Edinburgh in 1900, Murray[49] stated the following:

> *I feel sure that an explanation of much of the increase of maternal mortality from 1847 onwards will be found in, first the misuse of anaesthesia and second in the ridiculous parody which, in many hands, stands for the use of antiseptics. … Before the days of anaesthesia, interference was limited and obstetric operations were at a minimum because interference of all kinds increased the conscious suffering of the patient. … When anaesthesia became possible, and interference became more frequent because it involved no additional suffering, operations were undertaken when really unnecessary … and so complications arose and the dangers of the labor increased.*

Although it was not a direct complication of the use of anesthesia in obstetric practice, puerperal fever appeared to be an indirect consequence of it.

Changes in obstetric practice also had unexpected effects on anesthetic complications. During the first decades of the twentieth century, when cesarean deliveries were rare and obstetricians used only inhalation analgesia for delivery, few women were exposed to the risk of aspiration during deep anesthesia. As obstetric practice changed and cesarean deliveries became more common, this risk rose. The syndrome of aspiration was not identified and labeled until 1946, when obstetrician Curtis Mendelson[50] described and named it. The pathophysiology of the syndrome had already been described by Winternitz et al.,[51] who instilled hydrochloric acid into the lungs of dogs to simulate the lesions found in veterans poisoned by gas during the trench warfare of World War I. Unfortunately, the reports of these studies, although

excellent, did not initiate any change in practice. Change occurred only after several deaths of obstetric patients were highly publicized in lay, legal, and medical publications. Of course, rapid-sequence induction, currently recommended to reduce the risk for aspiration, creates another set of risks—those associated with a failed intubation.

The third lesson offered by the history of obstetric anesthesia concerns the role of basic science. Modern medicine developed during the nineteenth century after physicians learned to apply principles of anatomy, physiology, and chemistry to the study and treatment of disease. Obstetric anesthesia underwent a similar pattern of development. Studies of placental structure and function called physicians' attention to the transmission of drugs and the potential effects of drugs on the infant. Similarly, studies of the physiology and anatomy of the uterus helped elucidate potential effects of anesthesia on labor. In each instance, lessons from basic science helped improve patient care.

The fourth and perhaps the most important lesson is the role that patients have played in the use of anesthesia for obstetrics. During the nineteenth century, it was women who pressured cautious physicians to incorporate routine use of anesthesia into their obstetric practice. A century later, it was women again who altered patterns of practice, this time questioning the overuse of anesthesia for routine deliveries. In both instances, the pressure on physicians emanated from prevailing social values regarding pain. In 1900, the public believed that pain, and in particular obstetric pain, was destructive and something that should be avoided. Half a century later, with the advent of the natural childbirth movement, many people began to suggest that the experience of pain during childbirth, perhaps even in other situations, might have some physiologic if not social value. Physicians must recognize and acknowledge the extent to which social values may shape medical "science" and practice.[52,53]

During the past 75 years, scientists have accumulated a wealth of information about many processes integral to normal labor: the processes that initiate and control lactation; neuroendocrine events that initiate and maintain labor; the biochemical maturation of the fetal lung and liver; the metabolic requirements of the normal fetus and the protective mechanisms that it may invoke in times of stress; and the normal mechanisms that regulate the amount and distribution of blood flow to the uterus and placenta. At this point, we have only the most rudimentary understanding of the interaction of anesthesia with any of these processes. Only a fraction of the information available from basic science has been used to improve obstetric anesthesia care. Realizing the rewards from the clinical use of such information may be the most important lesson from the past and the greatest challenge for the future of obstetric anesthesia.

KEY POINTS

- Physicians have debated the safety of obstetric anesthesia since 1847, when James Young Simpson first administered anesthesia for delivery. Two issues have dominated the debate: the effects of anesthesia on labor and the effects of anesthesia on the newborn.
- Despite controversy, physicians quickly incorporated anesthesia into clinical practice, largely because of their patients' desire to avoid childbirth pain.
- Only after obstetric anesthesia was in use for many years did problems become apparent.
- Important milestones in obstetric anesthesia are the introduction of inhalation agents in 1847, the expanded use of opioids in the early decades of the twentieth century, and the refinement of regional anesthesia starting in the mid-twentieth century.
- Outstanding conceptual developments are (1) Zweifel's idea that drugs given to the mother cross the placenta and affect the fetus and (2) Apgar's idea that the condition of the newborn is the most sensitive assay of the quality of anesthetic care of the mother.
- The history of obstetric anesthesia suggests that the major improvements in patient care have followed the application of principles of basic science.

Physiologic Changes of Pregnancy

Rachel M. Kacmar, MD, Robert Gaiser, MD

CHAPTER OUTLINE

Marked anatomic and physiologic changes occur during pregnancy that allow the woman to adapt to the developing fetus and its metabolic demands. The enlarging gravid uterus places mechanical strain on the woman's body. Greater hormonal production by the ovaries and the placenta further alters maternal physiology. The hallmark of successful anesthetic management of the pregnant woman is recognition of these changes and appropriate adaptation of anesthetic techniques to account for them. The physiologic alterations of normal pregnancy and their anesthetic implications are reviewed in this chapter.

BODY WEIGHT AND COMPOSITION

The mean maternal weight increase during pregnancy is 17% of the prepregnancy weight, or approximately 12 kg.[1] It results from an increase in the size of the uterus and its contents (uterus, 1 kg; amniotic fluid, 1 kg; fetus and placenta, 4 kg), increases in blood volume and interstitial fluid (approximately 1 kg each), and deposition of new fat and protein (approximately 4 kg). The weight gain during pregnancy recommended by the Institute of Medicine is tiered based on prepregnancy body mass index (BMI; Table 2.1) and reflects the increasing incidence of obesity.[2] The expected weight increase during the first trimester in a nonobese individual is 1 to 2 kg, and there is a 5- to 6-kg increase in each of the last two trimesters. The recommended gain is less in obese individuals. Excessive weight gain during pregnancy is a risk factor for a long-term increase in BMI.[3]

CARDIOVASCULAR CHANGES

Physical Examination and Cardiac Studies

Pregnancy causes the heart to increase in size, a result of both greater blood volume and increased stretch and force of contraction.[4] These changes, coupled with the elevation of the

TABLE 2.1 Recommended Weight Gain during Pregnancy

Prepregnancy Body Mass Index (kg/m^2)	Total Weight Gain in kg (lb)	Rate of Weight Gain during Second and Third Trimester in kg/wk (lb/wk)
< 18.5	12.7–18.2 (28–40)	0.45 (1)
18.5–24.9	11.4–15.9 (25–35)	0.45 (1)
25.0–29.9	6.8–11.4 (15–25)	0.27 (0.6)

Modified from Rasmussen KM, Yaktine AL, eds. *Weight Gain During Pregnancy: Reexamining the Guidelines.* Washington, DC: National Academies Press; 2009.

BOX 2.1 Changes in the Cardiac Examination in the Pregnant Patient

- Accentuation of first heart sound (S1) and exaggerated splitting of the mitral and tricuspid components
- Typical systolic ejection murmur
- Possible presence of third heart sound (S3) and fourth heart sound (S4); no clinical significance
- Leftward displacement of point of maximal cardiac impulse

diaphragm from the expanding uterus, cause several changes in the physical examination and in cardiac studies.

Changes in heart sounds include accentuation of the first heart sound with exaggerated splitting of the mitral and tricuspid components (Box 2.1).[5] The second heart sound changes little, although the aortic-pulmonic interval tends to vary less with respiration during the third trimester, a finding without clinical significance. A fourth heart sound may be heard in 16% of pregnant women, although typically it disappears at term. A grade II systolic ejection murmur is commonly heard at the left sternal border[6]; the murmur is considered a benign flow murmur, attributable to cardiac enlargement from increased intravascular volume, which causes dilation of the tricuspid annulus and mild tricuspid regurgitation. Elevation of the diaphragm by the growing uterus shifts the heart anteriorly and to the left. The point of maximal cardiac impulse is displaced cephalad to the fourth intercostal space and left to at least the midclavicular line.

Echocardiography demonstrates left ventricular (LV) hypertrophy by 12 weeks' gestation with a 23% increase in LV mass from the first to the third trimester[7] and an overall 50% increase in mass at term.[8] This eccentric hypertrophy results from an increase in the size of the preexisting cardiomyocytes, resembling the changes that occur from repeated, strenuous exercise.[1] The annular diameters of the mitral, tricuspid, and pulmonic valves increase; 94% of term pregnant women exhibit tricuspid and pulmonic regurgitation, and 27% exhibit mitral regurgitation.[9] The aortic annulus does not dilate from normal pregnancy-induced physiologic changes.

The electrocardiogram typically changes, especially during the third trimester. Heart rate steadily increases during the first and second trimesters, and both the PR interval and the uncorrected QT interval are shortened. This has clinical implications for women with long QT syndrome (see Chapter 41). The QRS axis shifts to the right during the first trimester but may shift to the left during the third trimester.[10] Depressed ST segments and isoelectric low-voltage T waves in the left-sided precordial and limb leads are common.[11]

Central Hemodynamics

To accurately determine central hemodynamic values and/or changes during pregnancy, measurements should be made with the patient in a resting position with left uterine displacement to minimize vena caval compression. Comparisons must be made with an appropriate control, such as prepregnancy values or a matched group of nonpregnant women. If control measurements are made postpartum, a sufficient interval must elapse for parameters to have returned to prepregnancy values; this may take 24 weeks or more.[12] There is significant heterogeneity in cardiac output measurement using different noninvasive devices; these differences should be taken into account when caring for individual patients.[13]

Cardiac output begins to increase by five weeks' gestation and is 35% to 40% above baseline by the end of the first trimester.[8,14] It continues increasing throughout the second trimester to approximately 50% greater than nonpregnant values (Figs. 2.1 and 2.2).[8,12,15,16] Cardiac output does not change further during the third trimester.[17] Some studies have reported a decrease in cardiac output during the third trimester; however, typically this is with measurements made in the supine position and thus likely reflects vena caval compression rather than a true gestational decline.

The initial increase in cardiac output results from an increase in heart rate.[8] The heart rate increases 15% to 25% above baseline by the end of the first trimester and remains relatively stable for the remainder of the pregnancy.[8,12,14-16,18] Cardiac output continues to increase through the second trimester owing to an increase in stroke volume. Stroke volume increases by approximately 20% during the first trimester and by 25% to 30% above baseline during the second trimester.[8,12,14,18] The increased stroke volume correlates with increasing estrogen levels.[1] Stroke volume index decreases over the course of pregnancy, while cardiac index remains slightly increased from prepregnancy values.[17]

Left ventricular end-diastolic volume increases during pregnancy, whereas end-systolic volume remains unchanged, resulting in a larger ejection fraction.[8,12,14,15,18] Central venous, pulmonary artery diastolic, and pulmonary capillary wedge pressures are within the normal nonpregnant range.[16] The apparent discrepancy between left ventricular filling pressure and end-diastolic volume is explained by both hypertrophy and dilation, with the dilated ventricle accommodating a greater volume without an increase in pressure.

Myocardial contractility increases, as demonstrated by higher velocity of left ventricular circumferential fiber shortening (Fig. 2.3).[8,15,18] Tissue Doppler imaging, which is relatively independent of preload, has been used to assess diastolic function.[19] A mild degree of diastolic dysfunction may be seen during the third trimester compared with earlier in pregnancy and nonpregnant controls.[17]

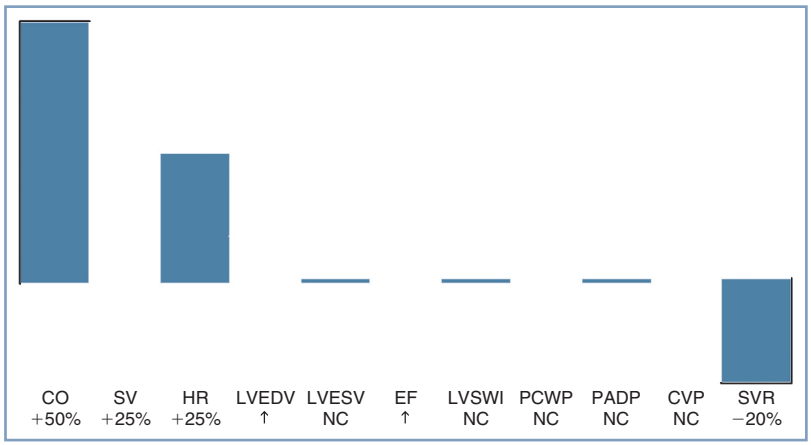

Fig. 2.1 Central Hemodynamic Changes at Term Gestation. Changes are relative to the nonpregnant state. *CO,* cardiac output; *SV,* stroke volume; *HR,* heart rate; *LVEDV,* left ventricular end-diastolic volume; *LVESV,* left ventricular end-systolic volume; *EF,* ejection fraction; *LVSWI,* left ventricular stroke work index; *PCWP,* pulmonary capillary wedge pressure; *PADP,* pulmonary artery diastolic pressure; *CVP,* central venous pressure; *SVR,* systemic vascular resistance; *NC,* no change. (Data from Conklin KA. Maternal physiological adaptations during gestation, labor, and puerperium. *Semin Anesth.* 1991;10: 221–234.)

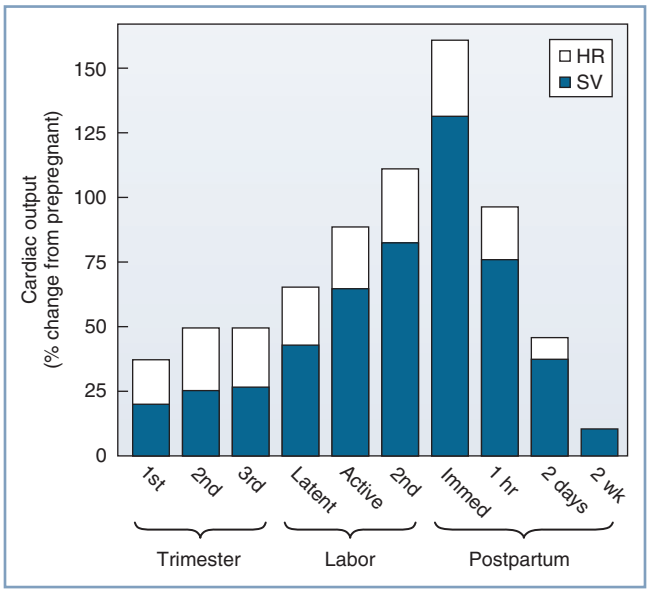

Fig. 2.2 Cardiac Output during Pregnancy, Labor, and the Puerperium. Values during pregnancy are measured at the end of the first, second, and third trimesters. Values during labor are measured between contractions. For each measurement, the relative contributions of heart rate *(HR)* and stroke volume *(SV)* to the change in cardiac output are illustrated.

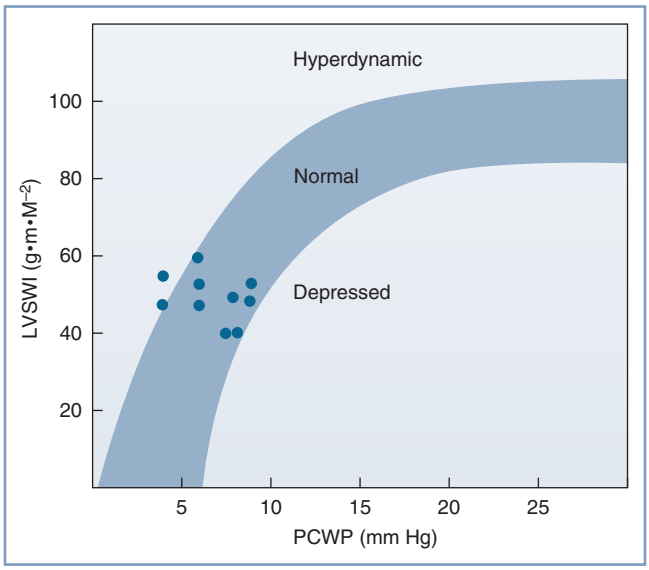

Fig. 2.3 Left ventricular function in late phase of third-trimester normotensive pregnant patients. *LVSWI,* left ventricular stroke work index; *PCWP,* pulmonary capillary wedge pressure. (Modified from Clark SL, Cotton DB, Lee W, et al. Central hemodynamic assessment of cardiac function. *Am J Obstet Gynecol.* 1989;161:439–442.)

The increase in cardiac output during pregnancy results in increased perfusion to the uterus, kidneys, and extremities. Uterine blood flow increases to meet the demands of the developing fetus from a baseline value of approximately 50 mL/min (prepregnancy) to a level at term of 700 to 900 mL/min.[20–22] During the second half of pregnancy, the proportion of cardiac output distributed to the uterine circulation increases from 5% to 12%.[23] Approximately 90% of this flow perfuses the intervillous space, with the balance perfusing the myometrium.[21] At term, skin blood flow is approximately three to four times the nonpregnant level, resulting in higher skin temperature.[24] Renal plasma flow is increased by 80% at 16 to 26 weeks' gestation but is only 50% above the prepregnancy baseline at term.[25]

The U.S. Department of Health and Human Services recommends that pregnant women have at least 150 minutes of moderate-intensity aerobic activity every week,[26] and the American College of Obstetricians and Gynecologists recommends 20 to 30 minutes per day[27]; however, most women do not achieve this goal. Pregnant women are less active, with only half as many meeting guidelines for vigorous activity compared with nonpregnant women.[28] For every two women who exercise before pregnancy, one will not do so during pregnancy. Failure to exercise increases risk for greater gestational weight gain.[29] Exercise is safe for the fetus[29,30]; in a study of 45 women, exercise on a treadmill of moderate intensity (40% to 59% of heart rate reserve) did not affect fetal heart or umbilical artery Doppler indices.[30]

During exercise, maximal oxygen consumption is greater in pregnancy,[31] especially during cardiovascular exercise. The rate of increase in minute ventilation is greater with exercise during pregnancy.[32] Cardiac output is also greater, primarily

from increased stroke volume[33] and oxygen delivery to the fetus.

Blood Pressure and Systemic Vascular Resistance

Positioning, gestational age, and parity affect blood pressure measurements. Brachial sphygmomanometry yields the highest measurements in the supine position and the lowest measurements in the lateral position, especially with the cuff on the upper arm.[34] Blood pressure increases with maternal age, and for a given age, nulliparous women have a higher mean pressure than parous women.[35] Systolic, diastolic, and mean blood pressure decrease during mid-pregnancy and return toward baseline as the pregnancy approaches term.[36] Diastolic blood pressure decreases more than systolic blood pressure, with early- to mid-gestational decreases of approximately 20%.[37]

The changes in blood pressure are consistent with changes in systemic vascular resistance, which decreases during early gestation, reaches its nadir (35% decline) at 20 weeks' gestation, and increases toward prepregnancy baseline during late gestation. Unlike blood pressure, however, systemic vascular resistance remains approximately 20% below the nonpregnant level at term.[12,16] A postulated explanation for the decreased systemic vascular resistance is the low-resistance uteroplacental vascular bed as well as systemic maternal vasodilation caused by prostacyclin, estrogen, and progesterone. The lower blood pressure often persists beyond pregnancy. A longitudinal study of 2304 initially normotensive women over 20 years showed that nulliparous women who subsequently delivered one or more infants maintained a blood pressure that was 1 to 2 mm Hg lower than women who did not have children.[37] This finding demonstrates that pregnancy may create long-lasting vascular changes. Advanced maternal age has been associated with higher median systemic vascular resistance during pregnancy, and pregnant women who smoke have demonstrated a lower systemic vascular resistance compared with nonsmoking parturients.[38]

Aortocaval Compression

The extent of compression of the aorta and inferior vena cava by the gravid uterus depends on positioning and gestational age. At term, partial vena caval compression occurs when the woman is in the lateral position, as documented by angiography.[39] This finding is consistent with the 75% elevation above baseline of femoral venous and lower inferior vena cava pressures.[40] Despite caval compression, collateral circulation maintains venous return, as reflected by the right ventricular filling pressure, which is unaltered in the lateral position.[16] Intra-abdominal pressure is often elevated in term pregnant patients regardless of BMI, but is significantly lower in the lateral position compared with supine.[41]

In the supine position, significant and sometimes complete compression of the inferior vena cava is evident at term.[42,43] Blood returns from the lower extremities through the intraosseous, vertebral, paravertebral, and epidural veins.[44] However, this collateral venous return is less than would occur through the inferior vena cava, resulting in a decrease in right atrial pressure.[45] Compression of the inferior vena cava occurs as early as 13 to 16 weeks' gestation and is evident from the 50% increase in femoral venous pressure observed when these women assume the supine position (Fig. 2.4).[46] By term, femoral venous and lower inferior vena caval pressures are approximately 2.5 times the nonpregnant measurements in the supine position.[40,46] Vena cava volume at term is significantly higher with a 30-degree lateral tilt compared with the supine position, whereas there is no difference between women in the supine position and those tilted 15 degrees.[43]

In the supine position, the aorta may be compressed by the term gravid uterus. This compression could account for lower pressure in the femoral versus the brachial artery in the supine position.[47,48] Angiographic studies in supine pregnant women showed partial obstruction of the aorta at the level of the lumbar lordosis and enhanced compression during periods of maternal hypotension.[49] Conversely, a comparison of magnetic resonance images of healthy women at term in the supine position compared with nonpregnant women showed no difference in aortic volume at the level of the mid- to upper lumbar vertebra.[43]

At term, the left lateral decubitus position is associated with less enhancement of cardiac sympathetic nervous system activity and less suppression of cardiac vagal activity than the supine or right lateral decubitus position.[50] Women who assume the supine position at term gestation experience a 10% to 20% decline in stroke volume and cardiac output,[51,52] consistent with the decrease in right atrial filling pressure. Blood flow in the upper extremities is normal, whereas uterine blood flow decreases by 20% and lower extremity blood flow decreases by 50%.[53] Perfusion of the uterus is less affected than that of the lower extremities because compression of the vena cava does not obstruct venous outflow via the ovarian veins.[54] The adverse hemodynamic effects of aortocaval compression are reduced once the fetal head is engaged.[47,48] The sitting position has also been shown to result in aortocaval compression, with a decrease in cardiac output of 10%.[55] Flexing the legs rotates the uterus to compress against the vena cava. Short intervals in the sitting position, such as occurs during epidural catheter placement, have no impact on uteroplacental blood flow.

Some term pregnant women exhibit an increase in brachial artery blood pressure when they assume the supine position, which is caused by higher systemic vascular resistance from compression of the aorta. Up to 15% of women at term experience bradycardia and a substantial decrease in blood pressure when supine, the so-called **supine hypotension syndrome**.[56] It may take several minutes for the bradycardia and hypotension to develop, and the bradycardia is usually preceded by a period of tachycardia. The syndrome results from a profound decrease in venous return and preload for which the cardiovascular system is not able to compensate.

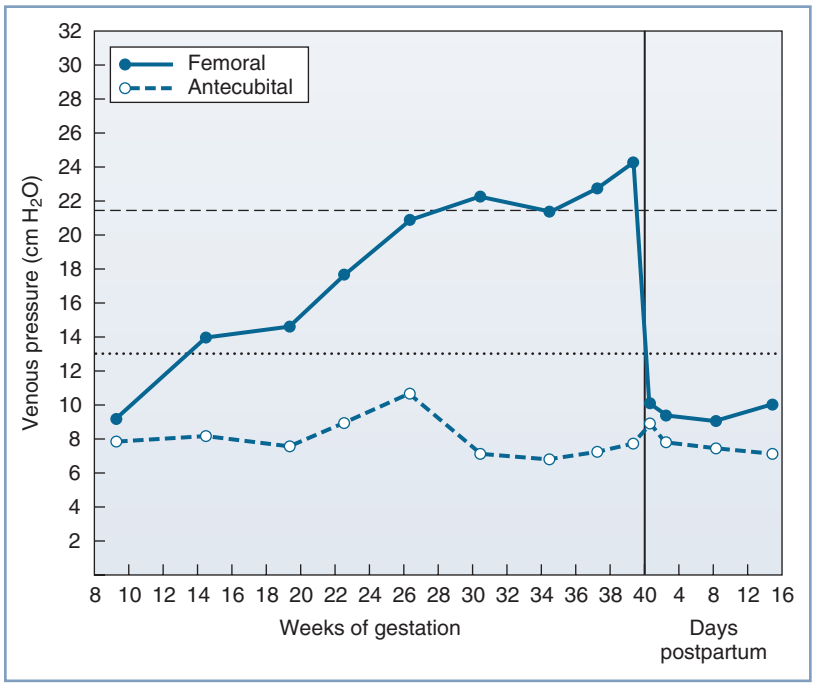

Fig. 2.4 Femoral and antecubital venous pressures in the supine position throughout normal pregnancy and the puerperium. (Modified from McLennan CE. Antecubital and femoral venous pressure in normal and toxemic pregnancy. *Am J Obstet Gynecol.* 1943; 45:568–591.)

Hemodynamic Changes during Labor and the Puerperium

Cardiac output during labor (but between uterine contractions) increases from prelabor values by approximately 10% in the early first stage, by 25% in the late first stage, and by 40% in the second stage of labor.[57–59] In the immediate postpartum period, cardiac output may be as much as 75% above predelivery measurements and 150% above prepregnancy baseline.[58] These changes result from an increase in stroke volume caused by greater venous return and alterations in sympathetic nervous system activity. During labor, uterine contractions displace 300 to 500 mL of blood from the intervillous space through the ovarian venous outflow system into the central circulation ("autotransfusion").[60–62] The postpartum increase in cardiac output results from relief of vena caval compression, diminished lower extremity venous pressure, sustained myometrial contraction, and loss of the low-resistance placental circulation.[59] Cardiac output decreases to just below prelabor values at 24 hours postpartum[60] and returns to prepregnancy levels between 12 and 24 weeks postpartum[12] (see Fig. 2.2). Heart rate decreases rapidly after delivery, reaches prepregnancy levels by 2 weeks postpartum, and is slightly below the prepregnancy rate for the next several months.[12,57] Other anatomic and functional changes of the heart are also fully reversible.[23,63]

THE RESPIRATORY SYSTEM

Despite the multiple anatomic and physiologic changes that occur during pregnancy, it is remarkable that pregnancy has a relatively minor impact on lung function.

Anatomy

The thorax undergoes both mechanical and hormonal changes during pregnancy. Relaxin (the hormone responsible for relaxation of the pelvic ligaments) causes relaxation of the ligamentous attachments to the lower ribs.[64] The subcostal angle progressively widens from approximately 69 to 104 degrees. The anteroposterior and transverse diameters of the chest wall each increase by 2 cm, resulting in an increase of 5 to 7 cm in the circumference of the lower rib cage. These changes peak at 37 weeks' gestation. The subcostal angle remains about 20% wider than the baseline value after delivery.[65] The vertical measurement of the chest cavity decreases by as much as 4 cm as a result of the elevated position of the diaphragm.

Capillary engorgement of the larynx and the nasal and oropharyngeal mucosa begins early in the first trimester and increases progressively throughout pregnancy.[66] The effect of estrogen on the nasal mucosa may cause symptoms of rhinitis and epistaxis. Nasal breathing commonly becomes difficult, and nasal congestion may contribute to the perceived shortness of breath of pregnancy.[67]

Airflow Mechanics

Inspiration in the term pregnant woman is almost totally attributable to diaphragmatic excursion[68] because of greater descent of the diaphragm from its elevated resting position and limitation of thoracic cage expansion because of its expanded resting position (Table 2.2). Both large- and small-airway function are minimally altered during pregnancy. The shape of flow-volume loops, the absolute flow rates at normal lung volumes,[69] forced expiratory volume in 1 second (FEV_1),

TABLE 2.2 Effects of Pregnancy on Respiratory Mechanics

Parameter	Change[a]

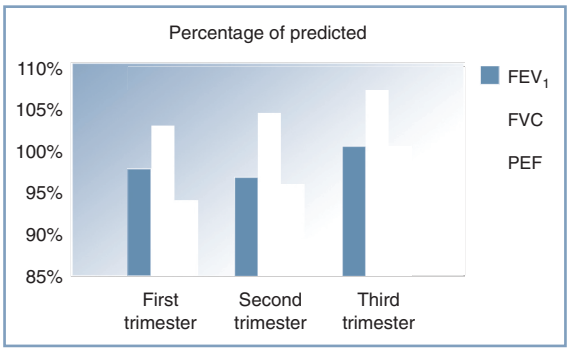

Fig. 2.5 Changes in airflow mechanics during pregnancy. The magnitude of the increase in flow rates is small. The forced expiratory volume in one second *(FEV_1)* is within the normal range of predictive values for nonpregnant individuals. *FVC,* forced vital capacity; *PEF,* peak expiratory flow. (Based on data from Grindheim G, Toska K, Estensen ME, Rosseland LA. Changes in pulmonary function during pregnancy: a longitudinal study. *BJOG.* 2012;119:94–101.)

the ratio of FEV_1 to forced vital capacity (FVC), and closing capacity are unchanged during pregnancy.[70] There is no significant change in respiratory muscle strength during pregnancy despite the cephalad displacement of the diaphragm. Furthermore, despite the upward displacement of the diaphragm by the gravid uterus, diaphragm excursion actually increases by 2 cm.[71]

The peak expiratory flow (PEF) rate achieved with a maximal effort after a maximal inspiration is often considered a surrogate for the FEV_1 and can be used to monitor asthma therapy. Studies of changes in PEF rate during pregnancy show conflicting results, likely reflecting differences in measurement devices and patient position. Harirah et al.[72] found that peak expiratory flow rate declined throughout gestation in all positions and that flow rates in the supine position were lower than those during standing and sitting. The mean rate of decline was 0.65 L/min per week, and PEF rate remained below normal at 6 weeks postpartum. By contrast, Grindheim et al.[73] reported that PEF rate increased throughout pregnancy starting at an average of 6.7 L/s in the early second trimester and peaking at 7.2 L/s at term (Fig. 2.5). These authors also reported that the FVC increased by 100 mL after 14 to 16 weeks' gestation, with the change being greater in parous than in primigravid women.[73]

Lung Volumes and Capacities

Lung volumes can be measured using body plethysmography or by inert gas techniques with slightly differing results.[74] By term, total lung capacity is slightly reduced,[75] whereas tidal volume increases by 45%, with approximately half the change occurring during the first trimester (Table 2.3 and Fig. 2.6). The early change in tidal volume is associated with a transient reduction in inspiratory reserve volume. Residual volume tends to decrease slightly, a change that maintains vital capacity. Inspiratory capacity increases by 15% during the third trimester because of increases in tidal volume and inspiratory reserve volume.[76,77] There is a corresponding decrease in expiratory reserve volume.[76,77] The functional residual capacity (FRC) begins to decrease by the fifth month of pregnancy with uterine enlargement and diaphragm elevation, and is decreased by 400 to 700 mL to 80% of the prepregnancy value at term.[76,77] The overall reduction is caused by a 25% reduction in expiratory reserve volume (200 to 300 mL) and a 15% reduction in residual volume (200 to 400 mL). Assumption of the supine position causes the FRC to decrease further to 70% of the prepregnancy value. The supine FRC can be increased by 10% (approximately 188 mL) by placing the patient in a 30-degree head-up position.[78]

TABLE 2.3 Changes in Respiratory Physiology at Term Gestation

Parameter	Change[a]
Lung Volumes	
Inspiratory reserve volume	+5%

TABLE 2.4 Blood Gas Parameters during Pregnancy

		TRIMESTER		
Parameter	**Nonpregnant**	**First**	**Second**	**Third**
$Paco_2$ in mm Hg (kPa)	40 (5.3)	30 (4.0)	30 (4.0)	30 (4.0)
Pao_2 in mm Hg (kPa)	100 (13.3)	107 (14.3)	105 (14.0)	103 (13.7)
pH	7.40	7.44	7.44	7.44
Bicarbonate (mEq/L)	24	21	20	20

tidal volume from 450 to 600 mL and a small increase in respiratory rate of 1 to 2 breaths/min.[79] This occurs primarily during the first 12 weeks of gestation with a minimal increase thereafter. The ratio of total dead space to tidal volume remains constant during pregnancy, resulting in an increase in alveolar ventilation of 30% to 50% above baseline. The increase in minute ventilation results from hormonal changes and from an increase in CO_2 production at rest by approximately 30% to 300 mL/min. The former is closely related to the blood level of progesterone,[80] which acts as a direct respiratory stimulant. The progesterone-induced increase in chemosensitivity also results in a steeper slope and a leftward shift of the CO_2-ventilatory response curve. This change occurs early in pregnancy and remains constant until delivery.[69]

Dyspnea is a common complaint during pregnancy, affecting up to 75% of women.[81] Contributing factors include increased respiratory drive, decreased $Paco_2$, increased oxygen consumption from the enlarging uterus and fetus, larger pulmonary blood volume, anemia, and nasal congestion. Dyspnea typically begins in the first or second trimester but improves as the pregnancy progresses. In a study in which 35 women were observed closely during pregnancy and postpartum, dyspnea was not caused by alterations in central ventilatory control or respiratory mechanical factors but rather to the awareness of the increased ventilation.[82] Exercise has no effect on pregnancy-induced changes in ventilation or alveolar gas exchange.[83] The hypoxic ventilatory response is increased during pregnancy to twice the normal level, secondary to elevations in estrogen and progesterone levels.[84] This increase occurs despite blood and cerebrospinal fluid (CSF) alkalosis.

During pregnancy, Pao_2 increases to 100 to 105 mm Hg (13.3 to 14.0 kPa) as a result of greater alveolar ventilation and a decline in $Paco_2$ (Table 2.4).[85–87] As pregnancy progresses, oxygen consumption continues to increase, and cardiac output increases to a lesser extent, resulting in a reduced mixed venous oxygen content and increased arteriovenous oxygen difference. After mid-gestation, pregnant women in the supine position frequently have a Pao_2 less than 100 mm Hg (13.3 kPa). This occurs because the FRC may be less than closing capacity, resulting in closure of small airways during normal tidal volume ventilation.[85] Moving a pregnant woman from the supine to the erect or lateral decubitus position improves arterial oxygenation and reduces the alveolar-to-arterial oxygen gradient. The increased oxygen tension facilitates the transfer of oxygen across the placenta to the fetus.

$Paco_2$ declines to approximately 30 mm Hg (4.0 kPa) by 12 weeks' gestation but does not change further during the remainder of the pregnancy. Although a gradient exists between the end-tidal CO_2 tension and $Paco_2$ in nonpregnant women, the two measurements are equivalent during early pregnancy,[88] at term gestation,[89] and in the postpartum period.[90] This is attributable to a reduction in alveolar dead space, which results from an increase in cardiac output and increased basilar atelectasis during pregnancy. The mixed venous Pco_2 is 6 to 8 mm Hg (0.8 to 1.1 kPa)

TABLE 2.5 Changes in Gastrointestinal Physiology during Pregnancy[a]

Parameter	TRIMESTER First	Second	Third	Labor	Postpartum (18 h)
Barrier pressure[b]	Decreased	Decreased	Decreased	Decreased	?
Gastric emptying	No change	No change	No change	Delayed	No change
Gastric acid secretion	No change	No change	No change	?	?
Proportion of women with gastric volume > 25 mL	No change	No change	No change	Increased	No change
Proportion of women with gastric pH < 2.5	No change	No change	No change	No change	No change

[a]Relative to nonpregnant state.
[b]Difference between intragastric pressure and tone of the lower esophageal high-pressure zone.

below the nonpregnant level from late in the first trimester until term.[1]

The respiratory alkalosis of pregnancy causes a compensatory increase in renal bicarbonate excretion and a reduction in serum bicarbonate concentration to approximately 20 mEq/L, the base excess by 2 to 3 mEq/L, and the total buffer base by approximately 5 mEq/L.[91] This compensation is incomplete, as demonstrated by the elevation of venous,[92] capillary,[93] and arterial[85] blood pH by 0.02 to 0.06 units (see Table 2.4). The decrease in serum bicarbonate affects the pregnant woman's ability to buffer an acid load. The slight respiratory alkalosis would normally shift the oxyhemoglobin saturation curve to the left, however a concurrent increase in 2,3-bisphosphoglycerate (2,3-BPG) causes the curve to shift slightly to the right.

Metabolism and Respiration during Labor and the Puerperium

Minute ventilation in the unmedicated parturient increases by 70% to 140% in the first stage of labor and by 120% to 200% in the second stage of labor compared with prepregnancy values.[94] Pain, anxiety, and coached breathing techniques all increase minute ventilation. $Paco_2$ may decrease to as low as 10 to 15 mm Hg (1.3 to 2.0 kPa). Oxygen consumption increases above the prelabor value by 40% in the first stage and by 75% in the second stage, secondary to the increased metabolic demands of hyperventilation, uterine activity, and maternal expulsive efforts.[94,95] The maternal aerobic requirement for oxygen exceeds oxygen consumption during labor, as is evident from the progressive elevation of blood lactate concentration, an index of anaerobic metabolism.[95–98] Effective neuraxial analgesia prevents these changes during the first stage of labor and mitigates the changes during the second stage of labor.[95,98]

FRC increases after delivery but remains below the prepregnancy volume for 1 to 2 weeks. Although minute ventilation decreases halfway toward nonpregnant values by 72 hours, oxygen consumption, tidal volume, and minute ventilation remain elevated until at least 6 to 8 weeks after delivery. The alveolar and mixed venous Pco_2 values increase slowly after delivery and are still slightly below prepregnancy levels at 6 to 8 weeks postpartum.[1]

THE GASTROINTESTINAL SYSTEM

Anatomy, Barrier Pressure, and Gastroesophageal Reflux

The stomach is displaced upward toward the left side of the diaphragm during pregnancy, and its axis is rotated approximately 45 degrees to the right from its normal vertical position. This altered position displaces the intra-abdominal segment of the esophagus into the thorax in most women, causing a reduction in tone of the lower esophageal high-pressure zone (LEHPZ), which normally prevents the reflux of gastric contents. Progestins also may contribute to relaxation of the LEHPZ.[99]

Approximately 30% to 50% of women experience **gastroesophageal reflux disease (GERD)** during pregnancy.[100] The prevalence of GERD is approximately 10% in the first trimester, 40% in the second trimester, and 55% in the third trimester. In the first trimester of pregnancy, basal LEHPZ pressure may not change, but the sphincter is less responsive to physiologic stimuli that usually increase pressure.[101] In the second and third trimesters, LEHPZ pressure gradually decreases to approximately 50% of basal values, reaching a nadir at 36 weeks' gestation and returning to prepregnancy values at 1 to 4 weeks postpartum (Table 2.5). Risk factors for GERD in pregnancy include gestational age, heartburn antecedent to pregnancy, and multiparity. Gravidity, prepregnancy BMI, and weight gain during pregnancy do not correlate with the occurrence of reflux, whereas maternal age has an inverse correlation.[102]

Gastrointestinal Motility

Gastric emptying is not altered during pregnancy. This has been demonstrated by studies that measured the absorption of orally administered acetaminophen[103–105] and by studies that assessed the emptying of a test beverage or meal by radiographic,[106] ultrasonographic,[105,107] dye dilution,[108] epigastric impedance,[109] and applied potential tomographic[110] techniques. In a study of morbidly obese women at term, no difference was noted between gastric emptying of 300 mL and 50 mL of water, suggesting that fasting guidelines should not differ for obese versus lean parturients.[111]

Esophageal peristalsis and intestinal transit are slowed during pregnancy,[107,112] which has been attributed to the

inhibition of gastrointestinal contractile activity by progesterone. However, this inhibition may be an indirect action that results from a negative effect of progesterone on the plasma concentration of motilin, which declines during pregnancy.[107] Up to 40% of women suffer from constipation at some time during their pregnancy.[113] The prevalence of constipation is greatest in the first two trimesters of gestation and declines in the third trimester.

Gastric Acid Secretion

Early work suggested that both basal and maximal gastric acid secretion decline in mid-gestation, reaching a nadir at 20 to 30 weeks' gestation.[114] Van Thiel et al.[115] demonstrated no difference in basal or peak gastric acid secretion in four pregnant women studied in each trimester and at 1 to 4 weeks postpartum, although a plasma gastrin level significantly lower than postpartum levels was observed during the first trimester. Levels of gastric pH and serum gastrin concentration were compared in 100 women scheduled for elective cesarean delivery and in 100 nonpregnant women undergoing gynecologic surgery.[116] The mean pH was lower in the pregnant group (2.4 versus 3.0), but serum gastrin levels were not different despite the fact that gastrin is secreted by the placenta from 15 weeks' gestation onward. This may reflect a dilutional effect of increased plasma volume. Other studies have shown that approximately 80% of both pregnant and nonpregnant women have a gastric pH of 2.5 or less, approximately 50% have gastric volumes of 25 mL or greater, and 40% to 50% exhibit both low pH and gastric volume greater than 25 mL.[117]

Nausea and Vomiting

Approximately 80% of pregnant women will experience nausea and vomiting during pregnancy.[118] The symptoms typically start between 4 to 9 weeks' gestation and may last until 12 to 16 weeks' gestation.[119] Of these women, 1% to 5% will develop symptoms that persist throughout the pregnancy, known as **hyperemesis gravidarum** (see Chapter 16).

Gastric Function during Labor and the Puerperium

Gastric emptying is slowed during labor, as shown by ultrasonographic imaging, emptying of a test meal, and the rate of absorption of oral acetaminophen.[120,121] Direct measurements show that the mean gastric volume increases.[122] However, in one study, postpartum gastric volume was found to be no different in parturients who consumed water in labor compared with those who consumed an isotonic sports drink composed of mixed carbohydrates and electrolytes.[123] Gastric acid secretion may decrease during labor because only 25% of parturients who are in labor have a gastric pH of 2.5 or lower.[124] Gastric emptying is also delayed during the early postpartum period but returns to prepregnancy levels by 18 hours postpartum.[125] Fasting gastric volume and pH values are similar to nonpregnant patients at 18 hours postpartum.[126–128] The effects of opioids and neuraxial analgesia on gastric emptying are discussed in Chapters 23 and 28.

THE LIVER AND GALLBLADDER

Liver size, morphology, and blood flow do not change during pregnancy, although the liver is displaced upward, posterior, and to the right during late pregnancy.

Serum levels of bilirubin, alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase increase to the upper limits of the normal range during pregnancy.[129] The total alkaline phosphatase activity increases twofold to fourfold, mostly from production by the placenta. Excretion of sulfobromophthalein into bile decreases, whereas the hepatic extraction and retention of this compound increases.[130]

Biliary stasis and greater secretion of bile with cholesterol increase the risk for gallbladder disease during pregnancy.[131] The incidence of gallstones is 5% to 12% in pregnant women.[132] One in 1600 to 1 in 10,000 women undergo cholecystectomy during pregnancy. Progesterone inhibits the contractility of gastrointestinal smooth muscle, leading to gallbladder hypomotility.[133] The size of the total bile acid pool increases by about 50% during pregnancy, and the relative proportions of the various bile acids change.[134] The changes in the composition of bile revert rapidly after delivery, even in patients with gallstones.

THE KIDNEYS

Owing to an increase in total intravascular volume, both renal vascular and interstitial volume increase during pregnancy. These increases are reflected in enlarged kidneys, with renal volume increased by as much as 30%.[135] Vasodilation of the kidneys contributes to the overall decline in systemic vascular resistance during the first trimester. The collecting system, including the renal calyces, pelvis, and ureters, dilates. Hydronephrosis may occur in 80% of women by mid-pregnancy.[136]

Both the glomerular filtration rate (GFR) and the renal plasma flow increase markedly during pregnancy secondary to reduced renal vascular resistance.[25] The renal blood flow is 75% greater than nonpregnant values by 16 weeks' gestation and is maintained until 34 weeks, when a slight decline occurs. By the end of the first trimester, the GFR is 50% greater than baseline, and this rate is maintained until the end of pregnancy. The GFR does not return to prepregnancy levels until 3 months postpartum. Because the GFR does not increase as rapidly or as much as the renal blood flow, the filtration fraction decreases from nonpregnant levels until the third trimester.[137] The role of nitric oxide in the renal vasodilation was tested and confirmed in a rat model.[138] Renin and aldosterone also both increase during pregnancy.[139]

Creatinine clearance is increased to 150 to 200 mL/min from the normal baseline values of 120 mL/min.[140] The increase occurs early in pregnancy, reaches a maximum by the end of the first trimester, decreases slightly near term, and returns to the prepregnancy level by 8 to 12 weeks postpartum.[137] These renal hemodynamic alterations are among the earliest and most dramatic maternal adaptations to pregnancy. The increased GFR results in reduced blood concentrations of nitrogenous metabolites. The blood urea nitrogen

concentration decreases to 8 to 9 mg/dL by the end of the first trimester and remains at that level until term.[140] Serum creatinine concentration is a reflection of skeletal muscle production and urinary excretion. In pregnancy, skeletal muscle production of creatinine remains relatively constant, but the GFR is increased, resulting in reduced serum creatinine concentration. The serum creatinine concentration decreases progressively to 0.5 to 0.6 mg/dL by the end of pregnancy. The serum uric acid level declines in early pregnancy because of the rise in GFR, to 2.0 to 3.0 mg/dL by 24 weeks' gestation.[141] Subsequently, the uric acid level begins to increase, reaching the prepregnancy level by the end of pregnancy. Tubular reabsorption of urate accounts for this restored uric acid level during the third trimester.

Total protein excretion and urinary albumin excretion are higher than nonpregnant levels. Average 24-hour total protein and albumin excretion are 200 mg and 12 mg, respectively (upper limits are 300 mg and 20 mg, respectively).[142,143] Proteinuria (> 300 mg/24 h) has been described without the diagnosis of preeclampsia.[144] However, women with isolated proteinuria are more likely to progress to preeclampsia than women with isolated hypertension. The protein-to-creatinine (P:C) ratio in a random urine sample correlates well with a 24-hour urine protein measurement, and a value of greater than 0.3 has been defined as the threshold for diagnosing preeclampsia.[145] The degree of proteinuria in normal pregnancy correlates with gestation. Baba et al.[146] suggested that in normotensive patients, a P:C ratio of > 0.75 may be the "rule-in" threshold for significant proteinuria.[146] Women with twin pregnancies have greater protein excretion compared with those with singleton pregnancies.[147]

Glucose is filtered and almost completely absorbed in the proximal tubule. In the nonpregnant state, a small amount of glucose is excreted. Pregnancy imposes a change in the glucose resorptive capacity of the proximal tubules, so all pregnant women exhibit an elevation of glucose excretion. Of pregnant women who have normal glucose tolerance to an oral load and normal glucose excretion when not pregnant, approximately half will exhibit a doubling of glucose excretion. Most of the remainder have increases of 3 to 10 times the nonpregnant amount, and a small proportion (< 10%) excrete as much as 20 times the nonpregnant amount.[148] Overall, the amount of glucose excreted in the third trimester is several times greater than that in the nonpregnant state. The normal nonpregnant pattern of glucose excretion is reestablished within 1 week after delivery.

HEMATOLOGY

Blood Volume

Maternal plasma volume expansion begins as early as 6 weeks' gestation and continues until it reaches a net increase of approximately 50% by 34 weeks' gestation (Table 2.6, Fig. 2.7).[149–152] After 34 weeks' gestation, the plasma volume stabilizes or decreases slightly. Red blood cell volume decreases during the first 8 weeks of pregnancy, increases to the prepregnancy level by 16 weeks, and undergoes a further rise to

TABLE 2.6 Hematologic Parameters at Term Gestation

Parameter	Change[a] or Actual Measurement
Blood volume	+45%[a]
Plasma volume	+55%[a]
Red blood cell volume	+30%[a]
Hemoglobin concentration (g/dL)	11.6
Hematocrit	35.5%

Modified from Conklin KA. Maternal physiological adaptations during gestation, labor, and puerperium. *Semin Anesth.* 1991;10:221–234.

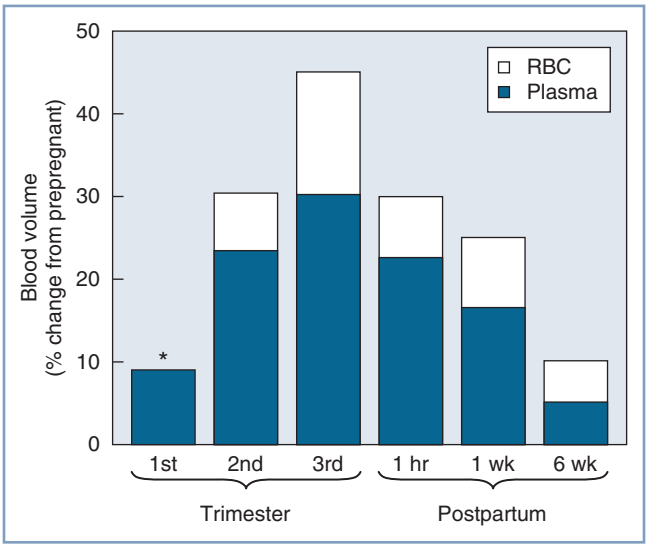

Fig. 2.7 Blood Volume during Pregnancy and the Puerperium. Values during pregnancy measured at the end of the first, second, and third trimesters. Postpartum values measured after a vaginal delivery. The values for red blood cell volume *(RBC)* and plasma volume *(Plasma)* do not represent the actual percentage of change in these parameters but rather reflect the relative contribution of each to the change in blood volume. The asterisk indicates that RBC volume is below the prepregnancy volume at the end of the first trimester.

30% above the prepregnancy level at term.[150,152,153] The red blood cell volume increases in response to elevated erythropoietin concentration[154] and the erythropoietic effects of progesterone, prolactin, and placental lactogen. The increase in plasma volume exceeds the increase in red blood cell volume, resulting in the **physiologic anemia of pregnancy.** Hemoglobin concentration (hematocrit), which typically ranges from 12.0 to 15.8 g/dL (35.4% to 44.4%) in the nonpregnant woman, decreases to 11.6 to 13.9 g/dL (31% to 41%) in the first trimester, 9.7 to 14.8 g/dL (30% to 39%) in the second trimester, and 9.5 to 15.0 g/dL (28% to 40%) in the third trimester (Fig. 2.8).[150,152,153,155] Women who do not receive iron supplements during pregnancy have greater decreases in hemoglobin concentration and hematocrit.[152]

The increase in plasma volume results from fetal and maternal hormone production, and several systems may play a role. The maternal concentrations of estrogen and progesterone

increase nearly 100-fold during pregnancy. Estrogens increase plasma renin activity, enhancing renal sodium absorption and water retention via the renin-angiotensin-aldosterone system. Fetal adrenal production of the estrogen precursor dehydroepiandrosterone may be the underlying control mechanism. Progesterone also enhances aldosterone production. These changes result in marked increases in plasma renin activity and aldosterone level as well as in retention of approximately 900 mEq of sodium and 7000 mL of total body water. The concentration of plasma adrenomedullin, a potent vasodilating peptide, increases during pregnancy and correlates significantly with blood volume.[156]

Blood volume is positively correlated with the size of the fetus in singleton pregnancies and is greater in multiple gestations.[151] The physiologic hypervolemia facilitates delivery of nutrients to the fetus, protects the mother from hypotension, and reduces the risks associated with hemorrhage at delivery.[153,157] The decrease in blood viscosity from the lower hematocrit creates lower resistance to blood flow, which may be an essential component of maintaining the patency of the uteroplacental vascular bed.

Plasma Proteins

Plasma albumin concentration decreases from a nonpregnant range of 4.1–5.3 g/dL to ranges of 3.1–5.1 g/dL in the first trimester, 2.6–4.5 g/dL in the second trimester, and 2.3–4.2 g/dL in the third trimester (Table 2.7).[155,158,159] The globulin level decreases by 10% in the first trimester and then increases throughout the remainder of pregnancy to 10% above the prepregnancy value at term.[158] The albumin-globulin ratio decreases during pregnancy from 1.4 to 0.9, and the total plasma protein concentration decreases from 7.8 to 7.0 g/dL.[159] Maternal colloid osmotic pressure decreases by approximately 5 mm Hg during pregnancy.[16,160,161] The plasma cholinesterase concentration falls by approximately 25% during the first trimester and remains at that level until the end of pregnancy.[162]

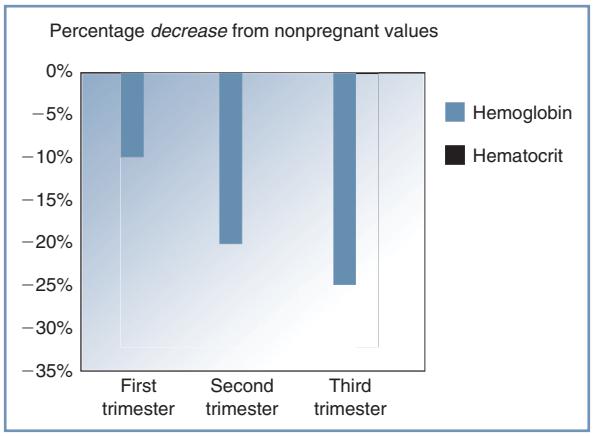

Fig. 2.8 The Decrease in Both Hemoglobin Concentration and Hematocrit during Pregnancy Underlies the Physiologic Anemia of Pregnancy. The decrease is greater for hematocrit, and the greatest decreases occur during the third trimester. (Based on data from Abbassi-Ghanavati M, Greer LG, Cunningham FG. Pregnancy and laboratory studies: a reference table for clinicians. *Obstet Gynecol.* 2009;114:1326–1331.)

Coagulation

Pregnancy is associated with enhanced platelet turnover, clotting, and fibrinolysis (Box 2.2). Thus, pregnancy represents a state of accelerated but compensated intravascular coagulation.

BOX 2.2 Changes in Coagulation and Fibrinolytic Parameters at Term Gestation[a]

Increased Factor Concentrations
- Factor I (fibrinogen)
- Factor VII (proconvertin)
- Factor VIII (antihemophilic factor)
- Factor IX (Christmas factor)
- Factor X (Stuart-Prower factor)
- Factor XII (Hageman factor)

Unchanged Factor Concentrations
- Factor II (prothrombin)
- Factor V (proaccelerin)

Decreased Factor Concentrations
- Factor XI (thromboplastin antecedent)
- Factor XIII (fibrin-stabilizing factor)

Other Parameters
- Prothrombin time: shortened 20%
- Partial thromboplastin time: shortened 20%
- Thromboelastography: hypercoagulable
- Fibrinopeptide A: increased
- Antithrombin III: decreased
- Platelet count: no change or decreased
- Fibrin degradation products: increased
- Plasminogen: increased
- Plasminogen activator inhibitor-II: increased

[a]Relative to nonpregnant state.

TABLE 2.7 Plasma Protein Values during Pregnancy

Protein	Nonpregnant	TRIMESTER		
		First	Second	Third
Total protein (g/dL)	7.8	6.9	6.9	7.0
Albumin (g/dL)	4.5	3.9	3.6	3.3
Globulin (g/dL)	3.3	3.0	3.3	3.7
Albumin/globulin ratio	1.4	1.3	1.1	0.9
Plasma cholinesterase		–25%	–25%	–25%
Colloid osmotic pressure (mm Hg)	27	25	23	22

Increases in platelet factor 4 and beta-thromboglobulin signal elevated platelet activation, and the progressive increase in platelet distribution width and platelet volume are consistent with greater platelet consumption during pregnancy.[163–165] Platelet aggregation in response to collagen, epinephrine, adenosine diphosphate, and arachidonic acid is increased.[166] Some investigators have noted a decrease in platelet count,[165,167] whereas others have noted no change,[163,164] suggesting that increased platelet production compensates for greater activation. The platelet count usually decreases during the third trimester, with an estimated 8% of pregnant women having a platelet count less than 150,000/mm^3 and 0.9% of pregnant women having a platelet count less than 100,000/mm^3.[164,168] The most common causes of thrombocytopenia are **gestational thrombocytopenia,** hypertensive disorders of pregnancy, and idiopathic thrombocytopenia. The decrease in platelet count in the third trimester is caused by increased destruction and hemodilution.[169] Gestational thrombocytopenia is an exaggerated normal response.

The concentrations of most coagulation factors, including fibrinogen (factor I), proconvertin (factor VII), antihemophilic factor (factor VIII), Christmas factor (factor IX), Stuart-Prower factor (factor X), and Hageman factor (factor XII), increase during pregnancy. The increase in factor VIII is generally more marked in the third trimester. The concentrations of some factors increase by more than 100% (factors VII, VIII, IX, and fibrinogen).[169–172] Prothrombin (factor II) and proaccelerin (factor V) concentrations do not change, whereas the concentrations of thromboplastin antecedent (factor XI) and fibrin-stabilizing factor (factor XIII) decrease.[171–173] An increase in most factor concentrations, shortening of the prothrombin time (PT) and activated partial thromboplastin time (aPTT),[170] an increase in fibrinopeptide A concentration, and a decrease in antithrombin III concentration suggest activation of the clotting system (PT decreases from a nonpregnant range of 12.7–15.4 seconds to a range of 9.6–12.9 seconds in the third trimester, and aPTT decreases from a range of 26.3–39.4 seconds in nonpregnant women to a range of 24.7–35.0 seconds in the third trimester).[174] Protein S activity decreases steadily during pregnancy, reaching the lowest values at delivery.[175]

Thromboelastrography (TEG) demonstrates evidence of hypercoagulability in pregnancy. These changes (decrease in R and K values, increase in the α angle and maximum amplitude [MA], and decrease in measures of lysis) are observed as early as 10 to 12 weeks' gestation and are even greater during labor (Fig. 2.9).[176–178] Compared with samples taken during labor, TEG has demonstrated increased lysis in the postpartum period, possibly caused by the loss of placental expression of plasminogen activator inhibitor-2.[179] *In vitro,* exogenous oxytocin decreases R and K values, while increasing the α angle.[180] The *in vivo* effects of exogenous oxytocin are not known. Rotational thromboelastometry (ROTEM) during pregnancy does not demonstrate significant changes from the nonpregnant state compared with term parturients.[181]

The greater concentration of fibrin degradation products signals increased fibrinolytic activity during gestation.[163]

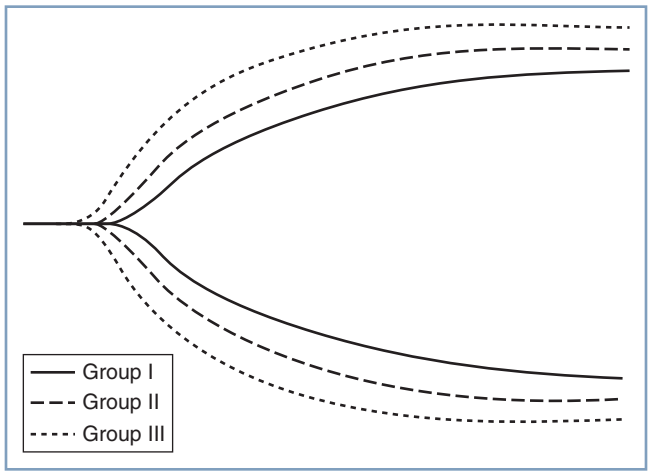

Fig. 2.9 Comparative thromboelastographs in nonpregnant (Group I), nonlaboring term pregnant (Group II), and laboring (Group III) women. (From Steer PL, Krantz HB. Thromboelastrography and Sonoclot analysis in the healthy parturient. *J Clin Anesth.* 1993;5:419–424.)

D-dimer values increase across gestation and remain higher than prepregnancy values in the postpartum period.[182,183] The marked elevation in the plasminogen concentration also is consistent with enhanced fibrinolysis.[184]

Hematology and Coagulation during the Puerperium

Blood loss during normal vaginal delivery and the early puerperium is approximately 600 mL.[185] The normal physiologic changes of pregnancy allow the healthy parturient to compensate for this loss. However, blood loss after either vaginal or cesarean delivery is often underestimated, and the discrepancy between actual and estimated blood loss is greater with increasing blood loss (see Chapter 37).[186]

Blood volume decreases to 125% of the prepregnancy level during the first postpartum week,[185] followed by a more gradual decline to 110% of the prepregnancy level at 6 to 9 weeks postpartum (see Fig. 2.7). The hemoglobin concentration and hematocrit decrease during the first 3 days postpartum, increase gradually during the next 3 days (because of a reduction in plasma volume), and continue to increase to prepregnancy measurements by 3 weeks postpartum.[187]

Cesarean delivery results in a blood loss of approximately 1000 mL within the first few hours of delivery.[185] The hematocrit in the immediate postpartum period is lower after cesarean delivery than after vaginal delivery because of the greater blood loss during cesarean delivery.[185]

Albumin and total protein concentrations and colloid osmotic pressure decline after delivery and gradually return to prepregnancy levels by 6 weeks postpartum.[160] The plasma cholinesterase value decreases below the predelivery level by the first postpartum day and remains at that decreased level during the next week.[162] Globulin concentrations are elevated throughout the first postpartum week.[158]

Beginning with delivery and during the first postpartum day, there is a rapid decrease in the platelet count and in the

concentrations of fibrinogen, factor VIII, and plasminogen and an increase in antifibrinolytic activity.[188] Clotting times remain shortened during the first postpartum day,[189] and TEG remains consistent with a hypercoagulable state, although lysis may increase.[179,180] During the first 3 to 5 days postpartum, increases are noted in the fibrinogen concentration and platelet count, changes that may account for the greater incidence of thrombotic complications during the puerperium.[189] The coagulation profile returns to the nonpregnant state by 2 weeks postpartum.[188]

THE IMMUNE SYSTEM

The blood leukocyte count increases progressively during pregnancy from the prepregnancy level of approximately 6000/mm^3 to between 9000 and 11,000/mm^3.[167] This change reflects an increase in the number of polymorphonuclear cells, with the appearance of immature granulocytic forms (myelocytes and metamyelocytes) in most pregnant women. The proportion of immature forms decreases during the last 2 months of pregnancy. The lymphocyte, eosinophil, and basophil counts decrease, whereas the monocyte count does not change. The leukocyte count increases to approximately 13,000/mm^3 during labor and increases further to an average of 15,000/mm^3 on the first postpartum day.[187] By the sixth postpartum day, the leukocyte count decreases to an average of 9250/mm^3, although the count is still above normal at 6 weeks postpartum.

Despite an increased concentration, polymorphonuclear leukocyte function is impaired during pregnancy, as evidenced by depressed neutrophil chemotaxis and adherence.[190] This impairment may account for the greater incidence of infection during pregnancy and improved symptoms in some pregnant women with autoimmune diseases (e.g., rheumatoid arthritis). Levels of immunoglobulins A, G, and M are unchanged during gestation, but humoral antibody titers to certain viruses (e.g., herpes simplex, measles, influenza type A) are decreased.[191]

During pregnancy, the uterine mucosa is characterized by a large number of maternal immune cells found in close contact with the trophoblast. The fetal expression of paternal antigens requires adaptations in the maternal immune system so that the fetus is not perceived by the mother as "foreign."[192,193] This "immune tolerance" occurs because of a lack of fetal antigen expression, because of separation of the mother from the fetus, or from a functional suppression of the maternal lymphocytes.[194] During the first trimester of pregnancy, T lymphocytes express granulysin, a novel cytolytic protein that provides a protective role at the maternal-fetal interface.[195] Human T cells may be classified into T-helper cells types 1 and 2 (Th1 and Th2) on the basis of their cytokine production. Successful pregnancy is associated with a predominant Th2 cytokine profile. Th1 cytokines are detrimental to pregnancy. These cells also produce natural antimicrobial agents within the uterus, which are important for prevention of uterine infection during pregnancy.[196] Maternal immunoglobulin E (IgE) production increases with pregnancy, and women with a history of pregnancy have higher baseline IgE and experience a slower decline in IgE levels as they age.[197]

NONPLACENTAL ENDOCRINOLOGY

Thyroid Function

The thyroid gland enlarges by 50% to 70% during pregnancy because of follicular hyperplasia and greater vascularity. The estrogen-induced increase in thyroid-binding globulin results in a 50% increase in total triiodothyronine (T_3) and thyroxine (T_4) concentrations during the first trimester, which are maintained until term.[198] The concentrations of free T_3 and T_4 do not change. The concentration of thyroid-stimulating hormone (TSH) decreases during the first trimester but returns to the nonpregnant level shortly thereafter and undergoes no further change during the remainder of pregnancy. The fetal thyroid gland cannot produce thyroid hormone until the end of the first trimester and relies solely on maternal T_4 production during this critical time of development and organogenesis.

Approximately 4% to 7% of women of childbearing age are either hypothyroid or at risk for hypothyroidism during pregnancy.[199] Only 20% to 30% of affected women demonstrate symptoms of hypothyroidism, likely because symptoms of hypothyroidism mimic features of pregnancy.[200] In a large study of 502,036 pregnant women, 15% of tested women had **gestational hypothyroidism,** with 33% of these women demonstrating symptoms.[201] Based on these results, many physicians advocate universal screening, which appears to be cost-effective, given the risk for decreased intelligence in the offspring, miscarriage, and postpartum bleeding if hypothyroidism is left untreated.[202]

Glucose Metabolism

Mean blood glucose concentration remains within the normal range during pregnancy, although the concentration may be lower in some women during the third trimester compared with nonpregnant individuals.[203] This finding is explained by the greater glucose demand of the fetus and the placenta. The relative hypoglycemic state results in fasting hypoinsulinemia. Pregnant women also exhibit exaggerated starvation ketosis.

Pregnant women are relatively insulin resistant because of hormones such as placental lactogen secreted by the placenta.[204] The blood glucose levels after a carbohydrate load are greater in pregnant women than in nonpregnant women, despite a hyperinsulinemic response. These changes resolve within 24 hours of delivery.

Adrenal Cortical Function

The concentration of corticosteroid-binding globulin (CBG) doubles during gestation as a result of an estrogen-induced enhancement of hepatic synthesis.[205] The elevated CBG value results in a 100% increase in the plasma cortisol concentration at the end of the first trimester and a 200% increase at term. The concentration of unbound, metabolically active cortisol at the end of the third trimester is two and one-half times the nonpregnant level. The increase in free cortisol

results from greater production and reduced clearance. An increase in CBG concentration and a decrease in the serum albumin level affect the protein binding of corticosteroids. CBG binding capacity usually saturates at low concentrations of glucocorticoids. Clearance of betamethasone is greater during pregnancy, possibly because the drug is metabolized by placental enzymes.[206]

THE MUSCULOSKELETAL SYSTEM

Back pain during pregnancy is common. In a cohort study of 200 consecutive women without back pain at the start of pregnancy, 19% complained of backache at 12 weeks' gestation, and the incidence increased to 47% at 24 weeks' gestation, peaking at 49% at 36 weeks' gestation and declining to 9.4% after delivery.[207] In another study that showed a relatively high prevalence of low back pain during pregnancy, only 32% of women reported this to their physician and only 25% of providers recommended specific therapy.[208]

The etiology of the back pain is multifactorial (see Chapter 47). One theory is that the enlarging uterus results in exaggerated lumbar lordosis, placing mechanical strain on the lower back. The hormonal changes of pregnancy may also play a role. Relaxin, a polypeptide hormone of the insulin-like growth factor family, is associated with remodeling of collagen fibers and pelvic connective tissue, permitting the aforementioned lordosis. The primary source of circulating relaxin is the corpus luteum; the placenta is a secondary source. Serum relaxin level in early pregnancy is positively correlated with the presence of back pain.[209] During pregnancy, gait also changes and there is an increase in anterior tilt of the pelvis to maintain body stability,[210] which may cause further stress on the vertebral column, leading to increased pain.

Women who have low back pain in pregnancy have a very high risk for a new episode during a subsequent pregnancy.[211] In the majority of patients, low back pain during pregnancy responds to activity and postural modification. Exercises to increase the strength of the abdominal and back muscles are helpful. Scheduled rest periods with elevation of the feet to flex the hips and decrease the lumbar lordosis help relieve muscle spasm and pain.[212]

The enhancement of the lumbar lordosis during pregnancy alters the center of gravity over the lower extremities (Fig. 2.10) and may lead to other mechanical problems. Exaggerated lumbar lordosis tends to stretch the lateral femoral cutaneous nerve, possibly resulting in **meralgia paresthetica,** with paresthesia or sensory loss over the anterolateral thigh. Anterior flexion of the neck and slumping of the shoulders usually accompany the enhanced lordosis, sometimes leading to a brachial plexus neuropathy.

Mobility of the sacroiliac, sacrococcygeal, and pubic joints increases during pregnancy in preparation for passage of the fetus. A widening of the pubic symphysis is evident by 30 weeks' gestation. These changes are attributable to relaxin and the biomechanical strain of pregnancy on the ligaments.[213] Relaxin may also contribute to the greater incidence of carpal tunnel syndrome during pregnancy by changing the nature of the connective tissue so that more fluid is absorbed.[214]

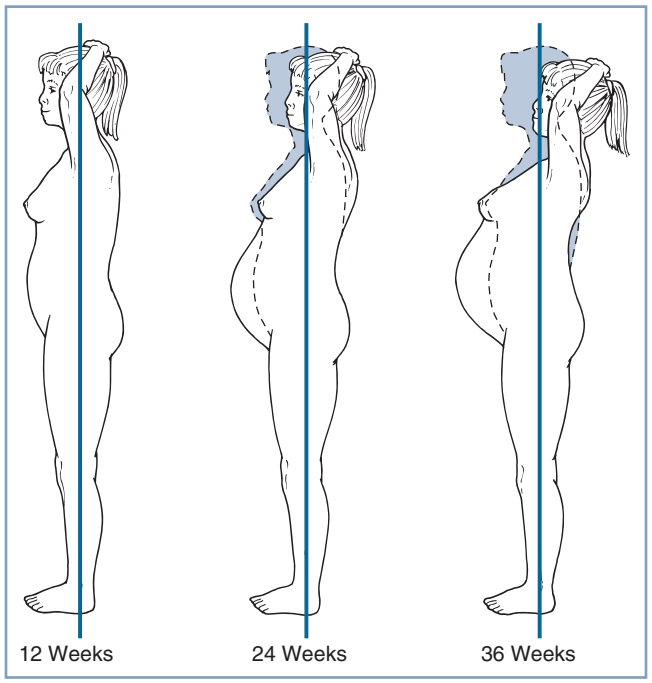

Fig. 2.10 Changes in Posture during Pregnancy. The first and the subsequent dotted-line figures represent a woman's posture before growth of the uterus and its contents have affected the center of gravity. The second and third solid figures show that as the uterus enlarges and the abdomen protrudes, the lumbar lordosis is enhanced and the shoulders slump and move posteriorly. (Modified from Beck AC, Rosenthal AH. *Obstetrical Practice.* Baltimore, MD: Williams & Wilkins; 1955:146.)

The human fetus requires approximately 30 g of calcium for skeletal development by the time of term delivery.[215] Although intestinal absorption of calcium by the mother increases from as early as 12 weeks' gestation to meet this increased demand, it is insufficient to meet fetal demand and thus the maternal skeleton undergoes calcium resorption.[216] This does not cause long-term changes in skeletal calcium content or strength. Pregnant women with a twin gestation have a much higher calcium requirement. Compared with singleton pregnancies, there is a larger increase in maternal bone resorption in twin gestation.[217]

THE NERVOUS SYSTEM

Sleep

Sleep disturbances from mechanical and hormonal factors occur commonly during pregnancy. Latency and duration of rapid eye movement (REM) sleep are influenced by changes in progesterone and estrogen concentrations. Pregnant women have more complaints of insomnia and daytime sleepiness. The American Academy of Sleep Medicine defined **pregnancy-associated sleep disorder** as the occurrence of insomnia or excessive sleepiness that develops in the course of pregnancy.[218] In a cohort study of 189 healthy nulliparous women, Facco et al. reported that mean (± SD) sleep duration

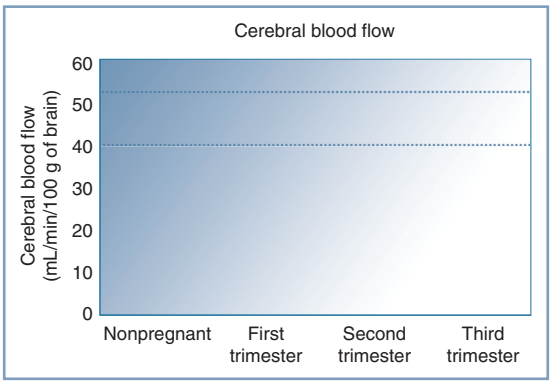

Fig. 2.11 Cerebral Blood Flow during Pregnancy. Cerebral blood flow increases as pregnancy progresses and is attributable to vasodilation from the hormonal changes of pregnancy. This increase in cerebral blood flow explains the increased risk for complications in patients with intracranial pathology as pregnancy progresses. (Based on data from Nevo O, Soustiel JF, Thaler I. Maternal cerebral blood flow during normal pregnancy: a cross-sectional study. *Am J Obstet Gynecol.* 2010;203:475.e1–6.)

was shorter in the third trimester (7.0 ± 1.2 hours) compared with the baseline period between 6 and 20 weeks' gestation (7.4 ± 1.2 hours).[219]

Sleep characteristics change as pregnancy progresses.[220] Early pregnancy is characterized by increased total sleep time and decreased stage 3 and 4 non-REM sleep, whereas late pregnancy is characterized by decreased total sleep time, increased waking after sleep onset, and decreased REM sleep.[220] Sleep may be poor for up to 3 months postpartum.[221] Upper airway changes lead to increased airflow resistance and snoring. Although only 4% of nonpregnant women snore, as many as 23% of pregnant women snore by the third trimester. Snoring is more common in women with preeclampsia.

Pregnancy is associated with **transient restless legs syndrome,** a disorder in which the patient experiences the need to move her legs. The incidence ranges from 15% in the first trimester to 23% in the third trimester.[222]

Central Nervous System

Cerebral blood flow increases in pregnancy. Nevo et al.[223] measured cerebral blood flow in 210 women at different gestational ages and found that it increased from 44.4 mL/min/100 g during the first trimester to 51.8 mL/min/100 g during the third trimester (Fig. 2.11). The increase was secondary to a decrease in cerebrovascular resistance and an increase in internal carotid artery diameter. Other changes in the brain that occur during pregnancy include (1) an increase in permeability of the blood-brain barrier caused by decreased cerebrovascular resistance with an increase in hydrostatic pressure and (2) an increase in capillary density in the posterior cerebral cortex.[224]

Women experience an elevation in the threshold to pain and discomfort near the end of pregnancy and during labor.[225] The mechanism, although unclear, may be related to the effects of progesterone and endorphins. Elevated concentrations of endorphins and enkephalins are found in the plasma and CSF of parturients,[226] and opioid antagonists abolish pregnancy-induced analgesia to visceral stimulation in experimental animals.[227]

Vertebral Column

Anatomic and mechanical changes occur to the vertebral column during pregnancy. The epidural space can be regarded as a rigid tube that contains two fluid-filled distensible tubes, the dural sac and the epidural veins. The volume of epidural fat and the epidural venous plexus enlarge during pregnancy, and spinal CSF volume is reduced.[42]

In the lateral position, lumbar epidural pressure is positive in term pregnant women but negative in more than 90% of nonpregnant women.[228] Turning a parturient from the lateral to the supine position increases the epidural pressure. Epidural pressure also increases during labor because of increased diversion of venous blood through the vertebral plexus secondary to either enhanced compression of the inferior vena cava in the supine position or greater intra-abdominal pressure during pain and pushing. The epidural pressure returns to the nonpregnant level by 6 to 12 hours postpartum.

Despite compression of the dural sac by the epidural veins, the CSF pressure in pregnant women is the same as in nonpregnant women.[229] Uterine contractions and pushing during labor result in an increase in CSF pressure that is secondary to acute increases in epidural vein distention.

Sympathetic Nervous System

Dependence on the sympathetic nervous system for maintenance of hemodynamic stability increases progressively throughout pregnancy and reaches a peak at term.[230–232] The dependence on the sympathetic nervous system returns to that of the nonpregnant state by 36 to 48 hours postpartum.

ANESTHETIC IMPLICATIONS

Positioning

Aortocaval compression, decreased blood pressure and cardiac output, and impairment of uteroplacental blood flow can occur when a pregnant woman is placed in the supine position. This may compromise fetal well-being and neonatal outcome during labor or cesarean delivery.[233–235] Studies performed with pregnant women placed in the lateral position have not shown major decreases in cardiac output.[236,237] When baseline maternal blood pressure is maintained with intravenous fluid and vasopressors, there is no difference in umbilical artery base excess or pH between supine patients and patients tilted 15 degrees undergoing cesarean delivery.[238] Taken together, these data suggest that the supine position should be avoided after 20 weeks' gestation, and the uterus should be tilted greater than 15 degrees if maternal blood pressure cannot be maintained at the baseline level (Fig. 2.12).[43,238]

Blood Replacement

At delivery, maternal vascular capacitance is reduced by the volume of the intervillous space (at least 500 mL). Therefore, during vaginal or cesarean delivery, this volume of blood does

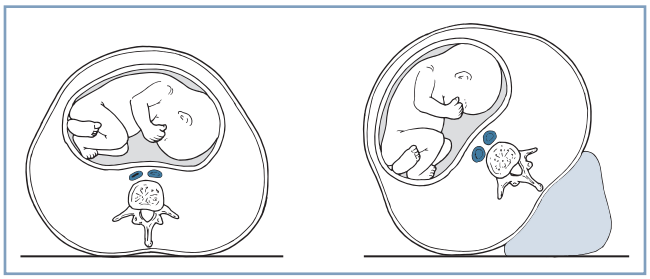

Fig. 2.12 Compression of the aorta and inferior vena cava in the supine *(left)* and lateral tilt *(right)* positions. (Redrawn from Camann WR, Ostheimer GW. Physiologic adaptations during pregnancy. *Int Anesthesiol Clin.* 1990;28:2–10.)

BOX 2.3 Considerations for General Anesthesia during Pregnancy

Drugs

- Propofol
  - Induction dose decreased
  - Elimination half-life unaltered
- Thiopental
  - Induction dose decreased
  - Elimination half-life prolonged
- Volatile anesthetic agents
  - Minimum alveolar concentration (MAC) decreased, but unclear whether hypnotic dose requirement differs from that in nonpregnant women
  - Speed of induction increased
- Succinylcholine
  - Duration of blockade unaltered
- Rocuronium
  - Increased sensitivity
- Chronotropic agents and vasopressors
  - Decreased sensitivity

Tracheal Intubation

- Increased rate of decline of Pa_{O_2} during apnea
- Smaller endotracheal tube required (6.5 or 7.0 mm)
- Increased risk for difficult or failed mask ventilation
- Increased risk for failed intubation with traditional laryngoscopy
- Increased risk for bleeding with nasal instrumentation

not need to be replaced and should not be considered in the estimation of blood loss for replacing red blood cells. Hemoconcentration occurs as maternal blood volume declines from 94 mL/kg at term to 76 mL/kg during the postpartum period; this should be considered in the decision whether a parturient should receive crystalloid, colloid, or blood for volume replacement.[150]

General Anesthesia

Airway Management, Oxygenation, and Ventilation

Changes in the maternal airway and respiratory physiology mandate modification of airway management during pregnancy (Box 2.3) (see Chapter 29). The proportion of pregnant women with a Mallampati IV classification increases by 34% between 12 and 38 weeks' gestation.[239] Vascular engorgement of the airway results in edema of the oral and nasal pharynx, larynx, and trachea,[240] which may lead to difficult tracheal intubation and difficult mask ventilation. Airway edema may be exacerbated in patients with upper respiratory tract infection or preeclampsia and in those who have been pushing for a long time during the second stage of labor.

Pregnant women become hypoxemic more rapidly than nonpregnant women during episodes of apnea because FRC is reduced, oxygen consumption is increased, and FRC is less than closing capacity in up to 50% of supine individuals. During apnea accompanying rapid-sequence induction of general anesthesia, Pa_{O_2} decreases twice as rapidly (139 versus 58 mm Hg/min [18.5 versus 7.7 kPa/min]) in pregnant versus nonpregnant women.[241] Denitrogenation is achieved faster in pregnant versus nonpregnant women because of elevated minute ventilation and decreased FRC. However, after complete denitrogenation via inhalation of 100% oxygen, parturients tolerate only 2 to 3 minutes of apnea, versus 9 minutes in nonpregnant patients, before oxygen saturation decreases to less than 90%.

Ventilation during general anesthesia should be adjusted to maintain Pa_{CO_2} at approximately 30 mm Hg (4 kPa). This can be achieved with minute ventilation of 121 mL/kg/min; in comparison, 77 mL/kg/min is required to maintain a comparable Pa_{CO_2} in nonpregnant women.[242] Decreased plasma bicarbonate concentration reduces buffering capacity in pregnancy. Allowing the Pa_{CO_2} to increase to the normal level for nonpregnant women results in respiratory acidosis.

Intravenous and Inhalation Anesthetics

The **propofol** requirement decreases 10% during the first trimester[243]; this decrease does not correlate with progesterone levels. The elimination half-life of propofol is unaffected by pregnancy, though clearance may be higher.[244]

The rate of rise of alveolar to inspired anesthetic concentration ratio (F_A/F_I) of **volatile anesthetics,** and thus the speed of induction, is increased during pregnancy because of greater minute ventilation and reduced FRC, despite higher cardiac output.

The minimum alveolar concentration (MAC) for volatile anesthetics is up to 40% lower in pregnancy.[245–247] Although MAC is a spinal nociceptive reflex that involves both sensory and motor components,[248] practitioners have interpreted this decrease in MAC as indicating that pregnant patients have a decreased requirement for inhaled anesthetics. However, this interpretation has been questioned. Ueyama et al.[249] compared bispectral index values in 15 patients undergoing cesarean delivery with sevoflurane general anesthesia with the values in 15 patients undergoing elective gynecologic surgery and found no difference between groups. This finding suggests that the hypnotic effect of sevoflurane was not enhanced by pregnancy. The investigators concluded that although pregnancy may decrease MAC, it does not decrease volatile anesthetic requirements, and suggested that parturients should be given the same dose of volatile anesthetics as nonpregnant patients. Further work is required to confirm these findings.

Laboring women may differ from nonlaboring women. Yoo et al.[250] observed lower bispectral index values with a standard sevoflurane–nitrous oxide anesthetic in women with prior labor compared with nonlaboring parturients. Similarly, Erden et al.[251] observed lower sevoflurane requirements to reach a bispectral index target value of 40 to 55 in laboring compared with nonlaboring parturients undergoing cesarean delivery.

Muscle Relaxants

Pseudocholinesterase activity is decreased by 24% before delivery and by 33% on the third postpartum day.[252] It returns to normal 2 to 6 weeks postpartum. The reduced activity does not usually result in clinically relevant prolongation of paralysis after a single dose of **succinylcholine.** Twitch height recovery after administration of succinylcholine is similar between pregnant and nonpregnant women, and recovery may even be faster because the larger volume of distribution results in a lower initial drug concentration and a shorter time before the threshold for recovery is attained. Pregnant women may be less sensitive than nonpregnant women to comparable plasma concentrations of succinylcholine, a feature that also may contribute to more rapid recovery during pregnancy.

Pregnant and postpartum women exhibit enhanced sensitivity to the aminosteroid muscle relaxants **vecuronium** and **rocuronium.**[253,254] The greater sensitivity to vecuronium is not explained by altered pharmacokinetics because the drug exhibits increased clearance and a shortened elimination half-life in pregnant women.[255] The mean onset time and clinical duration of **cisatracurium** are significantly shorter in women immediately after delivery than in nonpregnant women.[256]

Chronotropic Agents and Vasopressors

Pregnancy reduces the chronotropic response to **isoproterenol** and **epinephrine** because of down-regulation of beta-adrenergic receptors.[257] These agents are less-sensitive markers of intravascular injection during administration of an epidural test dose in pregnant patients than in nonpregnant patients. Because of down-regulation of adrenergic receptors, treatment of hypotension requires higher doses of vasopressors such as **phenylephrine** in pregnant women than in nonpregnant women.

Neuraxial Analgesia and Anesthesia

Technical Considerations and Positioning

Increased lumbar lordosis during pregnancy may reduce the vertebral interspinous gap and change the lumbar angulation of spinous processes, thus creating technical difficulty in administering neuraxial anesthesia (Box 2.4 and Fig. 2.13) (see Chapter 12). Widening of the pelvis results in a head-down tilt when a pregnant woman is in the lateral position (Fig. 2.14). This may increase the rostral spread of hyperbaric local anesthetics when injected intrathecally with patients in the lateral position. The flow of CSF from a spinal needle is unchanged throughout gestation because pregnancy does not alter CSF pressure.[229] However, flow rate may increase during a uterine contraction because of increased CSF pressure.

BOX 2.4 Neuraxial Anesthesia: Anesthetic Implications of Maternal Physiologic Changes

Technical Considerations
- Lumbar lordosis increased[a]
- Apex of thoracic kyphosis at higher level[a]
- Head-down tilt when in lateral position

Treatment of Hypotension
- Decreased sensitivity to vasopressors[a]

Local Anesthetic Dose Requirements[b]
- Subarachnoid dose reduced 25%[a]
- Epidural dose unaltered or slightly reduced[a]

[a]Compared with nonpregnant women.
[b]Change in the segmental dose requirement.
Modified from Conklin KA. Maternal physiologic adaptations during gestation, labor, and the puerperium. *Semin Anesth.* 1991;10:221–234.

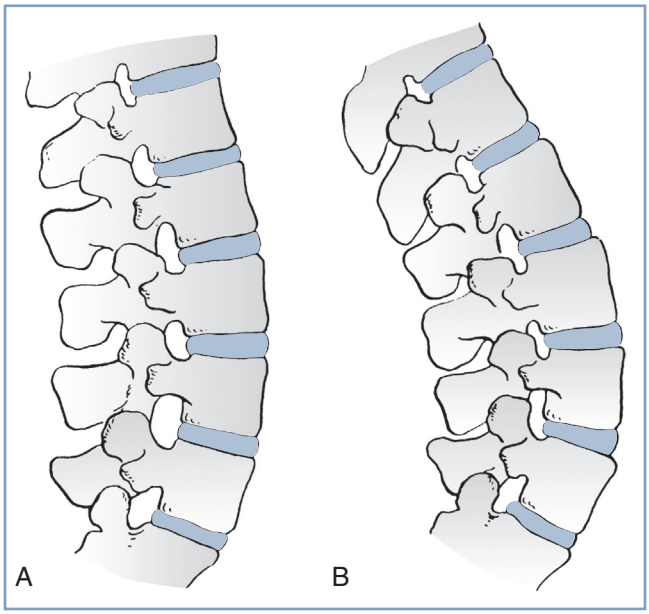

Fig. 2.13 Effects of Pregnancy on the Lumbar Spine. **A,** Nonpregnant. **B,** Pregnant. There is a marked increase in lumbar lordosis and a narrowing of the interspinous spaces during pregnancy. (Modified from Bonica JJ. *Principles and Practice of Obstetric Analgesia and Anesthesia,* Volume 1. Philadelphia, PA: FA Davis; 1967:35.)

Local Anesthetic Dose Requirement

Pregnant patients show decreased local anesthetic dose requirement in the first trimester. This change occurs well before significant mechanical changes have occurred in the vertebral canal,[258] suggesting that there are pregnancy-induced alterations in nerve tissue sensitivity, either directly or indirectly from changes in hormone concentrations.[259]

Pregnant women exhibit a more rapid onset and a longer duration of spinal anesthesia than nonpregnant women who

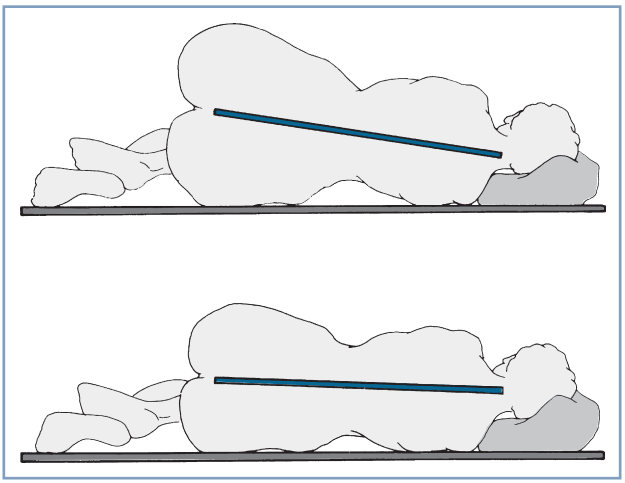

Fig. 2.14 Pelvic widening and resultant head-down tilt in the lateral position during pregnancy. *Upper panel,* pregnant; *lower panel,* nonpregnant. (Modified from Camann WR, Ostheimer GW. Physiological adaptations during pregnancy. *Int Anesthesiol Clin.* 1990;28:2–10.)

receive the same dose of local anesthetic. These results are consistent with enhanced neural sensitivity to local anesthetics; pregnancy-associated elevation in CSF pH may contribute to these effects.[260–262] The dose of hyperbaric local anesthetic required in term pregnant women is 25% lower than that in nonpregnant women.[263,264] This is attributed to the following factors: (1) reduction of spinal CSF volume, which accompanies distention of the vertebral venous plexus[42]; (2) enhanced neural sensitivity to local anesthetics; (3) increased rostral spread when injections are made with the patient in the lateral position; (4) inward displacement of intervertebral foraminal soft tissue, resulting from increased abdominal pressure[265]; and (5) a higher level of the apex of the thoracic kyphosis (the lowest point of the thoracic spinal canal in the supine position) during late pregnancy (see Fig. 12.4).[266] Spinal dose requirements change rapidly in the postpartum period, with segmental dose requirements returning to those of nonpregnant women within 24 to 48 hours[267] as spinal CSF volume expands with the relief of vena caval compression. In contrast to spinal anesthesia, pregnancy appears to have less effect on the spread of epidural anesthesia.[268,269]

Pregnancy does not enhance the susceptibility of ewes to the neurotoxicity of lidocaine or to the cardiac toxicity of bupivacaine (see Chapter 13). The incidence of lethal ventricular arrhythmias is no greater in pregnant than in nonpregnant ewes treated with bupivacaine, ropivacaine, or levobupivacaine.[270]

Hypotension during Neuraxial Analgesia and Anesthesia

Pregnancy increases dependence on the sympathetic nervous system for the maintenance of venous return and systemic vascular resistance.[231] This, together with the effects of aortocaval compression, means that pregnant patients are particularly prone to hypotension and hemodynamic instability from the sympathetic block induced by neuraxial anesthesia. Management of hypotension is discussed in Chapter 26.

Effects of Neuraxial Anesthesia on Respiratory Function

FRC diminishes during neuraxial anesthesia, resulting in an increase in respiratory dead space and ventilation-perfusion mismatch. Abdominal muscles are important for forced expiration and coughing, and paralysis of these muscles during neuraxial anesthesia decreases peak expiratory flow rate, maximum expiratory pressure, and the ability to increase intra-abdominal and intrathoracic pressures during coughing.[271–273]

KEY POINTS

- Pregnancy results in various anatomic and physiologic changes that allow the mother to adapt to the growing fetus and allow the fetus to develop.
- Cardiac output increases during pregnancy as a result of an increase in stroke volume and heart rate. A pregnant woman with cardiovascular disease may not be able to meet this greater demand.
- Pregnant women have greater sympathetic tone than nonpregnant women.
- Beginning at mid-pregnancy, assumption of the supine position may result in compression of the inferior vena cava and aorta by the gravid uterus, which may result in decreases in both cardiac output and uteroplacental perfusion. Severe hypotension and bradycardia in the supine position is called the *supine hypotension syndrome.*
- Pregnant women should not lie supine after 20 weeks' gestation without aggressive maintenance of baseline blood pressure. The uterus should be displaced to the left by placement of a wedge underneath the right hip or by tilting the operating table, or the pregnant women should assume the full lateral position.
- The greater blood volume of pregnancy allows the parturient to tolerate the blood loss of delivery, within limits, with minimal hemodynamic perturbation. Maternal vascular capacitance is reduced at the time of delivery.
- Oxygen demand and delivery are greater during pregnancy and further increase during labor and delivery.
- Minute ventilation increases whereas functional residual capacity decreases during pregnancy. It is not uncommon for the pregnant women to experience dyspnea.
- Pregnancy is a state of partially compensated respiratory alkalosis.
- Gastric volume, emptying, and pH are unaltered during pregnancy, but lower esophageal sphincter tone may be reduced with increased risk for gastroesophageal reflux.
- Pregnancy and the immediate postpartum period are considered hypercoaguable states.
- Mechanical changes in the vertebral column influence neuraxial analgesia and anesthesia.
- Minimum alveolar concentration (MAC) values for the volatile anesthetics are decreased during pregnancy.

However, it is unclear whether the hypnotic dose requirement is altered during pregnancy.
- Pregnant women have a rapid decrease in Pao_2 during periods of apnea.
- Pregnant women are at increased risk for failed tracheal intubation.
- Pregnant women are less responsive to vasopressors than nonpregnant women.

Uteroplacental Blood Flow

Warwick D. Ngan Kee, BHB, MBChB, MD, FANZCA, FHKCA, FHKAM (Anaesthesiology)

CHAPTER OUTLINE

The uteroplacental circulation develops to provide the blood flow and delivery of oxygen and nutrients essential for growth and development of the fetus and placenta. Abnormalities in development are associated with complications such as preeclampsia, fetal growth restriction, and preterm labor, and may even predispose to the development of cardiovascular disease during subsequent adulthood.[1] Acute reduction in uteroplacental blood flow may rapidly threaten fetal viability. The uteroplacental circulation may be affected by circadian changes,[2] disease, parturition, and anesthetic techniques and drugs. An understanding of the regulation of uteroplacental circulation is an important foundation for the safe provision of obstetric anesthesia and in the management of many pregnancy-related diseases. Because of ethical considerations, much of the available knowledge comes from studies in animals, particularly sheep but also nonhuman primates and other species. It is important to consider possible interspecies differences and to critically examine the methodology and context of animal research when extrapolating findings into recommendations for clinical care.

ANATOMY AND STRUCTURE

The blood supply to the uterus is derived mainly from the uterine arteries (Fig. 3.1) with a smaller, variable contribution from the ovarian arteries. Although the pelvic vasculature shows anatomic variation,[3] the uterine artery arises bilaterally from the anterior division of the internal iliac (hypogastric) artery, whereas the ovarian artery arises from the anterolateral abdominal aorta below the renal arteries. The uterine artery passes medially to the side of the uterus, where it supplies branches to the cervix and vagina and ascends between the two layers of the broad ligament, yielding arcuate arteries that supply the body of the uterus to the junction with the fallopian tubes. During pregnancy, flow may differ between the right and left uterine arteries; Konje et al.[4] estimated that vessel diameter was approximately 11% greater and blood flow was approximately 18% greater in the uterine artery on the same side as the placenta compared with the contralateral artery. Anastomoses are formed with the contralateral uterine artery, the vaginal arteries, and the ovarian arteries.

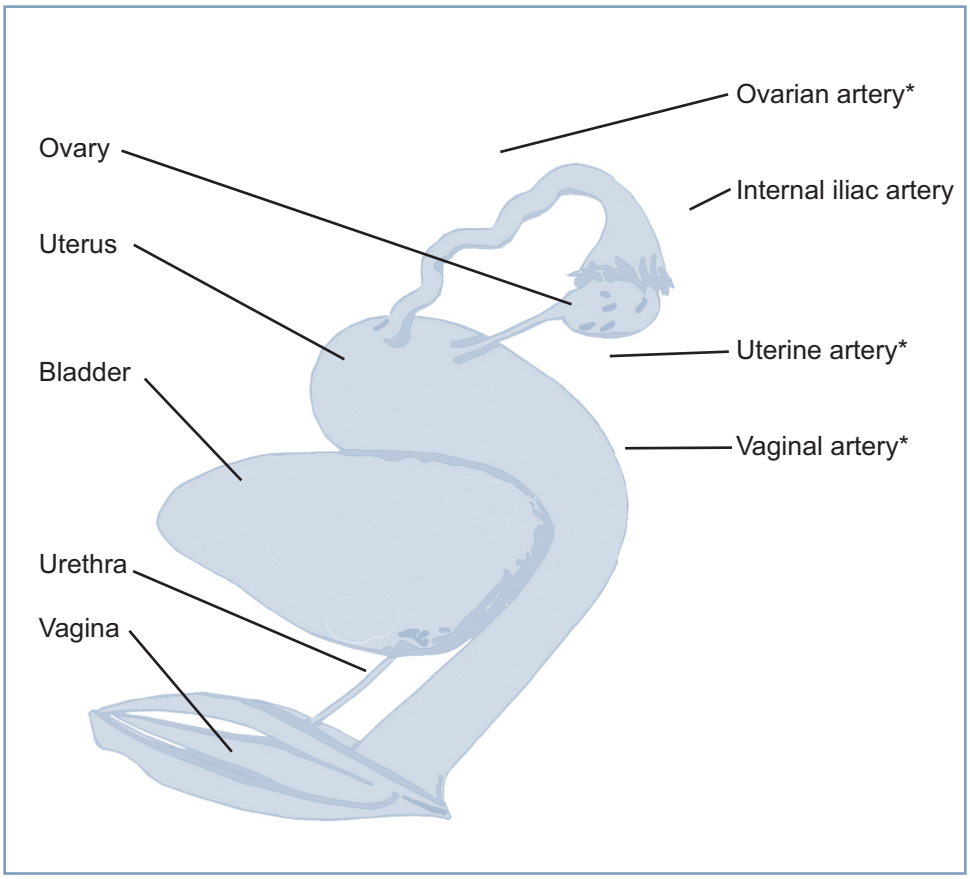

Fig. 3.1 Arterial supply to the female reproductive tract. *The female reproductive tract, particularly the uterus, has a rich network of collateral blood flow from both ipsilateral and contralateral vessels. Variations in the origin of arterial vessels and the presence of anastomoses (i.e., between left and right uterine arteries, or uterine to ovarian arteries) are common. During maternal hemorrhage, this network can thwart attempts to obtain hemostasis through vessel ligation or embolization. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

The arcuate arteries give rise to small branches that supply the myometrium and large radial arteries that branch deeply and enter the endometrium to form the convoluted spiral arteries. During gestation, trophoblastic invasion of the spiral arteries results in loss of smooth muscle and loss of contractile ability, leading to vasodilation with decreased resistance and increased blood flow. Abnormal or inadequate trophoblastic invasion is integral to the pathophysiology of preeclampsia (see Chapter 35).

From the spiral arteries, oxygenated maternal blood enters the intervillous space in fountainlike jets. Blood traveling toward the chorionic plate bathes the villi, permitting the exchange of oxygen, nutrients, and wastes between maternal and fetal blood. Maternal blood then returns to the basal plate and drains into multiple collecting veins. Venous drainage of the uterus occurs via the uterine veins to the internal iliac veins and also via the ovarian veins (utero-ovarian plexus) to the inferior vena cava on the right and the renal vein on the left.[5]

The uterine artery and other branches of the anterior division of the internal iliac artery, and the ovarian artery, may be targeted during angiographic embolization procedures for treatment of obstetric and gynecologic hemorrhage[3] and for the treatment of uterine fibroids.[6]

CHANGES AND FUNCTION DURING PREGNANCY

Pregnancy-Induced Changes

Uterine blood flow increases dramatically during pregnancy, rising from 50 to 100 mL/min before pregnancy to 700 to 900 mL/min at term, depending on the method of measurement (Fig. 3.2). Studies in sheep have shown that increases in uterine blood flow can be divided into three phases.[7] An initial phase, most likely controlled by the ovarian hormones estrogen and progesterone, occurs before and during implantation and early placentation. A second phase results from the growth and remodeling of the uteroplacental vasculature to support further placental development. The third phase results from progressive uterine artery vasodilation to meet the markedly increased nutrient requirements of the rapidly growing fetus. When expressed in terms of uterine weight, however, uterine flow per gram of tissue is particularly high in early gestation, and this ratio decreases

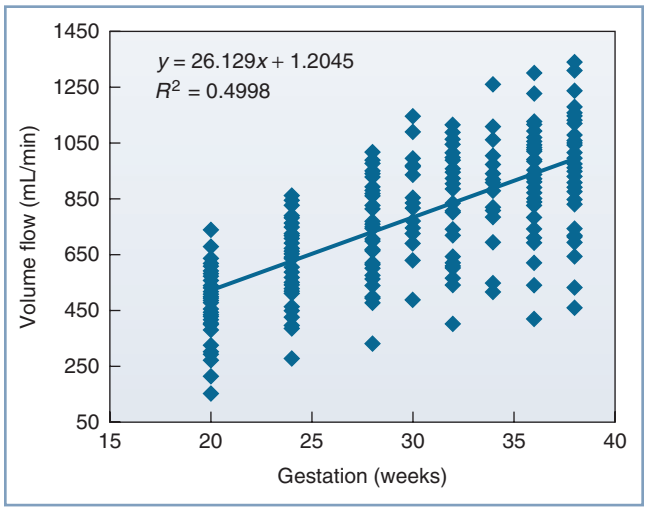

Fig. 3.2 Changes in uterine artery blood flow with gestation. (From Konje JC, Kaufmann P, Bell SC, Taylor DJ. A longitudinal study of quantitative uterine blood flow with the use of color power angiography in appropriate for gestational age pregnancies. *Am J Obstet Gynecol.* 2001;185:608–613.)

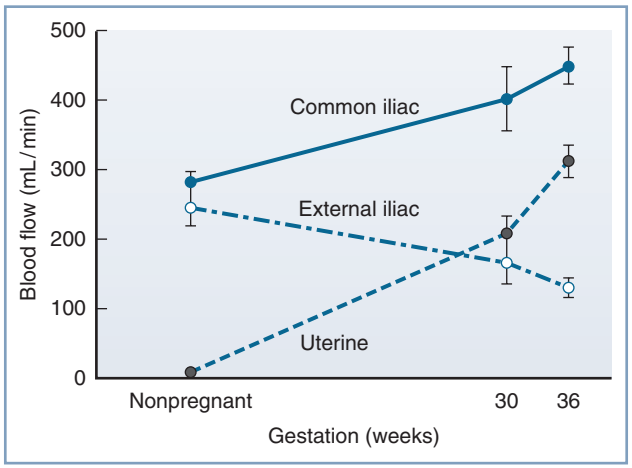

Fig. 3.3 Redistribution of blood flow in pelvic blood vessels during pregnancy determined unilaterally by Doppler ultrasonography. Blood flow increased in the common iliac and uterine arteries but decreased in the external iliac artery, indicating that redistribution of flow favors uterine perfusion. Data are mean ± SEM. (Modified from Palmer SK, Zamudio S, Coffin C, et al. Quantitative estimation of human uterine artery blood flow and pelvic blood flow redistribution in pregnancy. *Obstet Gynecol.* 1992;80:1000–1006.)

as pregnancy progresses.[7] In comparison, umbilical blood flow, expressed as a function of fetal weight, is relatively constant throughout most of pregnancy and is estimated to be 110 to 120 mL/min/kg.[8] Uterine blood flow is increased in twin pregnancy, but the flow per unit of estimated fetal weight is similar to that in a singleton pregnancy.[9] The progressive increase in uteroplacental blood flow during pregnancy is matched by a concurrent increase in blood flow on the fetal side (fetoplacental blood flow). However, despite suggestions of the possibility of intrinsic flow matching, it is believed that these circulations are independently regulated.[10]

Distribution of Blood Flow

Uterine blood flow at term represents a greater proportion of cardiac output (approximately 12%) than in early pregnancy (approximately 3.5%).[11] Regional distribution of blood flow within the pelvis also changes during gestation. Palmer et al.[12] observed that increases in common iliac artery blood flow during pregnancy were associated with corresponding increases in uterine artery blood flow but also with decreases in external iliac artery blood flow. This pattern effectively constitutes a "steal" phenomenon, in which blood flow in the pelvis is preferentially redistributed toward the uterus (Fig. 3.3).

Primate studies have shown that 80% to 90% of total uterine blood flow perfuses the placenta at term, with the remainder supplying the myometrium and nonplacental endometrium.[13] The placental and nonplacental vasculatures are anatomically and functionally distinct, and regulation of perfusion through these vascular beds differs.[13] Therefore, it is important to differentiate studies that measure total uteroplacental blood flow versus placental blood flow.

Functional Classification

Placental vascular function varies among species. The human multivillous model is commonly believed to function as a "venous equilibrator," in which oxygen tension in the umbilical vein approximates that in the uterine veins. In contrast, the placenta in some species (e.g., rodents) functions as a countercurrent exchanger. The more efficient function of the latter is reflected by the higher fetoplacental weight ratio in rodents (20:1) than in humans (6:1).[14]

Autoregulation

Studies of pressure-flow relationships suggest that the nonpregnant uterine circulation exhibits autoregulation, alternately vasoconstricting or vasodilating in response to a number of different stimuli.[15] In contrast, in pregnancy the placental and nonplacental circulations have differing properties. Animal studies have demonstrated that the uteroplacental circulation is a widely dilated, low-resistance system with perfusion that is largely pressure-dependent.[16,17] However, a study in pregnant rabbits found that uteroplacental blood flow was relatively constant over a wide range of perfusion pressures.[18] During hemorrhage in pregnant rats, uterine vascular resistance *increased* as systemic blood pressure and uterine blood flow decreased, thereby demonstrating an absence of autoregulation. Moreover, although the uteroplacental circulation is often considered to be maximally vasodilated with little or no ability for autoregulation,[16] further vasodilation has been observed in response to systemically administered estrogen, prostacyclin, bradykinin, and acetylcholine.[19–21] These discrepancies may be explained by changes in the nonplacental uterine vasculature, which accounts for a small fraction of total uteroplacental blood flow but appears to have similar

autoregulatory responses during pregnant and nonpregnant states; this feature contrasts with the limited autoregulatory ability of the placental circulation.[22] Laird et al.[17] found that reducing arterial pressure by 22% with an inflatable aortic occluder in pregnant rabbits produced a reduction in total uteroplacental and placental blood flow but no significant change in myoendometrial blood flow. Clinically, limited autoregulation means that placental blood flow may diminish with reductions in maternal blood pressure (e.g., during hemorrhage or neuraxial anesthesia).

Margin of Safety

Studies in animals have demonstrated that, in normal physiologic conditions, uterine blood flow exceeds the minimum required to satisfy fetal oxygen demand.[23] Although this feature confers a margin of safety that protects the fetus from fluctuations in uterine blood flow,[24] decreases in fetal Po_2 and progressive metabolic acidosis can occur with reductions in uteroplacental blood flow, depending on the magnitude and duration.[25] However, the relationship between uterine blood flow and oxygen transfer appears nonlinear and suggests that uteroplacental blood flow can decrease by as much as 50% for limited periods before fetal oxygen uptake decreases and metabolic acidosis occurs.[23]

Studies in sheep have shown that although uterine blood flow varies over a wide range, fetal oxygen uptake remains relatively constant, suggesting that the efficiency of oxygen extraction is greater when perfusion decreases.[26] Using an inflatable balloon occluder around the terminal aorta to reduce uterine blood flow in sheep, Wilkening and Meschia[23] found that at high levels of oxygen delivery, fetal oxygen uptake was not significantly affected by variations in uterine blood flow; moreover, fetal oxygen uptake became flow-dependent only when uterine oxygen delivery was reduced to less than half the baseline value. Boyle et al.,[27] investigating the effects of acute uterine arterial embolization with microspheres in sheep, found a linear decrease in fetal aortic oxygen tension as uterine blood flow decreased. However, uterine oxygen consumption did not decrease and fetal hydrogen ion concentration did not increase until uterine blood flow had decreased to approximately 50% of the baseline value. As uterine blood flow diminished, a reduction in uterine venous oxygen content and a greater arteriovenous oxygen content difference were observed, indicating an increase in oxygen extraction. Gu et al.[28] reported comparable findings with the compression of the common uterine artery by an inflatable occluder in sheep.

Although the preceding experiments were conducted in sheep, the same principles may apply to humans. The human placenta, like the sheep placenta, is a relatively inefficient oxygen exchanger. Thus, in humans and sheep, the transfer rate of oxygen is affected less by decreases in placental perfusion than it is in animals with more efficient placentas, such as the rabbit and guinea pig. This difference may afford some protection in humans, because alterations in placental perfusion in animals with more efficient placentas frequently result in spontaneous abortion.[29] Animal data would also suggest the presence of a significant physiologic buffer that protects the fetus during transient fluctuations in uteroplacental perfusion (e.g., changes in endogenous vasoconstrictor levels, uterine contractions, and parturition).[30] This may partially explain why clinical studies have failed to demonstrate fetal acidosis when alpha-adrenergic agonists are used to maintain maternal blood pressure during neuraxial anesthesia,[31] despite experimental data showing that these agents reduce uteroplacental perfusion in laboratory animals.[32] These observations are based on an assumption of normal physiology; the presence of pathology likely diminishes any margin of safety.

Changes during Parturition

With the onset of the uterine contractions of labor, uteroplacental perfusion undergoes cyclical changes. During uterine contractions, a decrease in perfusion occurs that is inversely related to the strength of the contraction and the increase in intrauterine pressure.[30] Conversely, during uterine relaxation, there is a period of hyperemia when perfusion is increased. Placental perfusion is believed to be more sensitive to these contraction-induced changes than myometrial or endometrial blood flow.[33] Within the first few hours of parturition, uterine blood flow in sheep decreases on average by 50% or more, although there is notable interindividual variation.[34]

Clinical Determinants of Uterine Blood Flow

In the acute setting, uterine blood flow is related to perfusion pressure (the difference between uterine arterial pressure and uterine venous pressure) and vascular resistance, as represented in the following equation:

$$\text{Uterine blood flow} = \frac{\text{Uterine perfusion pressure}}{\text{Uterine vascular resistance}} \quad (1)$$

There are several ways that uterine blood flow can decrease (Box 3.1). First, uterine blood flow may decline with reductions in perfusion pressure because of decreased uterine arterial pressure (e.g., during systemic hypotension from hemorrhage, aortocaval compression, or sympathetic blockade during neuraxial anesthesia). Second, uterine blood flow may decline with reductions in perfusion pressure caused by increased uterine venous pressure (e.g., from vena caval compression, increased intrauterine pressure during uterine contractions, effects of drugs such as oxytocin and cocaine, and bearing down during the second stage of labor). Third, uterine blood flow may decline because of increased uterine vascular resistance (e.g., from endogenous vasoconstrictors released in response to stress, exogenous vasoconstrictors, and compression of endometrial spiral arterioles with uterine contractions).[33]

MECHANISMS OF VASCULAR CHANGES AND REGULATION

Vascular Changes during Pregnancy

Because mean arterial pressure decreases slightly during pregnancy, the increase in uteroplacental blood flow is

BOX 3.1 Causes of Decreased Uterine Blood Flow

Decreased Perfusion Pressure

Decreased uterine arterial pressure:

- Supine position (aortocaval compression)
- Hemorrhage/hypovolemia
- Drug-induced hypotension
- Hypotension during sympathetic blockade

Increased uterine venous pressure:

- Vena caval compression
- Uterine contractions
- Drug-induced uterine tachysystole (oxytocin, local anesthetics)
- Skeletal muscle hypertonus (seizures, Valsalva maneuver)

Increased Uterine Vascular Resistance

Endogenous vasoconstrictors:

- Catecholamines (stress)
- Vasopressin (in response to hypovolemia)

Exogenous vasoconstrictors:

- Epinephrine
- Vasopressors (phenylephrine > ephedrine)
- Local anesthetics (in high concentrations)

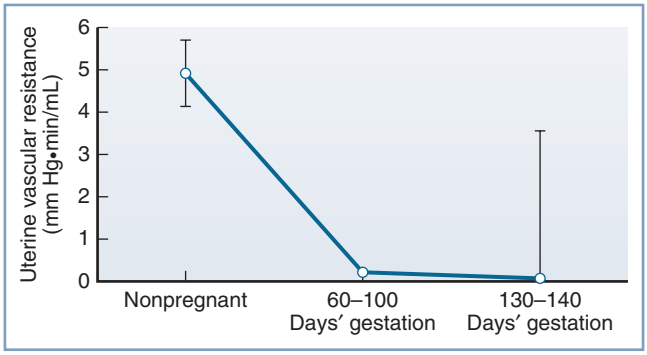

Fig. 3.4 Changes in uterine vascular resistance with gestation. Data are mean ± SE. (Modified from Rosenfeld CR. Distribution of cardiac output in ovine pregnancy. *Am J Physiol.* 1977;232:H231–H235.)

dependent on a substantial decrease in uterine vascular resistance (Fig. 3.4), together with increased cardiac output and intravascular volume. The main factors contributing to the decrease in vascular resistance include vascular remodeling, changes in vascular reactivity, and the development of the widely dilated placental circulation.

Vascular remodeling of arteries in the uterus during pregnancy is believed to include increases in both vessel diameter and vessel length. In humans, both vessel lengthening and straightening of coiled vessels may occur[11]; the effects of changes in vessel diameter dominate, resulting in an overall decrease in resistance. Palmer et al.,[12] using serial Doppler studies during pregnancy, observed that uterine artery diameter is doubled by 21 weeks' gestation, whereas there is no change in the diameter of the common iliac or external iliac arteries. These investigators also showed that uterine artery mean flow velocity increased progressively during pregnancy to values eight times greater than those of nonpregnancy. In parallel with arterial changes, there is also structural remodeling of uterine veins in pregnancy, including increases in diameter and distensibility and decreases in elastin content.[35] Although blood viscosity decreases during pregnancy and also contributes to reduced uterine vascular resistance, this is considered a relatively minor effect compared with vascular changes.[36]

Changes in vascular reactivity during pregnancy include a vasodilatory response that is meditated at endothelial and vascular smooth muscle levels.[37] The growth of the placenta creates a low-resistance vascular pathway by eliminating the intramyometrial microcirculation and creating an intervillous space.[38] This has functional characteristics of an arteriovenous shunt.[14]

The mechanisms underlying the vascular changes during pregnancy are incompletely understood. Contributing factors include steroid hormones, decreased response to vasoconstrictors, endothelium-derived vasodilators, increased shear stress, and venoarterial exchange.

Steroid Hormones

Estrogen has a fundamental role in the short- and long-term uterine vascular changes during pregnancy. Plasma concentration of estrogen, initially derived from the ovaries and later predominantly from the placenta, rises concomitantly with the increase in uterine blood flow during pregnancy. Exogenously administered estrogen causes uterine vasodilation and a marked rise in uterine blood flow, independent of systemic effects.[39] Angiogenic and vasodilatory effects of estrogen are meditated via estrogen receptors ER-α and ER-β, which are structurally and functionally distinct. Most of these receptors are located in the nucleus and mediate genomic effects by regulating transcription of genes that are particularly responsible for the longer-term uterine angiogenic responses. There are also membrane receptors that mediate nongenomic effects by up-regulating endothelial production of nitric oxide through the activation of endothelial nitric oxide synthase (eNOS) and the augmentation of eNOS protein expression.[40]

Progesterone modulates the effect of estrogen on uterine blood flow. In a nonpregnant sheep model, exogenous progesterone administered alone had no uterine vasodilatory effect but had an inhibitory effect when combined with estrogen.[37] Progesterone down-regulates expression of estrogen receptors.[41] An increase in the estrogen-progesterone ratio parallels the increase in uterine blood flow in late pregnancy in many species.[42]

Plasma **cortisol** levels approximately double during pregnancy. Cortisol has both systemic and local effects on uterine blood flow. Systemically, cortisol contributes to regulation of uterine blood flow by increasing plasma volume. Although cortisol is believed to decrease eNOS protein expression and decrease nitric oxide release, it potentiates the response to vasoconstrictor agents including angiotensin II, vasopressin, and norepinephrine. Attenuation of these effects occurs during pregnancy.[37]

Decreased Response to Vasoconstrictors

In pregnancy, there is a generalized reduction in response to endogenous and exogenous vasoconstrictors, including angiotensin II, endothelin, thromboxane, epinephrine, norepinephrine, phenylephrine, serotonin, and arginine vasopressin.[43–45] The relative refractoriness of the systemic and uterine circulations varies for different agents, which has important implications for the regulation and maintenance of uteroplacental blood flow.

During pregnancy, concentrations of **angiotensin II** in maternal blood are increased twofold to threefold[46]; however, the vasopressor response to angiotensin II is attenuated.[47] This refractoriness is diminished in patients in whom preeclampsia develops.[47] The uterine circulation is less responsive to angiotensin II than the systemic circulation. Thus, infusion of physiologic doses of angiotensin II has been shown to have minimal effect on uteroplacental blood flow while increasing systemic blood pressure.[48] The difference in sensitivity of the uterine and systemic circulations to angiotensin II is considered an important physiologic adaptation during pregnancy that contributes to the redistribution of cardiac output, the increase in uterine blood flow, and possibly the maintenance of uterine blood flow during normal fluctuations in blood pressure.[49]

Sensitivity to vasoconstrictors such as **epinephrine**, **norepinephrine**, and **phenylephrine** is attenuated during pregnancy.[50] This may explain why relatively large doses of vasoconstrictors are often required to maintain blood pressure during spinal anesthesia for cesarean delivery.[31] In contrast to the responses to angiotensin II, the uterine circulation is *more* responsive to these agents than the systemic circulation.[50] Thus, during hemorrhage or other major stresses that result in large catecholamine release, it is unlikely that uteroplacental perfusion will be preferentially preserved above essential maternal perfusion.[51]

The mechanism underlying the difference in vascular sensitivity between the uterine and systemic circulations is unclear, but distribution of receptor subtypes is believed to be important.[52] For example, there are two distinct subtypes of angiotensin II receptors: AT_1R and AT_2R. In most tissues, including systemic vascular smooth muscle, AT_1R receptors are predominant and mediate vasoconstriction. However, AT_2R receptors, which do not mediate smooth muscle contraction, account for 75% to 90% of angiotensin II binding in uterine artery and myometrium.[53,54]

Vasodilators

The greater synthesis and higher circulating concentrations of endothelial-derived vasodilators during pregnancy are believed to modulate systemic and uterine vascular responses to angiotensin II and other vasoconstrictors.[55] Uterine vascular production of **prostacyclin** is greater than systemic vascular production, which probably contributes to maintaining uteroplacental blood flow in opposition to the effects of circulating vasoconstrictors.[56] An enhanced response to angiotensin II during pregnancy has been demonstrated with the systemic and local infusion of indomethacin (which blocks prostacyclin production).[57] However, inhibition of prostaglandin synthesis by an infusion of indomethacin induces only a transient decrease in uteroplacental blood flow, indicating that uteroplacental blood flow is not solely dependent on the continued production of prostacyclin.[55]

Nitric oxide is synthesized from arginine in vascular endothelial cells and stimulates soluble guanylate cyclase in vascular smooth muscle, resulting in vascular relaxation through increases in cyclic guanosine monophosphate. Synthesis of nitric oxide is an important mechanism underlying changes in systemic and uterine vascular resistance, attenuated responses to vasoconstrictors, and vascular effects of estrogen during pregnancy.[58] During pregnancy, uterine arteries have increased eNOS activity, higher levels of eNOS messenger ribonucleic acid and eNOS protein, and increased biosynthesis of nitric oxide and cyclic guanosine monophosphate.[58,59] Removal of the vascular endothelium diminishes or eliminates the refractoriness of the uterine artery to vasoconstrictors,[44] and inhibition of nitric oxide synthesis by *N*-nitro-L-arginine methyl ester (L-NAME) decreases uterine blood flow and also reverses refractoriness to vasoconstrictors.[60] Long-term inhibition of nitric oxide synthase causes hypertension and fetal growth restriction in rats.[61]

Other Vasoactive Substances

Atrial and **brain natriuretic peptides** attenuate the response to angiotensin II, and intravenous infusion of atrial natriuretic peptide reduces blood pressure while increasing uterine blood flow in preeclamptic women.[62] **Protein kinase C** activity is decreased in uterine, but not systemic, arteries of pregnant sheep and may cause vasodilation and an increase in uterine blood flow; this may have a regulatory effect on local ovarian and placental estrogen production.[42] Studies in rats have shown a decrease in endogenous endothelin-dependent vasoconstrictor tone in uteroplacental vessels, which may contribute to the increase in placental blood flow in late gestation.[63] Uterine vascular resistance in early pregnancy may be increased by **relaxin,** which may have a role in modulating the effects of estrogen and progesterone.[64] **Placental protein 13** has been shown to be a potent vasodilator of both uterine and systemic blood vessels *in vitro,* and it has been suggested that this peptide might contribute to the vasodilation that occurs during human pregnancy.[65] The use of **vasopressin** to prevent spinal anesthesia–induced hypotension has been reported in the care of patients with pulmonary hypertension, but its use as a vasoconstrictor in pregnancy has not been well studied.[66]

Shear Stress

Shear stress, the frictional forces on the vessel wall from blood flow, is believed to be an important stimulus for uteroplacental vasodilation and remodeling.[67] The reduction in downstream resistance resulting from the formation of the placenta would be expected to increase the upstream flow velocity and thus shear stress.[38] Nitric oxide is considered an important mediator of this effect because increases in eNOS expression and

nitric oxide production are witnessed with shear stress and because stripping the endothelium or pretreatment with L-NAME reduces or abolishes flow-induced vasodilation.[67] Studies *in vitro* have shown that shear stress also increases endothelial production of prostacyclin.

Venoarterial Signaling

It has been postulated that growth factors or signal substances secreted by the placenta and/or myometrium could pass from uterine veins to adjacent uterine arteries; this may provide a system whereby the uterus and placenta regulate their own perfusion.[38] Possible candidates for signal substances include vascular endothelial growth factor and placental growth factor. The importance of this mechanism in humans is uncertain.

METHODS OF MEASUREMENT OF UTEROPLACENTAL BLOOD FLOW

Many techniques have been used to measure uteroplacental blood flow in animals and humans. The approaches used in different studies have varied according to the nature of the experimental question, the existing state of technology, and ethical considerations and limitations. All methods have an inherent potential for error.

Many past studies of uterine artery flow have measured flow in only one uterine artery, which may not be an accurate representation of total flow, depending on the location of the placenta (see earlier discussion). The parameter of greatest clinical interest is placental perfusion, but this is not always differentiated from total uterine blood flow, and the two circulations may vary independently. However, in most circumstances, the measurement of intervillous blood flow provides a close approximation of functional placental blood flow. Ovarian arterial blood flow is generally not measured, although studies in primates suggest that it may contribute as much as one-sixth of placental perfusion.[68]

Early studies of uteroplacental blood flow involved a number of substances that could affect maternal hemodynamics (e.g., nitrous oxide) or myometrial activity (e.g., 4-aminoantipyrine) and relied on the Fick principle. This principle, which calculates blood flow by the measurement of a marker substance entering and leaving an organ, is subject to error in the uterus, where a number of veins are responsible for collecting venous effluent.[69] In animals, placental perfusion can also be measured by the injection of radioactive microspheres. This method allows for the separate calculation of placental and myometrial blood flows but only provides information from a single point in time. Total uterine arterial blood flow can also be measured (or estimated) with the use of surgically implanted electromagnetic or Doppler flow probes.

In humans, placental perfusion can be measured by the injection of trace amounts of radioactive substances, typically ^{133}xenon.[70] During the washout phase, the rapid decrease in measured radioactivity over the placenta is calculated as a biexponential or triexponential process. The most rapid decay constant is ascribed to intervillous perfusion. Alternatively, radioactively tagged proteins (e.g., albumin) can be injected and measured by scintigraphy over the placenta.[71] Although the accuracy of these methods for determining absolute flow is limited, their ability to measure relative change over time is adequate in most cases.

Clinically, the most common method of assessing flow in the uterine arteries is Doppler ultrasonography.[72] The uterine artery can be identified transabdominally or transvaginally. Color flow aids vessel identification. Blood flow can be quantified by measuring the mean flow velocity and vessel cross-sectional area.

Flow velocity is calculated by applying the principle of Doppler shift. A pulsed ultrasound signal from a stationery transducer is directed toward the vessel with an angle of insonation (θ) less than 60 degrees. Reflections scattered from the red blood cells are received. Because the red blood cells are moving, the frequency of the received signal differs from the transmitted frequency (f_0) by an amount known as the Doppler shift (Δf). This shift is proportional to the red blood cell flow velocity (V_{RBC}) according to the following equation:

$$\Delta f = \frac{2 \times f_0 \times V_{REL}}{c} \quad \textbf{(2)}$$

where c is the speed of sound propagation in tissue and V_{REL} is the vector component of the velocity of flow relative to the direction of the transducer. The latter takes into account the difference between the direction of the ultrasound signal from the direction of flow according to θ (Fig. 3.5). V_{RBC} is related to the relative velocity of flow in the direction of the probe (V_{REL}) according to the following equation:

$$V_{RBC} = \frac{V_{REL}}{\cos\theta} \quad \textbf{(3)}$$

Combining Eqs. 2 and 3 gives the following equation:

$$V_{RBC} = \frac{\Delta f}{f_0} \times \frac{c}{2 \times \cos\theta} \quad \textbf{(4)}$$

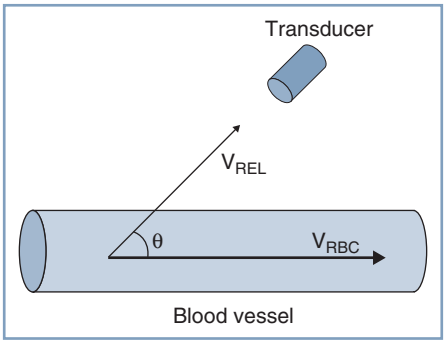

Fig. 3.5 Principles of use of Doppler ultrasonography to estimate blood flow. Blood flow is calculated as the product of blood vessel cross-sectional area and mean flow velocity in the vessel (V_{RBC}). The latter is derived from the measured flow velocity relative to the direction of the probe (V_{REL}) and requires precise determination of the angle of insonation (θ).

Thus, the flow velocity is estimated from the ratio of the Doppler shift frequency to the transmitted frequency, multiplied by the speed of sound propagation, and divided by two times the cosine of the insonation angle.

An estimation of the volume of blood flow (Q) can be made by multiplying mean velocity by the vessel cross-sectional area (A), which is estimated with two-dimensional (B-mode) ultrasonography:

$$Q = V_{RBC} \times A \quad \textbf{(5)}$$

However, measurement of absolute flow using this technique is prone to difficulty and error, both from inaccurate measurement of vessel cross-sectional area (e.g., arteries pulsate during the cardiac cycle) and from inaccurate measurement of flow (e.g., from inaccuracies in measurement of θ). Therefore, for diagnostic purposes, a number of indices related to vascular impedance are derived from the flow velocity waveform that are independent of θ.[73] These rely on the fact that the uterine vascular bed normally has low resistance with flow continuing during diastole. If distal resistance is increased, diastolic velocity decreases relative to systolic velocity resulting in a waveform showing greater pulsatility. Commonly derived indices (Fig. 3.6) are:

$$\text{Systolic} - \text{diastolic}\left(\frac{S}{D}\right)\text{ratio} = \frac{\text{Systolic (maximal) velocity}}{\text{Diastolic (minimal) velocity}} \quad \textbf{(6)}$$

$$\text{Pulsatility index (PI)} = \frac{\text{(Systolic [maximum] velocity} - \text{Diastolic [minimum] velocity)}}{\text{Mean velocity}} \quad \textbf{(7)}$$

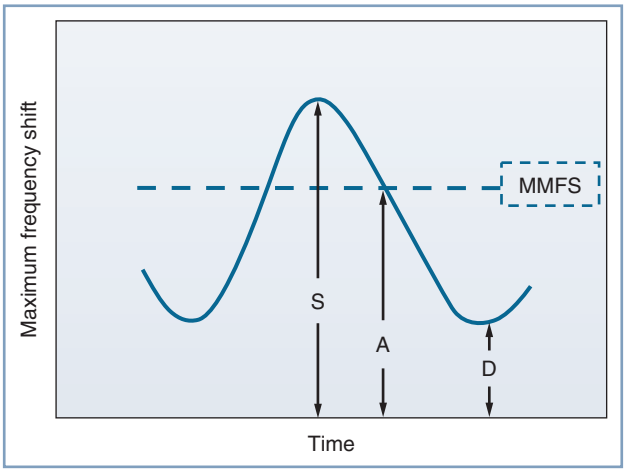

Fig. 3.6 Schematic diagram showing elements of typical Doppler waveform of the uterine artery. *S,* peak systolic frequency shift (maximum velocity); *D,* end-diastolic frequency shift (minimum velocity); *A,* temporal averaged frequency shift (mean velocity) averaged over one cardiac cycle; *MMFS,* mean maximum frequency shift. Derived indices include systolic/diastolic (S/D) ratio = S/D, pulsatility index (PI) = (S – D)/A, and resistance index (RI) = (S – D)/S.

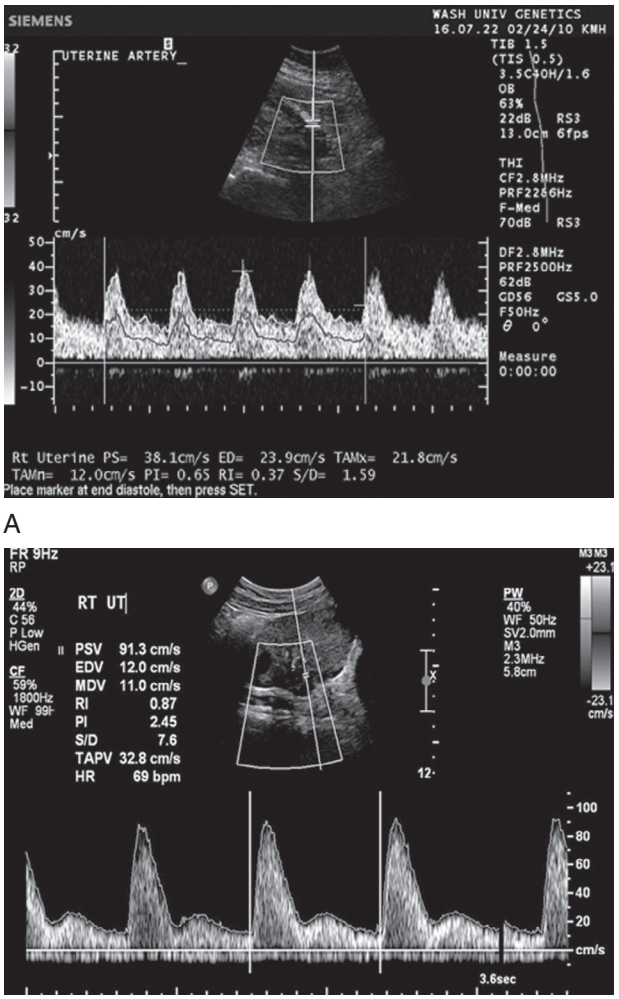

Fig. 3.7 Normal (A) and abnormal (B) uterine artery Doppler waveforms. The normal waveform has no notching and normal pulsatility. The abnormal waveform shows notching and increased pulsatility. (From Tuuli M, Odibo AO. The role of serum markers and uterine artery Doppler in identifying at-risk pregnancies. *Clin Perinatol.* 2001;38:1–19.)

$$\text{Resistance index (RI)} = \frac{\text{(Systolic [maximum] velocity} - \text{Diastolic [minimum] velocity)}}{\text{Systolic [maximum] velocity}} \quad \textbf{(8)}$$

In early pregnancy, uterine artery flow is very pulsatile with high systolic flow and low diastolic flow. As gestation progresses, resistance gradually decreases. Abnormal patterns, including persistence of high resistance, diastolic notching, the absence of end-diastolic flow, or reversal of diastolic flow, are predictive of the development of abnormalities such as preeclampsia or fetal growth restriction. Examples of normal and abnormal uterine artery Doppler tracings are shown in Fig. 3.7.[74] Doppler velocimetry is also applied to the umbilical vessels for antepartum fetal assessment (see Chapter 6). Other methods of clinically evaluating the uteroplacental circulation

BOX 3.2 Effects of Neuraxial Anesthesia on Uterine Blood Flow

Increased uterine blood flow as a result of:
- Pain relief
- Decreased sympathetic activity
- Decreased maternal hyperventilation

Decreased uterine blood flow as a result of:
- Hypotension
- Unintentional intravenous injection of local anesthetic and/or epinephrine
- Absorbed local anesthetic (little effect)

include the use of two-dimensional and three-dimensional Doppler, power Doppler, contrast-enhanced ultrasonography, and functional magnetic resonance imaging.[75]

NEURAXIAL ANESTHESIA

The effect of neuraxial anesthesia on uteroplacental blood flow depends on the complex interaction of many factors (Box 3.2). Pain and stress during labor may reduce uteroplacental blood flow through sympathetic stimulation and the release of circulating catecholamines. Shnider et al.[76] observed that acute stress increased plasma norepinephrine concentrations by 25% and decreased uterine blood flow by 50% in gravid ewes. In laboring women, stress is associated with increased plasma epinephrine concentration and abnormal fetal heart rate patterns. Effective pain relief with neuraxial analgesia decreases circulating concentrations of catecholamines[77] and reduces hyperventilation and therefore may help protect uteroplacental blood flow. In the absence of hypotension, epidural anesthesia does not change uteroplacental blood flow in pregnant sheep.[78] Results from human studies are variable, partly because of differences in study design, techniques used, and clinical circumstances. However, most studies have shown no change or an increase in uteroplacental blood flow after administration of epidural analgesia.[79,80] Some studies have shown an increase in uterine vascular resistance indices,[81,82] but with no effect on neonatal outcomes. There is evidence that in women with preeclampsia, epidural analgesia using a plain local anesthetic may reduce uterine artery resistance[79] and increase intervillous blood flow.[83] Ginosar et al.[84] reported that antenatal continuous epidural infusion of ropivacaine in preterm women with preeclampsia reduced uterine artery resistance. Further work is required to determine whether this might have therapeutic potential for short-term prolongation of pregnancy.

Fetal bradycardia is sometimes observed after initiation of neuraxial labor analgesia and has been attributed to decreases in uteroplacental blood flow; the mechanism for this association is unclear. Although alterations in uteroplacental blood flow have been primarily attributed to maternal hypotension and respiratory depression, another postulated mechanism is uterine tachysystole caused by a rapid decrease in circulating catecholamine concentrations (see Chapter 23).[85] Additional studies are needed to evaluate the relationship between neuraxial analgesic techniques, uteroplacental blood flow, and fetal bradycardia.

Hypotension

Hypotension occurring during neuraxial blockade, depending on its magnitude and duration, may decrease uteroplacental blood flow for several reasons, including reduction in perfusion pressure,[16] reflex release of endogenous vasoconstrictors, diversion (steal) of blood to the lower limbs,[86] and response to administered vasopressors.[32] The rapid and extensive sympathetic blockade during spinal anesthesia, and some of the methods used to treat hypotension, may account for the observation that umbilical arterial blood pH is lower with spinal anesthesia than with epidural or general anesthesia for cesarean delivery.[87]

Intravenous Fluid Loading

Studies of the effect of intravenous fluid boluses used in conjunction with assessment of the uteroplacental circulation have had mixed results. Most Doppler studies have shown that fluid preload before the initiation of neuraxial analgesia does not change vascular resistance indices,[88] although a decrease has been reported in one study.[89]

Vasopressors

The effects of vasopressors on uteroplacental blood flow and the resulting implications for clinical drug selection are controversial. Animal and *in vitro* studies have observed that uteroplacental blood flow was better maintained using ephedrine than with alpha-adrenergic agonists such as phenylephrine, metaraminol, and methoxamine,[32] which likely reflects the predominant beta-adrenergic effects of ephedrine. In addition, *in vitro* studies in pregnant sheep evaluating the effects of ephedrine on blood vessels have demonstrated enhanced vasoconstrictor activity on the femoral versus uterine vessels and decreased uterine artery vasoconstriction as a result of nitric oxide release.[90] In contrast, an increase in the uterine arteriolar vasoconstrictor response to phenylephrine has been observed during pregnancy.[91] However, in clinical studies, umbilical arterial blood pH and base excess have been observed to be greater with the use of alpha-adrenergic agonists compared with ephedrine for maintaining maternal blood pressure during spinal anesthesia for cesarean delivery.[92–98] A comparison of different infusion regimens of phenylephrine, titrated to maintain maternal systolic blood pressure near baseline, observed no depression of fetal pH and base excess despite very large total doses (up to 2500 μg) before delivery.[31] In contrast, large doses of ephedrine administered to maintain blood pressure during spinal anesthesia for cesarean delivery depressed umbilical arterial blood pH and base excess in a dose-dependent manner.[99]

The explanation for the discrepancy between experimental and clinical data is complex and incompletely understood. Animal studies are not always appropriate models for clinical situations. Under clinical conditions, Doppler studies have

shown some evidence that uterine vascular resistance is increased by alpha-adrenergic agonists,[93] but this finding has not been consistent.[98] Although data suggest that alpha-adrenergic agonists increase uterine vascular resistance more than systemic vascular resistance, the difference may be primarily caused by an effect in the myometrium, with relative sparing of the vessels that perfuse the placenta.[100] In addition, uteroplacental blood flow in humans has a margin of safety that appears to allow modest decreases in uterine blood flow (caused by clinically appropriate doses of alpha-adrenergic agonists) to occur without compromising oxygen transfer. Finally, the propensity of ephedrine to worsen fetal acid-base status may be related less to its effects on uteroplacental blood flow and more to direct beta-adrenergic receptor–mediated fetal metabolic effects. Compared with phenylephrine, ephedrine crosses the placenta to a greater extent and is associated with higher fetal levels of lactate, glucose, epinephrine, and norepinephrine.[101]

Thus, when considering the choice of vasopressor for clinical use, the anesthesia provider should consider the sum effect on fetal oxygen supply and demand balance rather than the isolated effects on uteroplacental blood flow. In this respect, clinical studies do not favor the use of ephedrine. Overall, to date, studies comparing ephedrine and other vasopressors in humans have not demonstrated differences in clinical neonatal outcome.

Limited data are available for the comparison of vasopressors in the presence of fetal compromise or placental insufficiency. Erkinaro et al.[102,103] developed a sheep model to compare the effects of phenylephrine and ephedrine after a period of experimental fetal hypoxia. Hypotension was induced by epidural anesthesia and then corrected with either phenylephrine or ephedrine. In an initial study, ephedrine was associated with better restoration of uterine artery blood flow, but no differences in fetal acid-base measurements or lactate concentration were observed.[102] However, in a second study, these investigators embolized the placenta with microspheres to model placental insufficiency and found that phenylephrine and ephedrine had similar effects on uterine blood flow, fetal pH, and base excess as found in the initial study, with the exception that fetal lactate concentration was greater in the phenylephrine group.[103] Although the investigators speculated that this exception might reflect impaired fetal clearance of lactate, the placental embolization may have narrowed the margin of safety for uteroplacental blood flow and increased fetal lactate production in the phenylephrine group.

In two studies, women with preeclampsia undergoing cesarean delivery with spinal anesthesia were randomized to receive phenylephrine or ephedrine for the prevention[104] or treatment[105] of spinal anesthesia-induced hypotension. Neither study identified differences in the acid-base status of the neonates between the two drugs, suggesting that either drug is appropriate for use in women with preeclampsia with potentially compromised uteroplacental circulation.

In summary, ephedrine and phenylephrine both continue to be used clinically for maintaining maternal blood pressure during the administration of neuraxial anesthesia (see Chapter 26). Although most experimental data suggest that uteroplacental perfusion is likely to be better maintained with ephedrine than with alpha-adrenergic agonists, this advantage may be outweighed by other considerations, such as differences in efficacy for maintaining blood pressure and direct fetal effects that occur from placental drug transfer.

Local Anesthetics

Studies *in vitro* have shown that local anesthetics constrict arteries directly and inhibit endothelium-mediated vasodilation.[106] High concentrations of local anesthetic can decrease uteroplacental blood flow by stimulating vasoconstriction and myometrial contractility.[107,108] A comparative study in pregnant sheep showed that bupivacaine was more potent than either lidocaine or 2-chloroprocaine in decreasing uterine blood flow.[108] However, the adverse effects of local anesthetics were seen only at concentrations in excess of those observed clinically, with two possible exceptions: (1) the unintentional intravenous injection of local anesthetic and (2) the use of local anesthetics for a paracervical block. At clinically relevant doses, no adverse effect on uteroplacental blood flow was reported.[109] Although initially the inherent vasoconstrictor properties of ropivacaine were a matter of concern, studies in animals[109] and humans[110] have not shown that administration of ropivacaine results in a reduction in uterine blood flow.

Epinephrine and α_2-Adrenergic Agonists

Wallis et al.[78] found that the epidural injection of 1.5% 2-chloroprocaine with epinephrine (10 μg/mL) produced a small, brief reduction in uterine blood flow in pregnant sheep. In contrast, Alahuhta et al.[111] reported that epidural bupivacaine with epinephrine (5 μg/mL) had no effect on intervillous blood flow in women undergoing cesarean delivery. Studies have not shown a reduction in uteroplacental blood flow as a result of the absorption of epinephrine from local anesthetic solutions given epidurally to healthy women during labor.[112] However, one study observed that the addition of epinephrine (85 to 100 μg) to epidural bupivacaine increased Doppler indices of uteroplacental vascular resistance in hypertensive parturients with chronic fetal asphyxia.[113] Therefore, some anesthesia providers avoid epidural administration of epinephrine-containing local anesthetic solutions to women with preeclampsia. Commonly, epinephrine (10 to 15 μg) is included in the epidural test dose. Marcus et al.[114] reported that repeated epidural injections of epinephrine (10 to 15 μg) did not decrease uterine blood flow in pregnant sheep; however, the same dose injected intravenously reduced uterine blood flow, with a maximum decrease of 43% observed at 1 minute.

The epidural and intrathecal administration of α_2-adrenergic agonists (e.g., clonidine, dexmedetomidine) has been a subject of clinical investigations. Intravenous, but not epidural, administration of clonidine decreased uterine blood flow in gravid ewes.[115]

Opioids

Intrathecal opioids have been implicated as contributing to a greater risk for fetal bradycardia when used for labor analgesia compared with non-intrathecal opioid neuraxial analgesic techniques.[116] The mechanism for this effect has been postulated as an increase in uterine tone and a resulting decrease in uteroplacental blood flow, although further research is needed. Craft et al.[117,118] observed that neither epidural fentanyl nor morphine had a significant effect on uterine blood flow in gravid ewes. Alahuhta et al.[119] reported that epidural sufentanil 50 μg did not alter uterine artery blood flow velocity waveform indices in laboring women. Intrathecal meperidine and sufentanil, however, may be associated with hypotension that may potentially decrease uterine blood flow.[120,121]

GENERAL ANESTHESIA

Intravenous Agents

Available data suggest that the commonly used induction agents have minimal or no direct adverse effect on uteroplacental blood flow. Allen et al.[122] found that thiopental inhibited the response of human myometrial arteries to contractile agents *in vitro* but had no effect on relaxation induced by prostacyclin. Alon et al.[123] reported that uterine blood flow did not change significantly during induction and maintenance of propofol anesthesia in pregnant sheep. Craft et al.[124] reported that uterine tone increased but uterine blood flow remained constant after an intravenous bolus of ketamine in pregnant sheep. Similarly, Strümper et al.[125] reported that neither racemic nor S^+-ketamine affected uterine perfusion in pregnant sheep. Few data are available on the direct effects of etomidate on uteroplacental blood flow.

During the intravenous induction of general anesthesia, uteroplacental perfusion may be affected by indirect mechanisms such as blood pressure changes and the sympathetic response to laryngoscopy and endotracheal intubation. Jouppila et al.[126] reported that intervillous blood flow decreased by 22% to 50% during induction of general anesthesia for cesarean delivery with thiopental 4 mg/kg, succinylcholine 1 mg/kg, and endotracheal intubation. Gin et al.[127] compared thiopental 4 mg/kg and propofol 2 mg/kg in patients undergoing elective cesarean delivery and found that venous plasma concentrations of epinephrine and norepinephrine increased after endotracheal intubation in both groups, but maximum norepinephrine concentrations were lower in the propofol group. No differences in neonatal outcomes were observed. Levinson et al.[128] found that intravenous ketamine increased blood pressure with a concomitant rise in uterine blood flow in pregnant sheep. Addition of a rapid-acting opioid (e.g., alfentanil, remifentanil) during induction of general anesthesia may minimize the increase in circulating catecholamines that occurs after laryngoscopy and endotracheal intubation.[129,130] Although the use of such opioids might attenuate any decrease in uterine blood flow, the potential for neonatal respiratory depression should be considered.

Inhalational Agents

Studies in pregnant sheep have shown that usual clinical doses (i.e., 0.5 to 1.5 minimum alveolar concentration [MAC]) of the volatile anesthetic agents, including isoflurane, desflurane, and sevoflurane, have little or no effect on uterine blood flow, although deeper planes of anesthesia are associated with reductions in cardiac output, maternal blood pressure, and uterine blood flow.[131] Nonetheless, high concentrations of inhalational agents (approximately 2 MAC) have been used during *ex utero* intrapartum treatment procedures without evidence of impaired fetal gas exchange.[132] A dose-dependent reduction in uterine tone caused by inhalational agents would be expected to increase uterine blood flow in clinical circumstances in which tone is increased (e.g., hyperstimulation with oxytocin, cocaine overdose, placental abruption). Overall, there is little reason to choose one inhalational agent over another on the basis of an agent's effects on uterine blood flow.

Ventilation

Although moderate levels of hypoxemia and hypercapnia do not affect uteroplacental blood flow,[133] marked alterations may reduce blood flow indirectly by mechanisms most likely involving sympathetic activation and catecholamine release. The effect of hypocapnia on uteroplacental blood flow is controversial. Some investigators have noted that hyperventilation with hypocapnia caused fetal hypoxia and metabolic acidosis in animals,[134] whereas others have found no effect.[135] Levinson et al.[136] observed that positive-pressure ventilation decreased uterine blood flow in pregnant sheep; however, because the addition of carbon dioxide did not improve uterine blood flow, the reduction in blood flow was attributed to the mechanical hyperventilation rather than the hypocapnia. In general, most authorities recommend that hyperventilation be avoided in pregnancy, in part because of concerns about uterine blood flow.

EFFECTS OF OTHER DRUGS AND INTERVENTIONS

Magnesium Sulfate

Magnesium sulfate increases uterine blood flow in normotensive and hypertensive pregnant sheep.[137,138] Although hypermagnesemia was found to exacerbate maternal hypotension during epidural anesthesia in pregnant sheep, no reduction in uterine blood flow was observed.[137] In women in preterm labor[139] and with preeclampsia with severe features,[140] magnesium sulfate caused a modest decrease in Doppler indices of uterine vascular resistance. Infusion of magnesium caused an increase in uterine blood flow, which was associated with an improvement in red blood cell deformability in women with preeclampsia or fetal growth restriction.[141]

Antihypertensive Agents

In patients with gestational hypertension, the effects of antihypertensive drugs on uteroplacental perfusion depend on

the interaction of their effects on uterine vascular resistance and systemic maternal blood pressure. In animal models of pharmacologically induced hypertension, hydralazine reduced maternal blood pressure but increased uteroplacental blood flow, reflecting a decrease in uterine vascular resistance.[142,143] Similar studies with labetalol have had varying results, showing increased,[144] decreased,[145] and no change[146] in uteroplacental blood flow. A study in preeclamptic women observed an increase in uterine artery resistance indices after hydralazine but not labetalol.[147] However, previous studies have generally demonstrated no significant change in uteroplacental blood flow with either drug,[148–151] indicating that other considerations are probably more important for guiding drug selection. Studies of methyldopa in patients with preeclampsia have found either a reduction[152] or no change[153] in indices of uterine and placental vascular resistance.

Calcium Entry–Blocking Agents

Verapamil 0.2 mg/kg was shown to decrease maternal blood pressure and uterine blood flow in pregnant sheep.[154] Studies with nifedipine have yielded conflicting results. Some animal studies have shown that nifedipine decreases uteroplacental blood flow and worsens the fetal condition, whereas human studies have shown either no change in uteroplacental blood flow or vascular resistance[155] or a decrease in vascular resistance.[156]

Vasodilators

Nitroglycerin was shown to relax human uterine arteries *in vitro*.[157] In women with abnormal uterine artery blood flow at 24 to 26 weeks' gestation, infusion of intravenous nitroglycerin decreased uterine resistance indices.[158] Similarly, transdermal nitroglycerin administered for 3 days to patients with preeclampsia and fetal growth restriction decreased uterine resistance indices.[159] However, Grunewald et al.[160] reported that an infusion of nitroglycerin in women with preeclampsia with severe features did not change the pulsatility index of the uterine artery. When interpreting such studies, clinicians should remember that increases in total uterine blood flow do not necessarily result in enhanced placental perfusion. Further work is required to define the utility of systemic vasodilators for improving uteroplacental blood flow in clinical practice.

Inotropic Drugs

Inotropic drugs are rarely indicated in obstetric patients. On the basis of studies of normal pregnant sheep, milrinone and amrinone may increase uterine blood flow, whereas dopamine and epinephrine may diminish it.[161,162] The choice of an inotropic agent should be based primarily on the desired efficacy (i.e., maternal considerations) rather than the potential direct effects on uterine blood flow. This is especially important during maternal resuscitation or cardiac arrest, when maternal welfare is the overriding priority and standard resuscitation drugs should be administered. Restoration of spontaneous circulation and adequate uterine perfusion pressure is far more important than avoidance of uterine vasoconstriction.

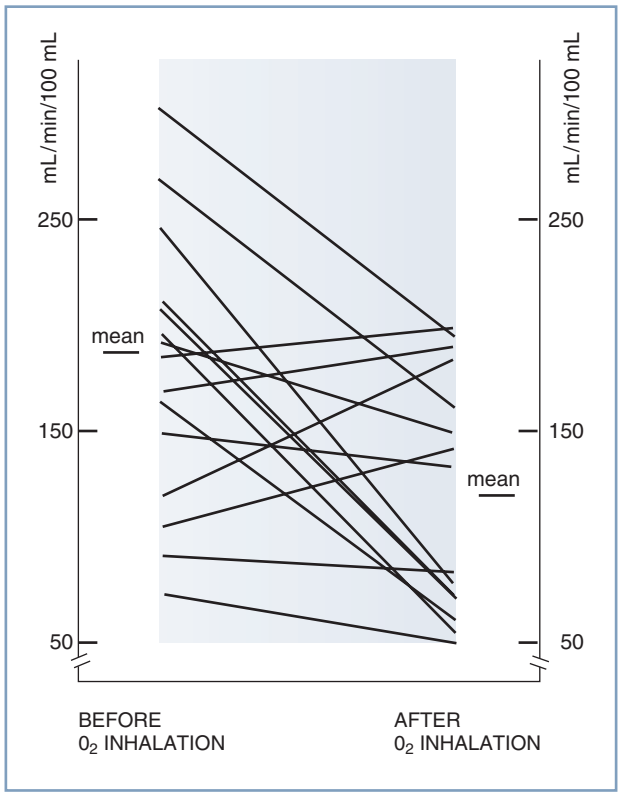

Fig. 3.8 Intervillous blood flow measured using an ^{133}Xenon method before and after inhalation of oxygen 5 L/min in 22 women with a pregnancy complication between 34 and 40 weeks' gestation. Data are shown for individual patients. Mean blood flow decreased significantly after inhalation of oxygen 5 L/min. (Redrawn from Jouppila P, Kirkinen P, Koivula A, Jouppila R: The influence of maternal oxygen inhalation on human placental and umbilical venous blood flow. *Eur J Obstet Gynecol Reprod Biol.* 1983;16:151–156.)

Oxygen Therapy

The effect of supplemental maternal oxygen therapy on uteroplacental blood flow is controversial. Jouppila et al.[163] measured intervillous blood flow using an ^{133}xenon clearance method in 22 women, all of whom had some form of pregnancy complication between 34 and 40 weeks' gestation. They reported that blood flow decreased significantly after inhalation of oxygen 5 L/min (Fig. 3.8) and suggested that this might be related to a vasoconstrictive effect of maternal hyperoxia. Although it is common practice to administer supplemental maternal oxygen as part of intrauterine resuscitation for suspected fetal compromise, evidence for the benefit of this practice is unclear.[164]

KEY POINTS

- Growth and development of the uteroplacental vasculature and progressive vasodilation allow uteroplacental blood flow to increase during pregnancy. Uteroplacental blood flow constitutes approximately 12% of maternal cardiac output at term.
- Many factors modulate the maintenance and regulation of uteroplacental blood flow, including altered responses to vasoconstrictors, increases in endothelium-derived vasodilators, and the effects of steroid hormones and shear stress.
- The uteroplacental circulation is a dilated, low-resistance vascular bed with limited ability for autoregulation. Flow may be reduced by a decrease in uterine arterial pressure, an increase in uterine venous pressure, or an increase in uterine vascular resistance.
- The uteroplacental circulation is composed of placental and nonplacental circulations that are anatomically and functionally dissimilar.
- Acute or chronic reductions in uteroplacental blood flow may threaten fetal viability and predispose to disorders such as preeclampsia and fetal growth restriction. In situations of an acute reduction in uteroplacental perfusion, there is a limited margin of safety; exceeding this limit may decrease fetal oxygen uptake with resultant metabolic acidosis.
- Animal studies are the principal source of uteroplacental blood flow data; thus, clinicians should carefully consider interspecies differences and study methodology when extrapolating experimental findings to clinical practice.
- Doppler ultrasonography is the method most commonly used clinically to assess uteroplacental blood flow in humans. Abnormal waveforms and indices of resistance may be predictive of complications such as preeclampsia, fetal growth restriction, and preterm labor.
- Neuraxial anesthesia can increase uterine blood flow by reducing pain and stress, or it can decrease uterine blood flow by causing hypotension.
- Although animal studies show that ephedrine protects uteroplacental blood flow better than alpha-adrenergic agonists such as phenylephrine, umbilical arterial blood pH and base excess are lower after administration of ephedrine. This effect may be related to a greater propensity of ephedrine to cross the placenta and have direct metabolic effects on the fetus.
- The doses of general anesthetic agents used clinically have minimal direct effects on uterine blood flow. General anesthesia may reduce uterine blood flow by causing decreased cardiac output and hypotension. Conversely, noxious stimulation during light anesthesia may precipitate the release of catecholamines, which results in decreased uterine blood flow.
- For cardiovascular emergencies in pregnant women, the choice of inotropic drug should depend primarily on the efficacy of the drugs to optimize the maternal condition, rather than on minor differences in uterine blood flow. Standard resuscitation drugs should be used in an emergency.

The Placenta: Anatomy, Physiology, and Transfer of Drugs

Mark I. Zakowski, MD, Andrew Geller, MD

CHAPTER OUTLINE

The placenta is a critical organ of great importance to obstetric anesthesia. Revered by ancient cultures as "the seat of the external soul" or "the bundle of life," the placenta is involved in many cultural rituals. Acknowledgment and understanding of the indispensable role of the placenta continues to evolve. The notion of the placenta as a passive conduit for oxygen, nutrients, and waste has been dispelled with the realization that the placenta is a complex and dynamic organ that serves critical functions of metabolism, nutrition, and hormonal maintenance during pregnancy. Maternal-placental conditions can affect the fetus during pregnancy with consequences into adulthood and even beyond into the next generation.[1]

The placenta brings the maternal and fetal circulations into close apposition without substantial interchange of maternal and fetal blood for the physiologic transfer of gases, nutrients, and wastes. This important exchange is accomplished within a complex structure that is almost entirely of fetal origin.

ANATOMY

Embryology

The blastocyst attaches to endometrial pinopodes (uterodomes), which express markers of endometrial receptivity (e.g., galectin-9),[2] and serine proteases and metalloproteinases (e.g., MMP-2 and MMP-9) initiate the remodeling of the uterine extracellular matrix. The syncytiotrophoblasts (invasive cells located at the margin of the growing conceptus), with the assistance of endometrial stromal cells, invade the decidua, capillaries, and arterioles until the blastocyst is surrounded by circulating maternal blood (trophoblastic lacunae).[3] The vitelline vein system develops in the embryonic yolk sac to enhance nutrient transport from the maternal blood through the trophoblast layer and chorionic plate into the chorionic cavity.[3] The embryo undergoes a dramatic acceleration in growth as its dependence on simple diffusion diminishes.[4]

At 2 weeks of development, the primitive extra-embryonic mesoderm (cytotrophoblast layer) begins to proliferate as cellular columns, carrying a syncytiotrophoblast covering and extending into the maternal blood lacunae; these represent *primary* villi. Development within the core of these primary villi marks the metamorphosis into *secondary* villi. Further cellular differentiation of the villi mesoderm into blood cells and vessels marks the transition into *tertiary* villi. Each villus develops connections within the chorionic plate and into the stalk connecting the developing embryo with the

primitive placenta. Penetration of the cytotrophoblast continues through the syncytiotrophoblastic layer until many of the villi reach the decidua and form *anchoring* villi (Fig. 4.1).[4] Villi undergo extensive branching into the lacunar (or intervillous) spaces, enlarging the surface area available for exchange. Villous maturation reduces the cytotrophoblast thickness, thereby shortening the distances required for diffusion.[4]

The embryo attaches to the chorion via a connecting body stalk. Mesodermal components of this stalk coalesce to form the allantoic (or rudimentary umbilical) vessels. The expansive open region at the ventral surface of the embryo constricts as the body wall grows, surrounding the yolk stalk, allantois, and developing vessels into a primitive umbilicus. The mature umbilical cord forms as the expanding amnion surrounds the connecting stalk and yolk sac.[4]

Placental development is a dynamic process influenced by many factors. **Nitric oxide** plays an important role in embryo development, implantation, and trophoblast invasion in diverse species.[5] Human endothelial nitric oxide synthase (eNOS) expression in the syncytiotrophoblast and early endothelium occurs in the first trimester and becomes more prominent throughout pregnancy. Angiogenesis depends on vascular endothelial growth factor (VEGF) and its receptors VEGFR-1 (Flt-1) and VEGFR-2 (Flk-1), transforming growth factor-β_1 (TGF-β_1), and angiopoietin 1 and 2, which exert their effects partially through nitric oxide. Hypoxia also plays an important role in placental development and angiogenesis by stimulating trophoblast invasion and differentiation via hypoxia-inducible factor-alpha, which activates VEGF and eNOS. Relative hypoxia must be maintained in early placental development because the placental-fetal unit cannot tolerate the oxidative stress of reactive oxygen species during organogenesis.[6] Oxygen levels influence the placental vascular sensitivity to vasodilators and vasoconstrictors. *In vitro* studies have shown that NOS inhibition and hypoxia independently increase placental perfusion pressure. Both of these effects are prevented by nitric oxide donors, suggesting a common pathway with the effect of hypoxia mediated partly by low NOS activity.[5]

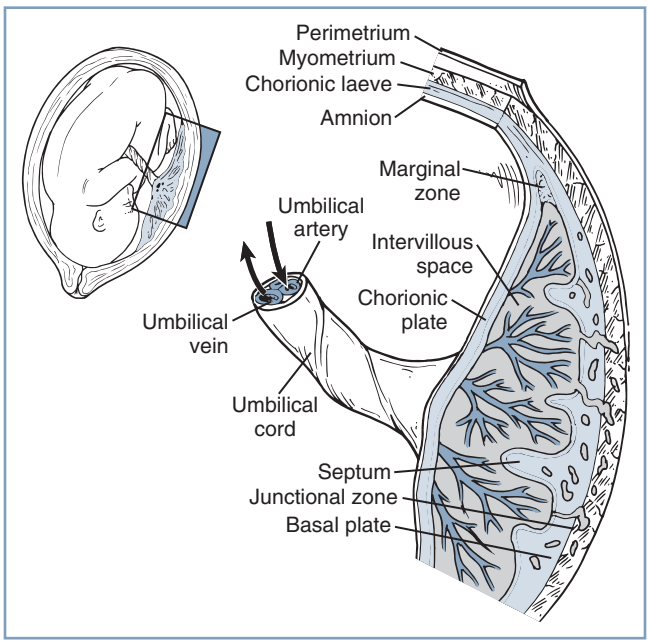

Fig. 4.1 The placenta is a complex structure that brings the maternal and fetal circulations into close apposition for exchange of substances. (Redrawn from Kaufmann P, Hans-Georg F. Placental development. In Polin RA, Fox WW, Abman SH, eds. *Fetal and Neonatal Physiology*. 3rd ed. Philadelphia, PA: Saunders; 2004:85–96.)

Preeclampsia is related, at least in part, to abnormal placental growth and implantation at early stages of development, resulting in the villous tree having longer capillaries with fewer branches (see Chapter 35).[5] Vascular dysfunction occurs mainly from changes in vascular structure and synthesis of nitric oxide rather than from altered responses to nitric oxide and vasoconstrictors.

The expression and control of DNA and genes affects placental development, fetal development, adult phenotype expression, and clinical diseases, even into subsequent generations.[1,7] Epigenetics explores the prolonged effect of maternal and paternal environmental influences; gene expression becomes altered by DNA methylation, histone modification, and noncoding RNA. At fertilization, global DNA methylation is erased so the genome is hypomethylated at the blastocyst stage (implantation).[7] Methylation of placental DNA increases with gestation, causing down- and up-regulation of genes associated with cell cycles and immune response, respectively.[8] Genomic imprinting causes the silencing of one allele-specific copy of a gene, which leads to extensive intraplacental and cotyledon mosaicism. *In vitro* fertilization, diet, and maternal diseases can influence epigenetic changes and subsequently alter DNA methylation.[9]

Altered gene methylation has been linked to clinical disease states.[7] Increased long interspersed nuclear element-1 *(LINE1)* gene methylation, as well as hypomethylation of 34 specific genes, are associated with early-onset preeclampsia.[10] By contrast, late-onset preeclampsia is associated with hypomethylation of only 4 genes.[10] These and other findings indicate that DNA and DNA regulatory changes influence early placental development as well as the occurrence of pregnancy-associated diseases.

Human studies have demonstrated fetal programming of childhood and adult diseases. Adults who were exposed *in utero* to episodes of malnutrition developed reduced glucose tolerance, atherogenic lipid profiles, and a doubled rate of cardiovascular diseases; these disease states were associated with hypomethylation of regulatory areas for insulin-like growth factor-2 and other genes.[1] *In utero* exposure to a high-fat diet can lead to an increased incidence of diabetes in offspring, and chronic maternal stress during pregnancy can lead to infant neurodevelopmental disorders.[1]

The placenta grows dramatically from the third month of gestation until term, with a direct correlation between placental growth and fetal growth. By term, the mature placenta is oval and flat, with an average diameter of 18.5 cm, weight of 500 g, and thickness of 23 mm. At term, the human fetal-placental weight constitutes 6% of maternal

weight.[11] The growth of the placenta and fetus is influenced by maternal anabolic status, placental growth hormone, insulin-like growth factor-1, leptin, and glucocorticoids.[12] Whether maternal or fetal in origin, increased glucocorticoids signal adverse environmental conditions and result in reduced glucose and amino acid transfer to the fetus. With 12 subtypes of glucocorticoid receptors, significant variations in placental-fetal development can occur, including alterations in placental remodeling, trophoblastic invasion, and angiogenesis inhibition.[13] Competition between the mother and fetus for resource allocation has been termed the *kinship theory,* in which imprinted genes influence the balance of nutrient allocation in a context-specific manner.[12]

Comparative Anatomy

Placentas of different species vary in their method of uterine attachment (adhesion, interdigitation, and fusion) and the number of tissue layers between the maternal and fetal circulations. The placental categorization system, called the Grossner classification, uses the number of tissue layers in the placental barrier to help differentiate species (Fig. 4.2).[14]

The ability of the placenta to transfer various substances differs among species. The markedly thicker epitheliochorial placenta found in sheep, a species commonly used for placental transfer studies, has three maternal layers (epithelium, connective tissue, and endothelium) that separate maternal from fetal blood. By contrast, the human hemochorial placenta lacks these maternal layers, which allows maternal blood to bathe fetal tissues directly (see Fig. 4.2). As a result, species differ in the transfer of substances through the placenta.

Vascular Architecture

Maternal

Under the initial hormonal influences of the corpus luteum, the uterine spiral arteries elongate and coil. Erosion of the decidua induces lateral looping of the already convoluted spiral arteries.[15] In late pregnancy, approximately 200 spiral arteries can supply approximately 600 mL/min of blood flow directly to the fetus through the placenta.[15] The vasodilation required to accommodate the increased flow is accomplished by the replacement of the elastic and muscular components of these arteries by cytotrophoblastic cells, and later by fibroid cells; vessel diameter increases up to 10-fold, while blood velocity and blood pressure decrease.[15] Inadequate uterine spiral artery development contributes to relative ischemia and the development of preeclampsia and fetal growth restriction, which was previously called intrauterine growth restriction (IUGR). Computer modeling of spiral artery flow indicates that high blood velocity in nondilated spiral arteries causes damage to the endothelium and placenta trophoblast.[16]

The **intervillous space** is a large cavernous expanse that develops from the fusion of the trophoblastic lacunae and the erosion of the decidua by the expanding blastocyst. Folds in the basal plate form septa that divide the space into 13 to 30 anatomic compartments or lobules for efficient transfer of material between maternal and fetal blood flow. Each lobule contains numerous villous trees that are also known as *cotyledons* or *placentomes.* The intervillous space of the mature placenta can accommodate 350 mL of maternal blood.

Maternal arterial blood leaves the funnel-shaped spiral arteries and enters the intervillous space. The blood moves into the nearly hollow, low-resistance area, where villi are very loosely packed (the intercotyledonary space), before entering a region of densely packed intermittent and *terminal* villi where placental exchange predominates (Fig. 4.3).[17] Maternal venous blood collects between neighboring villous trees in an area called the *perilobular zone.* Collecting veins penetrate the maternal plate at the periphery of the villous trees to drain perilobular blood from the intervillous space.

Fetal

Two coiled arteries in the umbilical cord bring fetal blood toward the placenta. These arteries divide into **chorionic arteries** that supply the 50 villous trees located in the placental lobules. At the base of each villous tree, the chorionic arteries are considered the *main villous stem* or *truncal arteries* (first-order vessels), which in turn branch into four to eight *ramal* or *cotyledonary arteries* (second-order vessels); as they pass toward the maternal plate, they further subdivide into *ramulus chorii* (third-order vessels) and, finally, *terminal*

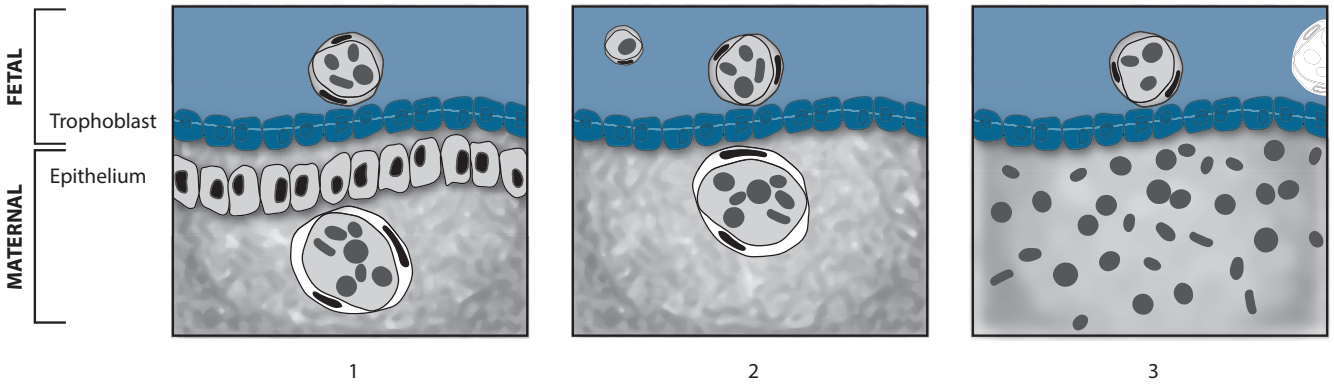

Fig. 4.2 Modification of Grossner's original classification scheme showing the number and types of tissue layers between the fetal and maternal circulation. Examples are as follows: (1) epitheliochorial, sheep; (2) endotheliochorial, dogs and cats; and (3) hemochorial, human and mouse. The gray discs represent red blood cells in vessels and the intervillous space. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

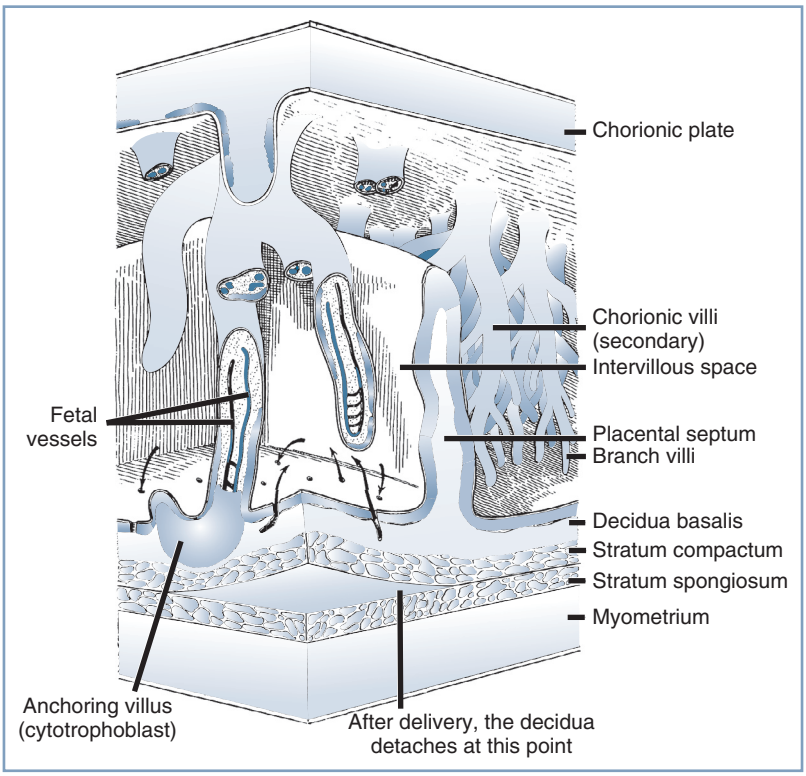

Fig. 4.3 The relationship between the villous tree and maternal blood flow. *Arrows* indicate the maternal blood flow from the spiral arteries into the intervillous space and out through the spiral veins. Fig. 4.4 *Right,* Cellular morphology of two terminal villi. *Left,* Higher magnification of the boxed region exhibiting the placental barrier between fetal and maternal blood. (Redrawn from Kaufmann P. Basic morphology of the fetal and maternal circuits in the human placenta. *Contrib Gynecol Obstet.* 1985;13:5–17.)

arterioles. The terminal arterioles lead through a neck region into a bulbous enlargement, where they form two to four narrow capillary loops. Here the large endothelial surface area and the near-absence of connective tissue allow optimal maternal-fetal exchange (Fig. 4.4).[18]

The **venous end of the capillaries** loops, narrows, and returns through the neck region to the collecting venules, which coalesce to form the larger veins in the stem of the villous trees, and as they perforate the chorionic plate, become **chorionic veins.** The venous tributaries combine to empty

into the one umbilical vein that delivers blood back to the fetus.

PHYSIOLOGY

Barrier Function

The placenta is an imperfect barrier that allows bidirectional transfer of many substances; the rate and amount of transfer depend on the permeability and the presence of various mechanisms to restrict movement. Many substances undergo specific or nonspecific binding within the placental tissues, thereby minimizing fetal exposure and accumulation; other substances are altered by the vast array of inducible and constitutive cytochrome P450 isoenzymes and transporters. Placental membrane thickness, which may influence the rate of diffusion, diminishes as gestation progresses[19]; however, the transfer rate of certain simple substances (e.g., glucose, water) differs very little among species, despite significant variations in placental thickness.

Maternal and fetal cellular components can cross the placental barrier by disruption of the trophoblastic layer or by active adhesion and transmigration (similar to blood-brain barrier migration).[20] Fetal cells may be pluripotent, and their DNA can be found in maternal organs for decades. Murine fetal progenitor cells have been found to migrate and assist with maternal wound healing.[21] These microchimeric fetal cells may contribute to maternal immunomodulation, development or worsening of autoimmune diseases (e.g., thyroiditis, lupus, and asthma), and healing of wounds, including neuronal tissue.[22] Placental exosomes, nanovesicles 30 to 100 nm in size found in maternal circulation that contain proteins and transcription-related materials, exert a maternal immunosuppressive effect. Placental microparticles, which are vesicular products of syncytiotrophoblast greater than 100 nm, also contain RNA and DNA fragments and affect fetal and maternal apoptosis, angiogenesis, and inflammation. Syncytial nuclei from the placental villous tree also enter the maternal circulation, reside in the lung, participate in maternal-fetal signaling, and assist in the delivery of retroviral proteins for immunomodulation.[3] An excess of microparticles has been observed in early-onset preeclampsia.

Hormonal Function

A sophisticated transfer of precursor and intermediate compounds in the maternal-fetal-placental unit allows placental enzymes to convert steroid precursors into estrogen and progesterone. This steroidogenic function of the placenta begins very early in pregnancy; by 35 to 47 days after ovulation, the placental production of estrogen and progesterone exceeds that of the corpus luteum (i.e., the ovarian-placental shift).[23]

The placenta also produces and stores a wide array of enzymes, binding proteins, and polypeptide hormones. For example, the placenta produces human chorionic gonadotropin, human placental lactogen (a growth hormone also known as human chorionic somatomammotropin), and factors that control hypothalamic function.[23] Production of proteins and steroid hormones allows the placenta to influence and control the fetal environment.[24]

Regulation of Placental Blood Flow

Maternal Blood Flow

Maternal blood enters the intervillous cotyledon space at a pressure of 70 to 80 mm Hg in an area that has relatively few villi.[15] The pressure and velocity of blood flow rapidly diminishes to 10 mm Hg as blood passes into an area of higher resistance created by the densely packed villi of the placentome.[19]

Fetal Blood Flow

In contrast to the maternoplacental circulation, which relies on vasodilation to increase flow, the increase in fetoplacental blood flow is primarily caused by vascular growth. Fetal perfusion of the placenta is not classically autoregulated; the placental vasculature is not innervated by the sympathetic nervous system. However, the fetus can modulate fetoplacental perfusion via: (1) endocrine effects of adrenomedullin, (2) net efflux/influx of water regulated by fetal blood pressure, and (3) local autoregulatory effects mediated by the paracrine vasodilators nitric oxide and acetylcholine.[25,26] Adrenomedullin release by the fetal adrenal glands assists in maintenance of tone in placental vessels. Fetal blood pressure changes cause net influx/efflux of water across the placenta that affects fetal intravascular volume and perfusion. Maternal hyperglycemia and hypoxemia[27] can alter regional fetal blood flow, probably through vascular mediators. Endothelium-derived relaxing factors, especially prostacyclin[28] and nitric oxide,[29] are important in the control of fetoplacental circulation. Hypoxia-induced fetoplacental vasoconstriction is mediated by a reduction in the basal release of nitric oxide.[30] This vasoconstrictor activity is functionally similar to that found in the lung (i.e., hypoxic pulmonary vasoconstriction) and allows optimal fetal oxygenation through redistribution of fetal blood flow to better-perfused lobules.[27] The placental vasculature constricts in response to graded hypoxia,[31] and may be more dependent upon angiotensin II than catecholamines.[32]

Transport Mechanisms

Substances are transferred across the placenta by one of several mechanisms.

Passive Transport

The passive transfer of molecules across a membrane depends on (1) concentration and electrochemical differences across the membrane, (2) molecular weight, (3) lipid solubility, (4) degree of ionization, and (5) membrane surface area and thickness. Passive transfer is driven principally by a concentration gradient and occurs through the lipid membrane (e.g., lipophilic molecules and water) or within protein channels that traverse the lipid bilayer (e.g., charged substances such as ions).[33] Drugs with a molecular weight less than 600 Da cross the placenta by passive diffusion.[34]

Facilitated Transport

Carrier-mediated adenosine triphosphate (ATP)–independent transport of relatively lipid-insoluble molecules down their concentration gradient is called *facilitated diffusion.* Facilitated diffusion differs from simple diffusion in several ways. Specifically, this mode of transfer exhibits (1) saturation kinetics, (2) competitive and noncompetitive inhibition, (3) stereospecificity, and (4) temperature influences (e.g., a higher temperature results in greater transfer). With *simple diffusion,* the net rate of diffusion is proportional to the difference in concentration between the two sides of the membrane. The rate of transfer is determined by the number of membranous carrier protein complexes and the extent of interaction between the carrier and the substance undergoing transport. This rate limitation is valid for facilitated diffusion only when transmembrane concentration differences are small. At higher concentration gradients, a maximum rate of transfer (V_{max}) is reached; thereafter, further increases in the concentration gradient do not affect the rate of transfer.[33] An example of facilitated diffusion is the transplacental transfer of glucose.

A special type of facilitated diffusion involves the "uphill" transport of a molecule linked to another substance traveling down its own concentration gradient. As such, the transfer is not directly driven by cellular energy expenditure. In most cases, sodium is the molecule that facilitates transport. For the membrane-bound carrier to transfer these molecules, both molecules must be bound to the carrier. This hybrid system is called *secondary active transport* or *co-transport.*[33] The transplacental transport of amino acids appears to occur principally through secondary active transport. Transporters may be affected by disease states (e.g., preeclampsia) or signaling molecules (e.g., elevated steroid levels).[35]

Active Transport

Active transport involves the movement of any substance across a cell membrane requiring energy from ATP hydrolysis. In general, active transport occurs against a concentration, electrical, or pressure gradient. Active transport also requires a protein membrane carrier that exhibits saturation kinetics and competitive inhibition. The best-known example of primary active transport is the translocation of sodium and potassium through the sodium-potassium adenosine triphosphatase (Na^+/K^+ ATPase) pump. Unlike most cell types, the placenta can self-generate creatinine, which assists in the regeneration of ATP and in meeting the high metabolic energy demands of the placenta.[36]

Active transport proteins include P-glycoprotein, breast cancer resistance protein, multidrug resistance protein, and the sodium/multivitamin transporter, as well as the many proteins involved in monoamine transport and xenobiotics.[35] These transport proteins play an important role in protecting the fetus from foreign and potentially teratogenic compounds. Drugs may compete with endogenous compounds of similar shape and charge for active transport.[35] P-glycoprotein transports many lipophilic drugs and antibiotics and removes cytotoxic compounds from the fetus; it exists on the maternal side of the trophoblastic cell membrane of the placenta and prevents compounds such as methadone and saquinavir (a protease inhibitor) from leaving the maternal blood, thus limiting fetal exposure.[37] Inhibition of these transporter proteins (e.g., inhibition of P-glycoprotein by verapamil) can significantly increase the fetal transfer of certain drugs, including midazolam, which is a substrate for P-glycoprotein. DNA transcription of transporters may be induced by drugs or disease states. Expression of transporters may change with gestational age.[38]

Pinocytosis

Pinocytosis is an energy-requiring process in which the cell membrane invaginates around large macromolecules that exhibit negligible diffusion properties. Although the contents of pinocytotic vesicles are subject to intracellular digestion, studies have demonstrated that the vesicles can move across the cytoplasm and fuse with the membrane at the opposite pole. This appears to be the mechanism by which immunoglobulin G is transferred from the maternal to the fetal circulation.

The placenta releases extracellular vesicles of various sizes and functions. Macrovesicles from the syncytiotrophoblast (20 to 500 μm) carry fetal protein, RNA, and other substances; microvesicles from membranes of stressed or apoptotic cells (0.1 to 1 μm) and exosomes (20 to 100 nm) contribute to feto-maternal communication.[39]

Other Factors That Influence Placental Transport

Other factors that affect maternal-fetal exchange include (1) maternal and fetal blood flow, (2) placental binding, (3) placental metabolism, (4) diffusion capacity, (5) maternal and fetal plasma protein binding, and (6) gestational age (the placenta is more permeable in early pregnancy).[40] Lipid solubility, pH gradients between the maternal and fetal environments for some basic drugs ("ion trapping"), and alterations in maternal or fetal plasma protein concentrations found in normal pregnancy[41] and other disease states (e.g., preeclampsia) may also alter net placental transport.

Transfer of Respiratory Gases and Nutrients

Oxygen

The placenta must provide approximately 8 mL O_2/min/kg fetal body weight for fetal growth and development, while adults only require 3 to 4 mL O_2/min/kg at rest.[42] As the "lung" for the fetus, the placenta has only one-fifth the oxygen transfer efficiency of the adult lung.[43] The human lung, with a surface area of 50 to 60 m^2 and a thickness of only 0.5 μm, has a very large oxygen diffusion capacity; in comparison, the placenta has a lower diffusion capacity because of its smaller surface area of 16 m^2 and a thicker membrane of 3.5 μm. Furthermore, 16% of uterine blood flow and 6% of umbilical blood flow are shunted through the placenta.[19]

Oxygen transfer across the placenta depends on the membrane surface area, membrane thickness, oxygen partial pressure gradient between maternal blood and fetal blood, oxygen affinity of maternal and fetal hemoglobin, and

relative maternal and fetal blood flows. As physically dissolved oxygen diffuses across the villous membranes, bound oxygen is released by maternal hemoglobin in the intervillous space and diffuses across the placenta. Several factors affect the fetal blood Po_2 once it reaches equilibration in the villi end-capillaries. First, the concurrent and countercurrent arrangements of maternal and fetal blood flow play a key role for placental oxygen transfer in various species. The almost complete equilibration of maternal and fetal Po_2 values suggests that a concurrent (or parallel) relationship between maternal blood and fetal blood exists within the human placenta (Fig. 4.5),[19,44] although others have described a multivillous, cross-current flow pattern. The functional anatomy of the placenta in many mammals involves more layers than the human placenta; thus, results of animal models can only provide evidence for trends, not values, in humans.

In humans, oxygen solubility is 10^{-4} M in plasma and 10^{-2} M in hemoglobin; thus, 99% of the oxygen content in blood is bound to hemoglobin. With an inspired FiO_2 of 1.0, the maximum maternal arterial Po_2 was 425 mm Hg on 100% O_2, but the fetal umbilical venous (UV) Po_2 was only 47 mm Hg, indicating a low diffusion capacity across the placenta.[45] The placenta receives less than 50% of the fetal cardiac output, and blood returning from the placenta admixes with the nonoxygenated blood in the fetal inferior vena cava, thus limiting fetal arterial Po_2.

Although some have called the human placenta "diffusion limited" because of the decreased ability of oxygen to cross the intervillous membrane, the delivery of oxygen to the fetus is predominantly flow limited. Maternal delivery of blood (i.e., oxygen) to the uterus is the predominant factor controlling fetal oxygen transfer. The high fetal hemoglobin concentration (17 mg/dL) accounts for the large oxygen content and the net delivery of large quantities of oxygen to the fetus. Fetal hemoglobin has a higher oxygen affinity and therefore a lower partial pressure at which it is 50% saturated (P_{50}: 18 mm Hg) than maternal hemoglobin (P_{50}: 27 mm Hg). This gradient produces a "sink" effect that enhances oxygen uptake by fetal red blood cells, keeping fetal Po_2 lower and promoting the transfer of additional oxygen across the placenta (see Fig. 5.7). The **Bohr effect** also augments the transfer of oxygen across the placenta. Specifically, fetal-maternal transfer of carbon dioxide makes maternal blood more acidic and fetal blood more alkalotic. These alterations of pH cause shifts in the maternal and fetal oxyhemoglobin dissociation curves, further enhancing the maternal oxygen transfer to the fetus in what is termed the "double" Bohr effect. This accounts for 2% to 8% of the transplacental transfer of oxygen.[46]

The placenta normally has a 50% reserve for changes in maternal or fetal blood flow by increasing venous extraction, a mechanism similar to that in adults. Based on umbilical venoarterial differences, human fetal oxygen uptake at term is 0.25 mmol/kg/min.[47] The metabolic activity of the placenta itself consumes up to 40% of the oxygen uptake. Placental oxygen consumption is stable, even with changes in maternal blood pressure and Po_2; 30% of placental oxygen is used for protein synthesis and almost 30% for Na^+/K^+ ATPase. The human placenta has a villous structure, which may be an adaptation for greater maternal flow and thus oxygen delivery, but at the expense of a smaller surface area and cross-current exchange mechanism.[48] However, the placenta does change in response to chronic hypoxia found at high altitudes, with an increased capillary volume and decreased capillary thickness providing a near-doubling of the oxygen diffusion capacity.[49]

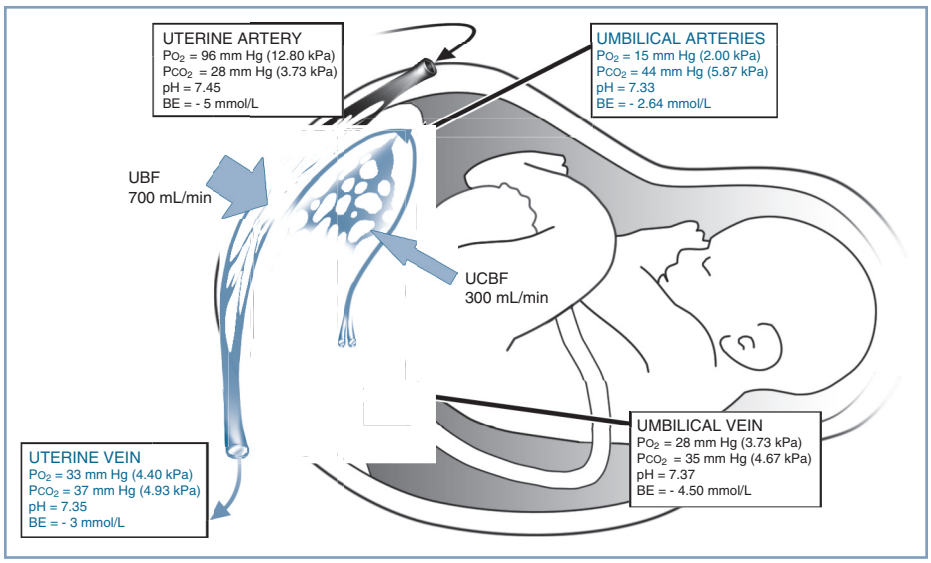

Fig. 4.5 The concurrent relationship between the maternal and fetal circulations within the placenta and the manner in which this arrangement affects gas transfer. These values were obtained from patients' breathing room air during elective cesarean delivery. *BE,* base excess; *Po_2,* partial pressure of oxygen; *Pco_2,* partial pressure of carbon dioxide; *UBF,* uterine blood flow; *UCBF,* umbilical cord blood flow. (Blood gas data from Ramanathan S. *Obstetric Anesthesia.* Philadelphia, PA: Lea & Febiger; 1988:27. Carbon Dioxide

The transfer of CO_2 occurs through a number of different forms, including dissolved CO_2, carbonic acid (H_2CO_3), bicarbonate ion (HCO_3^-), carbonate ion (CO_3^{2-}), and carbaminohemoglobin. Equilibrium between CO_2 and HCO_3^- is maintained by a reaction catalyzed by carbonic anhydrase in red blood cells. The P_{CO_2} gradient between fetal and maternal blood (i.e., 40 versus 34 mm Hg, respectively) drives fetal-maternal transfer. Carbon dioxide is 20 times more diffusible than oxygen and readily crosses the placenta.[50] The rapid movement of CO_2 from fetal capillary to maternal blood invokes a shift in the equilibrium of the carbonic anhydrase reaction (**La Chatelier principle**) that produces more CO_2 for diffusion. The transfer of CO_2 is augmented further by the production of deoxyhemoglobin in the maternal blood, which has a higher affinity for CO_2 than oxyhemoglobin (the **Haldane effect**). The resulting affinity may account for as much as 46% of the transplacental transfer of carbon dioxide.[44] Although a significant fetal-maternal concentration gradient exists for HCO_3^-, its charged nature impedes its transfer and contribution to CO_2 transport except as a source for CO_2 production through the carbonic anhydrase reaction.[51]

Glucose

Placental and fetal glucose demand is fulfilled by a stereospecific-facilitated diffusion system with glucose transporters, such as GLUT1 and GLUT3; the system is independent of insulin, a sodium gradient, or cellular energy.[52] Insulin does not cross the placenta; however, insulin receptors on the maternal side of the syncytiotrophoblast regulate nutrient transport through a signaling cascade involving the mammalian target of rapamycin complex (mTORC). Nutrient sensors for glucose, amino acids, oxygen, cytokines, growth factors, and energy levels stimulate mTORC1, a key sensing and signaling protein in the syncytiotrophoblast that regulates nutrient transport and growth.[53]

Amino Acids

Concentrations of amino acids are highest in the placenta, followed by UV blood and then maternal blood. The maternal-fetal transplacental transfer of amino acids is an active process that occurs principally through a linked translocation with sodium and facilitated diffusion. Pregnancies with fetal growth restriction have reduced amino acid transport with an inability to increase transport despite higher maternal levels of essential amino acids than occur in healthy pregnancies.[54] Fetal growth restriction and hypoxia increase the breakdown of the amino acid tryptophan, which decreases serotonin (vasodilator) production.[55]

Fatty Acids

Free fatty acids readily cross the human, but not ovine, placenta. The essential fatty acids, linoleic and alpha-linolenic acid, are transferred across the placenta with a peak of 7 g/day at term. The placental basal membrane has specific binding sites for very low-density, low-density, and high-density lipoproteins. Lipase activity in the placenta converts triglycerides to nonessential fatty acids. The placenta does not elongate fatty acid chains, whereas the fetus does. Fatty acid transport occurs primarily by simple diffusion; however, fatty acid–binding proteins (FABPpm, FAT/CD36, and FATP), facilitate transport. Nonessential fatty acids are albumin bound and may displace other protein-bound substances, including drugs.[56]

The placenta is a source of fatty acid synthase responsible for straight chain fatty acid catabolism and is regulated by insulin levels. Dysregulation of placental fatty acid synthase may be responsible for hypertension, insulin resistance, and fetal and placental growth abnormalities.[57]

DRUG TRANSFER

Placental permeability and pharmacokinetics determine the fetal exposure to maternal drugs. Animal models (e.g., pregnant ewes, guinea pigs) have been used to assess the placental transport of drugs; however, interspecies differences in placental anatomy and physiology limit the application of these data to humans.[58]

The inaccessibility of the placenta *in situ* and concerns for maternal and fetal safety have limited direct studies of the human placenta. Data regarding the transplacental transfer of anesthetic agents have been extrapolated primarily from single measurements of drug concentrations in maternal and umbilical cord blood samples obtained at delivery. Most studies have reported fetal-to-maternal (F/M) ratios of drug concentration using maternal and umbilical vein blood (to represent fetal blood concentrations). Drug concentrations are influenced by drug metabolism in the mother, the placenta, and the fetus and by changes during delivery (e.g., altered uteroplacental blood flow).[58]

A dual-perfused, *in vitro* human placental model allows for the independent perfusion of the maternal and fetal sides of the placenta and thereby the investigation of maternal-fetal (or fetal-maternal) transport.[58] Equilibration studies (i.e., recirculating maternal and fetal perfusates) can give an indication of final drug ratios; when a non-recirculating design is used, the steady-state clearance of a drug can be determined for either direction (maternal to fetal *or* fetal to maternal). This method has been used to assess the placental transfer of anesthetic agents (e.g., bupivacaine,[59] ropivacaine, alfentanil,[60] and sufentanil[61]). Transfer across the placenta may be reported as drug clearance or as a ratio referred to as the **transfer index** (i.e., drug clearance/reference compound clearance). The use of a transfer index allows for interplacental comparisons by accounting for differences between placentas (e.g., lobule sizes). Commonly used reference compounds are either flow limited (e.g., antipyrine, tritiated water) or membrane limited (e.g., creatinine). These studies have enhanced our understanding of the placental transfer of anesthetic drugs (Box 4.1).

Pharmacokinetic Principles

Factors affecting drug transfer across the human placenta include lipid solubility, protein binding, tissue binding, pK_a,

BOX 4.1 Transplacental Transfer of Anesthetic Drugs

Drugs That Readily Cross the Placenta

Anticholinergic Agents
- Atropine
- Scopolamine

Antihypertensive Agents
- Beta-adrenergic receptor antagonists
- Nitroprusside
- Nitroglycerin

Benzodiazepines
- Diazepam
- Midazolam

Induction Agents
- Propofol
- Ketamine
- Etomidate
- Thiopental
- Dexmedetomidine

Inhalation Anesthetic Agents
- Halothane
- Isoflurane
- Sevoflurane
- Desflurane[a]
- Nitrous oxide

Local Anesthetics

Opioids

Vasopressor
- Ephedrine

Drugs That Do Not Readily Cross the Placenta

Anticholinergic Agent
- Glycopyrrolate

Anticoagulant
- Heparin

Muscle Relaxants
- Succinylcholine
- Nondepolarizing agents

Nondepolarizing Agent Binder
- Sugammadex

Vasopressor
- Phenylephrine

[a]Experimental data for desflurane are lacking, but, based on physical characteristics similar to other halogenated anesthetics, placental transfer is assumed.

pH, and blood flow (Table 4.1). High lipid solubility may readily enable cell membrane (lipid bilayer) penetration but may also cause the drug (e.g., sufentanil) to be trapped within the placental tissue.[61] Highly protein-bound drugs are affected by the concentration of maternal and fetal plasma proteins, which varies with gestational age and disease. Some drugs (e.g., diazepam) bind to albumin, whereas others (e.g., sufentanil, cocaine) bind predominantly to α_1-acid glycoprotein (AAG). Although the free, unbound fraction of drug equilibrates across the placenta, the total drug concentration is greatly affected by both the extent of protein binding and the quantity of maternal and fetal proteins; fetal blood typically contains less than one-half the concentration of AAG than maternal blood (Table 4.2).[62] Albumin binds primarily acidic and lipophilic compounds, whereas AAG binds more basic compounds; fetal levels of both albumin and AAG increase from the first trimester to term.[63]

The pK_a of a drug determines the fraction of drug that is non-ionized at physiologic pH. Thus, fetal acidemia greatly enhances the maternal-fetal transfer (i.e., "ion trapping") of many basic drugs, such as local anesthetics and opioids (Fig. 4.6) (see Chapter 13).[64] Most anesthetic drugs are passively transferred, with the rate of blood flow (hence drug delivery) affecting the amount of drug that crosses the placenta.[65] One of the authors (M.I.Z.) has used the *in vitro* perfused human placenta model to perform a number of studies of the placental transfer of opioids (Table 4.3).

Inhalation Anesthetic Agents

The lipid solubility and low molecular weight of inhalation anesthetic agents facilitate rapid transfer across the placenta. A prolonged induction-to-delivery interval results in greater transfer of inhalation anesthetic agents across the placenta.[66]

Isoflurane distributes rapidly across the placenta during cesarean delivery, resulting in an F/M ratio of approximately 0.71.[67] **Sevoflurane** has an F/M ratio of 0.38[68] and causes dose-dependent vasodilation of placental vessels that is not mediated by nitric oxide.[69] There are no published data regarding the placental transfer of **desflurane.**

Nitrous oxide also rapidly crosses the placenta, with an F/M ratio of 0.83 within 3 minutes.[70] Maternal administration of nitrous oxide decreases fetal central vascular resistance by 30%,[71] and a prolonged induction to delivery interval may cause neonatal depression. Diffusion hypoxia may occur during the rapid elimination of nitrous oxide from the neonate; assessment of oxygenation for any neonate exposed to nitrous oxide immediately before delivery appears prudent.

Following nitrous oxide exposure, patients homozygous for polymorphisms (1298A>C and 677C>T) in the methylenehydrofolate reductase gene *(MTHFR)* have increases in plasma homocysteine levels of up to 76%.[72] Moreover, these genetic polymorphisms can significantly augment the inactivation of methionine synthase[73]; a 1-hour exposure to 50% nitrous oxide can result in an 82% reduction in fetal methionine synthase activity,[74] and a 2-hour exposure can result in epigenetic modifications and decreases in brain-derived neurotrophic factor.[75] Whether fetal exposure to nitrous oxide contributes to adverse effects as a result of inactivation of methionine synthase is not known.[74]

Induction Agents

The lipophilic characteristics that make anesthetic agents ideal for the induction of anesthesia (i.e., ability to cross the blood-brain barrier) also enhance their transfer across the placenta.

Propofol

A 2- to 2.5-mg/kg bolus dose of propofol, the most widely used induction agent for general anesthesia, results in a

TABLE 4.1 Factors Affecting Placental Transfer of Drug (Maternal to Fetal)

	Increased Transfer	Decreased Transfer
Size: molecular weight (Da)	< 1000	> 1000
Charge of molecule	Uncharged	Charged
Lipid solubility	Lipophilic	Hydrophilic
pH versus drug pK_a[a]	Higher proportion of un-ionized drug in maternal plasma	Higher proportion of ionized drug in maternal plasma
Placental efflux transporter[b] proteins (e.g., P-glycoprotein)	Absent	Present
Binding protein type	Albumin (lower binding affinity)[c]	α_1-Acid glycoprotein (AAG) (higher binding affinity)
Free (unbound) drug fraction	High	Low

Da, dalton.
[a]The pH relative to the pK_a determines the amount of drug that is ionized and un-ionized in both maternal and fetal plasma. Fetal acidemia enhances the maternal-to-fetal transfer (i.e., "ion trapping") of basic drugs such as local anesthetics and opioids.
[b]The efflux transporter pumps substances in a fetal-to-maternal direction.
[c]*Note:* albumin concentration is higher in the fetus, and AAG concentration is higher in the maternal circulation.

TABLE 4.2 Concentrations of Proteins That Bind Drugs

	Maternal	Umbilical Cord
Albumin	33.1 g/L	37.1 g/L[a]
$Alpha_1$-acid glycoprotein (AAG)	0.77 g/L	0.26 g/L[a]

[a]$P < .05$.

Clearance index, FTM	0.5	0.91	0.78	0.61	0.76

Clearance index, Clearance drug/clearance antipyrine (a flow-limited reference compound); *FTM,* fetal-to-maternal (direction); *MTF,* maternal-to-fetal (direction); *placenta drug ratio,* placenta drug concentration/g placental tissue/maternal drug concentration.
Data from nonrecirculated experiments, using perfusate Media 199 without protein, with maternal flow 12 mL/min and fetal flow 6 mL/min.[60,61,97,100,104]

mean F/M ratio between 0.65 and 0.85.[76,77] A bolus dose of 2 mg/kg followed by a continuous infusion of 6 mg/kg/h or 9 mg/kg/h of propofol resulted in mean F/M ratios of 0.50 and 0.54, respectively.[78] These F/M ratios are similar to those found when propofol is given in early gestation (at 12 to 18 weeks).[79] Propofol may have sedative effects on the neonate; in a randomized trial of propofol compared with thiopental for the induction of anesthesia for elective cesarean delivery, the maternal administration of propofol (2.8 mg/kg) resulted in lower 1- and 5-minute Apgar scores than thiopental (5 mg/kg).[80] Plasma levels of propofol in the neonate depend on the maternal dose and the time elapsed between drug administration and delivery of the neonate. Maternal propofol administration (2 mg/kg) within 10 minutes of delivery resulted in a mean umbilical vein propofol concentration of 0.32 μg/mL.[81]

Several factors that affect propofol transfer have been investigated with *in vitro* human placental perfusion models.[82–84] Increased maternal blood flow and reduced protein binding increase both placental tissue uptake and transplacental transfer of propofol.[78] Propofol is highly protein-bound to albumin. Thus, altered albumin concentrations in the mother or fetus will affect transplacental transfer and the total, but not free, concentration in the umbilical vein.[84] Propofol causes calcium channel–dependent vasodilation of human placental vessels *in vitro*.[85]

Ketamine

Ketamine, a phencyclidine derivative, rapidly crosses the placenta. Ketamine 2 mg/kg reached a mean F/M ratio of 1.26 in as little as 97 seconds when administered to the mother for vaginal delivery.[86] In a sheep study, fetal concentration was 25% less than maternal concentration at 10 minutes.[87]

Etomidate

Etomidate, a carboxylated imidazole, has long been used for the induction of general anesthesia. A dose of 0.3 to 0.4 mg/kg administered for cesarean delivery resulted in an F/M ratio of approximately 0.5.[88]

Barbiturates

A short-acting agent, **thiopental** quickly appears in UV blood after maternal injection, with a mean F/M ratio of 1.1.[89] The rapid transfer of the oxybarbiturate **methohexital** into the fetal circulation, with simultaneous peak concentrations in maternal blood and fetal blood, has been demonstrated by *in vivo* studies.[90] Human *in vitro* placental perfusion studies with an equal concentration of albumin in the maternal and fetal perfusates confirm that methohexital rapidly crosses the placenta in both maternal-to-fetal and fetal-to-maternal directions, with transfer indices of less than 0.5 at 30 minutes.[91]

Dexmedetomidine

In humans, dexmedetomidine, an α_2-adrenergic agonist, has an F/M ratio of 0.12, with evidence of significant placental tissue binding caused by high lipophilicity.[92]

Benzodiazepines

Highly un-ionized, lipophilic, and 95% protein-bound **diazepam** has an F/M ratio of 1 within minutes of maternal administration and a ratio of 2 at 60 minutes.[93] Less lipophilic, **lorazepam** requires almost 3 hours after administration for the F/M ratio to reach unity.[94] **Midazolam** is more polar, with an F/M ratio of 0.76 at 20 minutes after administration. The F/M ratio of midazolam, unlike that of other benzodiazepines, decreases rapidly; by 200 minutes it is only 0.3.[95]

Opioids

All opioids cross the placenta and can cause neonatal central nervous system and respiratory depression. The extent of placental transfer and duration of effects on the fetal and neonate depend on individual drug characteristics.

Historically, **meperidine** was often administered to mothers for systemic analgesia during labor (see Chapter 22). Intravenous maternal administration results in rapid transfer across the human placenta within 90 seconds.[96] F/M ratios for meperidine may exceed 1.0 after 2 to 3 hours; maternal levels fall more rapidly because of greater metabolism of the drug. This same time interval is associated with the greatest likelihood of neonatal depression, caused by the active drug metabolite normeperidine. Human placental perfusion studies *in vitro* demonstrated rapid placental transfer in both maternal-to-fetal and fetal-to-maternal directions with equal clearance profiles, minimal placental tissue binding, and no placental drug metabolism.[97] As maternal levels fall, the meperidine and normeperidine will transfer from the fetus back to the mother, correlating with the clinically observed decrease in neonatal sedation when delivery occurs more than 4 hours after maternal administration.

Morphine rapidly crosses the placenta with a mean F/M ratio of 0.61 and mean UV concentration of 25 ng/mL, resulting in a significant reduction in the biophysical profile score (primarily decreased fetal breathing and fewer fetal heart rate accelerations) within 20 minutes of maternal administration.[98] Intrathecal morphine results in a high F/M ratio of 0.92, although the absolute fetal concentrations are less than those associated with clinically significant fetal and neonatal side effects.[99] Human placental perfusion studies *in vitro* show that hydrophilic morphine exhibits membrane-limited transfer with a low placental tissue content and a fast washout.[100]

Fentanyl and its analogues have high lipophilicity and albumin binding (74%).[101] Epidural administration results in an F/M ratio between 0.37 and 0.57.[102] During early pregnancy, fentanyl is rapidly transferred and may be detected in the placenta and fetal brain.[103] Perfusion of the human placenta *in vitro* results in rapid bidirectional transfer, with the placenta acting as a moderate drug depot.[104]

Alfentanil has a low F/M ratio of 0.30, yet when given for induction of anesthesia results in a reduction of 1-minute Apgar scores.[105] Perfusion of the human placenta *in vitro* shows rapid and symmetric maternal-fetal and fetal-maternal transfers of alfentanil, with low placental drug uptake and rapid washout.[60]

Compared with fentanyl, **sufentanil** has a higher F/M ratio, 0.81. Higher lipid solubility and more rapid uptake by the central nervous system result in reduced vascular absorption from the epidural space, corresponding with less fetal exposure and risk for neonatal respiratory depression than fentanyl.[102] Human placental perfusion studies *in vitro* have confirmed the rapid transplacental transfer of sufentanil, which is influenced by differences in maternal and fetal plasma protein binding and fetal pH. High placental tissue uptake suggests that the placenta serves as a drug depot.[61]

Remifentanil undergoes rapid placental transfer. During cesarean delivery, average F/M ratios were 0.88 when remifentanil was administered by intravenous infusion (0.1 μg/kg/min) during epidural anesthesia[106] and 0.73 when it was given as a bolus (1 μg/kg) at induction of general anesthesia.[107] Excessive maternal sedation without adverse neonatal effects can occur during labor; the rapid metabolism of remifentanil by nonspecific esterases (context-sensitive half-time of 3 minutes) results in minimal fetal exposure. Remifentanil used for patient-controlled analgesia during labor, with bolus doses of 0.5 μg/kg, resulted in an F/M ratio of approximately 0.5 and a 20% incidence of fetal heart rate changes.[108] Infusion of remifentanil during cesarean delivery for 7 and 18 minutes resulted in F/M ratios of 0.63 and 0.65, respectively.[109] Continuous intravenous infusion compared with patient-controlled intravenous labor analgesia using remifentanil resulted in F/M ratios of 0.74 and 0.70, respectively.[110]

The systemic administration of an opioid agonist/antagonist for labor analgesia has been associated with few maternal, fetal, and neonatal side effects. Both **butorphanol** and **nalbuphine** rapidly cross the placenta, with mean F/M ratios of 0.84 and 0.74 to 0.97, respectively.[111,112] Nalbuphine resulted in "flattening" of the fetal heart rate tracing in 54% of cases. Buprenorphine, a lipophilic opioid agonist/antagonist used to treat opioid use disorder, has lower placental transfer, but greater placental uptake and metabolism, yielding an F/M ratio of 0.1.[112]

Nonopioid Analgesics

Acetaminophen freely crosses the placenta. The fetal liver is a major source of hematopoietic stem cells, and concern has been expressed regarding acetaminophen fetal liver toxicity impairing fetal immune development. In a mouse model, placental function, fetal development, and immune ontogeny were significantly impaired at doses mimicking plasma levels associated with multiple doses in humans.[113]

Local Anesthetics

Local anesthetic agents readily cross the placenta (see Chapter 13).

Muscle Relaxants

As fully ionized, quaternary ammonium salts, muscle relaxants do not readily cross the placenta; however, single doses of muscle relaxants can result in detectable fetal blood concentrations. Maternal administration of muscle relaxants for the induction of general anesthesia for cesarean delivery rarely affects neonatal muscle tone at delivery.

Succinylcholine is not detectable in UV blood at delivery after maternal doses less than 300 mg.[114] Neonatal neuromuscular blockade can occur when high doses are given repeatedly or when both the parturient and fetus are homozygous for atypical pseudocholinesterase deficiency.[115]

Nondepolarizing muscle relaxants have low F/M ratios: **pancuronium** (0.2),[116] **vecuronium** (0.06 to 0.11),[116,117] **rocuronium** (0.16),[118] and **atracurium** 0.07).[119] The F/M ratio of vecuronium nearly doubled as the induction-to-delivery interval increased from 180 to 420 seconds.[117] No published study has investigated the placental transfer of the atracurium isomer **cisatracurium.** However, laudanosine, a metabolite of atracurium and cisatracurium, has an F/M ratio of 0.14.[120] Although nondepolarizing muscle relaxant transfer rates are low, the fetal blood concentrations increase over time.[117]

Anticholinergic Agents

The placental transfer of anticholinergic agents correlates with their ability to cross the blood-brain barrier. **Atropine** is detected in the umbilical circulation within 1 to 2 minutes of maternal administration, and an F/M ratio of 0.93 is attained at 5 minutes.[121] **Scopolamine** also crosses the placenta easily; intramuscular administration results in an F/M ratio of 1.0 within 55 minutes.[122] By contrast, after intramuscular administration **glycopyrrolate** is poorly transferred across the placenta, with a mean F/M ratio of 0.22.[123] Maternal intravenous administration of glycopyrrolate does not result in a detectable fetal hemodynamic response, whereas atropine and scopolamine may directly increase fetal heart rate.

Anticholinesterase Agents

Neostigmine, pyridostigmine, and **edrophonium** are quaternary ammonium compounds that are ionized at physiologic pH and consequently undergo limited transplacental transfer.[124] Maternal administration of neostigmine does not reverse atropine-induced fetal tachycardia. However, small amounts of these agents do cross the placenta, and fetal bradycardia after maternal administration of neostigmine and glycopyrrolate has been reported.[125] Neostigmine may cross the placenta to a greater extent than glycopyrrolate; therefore, the combination of neostigmine and atropine should be considered for the reversal of nondepolarizing muscle relaxants in pregnant patients.[125] **Physostigmine** crossed the placenta in 9 minutes and reversed the fetal heart rate effect of scopolamine.[126]

Sugammadex

Sugammadex, which directly binds and reverses the neuromuscular blockade of steroidal muscle relaxants, has low placental transfer rates because of its molecular structure and high molecular weight.[127]

Antihypertensive Agents

Beta-adrenergic receptor antagonists have been commonly used as antihypertensive agents in pregnancy, despite early

investigations noting an association with fetal growth restriction and neonatal bradycardia, hypoglycemia, and respiratory depression.[128] Although a single dose of **propranolol** administered 3 hours before cesarean delivery has a F/M ratio of 0.26,[129] long-term administration during pregnancy results in F/M ratios greater than 1.0.[130] Maternal administration of **atenolol** and **metoprolol** leads to mean F/M ratios of 0.94 and 1.0, respectively.[131,132]

Labetalol, the most commonly used antihypertensive agent during pregnancy, particularly for women with preeclampsia, has a low F/M ratio of 0.38 with long-term oral administration, despite reports of mild neonatal bradycardia.[133] Beta-adrenergic receptor antagonist use during pregnancy, including labetalol, approximately doubles the risks for small-for-gestational-age, preterm births, and perinatal mortality even after adjusting for preeclampsia.[134] Preterm hypertensive women receiving labetalol had no acute change in umbilical artery or fetal middle cerebral resistance indices of flow.[135]

The ultra-short-acting beta-adrenergic receptor antagonist **esmolol** has a mean F/M ratio of 0.2 in gravid ewes.[136] However, fetal bradycardia requiring emergency cesarean delivery has been reported after its use to treat maternal tachydysrhythmia.[137]

Clonidine and **methyldopa** act through the central stimulation of alpha$_2$-adrenergic receptors; studies have reported mean F/M ratios of 0.89[138] and 1.17,[139] respectively. Therapeutic **magnesium** and **nifedipine** serum concentrations, but not clonidine, produce fetal vasodilation in human placental perfusion studies *in vitro.*[140] **Phenoxybenzamine**, an alpha-adrenergic receptor antagonist, has an F/M ratio of 1.6 with long-term maternal administration.[141]

Direct-acting vasodilators are used for short-term management of severe hypertension in pregnant women. With an F/M ratio of 1.0,[142] **hydralazine** increases the umbilical artery resistance index, indicating vasodilation, in hypertensive women,[135] and causes fetal vasodilation in *in vitro* studies.[143]

Sodium nitroprusside is lipid soluble, rapidly crosses the placenta, and can produce cyanide as a byproduct.[144] Sodium thiosulfate, the agent used to treat cyanide toxicity, does not cross the placenta in gravid ewes; however, it can be used to treat fetal cyanide toxicity by lowering maternal cyanide levels, thereby enhancing fetal-maternal transfer.[145]

Nitroglycerin crosses the placenta to a limited extent, with an F/M ratio of 0.18, and results in minimal changes in fetal umbilical blood flow, blood pressure, heart rate, and blood gas measurements in gravid ewes.[146] However, dinitrate metabolites found in both maternal and fetal venous blood indicate the capacity for placental biotransformation.[147] Indeed, placental tissue production of nitric oxide enhances the uterine relaxation caused by nitroglycerin *in vivo.*[148] In one *in vitro* study, in which prostaglandin $F_{2\alpha}$ induced fetal vasoconstriction, the following order of nitrovasodilator compound potency was observed: nitroglycerin ≥ sodium nitroprusside ≥ sodium nitrite ($NaNO_2$) ≥ S-nitroso-*N*-acetylpenicillamine (SNAP) = S-nitroso-*N*-glutathione (SNG).[149] SNG and $NaNO_2$ were significantly more potent under conditions of low oxygen tension. The antioxidants cysteine, glutathione, and superoxide dismutase significantly enhanced the vasodilatory effects of $NaNO_2$ only.[149]

Placental transfer of angiotensin-converting enzyme inhibitors may adversely affect fetal renal function. **Enalaprilat** rapidly crosses the placenta, and its maternal administration in high doses resulted in a 20% reduction in fetal arterial pressure in rhesus monkeys.[150]

Vasopressor Agents

Vasopressor agents are often administered to prevent or treat hypotension during the administration of neuraxial anesthesia in obstetric patients. **Ephedrine** readily crosses the placenta and results in an F/M ratio of 0.7.[151] In an *in vitro* human perfusion model that required supraphysiologic doses to obtain any effect, **phenylephrine** increased placental arterial pressure, but less so than ephedrine, whereas **epinephrine**, **norepinephrine**, and **methoxamine** had no effect.[152]

Ephedrine possesses 10 times greater lipid solubility than phenylephrine, with F/M ratios of 1.1 versus 0.17, respectively, in humans.[153] When administered during spinal anesthesia for cesarean delivery, ephedrine demonstrated lower pH and base excess, higher P_{CO_2}, and higher glucose, lactate, epinephrine, and norepinephrine concentrations in umbilical arterial blood than phenylephrine.[153] These differences may be caused by the beta-adrenergic agonist effects of ephedrine in the fetus.[153,154]

Cocaine, a common drug of abuse during pregnancy (see Chapter 53), has potent vasoconstrictor activity. Human placenta perfusion studies *in vitro* demonstrated rapid bidirectional transfer of cocaine, over a wide range of concentrations.[155] The active cocaine metabolites norcocaine and cocaethylene, but not the inactive metabolite benzoylecgonine, are also rapidly transferred.[156] Chronic maternal exposure to cocaine increases fetal concentrations; however, they remain lower than peak maternal levels.[157]

Several experiments have demonstrated the complexity of the placental and fetal effects of vasoconstrictor administration. Increasing fetal placental perfusion pressure with vasoconstrictors can cause a shift of fluid from the fetus to the maternal circulation.[158] In an *in vitro* experiment comparing the responses of placental and umbilical vessels, placental vessels responded to angiotensin II but not phenylephrine, whereas the opposite was observed with umbilical vessels.[32] The response of placental vessels to angiotensin II from women with preeclampsia was diminished compared with vessels from women without preeclampsia[32]; these findings suggest that angiotensin II may serve to maintain vascular tone in the healthy placenta. Infusion of placental growth factor (PlGF) enhanced endothelial nitric oxide-cGMP vascular relaxation and decreased vasoconstriction-induced hypertension in pregnant rats.[159]

Anticoagulants

Anticoagulation therapy is often necessary during pregnancy. Maternal administration of **warfarin** in the first trimester

results in placental transfer to the fetus, causing a higher rate of fetal loss and congenital anomalies.[160] After the first trimester, warfarin may be used in the setting of stroke or mechanical heart valves.[161] In contrast, **heparin** does not appear to cross the placenta, as measured by neonatal coagulation studies and the measurement of radiolabeled heparin in fetal lambs.[162] **Low-molecular-weight heparin** appears to have limited placental transfer. Maternal administration of **enoxaparin** does not alter fetal anti-IIa or anti-Xa activity,[163] and *in vitro* studies found no placental transfer of enoxaparin and **fondaparinux** (a pentasaccharide that selectively inhibits factor Xa). In contrast, **apixaban** exhibited rapid transfer (F/M 0.77) in an *ex-vivo* human placenta cotyledon model,[164] and **rivaroxaban** also rapidly crossed the placenta.[165] Several case reports discussed use of direct thrombin inhibitors as early as 9 weeks' gestation with successful delivery of healthy neonates.[166,167] Antiplatelet therapy (e.g., **aspirin, clopidogrel**) has been used successfully in the first trimester in dual therapy for coronary artery disease in the setting of drug-eluting stents.[168] **Abciximab,** a glycoprotein IIb/IIIa platelet inhibitor, did not transfer across the *in vitro* perfused human placenta, but did bind to the trophoblastic layer of the placenta.[169] **Dabigatran,** a reversible thrombin inhibitor, crosses the placenta with an F/M ratio of 0.33 at 3 hours.[170]

Drug Delivery Systems

New drug delivery systems may influence drug transfer and distribution across the human placenta. Liposome encapsulation, depending on the type and ionic charge, can affect placental transfer; anionic and neutral liposomes increase placental transfer, whereas cationic liposomes decrease placental transfer and placental tissue uptake.[171] Liposome encapsulation of valproic acid significantly reduces drug transfer and placental uptake.[172]

The increased use of nanoparticles creates concern for maternal and fetal exposure. The size, charge, and physiochemical properties of nanoparticles influence placental absorption and transfer. The polystyrene particles associated with these compounds have accumulated in the syncytiotrophoblast, presumably via an energy-dependent transport mechanism.[173] Nanoparticles 20 to 40 nm in diameter have induced trophoblast cell apoptosis; nanoparticles up to 500 nm in diameter can be measured in various fetal tissues 4 hours after administration to pregnant mice.[174]

Disease States

Disease states, such as diabetes, may affect the placental transfer of drugs. **Glyburide,** a second-generation sulfonylurea, is partially dependent on a P-glycoprotein active transport mechanism and demonstrates a lower F/M ratio (0.3) than the first-generation agents, even in the presence of a P-glycoprotein inhibitor.[175] A high level of protein binding (99.8%) may also contribute to the low transplacental transfer of glyburide; when protein levels are reduced *in vitro,* higher transfer rates are observed.[176] The thickened placenta found in diabetic patients may cause low transfer rates; however, no difference in maternal-fetal transfer of **metformin** has been observed between placentas from parturients with gestational diabetes and those from healthy parturients.[177]

Gestational age may alter placental transfer, although the direction of the alteration requires further evaluation. Although traditional belief holds that placentas from younger fetuses are more likely to transfer substances, one study has demonstrated that **methadone** transfer is 30% lower in human preterm placentas than in term placentas.[178] **Dexamethasone** and **betamethasone,** corticosteroids that are often administered to accelerate fetal lung maturity, increase *ABCB1* gene expression fourfold. ABCB1 is an efflux transporter protein; hence increased gene expression may increase fetal-maternal transfer of substrate molecules.[179]

Oxidative stress increases in preeclampsia, fetal growth restriction, and diabetes. The placenta does not have protective mechanisms to counteract oxidative stress, which damages the ability of syncytiotrophoblast mitochondria to generate energy.[180] Oxidative stress also alters nutrient transport because of increased membrane permeability and an inability to accumulate glucose.[181]

Nitrative stress, the covalent modification of proteins and DNA by peroxynitrite (formed by nitric oxide reacting with superoxide), may also affect maternal-fetal transfer.[182] Peroxynitrite reacts with tyrosine to form nitro-tyrosine, a negatively charged group, which may mimic phosphorylation. Nitration may result in loss or gain of protein function.

Chronic maternal stress increases maternal and fetal norepinephrine levels; transfer of maternal norepinephrine to the fetus may be limited by a reduction in the placental norepinephrine transporter (NET).[183] In the setting of preeclampsia, placental expression of NET is low, which may cause decreased trophoblast cell invasion during placental development.[184] By contrast, NET expression is increased when norepinephrine levels are reduced with metformin.[185]

Pravastatin may be protective of the endothelial layer of the placenta through proangiogenic, anti-inflammatory, antioxidant, and antithrombotic effects. *Ex-vivo* human studies did not demonstrate placental transfer; however, under hypoxic conditions pravastatin did decrease sFlt-1.[186]

Vitamin D helps modulate cytokines, inflammation, and insulin sensitivity, and a deficiency leads to increased risk for gestational diabetes, preeclampsia, and preterm delivery.[187]

Infection and Inflammation

Infections can alter placental perfusion, function, and transfer of medications. Viruses and bacteria may infect the placenta or uterine decidua by ascending from the reproductive tract or through the maternal bloodstream (see Chapter 36). Some viruses are infectious at a specific gestational age range because different cell types variably express surface receptors/proteins that viruses use as entry points into the cell.[188] Even in the absence of direct placental or fetal infection, placental function and neonatal outcomes may be altered in the presence of viruses.[188] Infections early in pregnancy may alter the invasive extravillous trophoblast, resulting in pregnancy complications

related to decreased placental perfusion (e.g., fetal growth restriction, preeclampsia). Viruses producing placental and/or fetal alterations include cytomegalovirus, varicella, measles, herpes simplex viruses 1 and 2, and the Zika and Lassa viruses.

Zika virus, transmitted via Aedes mosquitos or sexual transmission, may produce placental alterations, fetal damage, and microcephaly. The virus uses cell surface proteins such as glycoprotein T1M1 (expressed during mid- to late gestation by the syncytiotrophoblast and Hofbauer cells) and the TAM kinase receptors to invade the cell; HSV-2 co-infection can enhance expression of TAM receptors. Zika virus infection induces apoptosis of trophoblasts in the first trimester, and produces enlarged, hydropic chorionic villi, immature villi, and proliferation of Hofbauer cells (fetal macrophages), but no villous necrosis.[189]

Maternal inflammation can also affect placental function and result in increased risk for neurodevelopmental disorders later in life for offspring. In mid- to late pregnancy, maternal inflammation results in up-regulation of tryptophan hydroxylase-1 (TPH1), which causes a sustained increase in fetal 5-hydroxytryptamine (serotonin) in the fetal forebrain.[190] Because serotonin modulates key neurodevelopmental processes, including axon development, prenatal inflammation may lead to increased anxiety and depression in the offspring.

The placenta may be involved in sterile inflammation and the development of gestational vascular disease.[39] Placental inflammation alters drug transfer by increasing the ATP-binding cassette transporters, multidrug resistance protein 1 (MDR1) and breast cancer resistance protein (BCRP).[39] Perinatal inflammation may be associated with poorer neurodevelopmental outcomes after birth[191]; N-acetylcysteine (NAC) has been used for neuroprotection during chorioamnionitis in humans,[192] with preservation of fetal cerebrovascular coupling, and lipopolysaccharide-induced neonatal brain injury in rats.[193]

PLACENTAL PATHOLOGY

There has been a growing interest in the clinicopathologic correlation between placental abnormalities and adverse obstetric outcomes. In some cases, a skilled and systematic examination of the umbilical cord, fetal membranes, and placenta may provide insight into antepartum pathophysiology; in most of these cases, examination of the placenta confirms the clinical diagnosis (e.g., chorioamnionitis). Drugs, inflammation, and infection may produce placental abnormalities (e.g., cocaine causes chorionic villus hemorrhage and villous edema).[194] The significance of many findings (e.g., villous edema, hemorrhagic endovasculitis, chronic villitis), however, is unclear.

KEY POINTS

- The placenta is a dynamic organ with a complex structure. It brings two circulations close together for the exchange of blood gases, nutrients, and other substances (e.g., drugs).
- During pregnancy, anatomic adaptations result in substantial (near-maximal) vasodilation of the uterine spiral arteries; this leads to a low-resistance pathway for the delivery of blood to the placenta. Therefore, adequate uteroplacental blood flow depends on the maintenance of a normal maternal perfusion pressure.
- Placental transfer involves all of the physiologic transport mechanisms that exist in other organ systems.
- Physical factors (e.g., molecular weight, lipid solubility, degree of ionization) affect the placental transfer of drugs and other substances. In addition, other factors affect maternal-fetal exchange, including changes in maternal and fetal blood flow, placental binding, placental metabolism, diffusion capacity, and extent of maternal and fetal plasma protein binding.
- Lipophilicity, which enhances the central nervous system uptake of general anesthetic agents, also heightens the transfer of these drugs across the placenta. However, the placenta itself may take up highly lipophilic drugs, thereby creating a placental drug depot that limits the initial transfer of drug.
- Fetal acidemia can result in the "ion trapping" of both local anesthetics and opioids.
- Vasoactive drugs cross the placenta, may affect the fetal circulation, and may have effects on fetal metabolism.
- Inflammation and infection may affect placental function and transport across the placenta.
- Environmental factors influence epigenetic expression of genes, placental development, and fetal phenotypes.

Fetal Physiology

Mieke Soens, MD, Lawrence C. Tsen, MD

CHAPTER OUTLINE

Fetal life *in utero* differs significantly from postnatal life. The fetus relies completely on the mother and the placenta for basic metabolic needs such as nutrient delivery, gas exchange, acid-base balance, and electrolyte homeostasis. During gestation, the fetus gradually assumes the responsibility for many of the vital physiologic functions that must be assumed after the abrupt transition to physiologic independence at birth. Knowledge of fetal physiology, and the timing associated with these developmental changes, is necessary for the optimal provision of analgesia and anesthesia during pregnancy and childbirth.

FETAL ENVIRONMENT

Amniotic Fluid

The fetus is surrounded by amniotic fluid, a complex fluid that changes as the pregnancy progresses. Amniotic fluid serves a number of vital roles, including the facilitation of fetal growth, the provision of a microgravity environment that cushions the fetus, and the generation of a defense mechanism against invading microbes.[1] The formation and maintenance of amniotic fluid is an intricate process that depends on fetal maturation and maternal hydration, hormonal status, and uteroplacental perfusion.

Amniotic fluid during early embryogenesis is principally derived from maternal plasma by the passage of water and solutes through aquaporin water channels expressed in the fetal maternal membranes (amnion and chorion). The expression of aquaporins changes as gestation advances and with certain pathologic states, such as polyhydramnios.[2] Between 10 and 20 weeks' gestation, the volume of amniotic fluid increases in a predictable and linear manner from approximately 25 mL to 400 mL. During this period, the composition of amniotic fluid is similar to fetal extracellular fluid, owing to the absence of keratin in the fetal skin. After this period, the volume of amniotic fluid is a function of production, from fetal urine (600 to 1200 mL/day near term) and respiratory tract secretions (60 to 100 mL/kg fetal body weight/day), and removal through fetal swallowing (200 to 250 mL/kg fetal body weight/day).[3] Amniotic fluid volume is also influenced by intramembranous (between amniotic fluid and fetal blood within the placenta) and transmembranous (between amniotic fluid and maternal blood within the uterus) pathways in both physiologic and pathophysiologic states.[4] Finally, the status of maternal hydration and the amount of decidual prolactin may alter the transfer of amniotic fluid through fetal and maternal tissues. Amniotic fluid volume plateaus at 800 mL at around 28 weeks' gestation, after which it declines to approximately 400 mL at term.[3]

The *composition* of amniotic fluid undergoes more marked variation than its volume.[5] During the first trimester, amniotic fluid consists mostly of water and electrolytes and contains minimal protein. Keratinization of the fetal skin is complete by 25 weeks' gestation and decreases the permeability of fetal tissues to water and solutes. The impact of this process, coupled with the ability of the fetal kidneys to

produce urine, results in increased amniotic fluid concentrations of urea and creatinine, decreased concentrations of sodium and chloride, and reduced osmolality. By term, the osmolality of amniotic fluid is about 85% to 90% that of maternal serum.[5] A variety of carbohydrates, proteins, lipids, electrolytes, enzymes, and hormones, which vary in concentration depending on the gestational age, are also present; some of these elements, particularly the amino acids taurine, glutamine, and arginine, serve a nutritive function for mitotic cells involved in trophoblastic growth and placental angiogenesis.[1] An abundance of growth factors are found in amniotic fluid, including epidermal growth factor, transforming growth factor-alpha, transforming growth factor-beta 1, insulin-like growth factor-1, erythropoietin, and granulocyte colony-stimulating factor; many of these growth factors play an important role in fetal intestinal development.[1]

Antimicrobial defenses within the amniotic fluid are primarily composed of humoral mediators such as alpha-defensins, which are released from neutrophils, especially in the setting of preterm labor and/or chorioamnionitis. Other humoral mediators include lactoferrin, calprotectin, leukocyte protease inhibitor, and cathelicidin, which have significant activity against bacteria, viruses, and fungi.[6] Cellular mediators of the immune response are poorly characterized in amniotic fluid, and it remains unclear if the macrophages that are present serve a scavenging or an antimicrobial role. Neutrophils are usually absent from the amniotic fluid of a healthy fetus, and their presence typically signifies an inflammatory or infectious process.[1]

Biochemical and cellular analyses of amniotic fluid provide valuable information on chromosomal abnormalities, neural tube defects, prenatal infections, and most inborn errors of metabolism.[7,8] Several amniotic fluid–based indices, including the lecithin-sphingomyelin ratio, the phosphatidylglycerol level, lamellar body count, surfactant-to-albumin ratio, and electrical conductivity, are commonly used to assess fetal lung maturity.[9,10] Bilirubin levels can be determined by measuring the optical density of amniotic fluid, which assists in the monitoring of fetal hemolysis. Estimation of the amniotic fluid levels of S100-beta (a protein released from injured astrocytes) and cell-free fetal nucleic acids may serve as early screening tests for perinatal neurologic damage and fetal development, respectively.[11,12] Finally, amniotic fluid is a valuable reservoir for cell types of multiple lineages at different maturational ages; approximately 1% of these cells are pluripotent, thereby representing a novel source of stem cells.[13,14]

Oxygen Supply and Transport

The fetus has almost no oxygen reserve and depends on maternal sources of oxygen delivery. Acute hypoxia can have immediate, severe consequences, such as perinatal death, hypoxic encephalopathy, and cerebral palsy. Chronic reductions of oxygen supply often lead to fetal growth restriction and may have long-term consequences for brain, heart, and kidney function through epigenetic changes. Hypoxia-inducible factors (HIFs) act on specific signaling pathways that modify target gene expression. When hypoxia occurs during critical periods of heart development, apoptosis of cardiomyocytes can result, leading to a myocardium that is less resilient to ischemic insults in later life. In addition, chronic hypoxia can influence fetal development of brain and kidney function and metabolism, subsequently leading to problems in adulthood.[15,16]

Oxygen is an essential substrate for cell survival, because it serves as the final electron acceptor in the electron transport chain. When oxygen is scarce, the electron transport chain is compromised, resulting in decreased oxidative phosphorylation and adenosine triphosphate (ATP) production.[17] Hypoxia ensues when the demand for oxygen exceeds the available supply. In adult tissues, hypoxia occurs at oxygen tensions < 20 mm Hg (2.7 kPa) (normal, 40 mm Hg [5.3 kPa]). By contrast, in fetal tissues, hypoxia occurs at oxygen tensions < 17 mm Hg (2.3 kPa) (normal, 20 to 25 mm Hg [2.7 to 3.3 kPa]).[18,19] This implies that the environment for fetal development exhibits a smaller margin of safety before reaching a state of oxygen insufficiency and highlights the importance of maintaining adequate uteroplacental perfusion and fetal cardiac output to ensure fetal oxygen delivery. Ultimately, oxygenation of fetal tissues depends principally on the partial pressure of oxygen gradient between maternal and fetal blood and the different types of hemoglobin that exist in maternal and fetal blood.

Placental oxygen concentrations change with gestation. In early pregnancy, the placental intervillous space is free of maternal blood cells, thereby requiring the embryo to rely on endometrial secretions and maternal plasma for its energy requirements.[20,21] The first trimester placenta has (1) an oxygen partial pressure (Po_2) of approximately 20 mm Hg (2.7 kPa); (2) only a few capillaries, which are located mainly in the center of the mesenchymal core; and (3) a trophoblastic layer that is twice the thickness of that in the second trimester.[22] Moreover, the fetal red blood cells are nucleated, and the exocoelomic cavity contains antioxidant molecules instead of an oxygen transport system. These anatomic and physiologic features, which limit the transfer of oxygen and the creation of free radicals, protect the highly sensitive embryo from the effects of oxidative stress and keep the embryonic cells in their pluripotent state.[23,24] At the end of the first trimester, an exponential increase in fetal growth creates significant demands for oxygen and nutrients (Fig. 5.1). In response, cytotrophoblastic cells interact with the smooth muscle of maternal spiral arteries, resulting in vessel dilation and the provision of oxygen-rich maternal blood flow to the placenta (Fig. 5.2).[25]

The placenta acts as both a conduit and consumer of oxygen. The placenta is metabolically active and performs important roles in carbohydrate and amino acid metabolism, protein synthesis, and substrate transport. Almost 40% of the oxygen delivered to the pregnant uterus is needed to support the metabolic processes of the placenta.[26] During periods of hypoxia, the placenta appears to alter its metabolism to diminish its consumption of oxygen, most likely by increasing glycolysis.[27,28] This process can maintain fetal oxygen supply but, if hypoxia is ongoing, fetal growth restriction (also known as intrauterine growth restriction) may result.

When the oxygen supply is compromised, the fetus shunts blood flow from peripheral tissues to vital organs (see later discussion), converts to greater use of anaerobic pathways, and induces gene expression that enables improved survival in a low-oxygen environment.[17] The presence of fetal hemoglobin (hemoglobin F), with its higher concentration (approximately 18 g/dL) and greater affinity for oxygen than adult hemoglobin (see later discussion), results in a fetal arterial blood oxygen content that is only marginally lower than that in the adult, despite a lower oxygen tension.[29]

Shunting the intervillous space: new concepts in human uteroplacental vascularization. *Am J Obstet Gynecol*. 2005;192:323–332.)

Glucose and Lactate Metabolism

Glucose is the primary substrate for energy production in the fetus. Under normal conditions, gluconeogenesis is absent in mammalian fetuses; the only source of glucose is that which is transferred across the placenta.[30] Glucose uptake into fetal tissues is regulated by glucose transporters (GLUT) of which the expression increases or decreases in response to acute and chronic changes in fetal glucose concentration.[31] Fetal glucose concentration is linearly related to maternal concentration over a range of 3 to 5 mmol/L (54 to 90 mg/dL; Fig. 5.3); studies in isolated placentas suggest that this relationship continues up to a glucose concentration of 20 mmol/L (360 mg/dL).[32] The placenta uses the majority of glucose delivered to the uterus for oxidation, glycogen storage, and conversion to lactate, with the remainder being transferred to the umbilical venous blood by facilitated, carrier-mediated diffusion. The amount of glucose supplied to the fetus appears more than adequate during normal conditions; ovine uterine blood flow must be reduced by greater than 50% before a decrease in fetal glucose uptake or fetal arterial glucose concentration is observed.[33,34]

The umbilical cord blood glucose uptake is approximately 5 mg/kg/min at normal maternal arterial plasma glucose concentrations.[35] Because the umbilical glucose/oxygen quotient varies from approximately 0.5 in sheep[36] to 0.8 in human fetuses during labor,[37] it is assumed that substrates

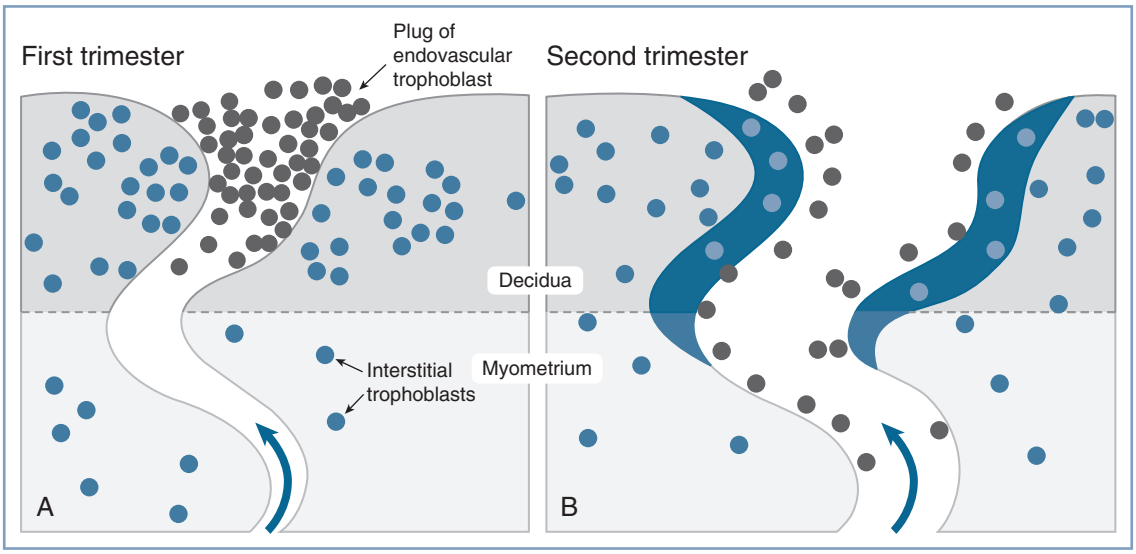

Fig. 5.2 Invasion and remodeling of the spiral arteries by endovascular and interstitial extravillous trophoblasts. (A) In the first trimester, the terminal portion of the spiral artery is blocked by a plug of endovascular trophoblast. Early placental and embryonic development occurs in a state of low oxygen tension, and nutrition at this early stage is derived from secretions from maternal endometrial glands. (B) After 10 to 12 weeks' gestation, the endovascular trophoblast plug dissolves and the endovascular trophoblast migrates into the myometrium, replacing endothelial cells, which undergo apoptosis. Maternal blood is now able to enter the intervillous space, the oxygen tension increases to 60 mm Hg, and nutrition changes from histotrophic to hemotrophic. (Modified from Pijnenborg R, Vercruysse L, Hanssens M. The uterine spiral arteries in human pregnancy: facts and controversies. *Placenta*. 2006;27:939–958.)

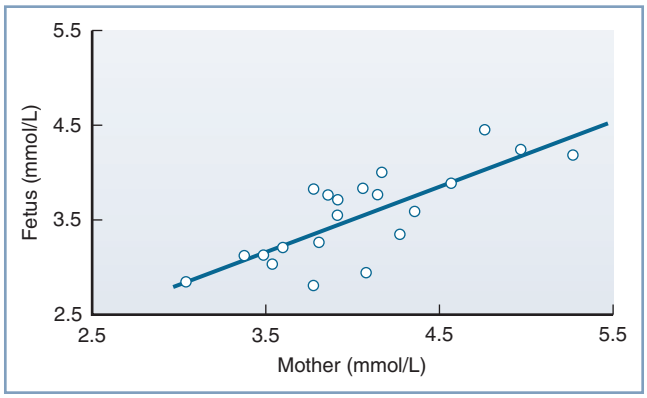

Fig. 5.3 The linear relationship between maternal and fetal blood glucose concentrations during the third trimester. Fetal blood was obtained by percutaneous umbilical cord blood sampling. (From Kalhan SC. Metabolism of glucose and methods of investigation in the fetus and newborn. In Polin RA, Fox WW, eds. *Fetal and Neonatal Physiology*. Vol I. Philadelphia, PA: WB Saunders; 1992:477–488.)

other than glucose are used to support fetal oxidative metabolism; it is estimated that lactate and amino acids provide approximately 25% each of the total fetal energy requirements.[38,39]

Lactate is produced even in well-oxygenated fetal lambs, with total lactate production being approximately 4 mg/kg/min.[40] Although the exact origin of fetal lactate is unclear, skeletal muscles and bones have been identified as sources of lactate production under resting conditions. Lactate production increases during episodes of acute hypoxemia, although this response may be blunted in fetuses previously exposed to oxidative stress.[41] Lactate consumption occurs in the fetal myocardium and liver.[42] Short-term exogenous lactate infusion in fetal lambs (sufficient to lower the pH to 7.20) results in transient fetal bradycardia and increased fetal breathing movements but no other adverse effects.[43]

Amino Acid and Lipid Metabolism

The fetus uses amino acids for protein synthesis, growth, and oxidation. Most maternal-to-fetal amino acid transfer occurs against a concentration gradient and involves energy-dependent transfer mechanisms. Under conditions in which fetal aerobic metabolism is decreased, amino acid uptake by the placenta and fetus may be reduced because it involves an expenditure of energy. Hypoxia results in a large reduction in nitrogen uptake in fetal lambs.[44] During maternal fasting, fetal amino acid uptake does not change; however, enhanced fetal proteolysis may occur, which subsequently results in amino acid oxidation or gluconeogenesis.

Lipid products are transferred from the mother to the fetus. The fetus requires free fatty acids for growth, brain development, and the deposition of body fat for postnatal life. Fatty acids are transferred across the placenta by simple diffusion. Ketones are also transferred by simple diffusion; in humans, the maternal/fetal ketone ratio is approximately 2.0.[45] The fetus can use ketones as lipogenic substrates or as energy substrates in the brain, kidney, heart, liver, and placenta.[46] Beta-hydroxybutyrate (fatty acid) metabolism can occur in the placenta, brain, and liver during episodes of fetal hypoglycemia that result from maternal fasting.[46] Cholesterol synthesis or free cholesterol diffusion does not appear to occur in the placenta.[47] However, there is a significant correlation between maternal and fetal concentrations of lipoprotein(a), implying that diffusion of lipoprotein(a) may occur.[47]

Thermoregulation

Intrauterine fetal temperature largely depends on maternal temperature. However, owing to the high metabolic rate in the fetus, the net flow of heat is from the fetus to the mother. Compared with the mother during the third trimester, the fetus produces approximately twice as much heat (on a weight-adjusted basis) and maintains a temperature 0.5° C higher.[48,49] This maternal-fetal difference in temperature remains relatively constant and is referred to as the "heat clamp."[50]

The placental circulation is responsible for approximately 85% of the heat exchange between the mother and fetus. The remaining 15% is dissipated through the fetal skin and transferred through the amniotic fluid and the uterine wall to the maternal abdomen.[51] As a consequence, fetal temperature may be rapidly affected by changes in umbilical blood flow; fetal temperatures rise quickly on occlusion of umbilical blood flow in both baboons and sheep.[52,53] In humans, fetal temperatures increase during uterine contractions, which may be a result of intermittent obstruction of umbilical cord blood flow.[54] Whether this rise in fetal temperature contributes to acute hypoxic-ischemic brain damage in the setting of umbilical cord prolapse is currently unknown. However, relatively small increases in temperature increase the sensitivity of the fetal brain to hypoxic injury.[55]

The fetus generates heat through high metabolic activity, as thermogenic mechanisms are not developed until the end of gestation and thus largely inactive *in utero.* Newborns are at high risk for rapid heat loss caused by amniotic fluid evaporation and a sudden decrease in ambient temperature.[49] Because of their small muscle mass, neonates are incapable of significant heat production through shivering; thus nonshivering thermogenesis plays an important role in maintaining temperature. Nonshivering thermogenesis occurs in brown adipose tissue, which is unique from other adipocytes owing to the significant presence of mitochondria, fat vacuoles, sympathetic innervation, and blood vessels. In the mitochondria of brown adipose tissue, ATP production is uncoupled from the oxidative process, resulting in an increase in heat production and oxygen consumption.[56] Nonshivering thermogenesis is inhibited *in utero,* most likely owing to the presence of adenosine and prostaglandin E_2, which have strong antilipolytic actions on brown tissue,[57,58] inadequate oxygen levels, and low levels of intrauterine catecholamines and thyroid hormones. The inhibition of nonshivering thermogenesis is believed to be beneficial to the fetus, in that it allows for conservation of oxygen and accumulation of brown adipose tissue.[50]

FETAL CARDIOVASCULAR SYSTEM

The cardiovascular system is one of the first functional organ systems in the developing fetus. The morphologic development of the human heart, from its first appearance as a heart tube to its development as a four-chambered structure, occurs between 20 and 44 days' gestation. Even before the development of the four-chambered heart, the valveless heart tube generates unidirectional flow, typically around 21 days' gestation.

Circulatory Pattern

Fetal circulation differs significantly from the postnatal circulation. The fetal cardiovascular system is anatomically arranged in such a way as to allow blood to bypass the lungs and provide maximal perfusion of the placenta, where gas and nutrient exchange occur. The fetal systemic circulation receives cardiac output from both the left and the right ventricle, with the ventricles working in *parallel.* In contrast, during postnatal life, the left and right circulations are separated and the ventricles work in *series.*

Fetal blood flow is characterized by three anatomic communications between the left and right circulations: the **ductus venosus,** the **foramen ovale,** and the **ductus arteriosus** (Fig. 5.4). Oxygenated blood travels from the placenta through the umbilical vein to the **ductus venosus,** which connects the umbilical vein with the inferior vena cava, thus bypassing the portal circulation and the liver. At mid-gestation, approximately 30% of the umbilical venous blood is shunted through the ductus venosus; from 30 to 40 weeks' gestation, this fraction decreases to approximately 20%, although a significant increase can occur in response to hypoxia (see later discussion).[59] Once in the right atrium, oxygenated blood preferentially flows through the **foramen ovale** to the left atrium and left ventricle, before entering the aorta and the systemic circulation. This mechanism ensures the delivery of well-oxygenated blood to the brain and the heart, which are the two organs with the highest oxygen requirements. The preferential shunting of ductus venosus blood through the foramen ovale into the left atrium is related to the umbilical venous pressure and the portocaval pressure gradient.

Deoxygenated blood from the head and upper extremities enters the right atrium through the superior vena cava and is preferentially directed into the right ventricle and the pulmonary artery. Because fetal pulmonary vascular resistance is higher than systemic vascular resistance, the majority of pulmonary artery blood flow crosses the **ductus arteriosus** into the descending aorta, which in turn supplies the lower extremities and hypogastric arteries. Deoxygenated blood returns to the placenta via the umbilical arteries for gas and nutrient exchange; only a small percentage travels through the lungs into the left atrium, the left ventricle, and the ascending aorta.

At birth, the fetus undergoes a significant and abrupt transition to a state of physiologic independence (see Chapter 9). Clamping of the umbilical cord results in a sudden increase in systemic vascular resistance, whereas expansion of the lungs and an increased alveolar oxygen tension result in decreased pulmonary vascular resistance. This allows for greater blood flow through the lungs, resulting in a decrease in right atrial pressure and an increase in left atrial pressure, ultimately leading to the functional closure of both the foramen ovale and the ductus arteriosus.

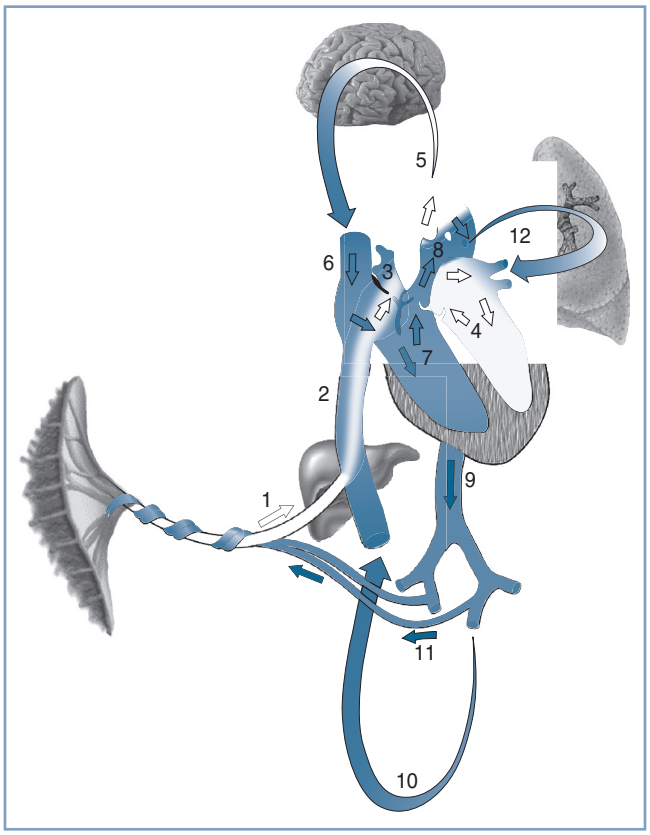

Fig. 5.4 Oxygenated blood leaves the placenta via the fetal umbilical vein *(1),* enters the liver where flow divides between the portal sinus and the ductus venosus, and then empties into the inferior vena cava *(2).* Inside the fetal heart, blood enters the right atrium, where most of the blood is directed through the foramen ovale *(3)* into the left atrium and ventricle *(4),* and then enters the aorta. Blood is then sent to the brain *(5)* and myocardium, ensuring that these cells receive the highest oxygen content available. Deoxygenated blood returning from the lower extremities and the superior vena cava *(6)* is preferentially directed into the right ventricle *(7)* and pulmonary trunk. The majority of blood passes through the ductus arteriosus *(8)* into the descending aorta *(9),* which in turn supplies the lower extremities *(10)* and the hypogastric arteries *(11).* Blood returns to the placenta via the umbilical arteries for gas and nutrient exchange. A small amount of blood from the pulmonary trunk travels through the pulmonary arteries *(12)* to perfuse the lungs. *Arrows* in this figure depict the direction and oxygen content [*white* (oxygenated), *blue* (deoxygenated)] of the blood in circulation. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Blood Volume

Human fetal intravascular volume is approximately 110 mL/kg, which is higher than that in postnatal life. However, approximately 25% of this blood volume is contained within the placenta; the blood volume within the fetal body is

estimated to be approximately 80 mL/kg.[60,61] Fetal intravascular volume is regulated through a complex interplay between the fetal heart, kidneys, and circulation and the placenta.[62] The fetus can adapt more quickly to changes in intravascular volume than the adult, owing to higher diffusion rates between fetal compartments.[63]

Transplacental transfer of water from mother to fetus depends on hydrostatic and osmotic pressures. The hydrostatic pressure is determined by the difference in pressures between the maternal intervillous space or capillaries and the fetal capillaries. The osmotic pressure is mainly determined by the presence of plasma proteins (i.e., colloid osmotic pressure). Transplacental water transfer is further regulated by angiotensin II. Adamson et al.[64,65] found that angiotensin II lowered the pressures in fetal placental exchange vessels, thereby promoting fluid transfer from the maternal to the fetal circulation. The production of angiotensin II is under control of the renin-angiotensin-aldosterone system in the fetal kidneys. A reduction in fetal arterial pressure results in an increase in fetal plasma renin activity, which results in subsequent increases in angiotensin I and II. The resulting expansion of intravascular volume augments fetal cardiac output and arterial pressure.

Cardiac Development

During gestation the fetal heart grows quickly and adapts to the continuously changing demands. The fetal myocardium grows primarily through cell division, whereas after delivery, cardiac mass increases as a result of cell enlargement.[66] This growth correlates with a prebirth transition from mononucleated cardiomyocytes, which contribute to heart growth by hyper*plasia,* to binucleated cardiomyocytes, which contribute to heart growth by hyper*trophy.*

The number of cardiac myofibrils and the transition in the type of cardiac troponins that are present during prenatal development can alter fetal heart contractility.[67] The change from fetal to adult troponin is associated with decreased sensitivity of the contractile apparatus to calcium. A heightened calcium sensitivity is important in the early development of the fetal heart, when the sarcoplasmic reticulum is immature.[68] With advancing gestational age, ejection fraction declines, but cardiac output (per unit of fetal weight) does not change owing to increasing ventricular volume. The fetal heart rate decreases over the course of gestation from 140 to 150 beats/min at 18 weeks' gestation to 120 to 140 beats/min at term.[69,70]

In utero developmental issues can have gestational and long-term heart consequences. Fetuses exposed to maternal diabetes demonstrate signs of biventricular diastolic dysfunction, right ventricular systolic dysfunction, and septal hypertrophy in the third trimester, compared with control subjects.[71] Human growth-restricted fetuses have smaller, more spherical hearts, impaired systolic longitudinal function, and mild impairment in diastolic function, compared with matched non–growth-restricted fetuses; these alterations have been observed to persist when examined even 10 years later.[72]

Ventricular Responses to Changes in Preload and Afterload

It is unclear whether fetal and adult hearts possess similar responses to preload and afterload. The adult heart responds in accordance with the Frank-Starling curve, which indicates that ventricular distention lengthens the diastolic fibers and results in augmented contractility. A number of studies have indicated that the fetal heart has a limited capacity to increase its stroke volume in response to an increase in preload (e.g., intravenous fluid infusion).[73,74] By contrast, other studies have observed that the fetal heart can accommodate increases in preload and afterload in a manner consistent with the Frank-Starling curve.[75,76] These seemingly contradictory findings may be partially explained if the fetal heart functions *in vivo* near the peak of the Frank-Starling curve. However, the left ventricular stroke volume is known to double at birth, which would not be in agreement with this hypothesis. A more plausible explanation is that cardiac compliance increases owing to myocardial functional maturity with increased gestation; this has been suggested by a decreasing ratio of mitral peak early diastolic filling velocity to early diastolic mitral annular velocity (E/e′) as the fetus matures.[77] Another explanation is that ventricular constraint, arising from tissues that surround the heart (chest wall, pericardium, and lungs), limits fetal ventricular preload and overall cardiac function *in utero*. Relief of this constraint at birth, as a result of lung aeration and clearance of liquid from the lungs, may then allow for an increase in left ventricular preload and subsequent stroke volume in the newborn.[78]

Studies investigating the effects of afterload on fetal ventricular function have observed a significant decrease in right ventricular stroke volume in response to increases in arterial pressure.[73] The same phenomenon occurs in the left ventricle, although to a lesser degree. In a study of fetal lambs, in which gradual constriction of the descending aorta was applied, stroke volume was maintained until high mean arterial pressures were achieved, after which decreases were observed. This decrease in stroke volume in the presence of high mean arterial pressure may represent the exhaustion of "preload reserve," which will typically allow the maintenance of stroke volume in the setting of increased afterload.[79]

Cardiac Output and Distribution

In postnatal life, the right and left ventricles operate in series and their output is approximately equal; as a consequence, cardiac output is defined through measurements of output from either ventricle. However, in the fetus, the systemic circulation receives blood from both the left and right ventricle in parallel (i.e., the sum of the right and left ventricular outputs, with the exception of a proportion of the right ventricular output that is delivered to the fetal lungs). At mid-gestation, the combined ventricular output (CVO) is approximately 210 mL/min, and it increases to approximately 1900 mL/min at 38 weeks' gestation (500 mL/min/kg).[74,80,81] During fetal life, the right ventricular volume is greater than the left

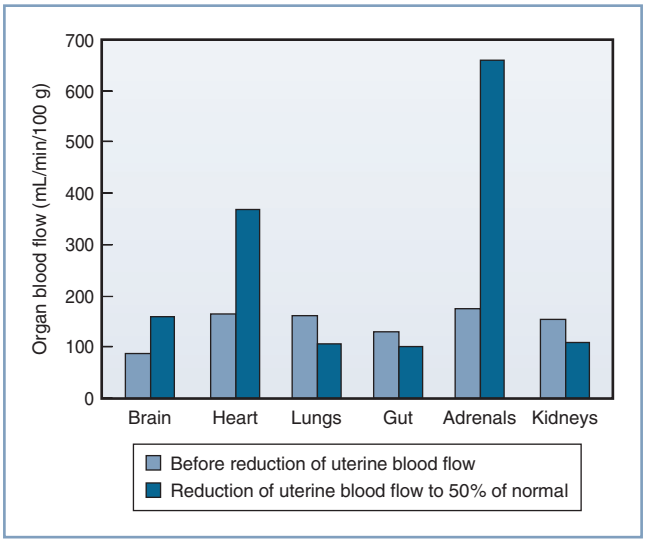

Fig. 5.5 Redistribution of combined ventricular output in fetal lambs during hypoxemia caused by reduced uterine blood flow. (Modified from Jensen A, Roman C, Rudolph AM. Effects of reducing uterine blood flow on fetal blood flow distribution and oxygen delivery. *J Dev Physiol.* 1991;15:309–323.)

ventricular volume during both systole and diastole, but stroke volume does not differ significantly between the two ventricles.[69]

Fetal cardiac output is sensitive to changes in fetal heart rate. As heart rate increases, cardiac output increases. As fetal heart rate decreases, fetal stroke volume increases only slightly, in part because of low fetal myocardial compliance. Although fetal bradycardia results in an extended diastolic filling time, the stiff fetal cardiac ventricles have limited ability to distend. Therefore, fetal bradycardia is associated with a marked drop in fetal cardiac output.

The distribution of the CVO in near-term fetal lambs and resting adult humans is shown in Fig. 5.5. The majority of fetal lamb CVO is distributed to the placenta (41%), the bone and skeletal muscle (38%), the gastrointestinal system (6%), the heart (4%), the brain (3%), and the kidneys (2%). In both fetal and adult animals, approximately equal volumes of blood are delivered to oxygen-uptake organs (i.e., the placenta before delivery, the lungs after delivery) and the oxygen-consuming organs.

The distribution of the CVO changes over the course of gestation and in certain conditions, such as hypoxia and hypovolemia. Interpretation of CVO data should be evaluated with the understanding that significant interspecies differences exist. For example, whereas lungs in the lamb fetus receive 10% or less of CVO, those in the human fetus receive approximately 20%. In human fetuses at 10 to 20 weeks' gestation, the brain receives approximately 15% of CVO,[82] but this fraction may be increased during circumstances of decreased placental perfusion, acidosis, and increased P_{CO_2}. In the rhesus monkey, the fraction of CVO devoted to cerebral blood flow was observed to increase from 16% to 31% during a hypoxic challenge.[83]

Fetal Blood Pressure

Fetal blood pressure increases with gestational age. Intracardiac (intraventricular) pressure recordings in the human fetus suggest that systolic pressure increases from 15 to 20 mm Hg at 16 weeks' gestation to 30 to 40 mm Hg at 28 weeks' gestation.[66] Substantial variation in blood pressure may be observed. The diastolic ventricular pressures undergo similar, albeit slower and smaller increases, from 5 mm Hg or less at 16 to 18 weeks' gestation to 5 to 15 mm Hg at 19 to 26 weeks' gestation.[66]

Regulation of Fetal Circulation

Fetal cardiovascular function continuously adapts to varying metabolic and environmental conditions through regulation by the neurologic and endocrine systems. The predominant form of neuroregulation occurs in response to baroreceptor and chemoreceptor afferent input to the autonomic nervous system and through modulation of myocardial adrenergic receptor activity. Thus, the autonomic nervous system functions to reversibly redirect blood flow and oxygen delivery as required.

Arterial baroreceptor function has been demonstrated in several different fetal animal models. The predominant baroreceptors are located within the vessel walls of the aortic arch and at the bifurcation of the common carotid arteries. These receptors project signals to the vasomotor center in the medulla, from which autonomic responses emanate. The baroreceptors are functional early in fetal development and undergo continuous adaptation to the increases in blood pressure observed over time.[84] A sudden increase in fetal mean arterial pressure—as occurs with partial or complete occlusion of the umbilical arteries—results in cholinergic stimulation and subsequent fetal bradycardia.

Peripheral chemoreceptors are present within the vessel walls of the aortic arch and at the bifurcation of the common carotid arteries. In some animal species, peripheral chemoreceptors are transiently present in the adrenal gland but disappear after birth.[85] The fetal aortic chemoreceptors are responsive even to small changes in arterial oxygenation,[86,87] which contrasts to the less active fetal carotid chemoreceptors. Dawes et al.[88] concluded that the carotid chemoreceptors are important for postnatal respiratory control, whereas the aortic chemoreceptors are more involved in the control of cardiovascular responses and the regulation of oxygen delivery. Central chemoreceptors, located in the medullar oblongata, appear to play little if any role in fetal circulatory responses.

The neural control of the fetal circulation is far more dependent on chemoreceptor-mediated responses than neural control of the adult circulation.[89] Acute fetal hypotension often stimulates a reflex response, which can include both bradycardia and vasoconstriction. Vasoconstriction is dependent on increases in both sympathetic autonomic activity and the rate of secretion of several vasoactive hormones, including arginine, vasopressin, renin, angiotensin, and aldosterone. Fetal bradycardia is most likely caused by activation of peripheral chemoreceptors.[89]

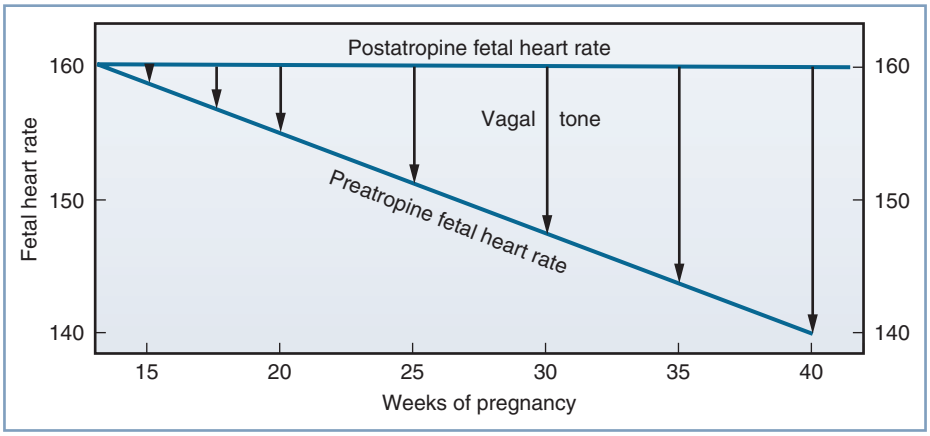

Fig. 5.6 The growing influence of the parasympathetic nervous system on fetal heart rate as gestation progresses. This parasympathetic activity is reversible with administration of atropine. (From Schifferli P, Caldeyro-Barcia R. Effects of atropine and beta-adrenergic drugs on the heart rate of the human fetus. In Boréus LO, ed. *Fetal Pharmacology*. New York, NY: Raven Press; 1973:264.)

Autonomic Nervous System

The autonomic nervous system is present early in gestation and plays a critical role in maintaining cardiovascular homeostasis. In the fetal chick heart, evidence of cholinergic innervation occurs as early as 3 days after fertilization (average incubation, 22 days). In the mammalian heart, inotropic and chronotropic responses to adrenergic agents have been measured as early as 4 to 5 weeks' gestation,[90] and the fetal myocardial pacemaker can be inhibited at this time by the cholinergic agonists carbamylcholine and acetylcholine.[91]

In comparing the parasympathetic cholinergic and sympathetic adrenergic nervous systems during gestation, the majority of studies indicate that the parasympathetic system appears earlier (8 weeks' gestation versus 9 to 10 weeks' gestation),[90,92,93] becomes more dominant as pregnancy progresses, and is more functionally complete at birth (Fig. 5.6). As a result, the baseline fetal heart rate is slower at term than at 26 weeks' gestation. The administration of atropine can result in fetal tachycardia by 15 to 17 weeks' gestation, which occurs before fetal bradycardia can be demonstrated with the administration of a beta-adrenergic receptor antagonist.[90]

Both parasympathetic and sympathetic systems undergo significant maturation during postnatal life, and full maturation of the vagal response is not observed until 1 to 2 months after delivery.[94,95] Similarly, although the contractile response of the fetal vasculature is less functional than the adult response, the fetal administration of an alpha-adrenergic receptor agonist can result in the redistribution of blood flow away from the kidneys, skin, and splanchnic organs and toward the heart, brain, placenta, and adrenal glands.[96] At birth, the autonomic nervous system can mediate a number of hemodynamic adjustments, including changes in heart rate and peripheral vascular resistance, and a redistribution of blood flow.[90]

FETAL PULMONARY SYSTEM

The lungs begin as small, saccular outgrowths of the ventral foregut endoderm. Although sacculi with type I and II pneumocytes and ventilatory capacity are present during the last trimester, true alveoli develop at approximately 36 weeks' gestation. The majority of alveolar development occurs postnatally, within the first 6 to 18 months of life, when further maturation of the microvasculature and the air-blood barrier occurs.[97]

The pulmonary vasculature develops early in gestation, with continuity between its capillary plexus and the heart occurring as early as 34 days' gestation.[98,99] The size and number of pulmonary arteries and veins increases over time; however, vessel reactivity to local and hormonal influences is not detectable until after 20 weeks' gestation.[100,101] From 20 to 30 weeks' gestation, the growth in the size of the pulmonary vascular bed combined with a reduction in pulmonary vascular resistance results in greater pulmonary blood flow (i.e., from 10% to 15% of the CVO to 25% of the CVO). During this time, alterations in maternal oxygenation have no effect on the fetal pulmonary vasculature.[82,100] However, after 30 weeks' gestation, blood flow to the lungs decreases slightly owing to a significant increase in pulmonary vascular resistance, diminishing the fraction of CVO to approximately 20%. Contemporaneously, the vasomotor tone and reactivity of the fetal circulation begins to respond to maternal hyperoxygenation with a decrease in pulmonary vascular resistance and an increase in pulmonary blood flow.[82,100] A study in near-term fetal lambs observed a 10-fold increase in pulmonary blood flow when fetal oxygen tension was increased from 24 to 46 mm Hg (3.2 to 6.1 kPa) because of pulmonary vasodilation[102]; however, this acute response is not sustained during prolonged exposures, suggesting the development of vasoregulatory mechanisms that oppose vasodilation.[103]

At birth, with the onset of breathing, a significant reduction in pulmonary vascular resistance occurs and the pulmonary blood flow increases from 21% to 100% of cardiac output to enable gas exchange in the lung.[103] A number of mechanical and molecular processes contribute to this perinatal pulmonary vasodilation. *In utero,* the fetal lungs are filled with fluid to maintain an appropriate level of expansion

for normal pulmonary development.[104] The expulsion of lung liquid, particularly with a vaginal birth, likely decreases extraluminal pressure on the pulmonary vasculature and leads to a decrease in pulmonary vascular resistance.[105] Breathing movements, shear stress created by an abrupt surge in pulmonary blood flow, and the development of alveolar surface tension are other mechanical factors that can decrease pulmonary vascular resistance.[106] Finally, the relative predominance of vasodilators (e.g., endothelium-derived nitric oxide, prostacyclin) versus vasoconstrictors (e.g., platelet-activating factor) at birth may also significantly decrease pulmonary vascular resistance.[107,108]

The amount and composition of pulmonary surfactant changes over the course of gestation. For example, the ratio of phosphatidylglycerol to phosphatidylinositol, and the ratio of lecithin to sphingomyelin, increases with gestation and may be used as markers of fetal lung maturity.[109] Fetal surfactant production can be accelerated by a number of factors, including glucocorticoids, thyroid hormones, and autonomic neurotransmitters. A glucocorticoid surge in the last weeks of gestation is required for normal lung development[110]; birth before this cortisol increase results in low levels of surfactant with the subsequent development of infant respiratory distress syndrome (IRDS). Consequently, the American College of Obstetricians and Gynecologists (ACOG) recommends a single course of corticosteroids for pregnant women between 24 and 34 weeks' gestation who are at risk for preterm delivery.[111]

Antenatal corticosteroid treatment causes maturation of pulmonary epithelial cells, differentiation of type II cells, and activation of various components of surfactant (e.g., surfactant proteins and phospholipids); the treatment causes additional pulmonary alterations in the structural components, fluid metabolism, production of growth factors, and presence of antioxidant enzymes and adrenergic receptors. The maternal administration of glucocorticoids such as betamethasone or dexamethasone has been associated with a 35% to 40% reduction in respiratory distress syndrome in preterm infants and a significant improvement in neonatal mortality.[112]

A disadvantage in respiratory morbidity and mortality of male infants born prematurely can be partially attributed to gender differences in surfactant production.[15,16] Higher levels of androgen and Müllerian-inhibiting substance in male fetuses adversely affects surfactant production, whereas estrogen promotes surfactant production in female fetuses.[16] Future therapies may need to be gender specific.

FETAL RENAL SYSTEM

Although fluid and electrolyte balance, and acid-base homeostasis, are primarily regulated and maintained by the placenta, the fetal kidneys play an important role in fetal development through amniotic fluid production. Fetal glomeruli begin to develop at 8 to 9 weeks' gestation and start producing urine at 10 weeks' gestation, which contributes significantly to amniotic fluid production.[113,114] By 20 weeks' gestation, greater than 90% of amniotic fluid is provided by the kidneys. Fetal oliguria and anuria can lead to lung hypoplasia and skeletal and tissue deformities (e.g., Potter sequence).[115] Glomerular filtration rate (GFR) increases over the course of gestation but remains low during fetal and early neonatal life. At birth, term newborns have a GFR of approximately 20 mL/min/1.73 m^2,[116,117] which increases to approximately 50 mL/min/1.73 m^2 by 1 month of age.[117] This early increase in GFR is believed to result from a large increase in the glomerular capillary surface area and the ultrafiltration coefficient, together with a small increase in the filtration pressure.[118,119] Thereafter, the GFR undergoes progressive increases and reaches adult levels between 1 and 2 years of age.[120]

The ability of the fetal kidneys to perform filtration, reabsorption, and secretion (i.e., tubular function) begins by 14 weeks' gestation and continues to develop postnatally. Immaturity of tubular function in preterm infants can lead to acidosis and salt wasting.[121,122] Renal function *in utero* is regulated by a variety of factors that control renal blood flow, glomerular filtration, and tubular function. The renin-angiotensin system is particularly important for normal fetal renal growth and development,[123] and maternal use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers is associated with renal agenesis and anomalies[124]; angiotensin II helps regulate blood pressure and the volume of fluid in the extravascular space.[125]

FETAL HEMATOLOGIC SYSTEM

Red blood cells, platelets, neutrophils, monocytes, and macrophages are all derived from a common progenitor cell.[126] In the developing embryo, hematopoiesis occurs at several anatomic sites in multiple waves. The first wave occurs in the yolk sac 30 days after conception and produces mostly primitive erythroid cells, but also macrophages and megakaryocytes.[127] The second wave also arises in the yolk sac but creates the same cells found in the adult human (i.e., erythroid, megakaryocyte, and several myeloid lineages). The third wave emerges from hematopoietic stem cells located within the major arteries of the embryo, yolk sac, and placenta. Hematopoietic stem cells migrate to the fetal liver and eventually seed the bone marrow, where they will reside for the remainder of life. The final wave of hematopoiesis produces all hematopoietic cell lineages, including B- and T-lymphocyte progenitor cells.[128,129] *In utero* exposure to various agents when hematopoietic stem cells are initially emerging can lead to programming alterations that impact the blood and immune systems throughout life[127]; for example, genome profiling of cord blood hematopoietic progenitor cells from neonates born to smokers demonstrates dysregulated gene pathways involved in hematopoietic cell lineage differentiation.[127]

Erythroid cells (red blood cells) are the first blood cells to develop. There are two developmentally and morphologically distinct erythroid lineages: primitive (embryonic) and definitive (adult). Cells of the primitive lineage support the transition from the rapidly growing embryo to fetus; primitive megaloblastic erythrocytes are much larger than definitive erythrocytes, express different globin genes, and differ in their

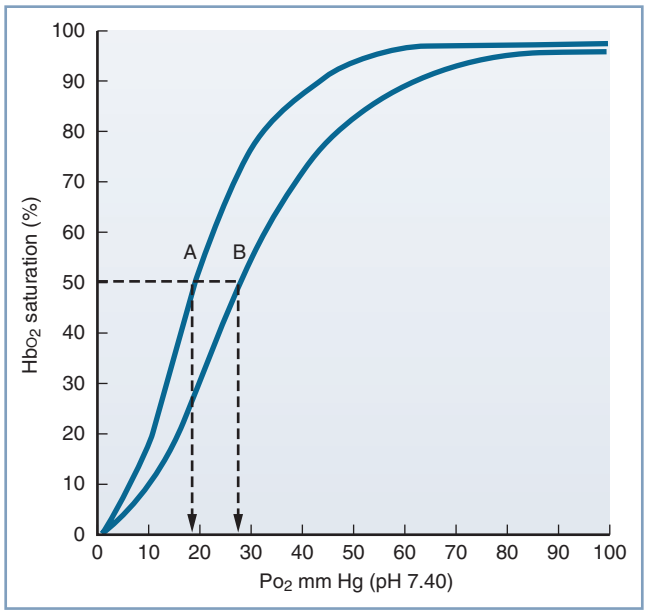

Fig. 5.7 Oxyhemoglobin saturation curves for fetal (A) and adult (B) human blood. The P_{50} is indicated by the *dashed vertical line.* (Modified from Delivoria-Papadopoulos M, DiGiacomo JE. Oxygen transport. In Polin RA, Fox WW, eds. *Fetal and Neonatal Physiology.* Vol 1. Philadelphia, PA: WB Saunders; 1992:807.)

oxygen-carrying capacity and response to low oxygen tension. By contrast, definitive erythrocytes are important during the transition from fetal to extrauterine life at birth. They are produced continuously from hematopoietic stem cells in the bone marrow and participate in a variety of normal physiologic processes throughout postnatal life.[126,130]

Fetal and adult human erythrocytes can be distinguished by their hemoglobin (hemoglobin F and A, respectively). The tetramer for hemoglobin F consists of two alpha (α) chains and two gamma (γ) chains (α2γ2), whereas the tetramer for hemoglobin A includes two alpha (α) chains and two beta (β) chains ($\alpha_2\beta_2$). The gamma chain and the beta chain contain the same number of amino acids (146), but their sequences differ by a total of 39 amino acids.[131] The change in expression from fetal to adult beta-globin genes begins at approximately 32 weeks' gestation and is completed after birth.[132]

Hemoglobin F has a greater affinity for oxygen and a lower affinity for 2,3-disphosphoglycerate (DPG) and exhibits a leftward shift in the oxyhemoglobin dissociation curve compared with hemoglobin A (Fig. 5.7).[133] These differences result in greater arterial oxygen saturation in fetal versus maternal blood for any given arterial oxygen pressure. This difference in oxygen affinity can be explained by a decreased interaction between the gamma chains of hemoglobin F and intraerythrocyte 2,3-DPG, the latter acting to lower oxygen affinity by binding and stabilizing the deoxygenated hemoglobin tetramer. As a consequence, 2,3-DPG decreases the oxygen affinity of hemoglobin F less than that of hemoglobin A.[134] Although fetuses and adults have similar intraerythrocyte 2,3-DPG concentrations, fetal blood exhibits a lower oxygen tension at which hemoglobin is 50% saturated (P_{50}). Hemoglobin F levels begin to decrease toward the end of pregnancy, resulting in a corresponding increase in the P_{50}. At term, hemoglobin A accounts for approximately 25% of total hemoglobin, and the P_{50} is approximately 19 mm Hg.[135]

Hemoglobin A levels begin to increase and 2,3-DPG concentrations transiently increase above usual fetal and adult levels during the first few months of life. During this time, the affinity of neonatal blood for oxygen is equivalent to that of the adult despite the persistence of 25% fetal hemoglobin.[133,135]

FETAL GASTROINTESTINAL SYSTEM

The gastrointestinal tract develops from the primitive digestive tube, which includes the foregut, midgut, and hindgut. The foregut receives its vascular supply from the celiac axis and gives origin to the oral cavity, pharynx, esophagus, stomach, and upper duodenum. The midgut, which receives its vascular supply from the superior mesenteric artery, develops into the distal duodenum, jejunum, ileum, cecum, appendix, and transverse colon. The hindgut receives its vascular supply from the inferior mesenteric artery, and it differentiates into the descending colon, the sigmoid colon, and the upper two thirds of the rectum.[136] Intestinal villi appear by 7 weeks' gestation, and active absorption of glucose and amino acids occurs by 10 and 12 weeks' gestation, respectively.[137] Peristaltic waves and gastrointestinal motility are initiated by 8 weeks' gestation. Teniae, the three longitudinal ribbons of smooth muscle on the outside of the colon, appear by 12 weeks' gestation and contract to produce the haustra (bulges) in the colon.[138] In the small intestine, Auerbach and Meissner plexuses of parasympathetic nerves provide motor and secretomotor innervation, respectively; the two plexuses are present as early as 8 weeks' gestation.[137] Aggregations of lymphoid nodules (i.e., Peyer patches) develop by 20 weeks' gestation in the ileum.[139]

Although the fetal environment and neonatal gut were once believed to be sterile, *in utero* transmission of microbes from mother to infant likely occurs. Jimenez et al.[140] demonstrated that specific bacteria introduced to the gut of pregnant animals could be recovered in the offspring at the time of sterile cesarean delivery. Similarly in humans, Collado et al.[141] observed shared microbiota features in placental, amniotic fluid, and infant meconium samples obtained during elective cesarean delivery, suggesting *in utero* microbial gut colonization. The early life microbiome is involved in immune system development, metabolic programming, neurodevelopment, and neonatal susceptibility to diseases.[142]

Swallowing

The fetus starts swallowing at approximately 15 weeks' gestation, and at term the fetus ingests 500 to 750 mL of amniotic fluid per day.[143] Fetal swallowing plays an important role in amniotic fluid homeostasis,[143] and the swallowed fluid appears to provide nutritional support for mucosal development within the gastrointestinal tract.[144] Intestinal growth occurs by duplication of intestinal crypts, a process that is promoted by the presence of trophic factors in amniotic fluid; these factors include epidermal growth factor (EGF),

hepatocyte growth factor, transforming growth factor α (TGF-α) and TGF-β, Insulin like growth factor-1 (IGF-1) and IGF-2, erythropoietin, granulocyte colony-stimulating factor (G-CSF), and cytokines.[145] Avila et al.[146] found that surgical obstruction of ingested fluid within the upper gastrointestinal tract resulted in restricted development of the gastrointestinal tract, liver, and pancreas.

The ingestion and intestinal absorption of nutrient-rich amniotic fluid also appears to play an important role in general fetal growth and development. In the fetal rabbit model, disorders of the upper gastrointestinal tract (e.g., esophageal obstruction, gastroschisis) lead to decreased intestinal nutrient absorption and decreased birth weight and crown-rump length.[147] Similar findings have been reported in human neonates with congenital esophageal atresia.[148]

Meconium

Meconium, which consists of water, intestinal secretions, squamous cells, lanugo hair, bile pigments, and blood, first appears in the fetal intestine between 10 and 12 weeks' gestation.[149] By 16 weeks' gestation, meconium moves into the colon.[150] Between 14 and 22 weeks' gestation, fetal colonic contents, as indicated by the presence of high levels of intestinal enzymes (i.e., disaccharidases, alkaline phosphatase), appear in the amniotic fluid.[151] After 22 weeks' gestation, a subsequent decline in the concentration of these gastrointestinal enzymes within the amniotic fluid is observed, which coincides with the development of anal sphincter tone.[151,152]

Meconium is continually cleared by fetal swallowing, leading to relatively clear amniotic fluid in the majority of pregnancies. The presence of meconium-stained amniotic fluid may therefore represent either decreased clearance or increased passage of meconium, which is observed in the presence of fetomaternal stress factors such as hypoxia and infection, independent of fetal maturation.[149] Meconium-stained amniotic fluid occurs more frequently with advanced gestational age and is common in post-term pregnancies.[153]

Although many fetuses with meconium-stained amniotic fluid are born without adverse sequelae, meconium can have detrimental effects on fetal organs and the placenta. Meconium may cause umbilical cord vessel constriction, vessel necrosis, and the production of thrombi, which can lead to altered coagulation, cerebral palsy, and neonatal seizures.[154] In addition, meconium may reduce the antibacterial properties of amniotic fluid by altering zinc levels.[149] Fetal aspiration of meconium also may neutralize the action of surfactant, promote lung tissue inflammation through the activation of neutrophils, and possibly result in meconium aspiration syndrome (see Chapter 9). Finally, in the presence of perinatal hypoxia, meconium also may contribute to vascular hypertrophy and possible pulmonary hypertension.[149]

FETAL NERVOUS SYSTEM

Over the course of gestation, the human brain and central nervous system begin to develop from a few embryonic cells to a complex system in which billions of neurons are arranged and interconnected; small, seemingly minor changes may have profound implications. For example, animal studies suggest that intrauterine exposure to a variety of drugs and medications, including certain anesthetic agents, at specific time intervals appears to result in anatomic, functional, and behavioral changes following birth (see Chapter 10).

Structural and Functional Brain Development

Primary neuromodulation and neural tube formation occur by 4 weeks' gestation. By 8 weeks, the rostral end of the neural tube gives rise to the prosencephalon, or forebrain; the mesencephalon, or midbrain; and the rhombencephalon, or hindbrain. These three segments further subdivide: the prosencephalon divides into the telencephalon and the diencephalon, and the rhombencephalon divides into the metencephalon and myelencephalon. These five subdivisions establish the primary organization of the central nervous system.[155]

The human subplate, the developmental anlage of the cerebral cortex, develops between 13 and 15 postconceptional weeks (PCW). The subplate layer is created to fulfill a critical, albeit transient, role as a location for synapses with cortical and thalamic projections; the subplate layer disintegrates between 24 and 28 weeks' gestation. A significant increase in cortical development, organization, and synapse formation begins by 20 weeks' gestation and continues postnatally; during the third trimester alone, the cerebral cortex volume increases fourfold.[156,157]

The first fetal movements are witnessed near the end of the first trimester. These initial movements have simple patterns and originate from spontaneous discharges within the spine and brainstem. The fetal movements become more organized and complex as the pregnancy progresses, with higher brain centers modulating the activity of the brainstem and spine.

The exact onset of electrocortical activity is unknown, but electroencephalographic (EEG) activity can be recorded in preterm infants as early as 24 weeks' gestation. Fetal EEG activity differs from that in the adult and is characterized by the presence of intermittent bursts of activity separated by periods of complete suppression. With maturation, these suppressed episodes become shorter and less frequent before completely disappearing in postnatal life. The early electrical activity within the nervous system controls several developmental processes, such as neuronal differentiation, migration, synaptogenesis, and formation of neuronal networks. For example, the initial spontaneous spinal and subcortical discharges are believed necessary for somatosensory development. As they elicit movements in the periphery, afferent signals establish topographic representation on the sensory cortex.[158–160]

Alterations in fetal brain and nervous system development can lead to major malformations. The Zika virus has been associated with an increase in the number of newborns with microcephaly, retinal abnormalities, hearing loss, and other neurologic complications, such as convulsions and hypotony, hydrocephalus, agyria, ventriculomegaly, and

brain calcifications.[161] The Zika virus is highly neurotropic and causes cell death in neuroprogenitor cells and immature cortical neurons.[162]

Cerebral Metabolism

The immature brain, similar to the adult brain, relies mostly on oxidative metabolism for the production of energy. However, owing to the limited capacity for mitochondrial oxidative phosphorylation and the lower partial pressures of oxygen observed *in utero,* anaerobic glycolysis exhibits a greater role during this developmental period than after delivery.[163,164] In the presence of aerobic conditions, glucose is converted to pyruvic acid (glycolysis), which enters the Krebs cycle and the mitochondrial cytochrome system to create chemical energy; this process converts 1 mole of glucose into 36 moles of ATP. By contrast, during anaerobic conditions, glycolysis is much less efficient, yielding only 2 moles of ATP for each mole of glucose.[165]

Although glucose represents the primary and predominant source of cerebral energy, the perinatal brain is uniquely capable of metabolizing other substrates, such as lactic acid and ketone bodies (i.e., β-hydroxybutyrate and acetoacetate). Lactic acid concentrations in the peripartum period are significantly elevated and may support over 50% of total cerebral oxidative metabolism in certain conditions such as hypoglycemia and hypoxia.[166,167] During hypoxic conditions, the fetal brain will also significantly decrease its energy consumption, as evidenced by fewer fetal movements and a slower EEG wave pattern.[168]

Cerebral Blood Flow

The development of the neural tube begins with formation of endothelium-lined vascular channels; by 10 weeks' gestation, an extensive network of leptomeningeal arteries covers the fetal brain, allowing vessels to sprout and penetrate the brain parenchyma. Subsequent vascular growth is most pronounced in rapidly developing areas of the brain.[163]

The fetal systemic circulation has unique features that ensure optimal oxygen delivery to the brain. Well-oxygenated blood from the umbilical vein and ductus venosus is preferentially shunted through the foramen ovale to the left side of the heart and the ascending aorta to supply the cerebral and coronary circulations. Hypoxia results in acute changes in fetal and placental vascular resistance, which leads to intense peripheral vasoconstriction (likely mediated by stimulation of chemoreceptors) and further shunting of umbilical venous blood through the ductus venosus. The fetal circulatory system is much more sensitive to hypoxemia than that in the adult, which helps maintain oxygen delivery to the developing brain and myocardium (Fig. 5.8).[169–171]

The redistribution of blood flow to the most actively developing regions of the fetal brain is at least partially the result of an adenosine-mediated mechanism. Adenosine, the breakdown product of ATP, accumulates during failure of ATP resynthesis and causes vasodilation of blood vessels and suppression of neuronal activity.[168] Other substances (e.g., nitric oxide, endogenous opioids, adrenomedullin) may also play a role in cerebral blood redistribution, but the exact mechanisms are incompletely understood.[172]

Nociception

Cutaneous sensory receptors are present in the human fetus at approximately 7 weeks' gestation, and a widespread network is established by 20 weeks. At term gestation, the density of cutaneous nociceptive receptors in the fetus is comparable to, and may even exceed, that of the adult.

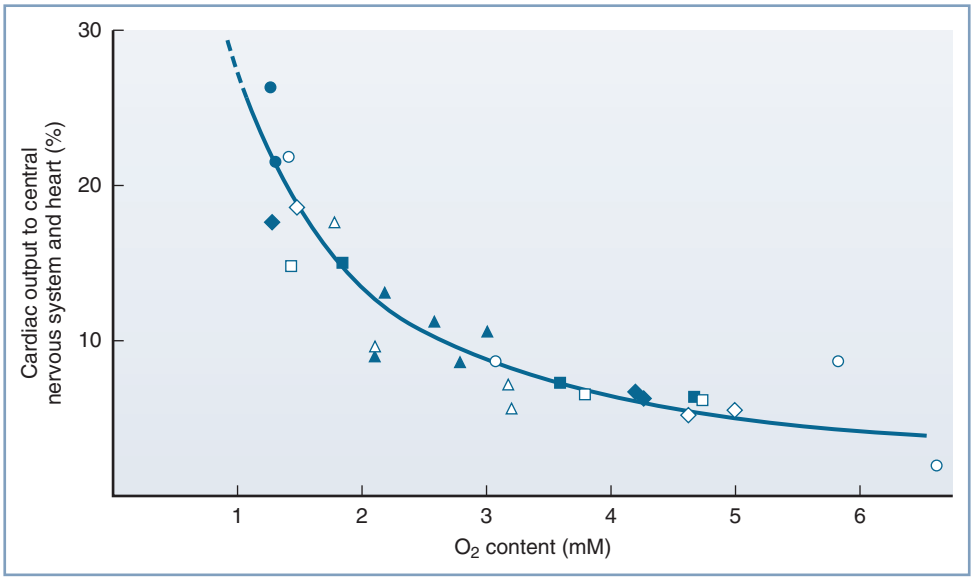

Fig. 5.8 The redistribution of cardiac output to the heart and central nervous system during hypoxemia in fetal lambs. Each symbol represents a measurement from an individual fetal lamb. (Modified from Sheldon RE, Peeters LLH, Jones MD Jr, et al. Redistribution of cardiac output and oxygen delivery in the hypoxic fetal lamb. *Am J Obstet Gynecol.* 1979;135:1071–1078.)

Although the development of sensory fiber-to-dorsal horn interneuron synapses has been reported to occur as early as 6 weeks' gestation,[173] differentiation of dorsal horn neurons begins at approximately 13 weeks' gestation; the laminar arrangement of dorsal horn neurons, replete with synaptic interconnections and neurotransmitter vesicles, is present in some regions of the spinal cord by 30 weeks' gestation.[174] At this time, the A-delta and C fibers make connections at the spinal cord level and with the surrounding dermatomes.

The neurons of the cerebral cortex develop by 20 weeks' gestation, and synaptogenesis of the thalamocortical connections is established between 20 and 24 weeks' gestation. Thalamocortical axons reach the somatosensory cortex at 24 to 26 weeks' gestation. Myelination of the pain pathways of the spinal cord and brainstem is completed during the second and third trimesters of gestation[175]; however, the process continues postnatally in other areas of the brain and in peripheral nerve fibers. Although optimal pain processing requires myelination of pain pathways, cortical maturation, dendritic arborization, and thalamocortical fiber synaptogenesis, it is unclear when nociception, the capacity to feel pain, develops within the fetus. As early as 18 weeks' gestation, human fetuses demonstrate pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli.[176–178] In studies of intrauterine blood transfusion in the human fetus, surgical needling of the intrahepatic vein (compared with needling of the insensate umbilical cord) is associated with evidence of a stress response, including increases in plasma beta-endorphin and cortisol levels and a diminution in the middle cerebral artery pulsatility index.[179] Administration of fentanyl 10 μg/kg blunts this stress response to intrahepatic needling.[180]

The immaturity of thalamocortical connections before 25 weeks' gestation suggests that cortical processing of external input before 25 weeks' gestation is unlikely.[181] However, as early as 25 weeks' postmenstrual age, near-infrared spectroscopy has demonstrated cortical activity in response to noxious stimuli in preterm neonates.[182,183] Facial responses to painful stimuli (similar to those seen in adults) can be provoked in preterm neonates born and assessed as early as 25 weeks' gestation, which suggests the development of functional pathways from the spinal cord to the brain.[184,185] However, the withdrawal from noxious stimuli or an increased release of stress hormones does not necessarily reflect an *awareness* of pain, because local spinal reflexes and hormonal release can occur without cortical involvement.[186] The experience of pain is a conscious subjective experience with emotional and affective components that requires higher-level cortical processing. Nociceptive processing begins in the peripheral neurons, which relay signals through the spinothalamic tract, the thalamus, and ultimately the cerebral cortex, where conscious perception of pain occurs.[187]

After birth, neonates appear to be more sensitive to pain, with lower pain thresholds, poor discriminative abilities, and a greater tendency to exhibit central sensitization in response to later noxious stimuli than adults. Early sensory experiences in the neonate can influence the development of nociceptive pathways.[188] Neonates and especially preterm infants who undergo numerous procedures in the neonatal intensive care unit and/or surgery have been observed to demonstrate altered pain perceptions later in life.[189] In the rodent model, tissue injury in early neonatal life results in an increased magnitude and duration of hyperalgesia after reinjury in later life, compared with those with no early life pain experience.[188] Collectively, these observations have prompted some investigators to conclude that noxious events in neonates, when pain pathways are still undergoing a learning or "tuning process," may result in structural functional and behavioral alterations in adult pain processing. Some of these long-term consequences may be attenuated by preemptive analgesia.[190]

The foregoing neuroanatomic and neurochemical evidence, in addition to the well-characterized behavioral and physiologic responses to pain, indicate that both the fetus and newborn infant have nociceptive pathways capable of communicating nociceptive stimuli from the periphery to the cerebral cortex and regulating the response via efferent inhibitory pathways. Current evidence suggests that fetal nociception at the level of the cortex occurs after the midpoint of pregnancy (i.e., between 24 and 30 weeks' gestation).

KEY POINTS

- Amniotic fluid serves a number of vital roles, including the facilitation of fetal growth, the provision of a microgravity environment that cushions the fetus, and the generation of a defense mechanism against invading microbes.
- The fetus depends on the mother and the placenta for its basic metabolic needs, such as nutrient delivery, gas exchange, and electrolyte and acid-base homeostasis.
- Fetal arterial blood Po_2 ranges from 20 to 30 mm Hg (2.7 to 4.0 kPa), and fetal development exists in a state of relative hypoxia compared with adult oxygen tension.
- Despite a lower fetal oxygen tension, the fetal arterial blood oxygen content is not much lower than that of the adult. This results from a higher oxygen-carrying capacity (hemoglobin concentration of 18 g/dL) and a higher affinity of hemoglobin F for oxygen, when compared with hemoglobin A.
- The fetus produces approximately twice as much heat (on a weight-adjusted basis) and maintains a temperature 0.5° C higher than the mother during the third trimester.
- The fetal circulation receives output from both the left and the right ventricle, with the ventricles working in parallel. Systemic blood flow consists of the sum of the right and left ventricular outputs, with the exception of the small

amount of blood delivered to the fetal lungs by the right ventricle.
- Fetal blood flow is characterized by three important communications between the left and right circulation: the ductus venosus, the foramen ovale, and the ductus arteriosus.
- Acute hypotension in the fetus stimulates a reflex response, which includes both bradycardia and vasoconstriction.
- The sympathetic nervous system at birth is not as well developed as the parasympathetic nervous system; however, it plays an important role in the hemodynamic adjustments at birth.
- Although fetal fluid and electrolyte balance, and acid-base homeostasis, are primarily regulated and maintained by the placenta, the fetal kidneys play an important role in fetal development through amniotic fluid production.
- The pulmonary surfactant system is one of the last systems to develop before birth. Surfactant assembly occurs in the type II alveolar cells, and components of surfactant are first detected between 24 and 28 weeks' gestation.
- Fetal hemoglobin has a greater oxygen affinity than adult hemoglobin, owing to a decreased interaction between hemoglobin F and 2,3-DPG. The P50 of fetal blood is significantly lower than that of adult blood.
- Fetal hypoxemia leads to a significant redistribution of cardiac output to the heart and the brain. This results in both a global increase in cerebral blood flow and a redistribution of blood flow within the fetal brain.
- Fetal swallowing plays an important role in amniotic fluid homeostasis, and the swallowed fluid appears to provide nutritional support for mucosal development within the gastrointestinal tract.
- The fetus has nociceptive pathways capable of communicating painful stimuli from the periphery to the cerebral cortex. Current evidence suggests that fetal nociception at the level of the cortex occurs after the midpoint of pregnancy (i.e., between 24 and 30 weeks' gestation).

Antepartum Fetal Assessment and Therapy

George M. Graham III, MD, Joong Shin Park, MD, PhD, Errol R. Norwitz, MD, PhD

CHAPTER OUTLINE

Obstetric care providers have two patients, the mother and the fetus. Although assessment of maternal health is relatively straightforward, assessment of fetal well-being is far more challenging. Several tests have been developed to assess the fetus during pregnancy, including some that are recommended for all pregnancies (e.g., ultrasonography for pregnancy dating) and others that are reserved only for women with pregnancy complications (e.g., middle cerebral artery Doppler velocimetry in pregnancies with isoimmunization). In addition, a limited number of fetal interventions are employed to improve fetal outcome, including some that are used more frequently and others rarely, such as maternal corticosteroid administration and intrauterine fetal procedures, respectively. A review is presented here of the tests available to assess fetal well-being in both low- and high-risk pregnancies and of the fetal therapies used during the antepartum period.

PRENATAL CARE IN LOW-RISK PREGNANCIES

Determination of Gestational Age

The mean duration of a singleton pregnancy is 280 days (40 weeks) from the first day of the last normal menstrual period in women with regular 28-day menstrual cycles. *Term,* defined as the period from 37 weeks' (259 days') to 42 weeks' (294 days') gestation, is the optimal time for delivery. However, both preterm births (defined as delivery before 37 weeks' gestation) and postterm births (delivery after 42 weeks' gestation) are associated with increased perinatal and neonatal morbidity and mortality, with variation occurring within this 5-week gestational age range. For this reason, the designations of *early term* (37 0/7 to 38 6/7 weeks' gestation), full term (39 0/7 to 40 6/7 weeks' gestation), and *late term* (41 0/7 to 41 6/7 weeks' gestation) were adopted.[1] Evaluation of fetal growth, efficient use of screening and diagnostic tests, appropriate initiation of fetal surveillance, and optimal timing of delivery all depend on accurate dating of the pregnancy.

Recommendations for determining the gestational age and estimated due date (EDD) have been established by the American College of Obstetricians and Gynecologists, the Society for Maternal-Fetal Medicine, and the American Institute of Ultrasound in Medicine (Box 6.1).[2] Determination of gestational age is most accurate when ultrasonographic measurement of the fetus or embryo is performed in the first trimester (up to and including 13 6/7 weeks' gestation). For pregnancies achieved by assisted reproductive technology (ART), the EDD should be assigned based on the age of the

BOX 6.1 Clinical Criteria Commonly Used to Confirm Gestational Age

- Reported date of last menstrual period (estimated due date can be calculated by subtracting 3 months and adding 7 days to the first day of the last normal menstrual period [Naegele's rule]) or date of assisted reproductive technology (intrauterine insemination or embryo transfer)
- The size of the uterus as estimated on bimanual examination in the first trimester, which should be consistent with dates
- The perception of fetal movement ("quickening"), which usually occurs at 18 to 20 weeks in nulliparous women and at 16 to 18 weeks in parous women
- Fetal heart activity, which can be detected with a nonelectronic fetal stethoscope by 18 to 20 weeks and with Doppler ultrasonography by 10 to 12 weeks
- Fundal height, which at 20 weeks in a singleton pregnancy should be approximately 20 cm above the pubic symphysis (usually corresponding to the umbilicus)
- Ultrasonography to determine fetal crown-rump length during the first trimester, or fetal biometry (biparietal diameter, head circumference, and/or femur length) during the second trimester

Data from the American College of Obstetricians and Gynecologists. Antepartum fetal surveillance. ACOG Practice Bulletin No. 9. Washington, DC, 1999 (reaffirmed 2009); American College of Obstetricians and Gynecologists. Management of postterm pregnancy. ACOG Practice Bulletin No. 55. Washington, DC, 2004 (reaffirmed 2009).

embryo and the date of transfer. Importantly, the EDD should be determined as soon as the last menstrual period (LMP) is recorded and the first accurate ultrasonographic examination is performed, and the EDD should be communicated to the patient and documented in the medical record. Assigning the EDD by the first day of the LMP is limited by inaccurate recall of the LMP, irregular cycle length, and variation in the timing of ovulation. One study reported that reliance on LMP alone leads to a false diagnosis of preterm birth and postterm pregnancy in one-fourth and one-eighth of cases, respectively.[3] For these reasons, ultrasonographic measurement of the embryo or fetus can improve the accuracy of the EDD, even when the LMP is known, and the earlier in pregnancy the ultrasonographic examination is performed, the greater the accuracy. In the first trimester, before 14 0/7 weeks' gestation, the mean of three crown-rump length (CRL) measurements should be used to establish or confirm the gestational age. In the second and third trimesters, at 14 0/7 weeks' gestation and beyond, biometric measurements should be used for dating. Measurements of the biparietal diameter, head circumference, femur length, and the abdominal circumference are used in a regression formula to calculate the gestational age and EDD. Assessment of gestational age in the third trimester (28 0/7 weeks' gestation and beyond) is the least accurate.[2] Guidelines for revising the EDD of pregnancy are based on the initial ultrasonographic examination. If the CRL dating differs by more than 5 days from the LMP dating before 9 0/7 weeks' gestation, then the EDD should be revised based on the CRL measurement. A difference of greater than 7 days between 9 0/7 and 15 6/7 weeks' gestation, greater than 10 days between 16 0/7 and 21 6/7 weeks' gestation, greater than 14 days between 22 0/7 and 27 6/7 weeks' gestation, and greater than 21 days at 28 0/7 weeks' gestation and beyond should be revised based on the ultrasonographic examination.[2]

Because the accuracy of gestational age assessment decreases with increasing gestational age, pregnancies without an ultrasonographic examination confirming or revising the EDD before 22 0/7 weeks' gestation should be considered suboptimally dated.[2,4] These pregnancies may benefit from a follow-up ultrasonographic examination 3 to 4 weeks after the initial ultrasonographic examination to confirm gestational age and assess interval growth to screen for fetal growth restriction.

Importantly, once the EDD is established it should rarely be revised, as discrepancies between gestational age and fetal measurements could indicate an abnormality in fetal growth, such as macrosomia or fetal growth restriction.[5]

Routine Ultrasonography

An ultrasonographic examination is recommended for all pregnancies,[6,7] given its ability to accurately determine gestational age, viability, fetal number, and placental location, and screen for fetal structural abnormalities in the second trimester.

Some studies have shown an improvement in perinatal outcome with the use of ultrasonography.[8,9] In a prospective trial of 9310 low-risk women randomly assigned to an ultrasonographic examination for screening at 16 to 20 weeks' gestation or for obstetric indications only, a significantly lower perinatal mortality rate was observed in the group undergoing screening (4.6 vs. 9.0 per 1000 births, respectively).[10] The screening examination allowed for earlier detection of major fetal malformations and multiple gestations, which enabled more appropriate care, and improved pregnancy dating and a lower rate of labor inductions for postterm pregnancies. In contrast, a subsequent large multicenter randomized clinical trial involving 15,151 low-risk women in the United States, designated the RADIUS study, concluded that screening ultrasonography did not improve perinatal outcomes and had no impact on the management of the anomalous fetus.[11] Although this trial was adequately powered, the highly selective entry criteria (less than 1% of pregnant women in the United States would have been eligible) and inappropriate primary outcomes for a low-risk population (perinatal morbidity and mortality) have been criticized.[12] Importantly, in the routine ultrasonography group, only 17% of major congenital anomalies were detected before 24 weeks' gestation. There is significant variability in the sensitivity of routine ultrasonographic examinations for the detection of fetal anomalies; in a large review of 36 studies with over 900,000 fetuses, the detection rate for fetal anomalies ranged from 15% to 80%.[13] The detection rates for malformations are improved when performed by an experienced operator at a tertiary center,[14] are higher for central nervous

system and urinary tract versus cardiac anomalies, and are lower in patients with a high body mass index (BMI).[15]

Evaluation of Fetal Growth

Normal fetal growth is a critical component of a healthy pregnancy and the subsequent long-term health of the child. An increased risk for delivering a small-for-gestational-age baby and/or having a preterm delivery is associated with low maternal gestational weight gain, while a higher risk for delivering a large-for-gestational-age baby and/or cesarean delivery is associated with excessive gestational weight gain.[16] The current recommendations for maternal weight gain in pregnancy were revised by the Institute of Medicine (IOM) in 2009 and are based on maternal prepregnancy BMI (Table 6.1).[17] The guidelines recommend that: (1) underweight and normal weight women gain approximately 1 pound (0.5 kg) per week in the second and third trimesters; (2) overweight and obese women gain approximately one-half pound (0.25 kg) per week in the second and third trimesters; and (3) all women try to be within the normal BMI range when they conceive.

The size, presentation, and lie of the fetus can be assessed with abdominal palpation. A systematic method of examination of the gravid abdomen was first described by Leopold and Sporlin in 1894.[18] Although the abdominal examination has several limitations (especially in the setting of a small fetus, maternal obesity, multiple pregnancy, uterine fibroids, or polyhydramnios), it is safe, is well tolerated, and may add valuable information to assist in antepartum management. Palpation is divided into four separate Leopold maneuvers (Fig. 6.1). Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and mother. The first maneuver, for example, involves measurement of the fundal height. The uterus can be palpated above the pelvic brim at approximately 12 weeks' gestation. Thereafter, fundal height should increase by approximately 1 cm per week, reaching the level of the umbilicus at 20 to 22 weeks' gestation (Fig. 6.2). Between 20 and 32 weeks' gestation, the fundal height (in centimeters) is approximately equal to the gestational age (in weeks) in healthy women of average weight with an appropriately growing fetus. However, there is a wide range of normal fundal height measurements. In one study, a 6-cm difference was noted between the 10th and 90th percentiles at each week of gestation after 20 weeks.[19] Moreover, maximal fundal height occurs at approximately 36 weeks' gestation, after which time the fetus drops into the pelvis in preparation for labor. For all of these reasons, reliance on fundal height measurements alone fails to identify more than 50% of fetuses with fetal growth restriction (also known as intrauterine growth restriction).[20] Serial fundal height measurements by an experienced obstetric care provider are more accurate than a single measurement and will lead to better diagnosis of fetal growth restriction, with reported sensitivities as high as 86%.[21]

TABLE 6.1 Recommendations for Weight Gain in Pregnancy

Mother's Body Mass Index	Recommended Weight Gain
18.5–24.9 kg/m^2 (normal weight)	11.2–15.9 kg (25–35 lb)
25–29.9 kg/m^2 (overweight)	6.8–11.2 kg (15–25 lb)
> 30 kg/m^2 (obese)	5.0–9.0 kg (11–20 lb)

Data from the Institute of Medicine. Nutritional status and weight gain. In Nutrition during Pregnancy. https://www.ncbi.nlm.nih.gov/books/NBK235222/. Accessed April 2018.

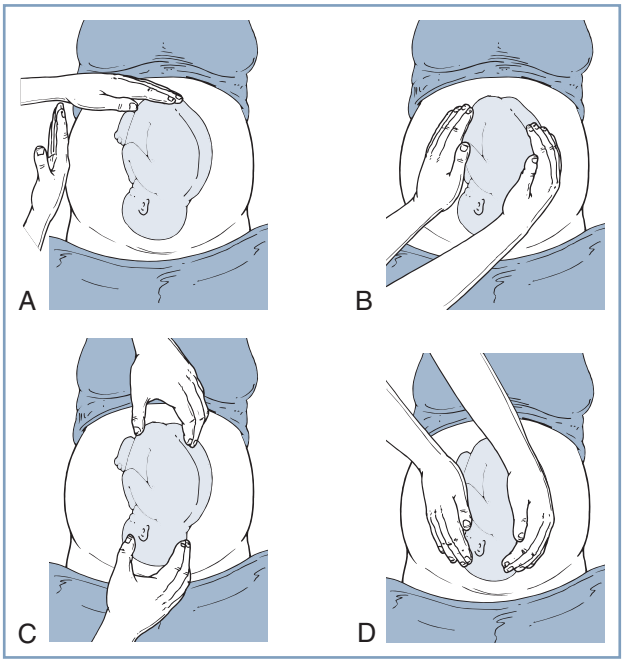

Fig. 6.1 Leopold maneuvers for palpation of the gravid abdomen.

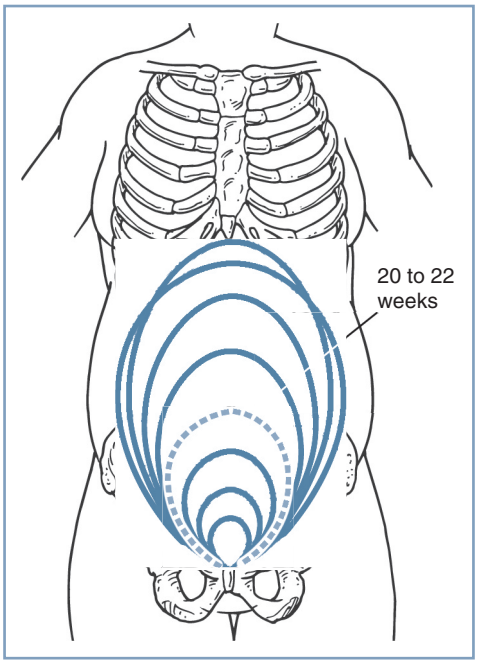

Fig. 6.2 Fundal height measurements in a singleton pregnancy with normal fetal growth.

If clinical findings suggest a fetal growth discrepancy between size and dates, ultrasonography is the modality of choice to evaluate and offer alternative explanations, such as multifetal pregnancy, polyhydramnios, fetal demise, and uterine fibroids. For many years, obstetric ultrasonography has used fetal biometry to define fetal size by weight estimations. This approach has a number of limitations. First, regression equations used to create weight estimation formulas are derived primarily from cross-sectional data for infants being delivered within an arbitrary period after the ultrasonographic examination. Second, these equations assume that body proportions (fat, muscle, bone) are the same for all fetuses.[21-32] Finally, growth curves for "normal" infants between 24 and 37 weeks' gestation rely on data collected from pregnancies delivered preterm, which are abnormal and probably complicated by some element of uteroplacental insufficiency, regardless of whether the delivery was spontaneous or iatrogenic. Despite these limitations, if the gestational age is well validated, the prevailing data suggest that prenatal ultrasonography can be used to verify an alteration in fetal growth in 80% of cases and to exclude abnormal growth in 90% of cases.[33]

Ultrasonographic estimates of fetal weight are commonly derived from mathematical formulas that use a combination of fetal measurements, especially the biparietal diameter, abdominal circumference, and femur length.[34] The abdominal circumference is the single most important measurement and is weighted more heavily in these formulas. Unfortunately, the abdominal circumference is also the most difficult measurement to acquire, and small differences in the measured value result in large changes in the estimated fetal weight (EFW). The accuracy of the EFW depends on a number of variables, including gestational age (in absolute terms, EFW is more accurate in preterm or growth-restricted fetuses than in term or macrosomic fetuses), operator experience, maternal body habitus, and amniotic fluid volume (ultrasound measurements are more difficult to acquire if the amniotic fluid volume is low). The EFW may differ from the birthweight by up to 20% in 95% of cases, and greater than 20% in the remaining cases.[35] Indeed, an ultrasonographic EFW at term is no more accurate than a clinical estimate of fetal weight made by an experienced obstetric care provider or the mother's estimate of fetal weight if she has delivered before.[36] Ultrasonographic estimates of fetal weight must therefore be evaluated within the context of the clinical situation and balanced against the clinical estimates. Serial ultrasonographic evaluations of fetal weight are more useful than a single measurement in diagnosing abnormal fetal growth. The ideal interval for fetal growth evaluations is every 3 to 4 weeks, because more frequent determinations may be misleading due to variations in the ultrasonographic measurements; however, in some cases, such as with fetuses suspected of growth restriction, evaluations can be performed every 2 weeks. The use of population-specific fetal growth curves based on maternal (e.g., weight or race[37]) or environmental factors have been demonstrated to improve the accuracy of ultrasonographic EFW, particularly in the setting of abnormal fetal growth. For example, growth curves derived from a population that lives at high altitude, where the fetus is exposed to lower oxygen tension, will be different from those derived from a population at sea level. However, the use of customized fetal growth curves has not yet been shown to improve outcomes.[35,38] Abnormal fetal growth can be classified as insufficient (fetal growth restriction) or excessive (fetal macrosomia).

Fetal Growth Restriction

Fetal growth restriction is associated with a number of significant adverse perinatal outcomes, including intrauterine demise, neonatal morbidity, and neonatal mortality.[35] In addition, growth-restricted fetuses are at increased risk for cognitive delay in childhood and chronic diseases, such as obesity, type 2 diabetes, coronary artery disease, and stroke in adulthood.[38,39]

The definition of *fetal growth restriction* is an EFW less than the 10th percentile for gestational age; by contrast, the term *small for gestational age* (SGA) is reserved for newborns with a birth weight less than the 10th percentile for gestational age.[39] Distinguishing the healthy, constitutionally-small-for-gestational age fetus from the pathologically growth-restricted fetus has been particularly difficult. Fetuses with an EFW less than the 10th percentile are not necessarily pathologically growth restricted or at risk for an adverse outcome. Conversely, an EFW above the 10th percentile does not necessarily mean that an individual fetus has achieved its growth potential, and such a fetus may still be at risk for perinatal mortality and morbidity.[35]

Fetal growth restriction results from suboptimal uteroplacental perfusion and fetal nutrition caused by different conditions that can be divided into maternal, fetal, and placental etiologies (Box 6.2).[35] Maternal disorders associated with fetal growth restriction include any condition that can potentially result in vascular disease, such as pregestational diabetes, hypertension, antiphospholipid antibody syndrome, autoimmune diseases and renal insufficiency, malnutrition, and substance abuse. Fetal conditions that may result in growth restriction include teratogen exposure, including certain medications; intrauterine infection; aneuploidy, most often trisomy 13 and trisomy 18; and some structural malformations, such as abdominal wall defects and congenital heart disease. Placental pathology resulting in poor placental perfusion can lead to fetal growth restriction. Umbilical cord abnormalities, such as velamentous or marginal cord insertion, have also been implicated in cases of fetal growth restriction.[35] In more than half of cases of growth restriction, the etiology may be unclear even after a thorough investigation.[39]

Fetal growth restriction is associated with an increased risk for stillbirth.[40] When the EFW measures less than the 10th percentile, the risk for stillbirth is 1.5%, which is twice the background risk for appropriately grown fetuses. The risk for stillbirth increases to 2.5% when the EFW is less than the 5th percentile.[41,42] The risk for stillbirth is further increased when fetal growth restriction occurs in the context of oligohydramnios or abnormal diastolic blood flow in the umbilical artery.[43]

BOX 6.2 High-Risk Pregnancies

Maternal Factors
- Preeclampsia (gestational proteinuric hypertension)
- Chronic hypertension
- Diabetes mellitus (including gestational diabetes)
- Maternal cardiac disease
- Chronic renal disease
- Chronic pulmonary disease
- Active thromboembolic disease

Fetal Factors
- Nonreassuring fetal testing (fetal compromise)
- Fetal growth restriction
- Isoimmunization
- Intra-amniotic infection
- Known fetal structural anomaly
- Prior unexplained stillbirth
- Multiple pregnancy

Uteroplacental Factors
- Premature rupture of fetal membranes
- Unexplained oligohydramnios
- Prior classic (high vertical) hysterotomy
- Placenta previa
- Placental abruption
- Vasa previa

Early and accurate diagnosis of fetal growth restriction coupled with appropriate intervention leads to an improvement in perinatal outcome. If fetal growth restriction is suspected clinically and on the basis of ultrasonography, a thorough evaluation of the mother and fetus is indicated. Referral to a maternal-fetal medicine specialist should be considered. Every effort should be made to identify the cause of the fetal growth restriction and to modify or eliminate contributing factors. The growth-restricted fetus should be monitored closely because of the increased risk for perinatal mortality. Monitoring should include serial ultrasonographic examinations for growth and amniotic fluid volume, and antenatal surveillance with umbilical artery velocimetry and antepartum testing (nonstress tests or biophysical profiles). The timing of delivery should be based on gestational age, the underlying etiology if known, results of antepartum testing and interval growth scans, and any additional risk factors for an adverse outcome, including maternal co-morbidities.[35]

Fetal Macrosomia

Fetal macrosomia, defined as growth beyond an absolute birth weight of 4000 g or 4500 g regardless of gestational age,[44] should be differentiated from the term *large for gestational age* (LGA), which implies a birth weight greater than or equal to the 90th percentile for a given gestational age. By definition, in the United States, 10% of all fetuses are LGA, 8% of all live-born infants weigh 4000 g or more, and 1.1% weigh more than 4500 g.[45]

In general, the risk for labor abnormalities (e.g., cephalopelvic disproportion, dysfunctional labor), maternal morbidity (e.g., cesarean delivery, postpartum hemorrhage, significant vaginal lacerations), and newborn complications (e.g., Apgar score less than 4 at 5 minutes, birth injuries, assisted ventilation greater than 30 minutes, neonatal intensive care unit admission) increases with birth weights between 4000 and 4499 g; newborn and maternal morbidity increases significantly with birth weights between 4500 and 4999 g; and perinatal mortality (e.g., stillbirth and neonatal mortality) increase with birthweights greater than 5000 g.[45] Shoulder dystocia, defined as a failure of delivery of the fetal shoulder(s) after initial attempts at downward traction, is the most serious consequence of fetal macrosomia, and requires additional maneuvers to effect delivery.[46] The fetal injuries associated with shoulder dystocia include fracture of the clavicle and damage to the nerves of the brachial plexus, resulting in Erb-Duchenne paralysis, of which the vast majority resolve by 1 year of age. Compared with a prevalence of 0.2% to 3.0% for all vaginal deliveries, the risk for shoulder dystocia at birthweights of 4500 grams or more is 9% to 14%, and increases further in the setting of maternal diabetes to 20% to 50%.[47,48]

Fetal macrosomia can be determined clinically by abdominal palpation (e.g., Leopold maneuvers) or with ultrasonography; although these two techniques appear to be equally accurate,[49] the ability to predict fetal macrosomia is poor, with a false-positive rate of 35% and a false-negative rate of 10%.[49,50] Estimated fetal weight measurements are less accurate in macrosomic fetuses than in normally grown fetuses, and factors such as low amniotic fluid volume, advancing gestational age, maternal obesity, and fetal position can compound these inaccuracies. Indeed, clinical examination has been shown to underestimate the birth weight by more than 0.5 kg in almost 80% of macrosomic fetuses.[50] A number of alternative ultrasonographic measurements have therefore been proposed in an attempt to better identify the macrosomic fetus, including fetal abdominal circumference alone,[51] umbilical cord circumference,[52] cheek-to-cheek diameter,[53] and subcutaneous fat in the mid humerus, thigh, abdominal wall, and shoulder.[54] However, these measurements remain investigational.

Despite the inaccuracy in the prediction of fetal macrosomia, an EFW should be documented by either clinical estimation or ultrasonography in all high-risk women at approximately 38 weeks' gestation. Suspected fetal macrosomia is not an indication for induction of labor, because induction does not improve maternal or fetal outcomes and may increase the risk for cesarean delivery.[44] The American College of Obstetricians and Gynecologists (ACOG) recommends performance of an elective cesarean delivery when the suspected birth weight exceeds 4500 g in a diabetic woman or 5000 g in a nondiabetic woman.[44] Similarly, a cesarean delivery is recommended in laboring women when the suspected birth weight exceeds 4500 g in the setting of a prolonged second stage of labor or arrest of descent in the second stage.[44]

Assessment of Fetal Well-Being

All pregnant women should receive regular antenatal care throughout their pregnancy, and fetal well-being should be

evaluated at every visit. Fetal heart activity should be assessed and the fetal heart rate (FHR) estimated. A low FHR (< 100 bpm) is associated with an increased risk for pregnancy loss, although congenital complete heart block should be excluded. In the latter half of pregnancy, physical examination of the abdomen should be performed to document fetal lie and presentation.

Fetal movements ("quickening") are typically reported at 18 to 20 weeks' gestation by nulliparous women and at 16 to 18 weeks' gestation by parous women; the presence of fetal movements is strongly correlated with fetal health. Although the mother appreciates only 10% to 20% of total fetal movements,[55] such movements are almost always present when she does report them.[56] Factors associated with a diminution in perceived fetal movements include increasing gestational age, smoking, decreased amniotic fluid volume, anterior placentation, and antenatal corticosteroid therapy. Decreased fetal movements may also be a harbinger of an adverse pregnancy event (e.g., stillbirth) that can be averted if detected early. For these reasons, a subjective decrease in perceived fetal movements in the third trimester should prompt an immediate investigation.

Published studies support the value of **fetal movement** charts ("kick counts") in the detection and prevention of fetal complications (including stillbirth) in both high- and low-risk populations.[57–59] The normal fetus exhibits an average of 20 to 50 (range of 0 to 130) gross body movements per hour, with fewer movements during the day and increased activity between 9:00 PM and 1:00 AM.[60] Several different schemes have been proposed to determine the baseline fetal activity pattern for an individual fetus after 28 weeks' gestation and to evaluate activity patterns that may represent fetal compromise. One commonly used scheme ("count-to-10") instructs the mother to rest quietly on her left side once each day in the evening (between 7:00 PM and 11:00 PM) and to record the time interval required to feel 10 fetal movements. Most patients with a healthy fetus will feel 10 movements in approximately 20 minutes; 99.5% of women with a healthy fetus feel this amount of activity within 90 minutes.[61] Under this scheme, failure to appreciate 10 fetal movements in 2 hours should prompt immediate fetal assessment. In one large clinical trial, institution of this fetal activity monitoring scheme resulted in a significant increase in hospital visits, labor induction, and cesarean deliveries, but also in a reduction in perinatal mortality from 44.5 to 10.3 per 1000 births.[61] Taken together, these data suggest that daily or twice-daily fetal "kick counts" should be performed after 32 weeks' gestation in high-risk pregnancies. Currently there is insufficient evidence to recommend this practice in low-risk pregnancies.

PRENATAL CARE IN HIGH-RISK PREGNANCIES

Approximately 20% of all pregnancies should be regarded as high risk (see Box 6.2). Because of the attendant risks to both the mother and fetus, additional efforts should be made to confirm fetal well-being throughout such pregnancies. In addition to the testing outlined previously, high-risk pregnancies should be monitored closely and regularly by a multidisciplinary team, including subspecialists in maternal-fetal medicine and neonatology, if indicated.

Goals of Antepartum Fetal Testing

The goal of antepartum fetal surveillance is the early identification of a fetus at risk for preventable neurologic injury or death. Numerous causes of neonatal cerebral injury exist, including congenital abnormalities, chromosomal abnormalities, intracerebral hemorrhage, hypoxia, infection, drugs, trauma, hypotension, and metabolic derangements (e.g., hypoglycemia, thyroid dysfunction). Antenatal fetal testing cannot reliably predict or detect all of these causes; however, those specifically associated with uteroplacental vascular insufficiency should be identified when possible. Antenatal fetal testing makes the following assumptions: (1) pregnancies may be complicated by progressive fetal asphyxia that can lead to fetal death or permanent neurologic handicap; (2) current antenatal tests can adequately discriminate between asphyxiated and nonasphyxiated fetuses; and (3) detection of asphyxia at an early stage can lead to an intervention that is capable of reducing the likelihood of an adverse perinatal outcome.

Unfortunately, it is not clear whether any of these assumptions are true, and nonreassuring fetal test results may reflect existing but not ongoing neurologic injury. At most, 15% of cases of cerebral palsy are thought to result from antepartum or intrapartum hypoxic-ischemic injury.[62,63] Despite these limitations, a number of antepartum tests have been developed in an attempt to identify fetuses at risk. These include the nonstress test (NST), biophysical profile (BPP), and contraction stress test (CST). Such tests can be used either individually or in combination. There is no consensus as to which of these modalities is preferred, and no single method has been shown to be superior.[64]

Antepartum Fetal Tests

All antepartum fetal tests should be interpreted in relation to the gestational age, the presence or absence of congenital anomalies, and underlying clinical risk factors.[65] For example, a nonreassuring NST in a pregnancy complicated by severe fetal growth restriction and heavy vaginal bleeding at 32 weeks' gestation has a much higher predictive value in identifying a fetus at risk for subsequent neurologic injury than an identical tracing in a well-grown fetus at 40 weeks, because of the higher prevalence of this condition in the former situation. It should be remembered that, in many cases, the efficacy of antenatal fetal testing in preventing long-term neurologic injury has not been validated by prospective randomized clinical trials. Indeed, because of ethical and medicolegal concerns, there are no studies of pregnancies at risk that include a nonmonitored control group, and it is highly unlikely that such trials will ever be performed.

Nonstress Test

The fetal NST, also known as fetal cardiotocography, investigates changes in the FHR pattern with time and reflects the maturity of the fetal autonomic nervous system; for this

reason, it is less useful in the very preterm fetus (< 28 weeks' gestation). The NST is noninvasive, simple to perform, inexpensive, and readily available in all obstetric units. However, interpretation of the NST is largely subjective. Although a number of different criteria have been used to evaluate these tracings, most obstetric care providers have used the definitions for FHR interpretation established in 1997, and updated in 2008, by the National Institute of Child Health and Human Development (NICHD) Research Planning Workshop (Table 6.2).[66,67]

By definition, an NST is performed before the onset of labor and does not involve invasive (intrauterine) monitoring. The test is performed by recording the FHR for a period of 20 to 40 minutes; the recording is then evaluated for the presence of periodic changes. The FHR is determined externally with use of Doppler ultrasonography, in which sound waves emitted from the transducer are deflected by movements of the heart and heart valves. The shift in frequency of these deflected waves is detected by a sensor and converted into heart rate. The FHR is printed on a strip-chart recorder running at 3 cm/min. A single mark on the FHR tracing therefore represents the average rate in beats per minute (bpm) of 6 fetal heart beats. The presence or absence of uterine contractions is typically recorded at the same time with an external tonometer. This tonometer records myometrial tone and provides information about the timing and duration of contractions, but it does not measure intrauterine pressure or the intensity of the contractions. Results of the NST are interpreted as reactive or nonreactive. An FHR tracing is designated *reactive* if there are two or more accelerations that peak, but not necessarily remain, at least 15 bpm for 15 seconds in a 20-minute period (Fig. 6.3).[66,67] For preterm fetuses (< 32 weeks' gestation), an FHR tracing is designated as reactive if there are two or more accelerations of at least 10 bpm for 10 seconds. A reactive NST is regarded as evidence of fetal health.[68,69]

TABLE 6.2 Interpretation of Antepartum Nonstress Test Results

Criterion	Definition
Baseline fetal heart rate (FHR)	Defined as the approximate mean FHR during a 10-min segment and lasting at least 2 min. The normal FHR is defined as 110 to 160 bpm.
Baseline FHR variability	Described as fluctuations in the baseline FHR of ≥ 2 cycles/min. It is quantified visually as the amplitude of peak-to-trough in bpm. Variability is classified as follows: • Absent: amplitude range undetectable • Minimal: amplitude range detectable but ≤ 5 bpm • Moderate: amplitude range 6 to 25 bpm • Marked: amplitude range > 25 bpm The normal baseline FHR variability is defined as moderate variability.
Accelerations	Defined as an abrupt increase in FHR above baseline. • At and after 32 weeks' gestation, an acceleration is defined as ≥ 15 bpm above baseline for ≥ 15 sec but < 2 min. • Before 32 weeks' gestation, an acceleration is defined as ≥ 10 bpm above baseline for ≥ 10 sec but < 2 min. A **prolonged acceleration** is defined as an acceleration lasting ≥ 2 min but < 10 min. If the duration is longer than 10 min, it is referred to as a "change in baseline" and not a prolonged acceleration.
Decelerations	Decelerations are not normal. However, some decelerations are a more serious sign of fetal compromise than others. The following three types of decelerations are recognized: • **Early decelerations** are characterized by a gradual decrease and return to baseline FHR associated with a uterine contraction. The onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the uterine contraction. • **Variable decelerations** are characterized by an abrupt decrease in the FHR to ≥ 15 bpm below the baseline and lasting for ≥ 15 sec but < 2 min. Abrupt is defined as < 30 sec from baseline to the nadir of the deceleration. When variable decelerations are associated with uterine activity, their onset, depth, and duration commonly vary with successive contractions. • **Late decelerations** are characterized by a gradual decrease and return to baseline FHR associated with a uterine contraction. Importantly, the deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction. Onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the uterine contraction. A **prolonged deceleration** is defined as a deceleration lasting ≥ 2 min but < 10 min. If the duration is longer than 10 min, it is referred to as a "change in baseline" and not a prolonged deceleration. **Recurrent decelerations** describe the presence of decelerations with more than 50% of uterine contractions in any 20-min period.

Data from the National Institute of Child Health and Human Development Research Planning Workshop. Electronic fetal heart rate monitoring: research guidelines for interpretation. *Am J Obstet Gynecol.* 1997;177:1385–1390.

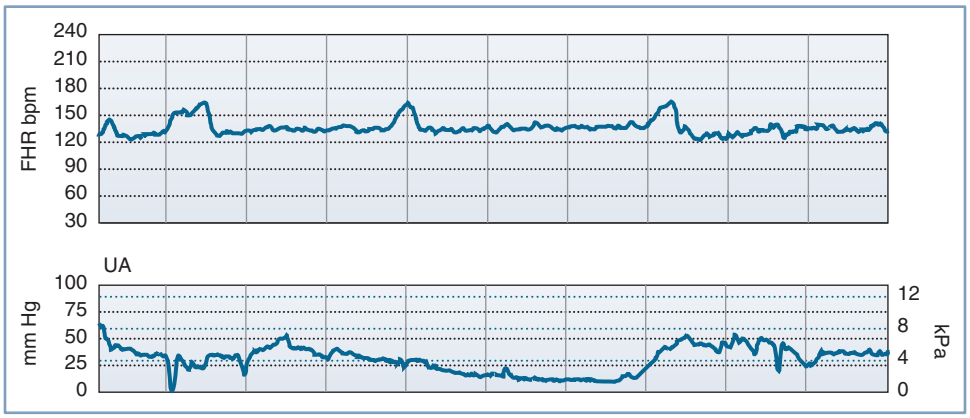

Fig. 6.3 A normal (reactive) fetal heart rate *(FHR)* tracing. The baseline FHR is normal (between 110 and 160 bpm), there is moderate variability (defined as 6 to 25 bpm from peak to trough), there are no decelerations, and there are two or more accelerations (defined as an increase in FHR of ≥ 15 bpm above baseline lasting at least 15 seconds) in a 20-minute period.

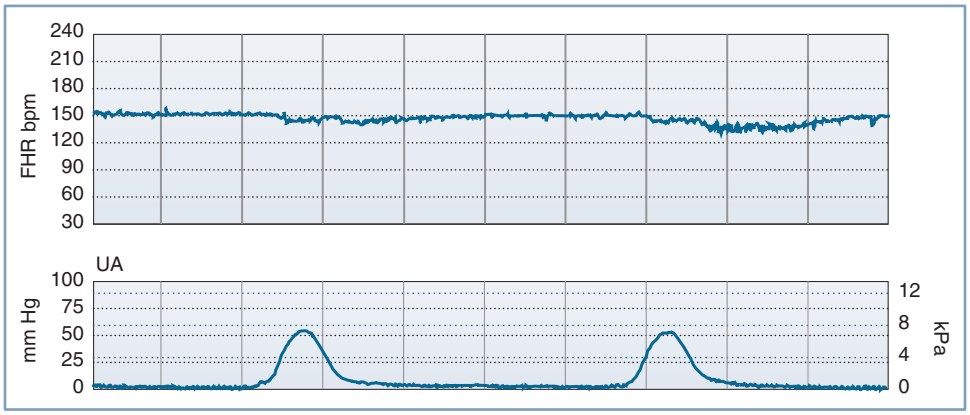

Fig. 6.4 An "at-risk" fetal heart rate *(FHR)* tracing. The baseline FHR is normal (between 110 and 160 bpm), but the following abnormalities can be seen: minimal baseline FHR variability (defined as 0 to 5 bpm from peak to trough), no accelerations, and decelerations that are late in character (start after the peak of the contraction) and repetitive (occur with more than half of the contractions).

A nonreactive NST does not achieve sufficient accelerations within a 40-minute period; this finding does not necessarily indicate a compromised fetus, as most often it is secondary to a fetal sleep cycle.[64] The interpretation of a nonreactive NST must consider the gestational age, the underlying clinical circumstance, and the results of previous FHR tracings. Only 65% of fetuses have a reactive NST by 28 weeks' gestation, whereas 95% do so by 32 weeks.[65,70] However, once a reactive NST has been documented in a given pregnancy, the NST should remain reactive throughout the remainder of the pregnancy. A nonreactive NST at term is associated with poor perinatal outcome in only 20% of cases. The significance of such a result at term depends on the clinical endpoint under investigation. If the clinical endpoint of interest is a 5-minute Apgar score less than 7, a nonreactive NST at term has a sensitivity of 57%, a positive predictive value of 13%, and a negative predictive value of 98% (assuming a prevalence of 4%). If the clinical endpoint is permanent neurologic injury, a nonreactive NST at term has a 99.8% false-positive rate.[71]

Visual interpretation of the FHR tracing involves the following components: (1) baseline FHR, (2) baseline FHR variability, (3) presence of accelerations, (4) presence of periodic or episodic decelerations, and (5) changes of FHR pattern over time. The definitions of each of these variables are summarized in Table 6.2.[66,67] The patterns are categorized as baseline, periodic (i.e., associated with uterine contractions), or episodic (i.e., not associated with uterine contractions). Periodic changes are described as *abrupt* or *gradual* (defined as onset-to-nadir time < 30 seconds or > 30 seconds, respectively). In contrast to earlier classifications, this classification makes no distinction between short-term and long-term variability, and certain characteristics (e.g., the definition of an acceleration) depend on gestational age.[66,67]

A normal FHR tracing is defined as having a normal baseline rate (110 to 160 bpm), normal baseline variability (i.e., moderate variability, defined as 6 to 25 bpm from peak to trough), presence of accelerations, and absence of decelerations. FHR accelerations typically occur in response to fetal movement, and usually indicate fetal health and adequate oxygenation.[66,67] At-risk FHR patterns demonstrate absence of baseline variability, combined with recurrent late or variable decelerations or substantial bradycardia (Fig. 6.4).

Intermediate FHR patterns have characteristics between the two extremes of normal and at-risk tracings already described.[66,67]

Persistent fetal tachycardia (defined as an FHR > 160 bpm) may be associated with fetal hypoxia, maternal fever, chorioamnionitis (intrauterine infection), administration of an anticholinergic or beta-adrenergic receptor agonist, fetal anemia, or tachyarrhythmia (see Table 6.2). Persistent fetal bradycardia (FHR < 110 bpm) may be a result of congenital heart block, administration of a beta-adrenergic receptor antagonist, hypoglycemia, or hypothermia; it may also indicate fetal hypoxia.[66,67] Both tachyarrhythmias and bradyarrhythmias require immediate evaluation.

Baseline FHR variability, perhaps the most important component of the NST, is determined on a beat-to-beat basis by the competing influences of the sympathetic and parasympathetic nervous systems on the fetal sinoatrial node. A variable FHR tracing, characterized by fluctuations that are irregular in both amplitude and frequency,[66,67] indicates that the autonomic nervous system is functioning and that the fetus has normal acid-base status. Variability is defined as absent, minimal, moderate, or marked (Fig. 6.5).[66,67] The older terms *short-term variability* and *long-term variability* are no longer used.[67] Normal (moderate) variability indicates the absence of cerebral hypoxia. With acute hypoxia, variability may be minimal or marked. Persistent or chronic hypoxia is typically associated with loss of variability. Reduced variability also may be the result of other factors, including maternal drug administration (Table 6.3), fetal arrhythmia, and neurologic abnormality (e.g., anencephaly).[66,67]

TABLE 6.3 Drugs That Affect the Fetal Heart Rate Tracing

Effect on the Fetus	Drug
Fetal tachycardia	Atropine
	Epinephrine (adrenaline)
	Beta-adrenergic agonists (ritodrine, terbutaline)
Fetal bradycardia	Antithyroid medications (including propylthiouracil)
	Beta-adrenergic antagonists (e.g., propranolol)
	Intrathecal or epidural analgesia
	Methylergonovine (contraindicated before delivery)
	Oxytocin (if associated with excessive uterine activity)
Sinusoidal fetal heart rate pattern	Systemic opioid analgesia
Diminished variability	Atropine
	Anticonvulsants (but not phenytoin)
	Beta-adrenergic antagonists
	Antenatal corticosteroids (betamethasone, dexamethasone)
	Ethanol
	General anesthesia
	Hypnotics (including diazepam)
	Insulin (if associated with hypoglycemia)
	Magnesium sulfate
	Systemic opioid analgesia
	Promethazine

Vibroacoustic Stimulation

Fetal vibroacoustic stimulation (VAS) refers to the response of the FHR to a vibroacoustic stimulus (82 to 95 dB) applied to the maternal abdomen for 1 to 2 seconds in the region of the fetal head. An FHR acceleration in response to VAS represents a positive result and is suggestive of fetal health. If VAS fails to produce an acceleration in the FHR, it may be repeated up to three times for progressively longer durations of up to 3 seconds.

VAS is a useful adjunct to shorten the time needed to achieve a reactive NST and to decrease the proportion of nonreactive NSTs at term, thereby precluding the need for further testing. In one study of low-risk women at term, VAS reduced the proportion of nonreactive NSTs over a 30-minute period by 50% (from 14% to 9%) and shortened the time needed to achieve a reactive NST by an average of 4.5 minutes.[72] VAS has no adverse effect on fetal hearing. The absence of an FHR acceleration in response to VAS at term is associated with an 18-fold higher risk for nonreassuring fetal testing in labor[73] and a 6-fold higher risk for cesarean delivery.[74]

Biophysical Profile

An NST alone may not be sufficient to confirm fetal well-being. In such cases, a biophysical profile (BPP) may be performed. The BPP combines an NST with an ultrasonographic scoring system performed over a 30-minute period. Initially described for testing of the postterm fetus, the BPP has since been validated for use in both term and preterm fetuses, but not during active labor.[75,76] The five variables described in the original BPP were (1) gross fetal body movements, (2) fetal tone (i.e., flexion and extension of limbs), (3) amniotic fluid volume, (4) fetal breathing movements, and (5) the NST (Table 6.4).[75] More recently, the BPP has been interpreted without the NST.

The individual variables of the BPP become apparent in the normal fetus in a predictable sequence: fetal tone appears at 7.5 to 8.5 weeks' gestation, fetal movement at 9 weeks, fetal breathing at 20 to 22 weeks, and FHR reactivity at 24 to 28 weeks. In the setting of antepartum hypoxia, these characteristics typically disappear in the reverse order of their appearance (i.e., FHR reactivity is lost first, followed by fetal breathing, fetal movements, and finally fetal tone).[76] The amniotic fluid volume, which is composed almost entirely of fetal urine in the second and third trimesters, is not influenced by acute fetal hypoxia or acute fetal central nervous system dysfunction. Rather, oligohydramnios (decreased amniotic fluid volume) in the latter half of pregnancy and in the absence of ruptured membranes is a reflection of chronic uteroplacental insufficiency and/or increased renal artery resistance leading to diminished urine output.[77] It predisposes

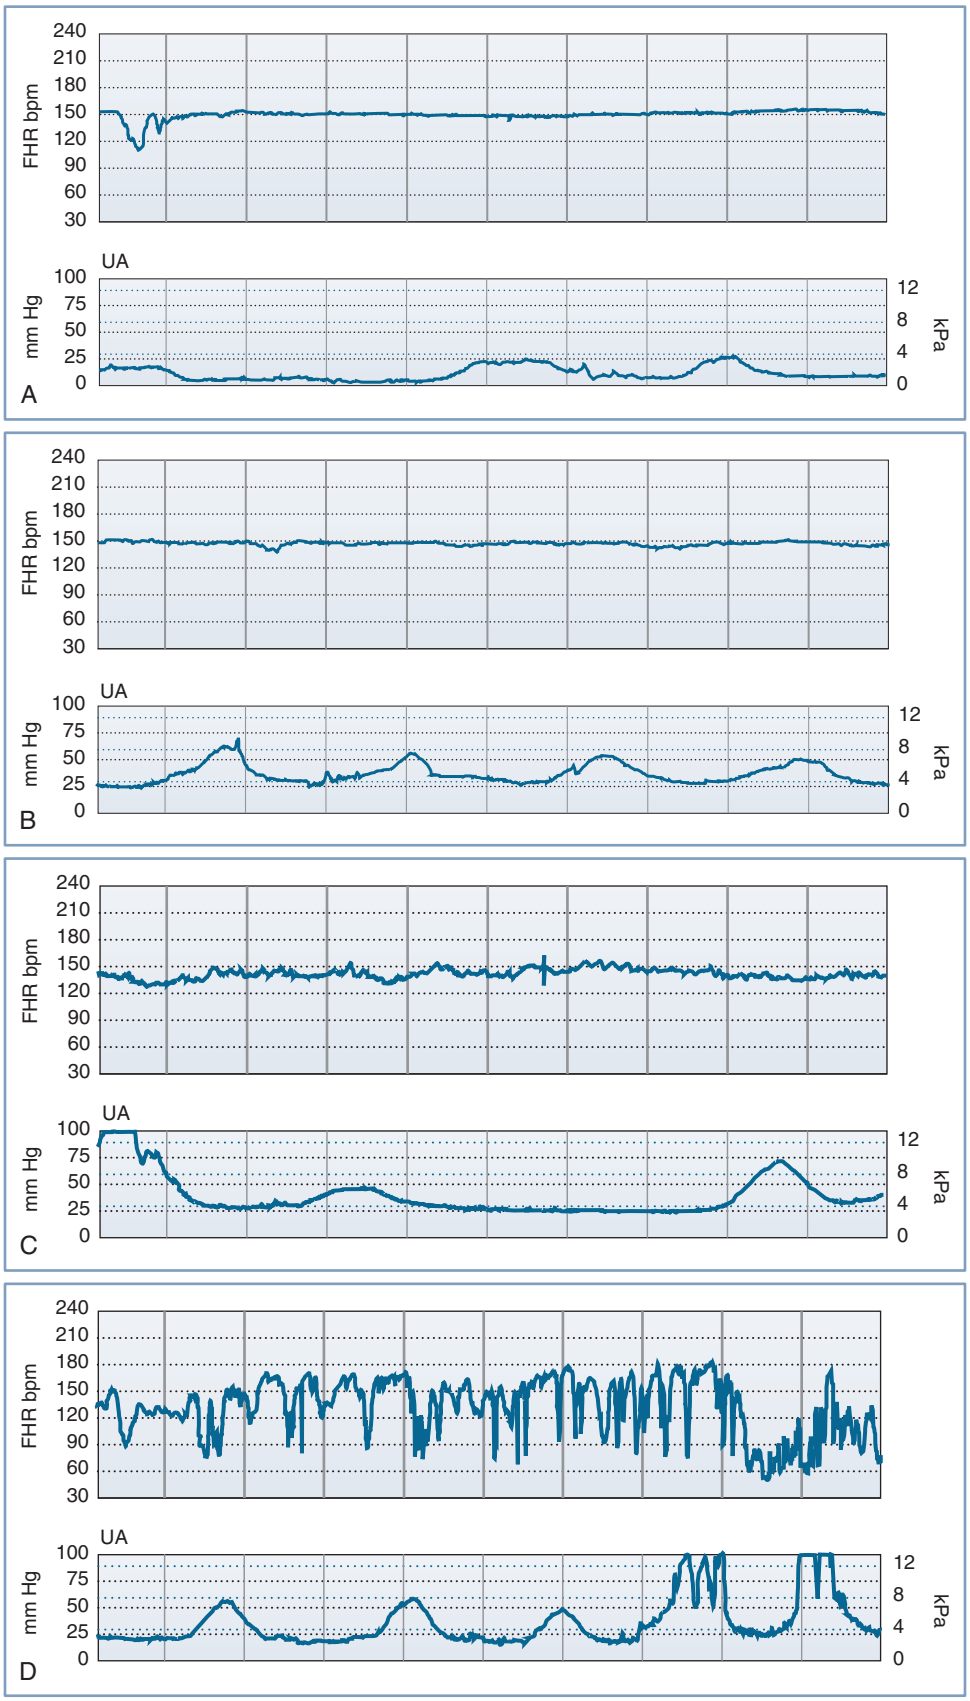

Fig. 6.5 Components of baseline fetal heart rate (FHR) variability. **A,** Absence of variability. **B,** Minimal variability (0 to 5 bpm from peak to nadir). **C,** Moderate variability (6 to 25 bpm from peak to nadir). **D,** Marked variability (> 25 bpm from peak to nadir).

TABLE 6.4 Characteristics of the Biophysical Profile

Biophysical Variable	Normal Score (Score = 2)	Abnormal Score (Score = 0)
FBM	At least one episode of FBM lasting at least 30 sec	Absence of FBM altogether or no episode of FBM lasting ≥ 30 sec
Gross body movements	At least three discrete body/limb movements in 30 min (episodes of active continuous movements should be regarded as a single movement)	Fewer than three episodes of body/limb movements over a 30-min period
Fetal tone	At least one episode of active extension with return to flexion of fetal limbs or trunk; opening and closing of hand are considered normal tone	Slow extension with return to partial flexion, movement of limb in full extension, or absence of fetal movements
Qualitative AF volume	At least one pocket of AF that measures ≥ 1 cm in two perpendicular planes	No AF pockets or an AF pocket measuring < 1 cm in two perpendicular planes
Reactive nonstress test	At least two episodes of FHR acceleration of ≥ 15 bpm lasting ≥ 15 sec associated with fetal movements over 30 min of observation	Fewer than two episodes of FHR acceleration or accelerations of < 15 bpm over 30 min of observation

AF, Amniotic fluid; *FBM,* fetal breathing movement; *FHR,* fetal heart rate.
Data from Manning FA. Fetal biophysical assessment by ultrasound. In: Creasy RK, Resnik R, eds. *Maternal-Fetal Medicine: Principles and Practice*. 2nd ed. Philadelphia, PA: WB Saunders; 1989:359.

to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, or meconium aspiration. An adverse pregnancy outcome (including a nonreassuring FHR tracing, low Apgar scores, and/or admission to the neonatal intensive care unit) is more common when oligohydramnios is present.[78,79] Weekly or twice-weekly screening of high-risk pregnancies for oligohydramnios is important because amniotic fluid can become drastically reduced within 24 to 48 hours.[80]

Although each of the five features of the BPP are scored equally (2 points if the variable is present or normal and 0 points if absent or abnormal, for a total of 10 points), they are not equally predictive of adverse pregnancy outcome. For example, amniotic fluid volume is the variable that correlates most strongly with adverse pregnancy events. The management recommended on the basis of the BPP score is summarized in Table 6.5.[81] A score of 8 or 10 is regarded as reassuring; a score of 6 is considered equivocal, and a score of 4 or less is abnormal. A score of 0 or 2 suggests nonreassuring fetal status (previously referred to as "fetal distress") and should prompt evaluation for immediate delivery.[76,82]

The *modified* BPP was developed to simplify and reduce the time necessary to complete an examination by focusing on the BPP components that are most predictive of outcome: (1) an NST, as an indicator of acute acid-base status, and (2) the amniotic fluid volume, as an index of uteroplacental function.[37] Composed of a reactive NST and a maximum vertical pocket of amniotic fluid greater than 2 cm, a *normal* modified BPP occurs in approximately 90% of examinations, and is as reliable as a full BPP in the prediction of fetal well-being. A full BPP is often performed if an abnormal result is obtained.

TABLE 6.5 Recommended Management Based on Biophysical Profile

Score	Interpretation	Recommended Management
8 or 10	Normal	No intervention
6	Suspect asphyxia	Repeat in 4 to 6 h Consider delivery for oligohydramnios
4	Suspect asphyxia	If ≥ 36 weeks' gestation or mature pulmonary indices, deliver immediately If < 36 weeks' gestation, repeat BPP in 4 to 6 h versus delivery with mature pulmonary indices If score persistently ≤ 4, deliver immediately
0 or 2	High suspicion of asphyxia	Evaluate for immediate delivery

Data from Manning FA. Fetal biophysical assessment by ultrasound. In Creasy RK, Resnik R, eds. *Maternal-Fetal Medicine: Principles and Practice*. 2nd ed. Philadelphia, PA: WB Saunders; 1989:359.

Contraction Stress Test

Also known as the oxytocin challenge test (OCT), the contraction stress test (CST) assesses the response of the FHR to uterine contractions induced by either intravenous oxytocin administration or nipple stimulation (which causes release of endogenous oxytocin from the maternal neurohypophysis). A minimum of three contractions for at least 40 seconds in a 10-minute period is required to interpret the test. A negative CST (no late or severe late decelerations with contractions) is reassuring and suggestive of a healthy, well-oxygenated fetus. A positive CST (late or severe variable decelerations with at least 50% of the contractions) is suggestive of a fetus suffering from impaired maternal-to-fetal oxygen exchange during uterine contractions and is associated with adverse perinatal outcome in 35% to 40% of cases (Fig. 6.6). A CST is defined as *equivocal* if FHR decelerations occur with contractions

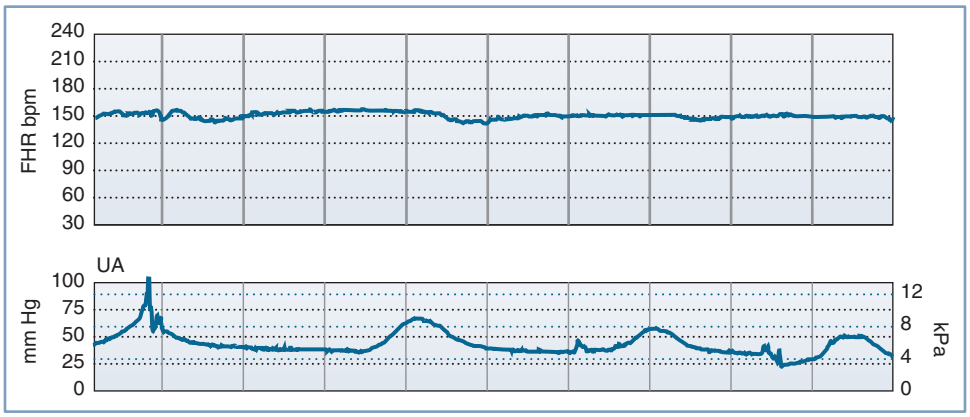

Fig. 6.6 A positive contraction stress test (CST) result. There are at least three contractions in a 10-minute period. The baseline fetal heart rate (FHR) is 130 bpm, there is minimal baseline FHR variability (defined as 0 to 5 bpm from peak to trough), and there are decelerations that are late in character (start after the peak of the contraction) and repetitive (occur with more than half of the contractions).

more frequently than every 2 minutes or lasting longer than 90 seconds, *equivocal-suspicious* if there are intermittent late decelerations or significant variable decelerations, and *unsatisfactory* if there are fewer than three contractions in 10 minutes or the FHR tracing is uninterpretable.[64] The combination of a positive CST and absence of FHR variability is especially ominous. Consideration should be given to immediate and urgent delivery of a fetus with a positive CST, with or without FHR variability. It should be noted, however, that the false-positive rate of this test exceeds 50%.[68] If the CST is uninterpretable or equivocal, the test should be repeated in 24 to 72 hours. Studies suggest that more than 80% of results of repeated tests are negative. The rate of antepartum intrauterine fetal demise within 1 week of a negative CST is 0.04%.[68,81]

Because this test is time-consuming, requires skilled nursing care, and necessitates an inpatient setting owing to the possibility of precipitating fetal compromise requiring emergency cesarean delivery, the CST is reserved for specific clinical indications. Moreover, there are a number of contraindications to its use, including placenta previa, placental abruption, prior classic (high-vertical) cesarean delivery, and risk for preterm labor. Despite these limitations, the CST allows for indirect evaluation of fetal oxygenation during periods of uterine contractions and diminished uteroplacental perfusion and may therefore provide a better assessment of fetal well-being and fetal reserve than either the NST or the BPP (Table 6.6).[64,68,83]

TABLE 6.6 False-Positive and False-Negative Rates for the Nonstress Test, Biophysical Profile, and Contraction Stress Test

Test	False-Positive Rate (%)	False-Negative Rate (per 1000 live births)[a]
NST	58	1.4–6.2
BPP:		0.7–1.2
• Score 6/10	45	
• Score 0/10	0	
CST	30	0.4–0.6

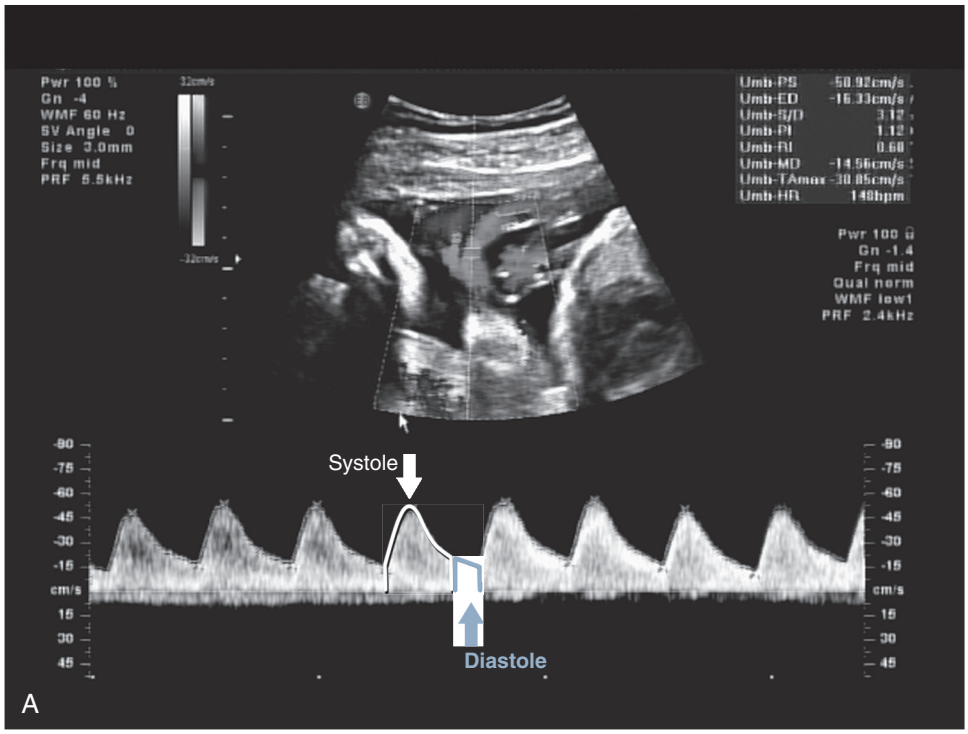
BPP, Biophysical profile; *CST,* contraction stress test; *NST,* nonstress test.
[a]Data are presented as perinatal mortality rate within 1 week of a reactive NST, a BPP score of 8 or 10, or a negative CST after adjustments for congenital anomalies and known causes.
Data from references 1, 84, 95, and 103.

Doppler Velocimetry

Doppler velocimetry can be used for the noninvasive measurement of fetal circulation, including the umbilical artery (UA), middle cerebral artery (MCA), and ductus venosus (DV). As one of the few arteries that normally has diastolic flow, the UA is frequently evaluated during pregnancy. Normally, UA resistance to blood flow from the fetus to the placenta falls progressively throughout pregnancy, reflecting an increase in the number of tertiary stem vessels. Factors that affect placental vascular resistance include gestational age, placental location, pregnancy complications (e.g., placental abruption, preeclampsia), and underlying maternal disease (chronic hypertension).[84] Doppler velocimetry is consequently used to evaluate growth-restricted fetuses, or growth discordance in twin gestations.

Decreased diastolic flow with a resultant increase in the systolic-to-diastolic (S/D) ratio suggests an increase in placental vascular resistance.[85,86] Severely abnormal UA Doppler velocimetry (defined as absence of or reversed diastolic flow) is consistent with the obliteration of 50% to 70% of the terminal villi; this ominous observation is associated with poor perinatal outcomes, particularly in the setting of fetal growth restriction (Fig. 6.7).[86–88] Delivery may be recommended for the presence of absent UA end-diastolic flow after 34 weeks' gestation, or reversed end-diastolic flow as early as 28 weeks' gestation.

The role of MCA or DV Doppler velocimetry in the management of fetal growth restriction pregnancies is not well defined. MCA Doppler velocimetry can evaluate if cerebral blood flow increases in response to hypoxia, which can be a useful adjunct to UA Doppler velocimetry. The cerebroplacental ratio, calculated by dividing the MCA pulsatility index



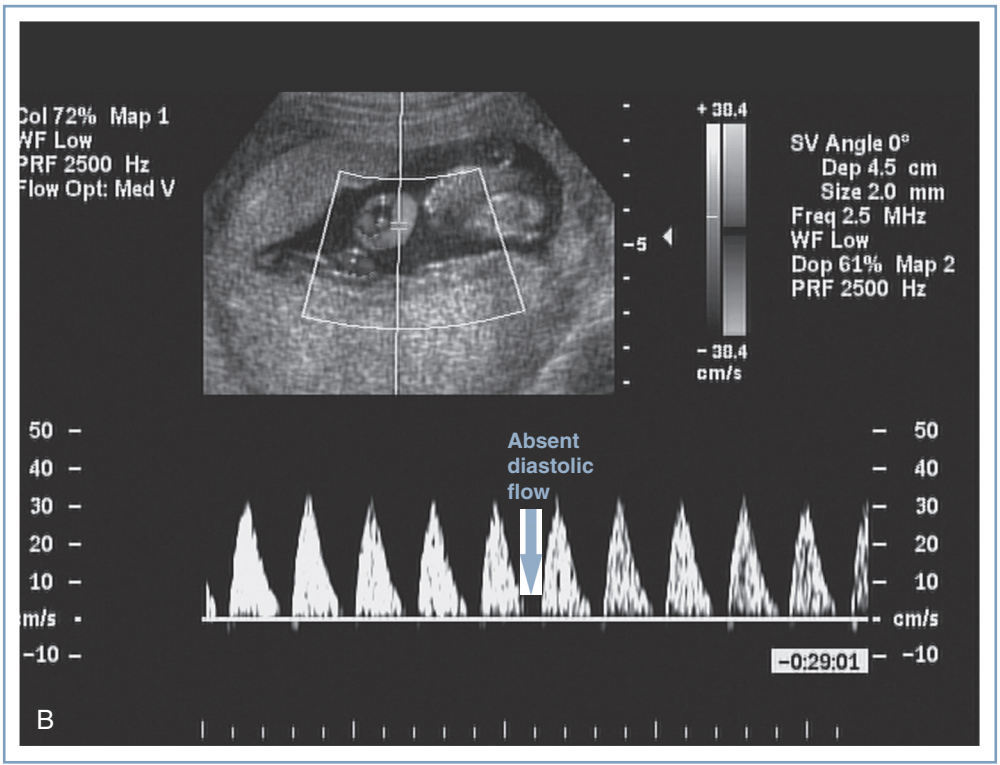


Fig. 6.7 Umbilical artery Doppler velocimetry. **A,** Normal waveform in the umbilical artery as shown on Doppler velocimetry. Forward flow can be seen during both fetal systole and diastole. **B,** Absent end-diastolic flow. Forward flow can be seen during systole, but there is no flow during diastole.

Continued

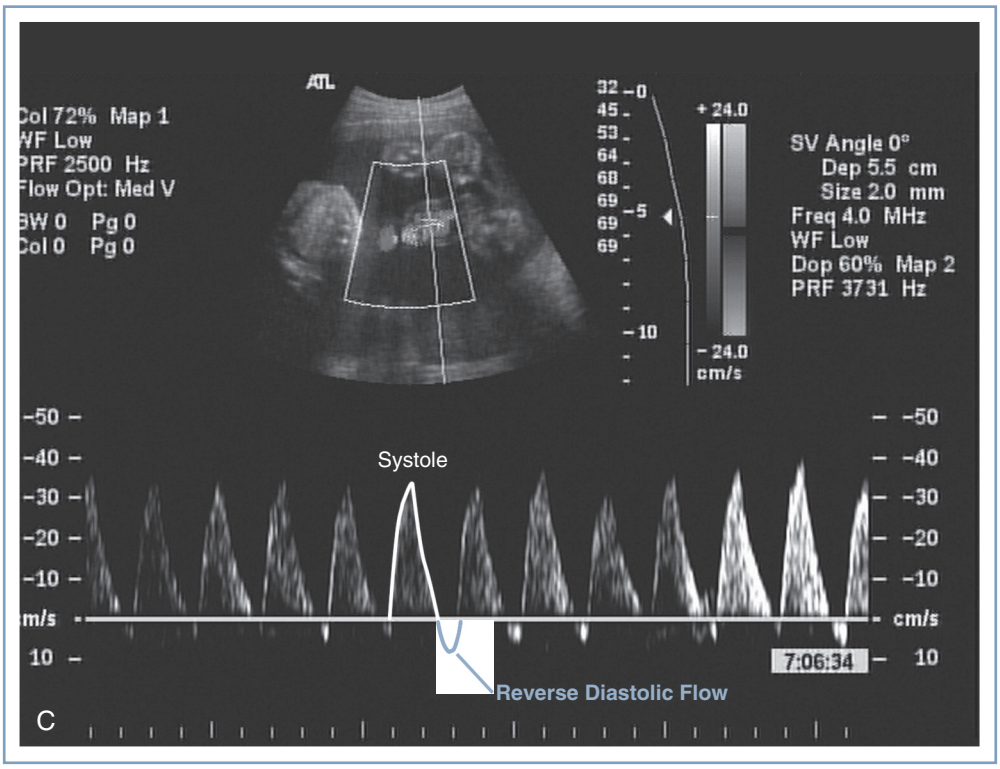

Fig. 6.7, cont'd C, Reverse diastolic flow. Forward flow can be seen during systole, but there is reverse flow in the umbilical artery during diastole, which is suggestive of high resistance to blood flow in the placenta.

by the UA pulsatility index, is another means of assessing cerebral blood flow. In fetuses with abnormal UA Doppler velocimetry, DV Doppler velocimetry may improve the predicted risk for hypoxia and stillbirth.

Preparation for delivery—including administration of corticosteroids for fetal lung maturity and transfer to a tertiary delivery center—should be considered when Doppler findings are severely abnormal in the setting of fetal growth restriction, regardless of gestational age. However, in the presence of a normally grown fetus, it is unclear how to interpret such findings. For these reasons, UA Doppler velocimetry should not be performed routinely in women at low risk for fetal abnormalities. Appropriate indications include fetal growth restriction, cord malformations, unexplained oligohydramnios, suspected or established preeclampsia, and, possibly, fetal cardiac anomalies.

UA Doppler velocimetry has not been shown to be useful in the evaluation of some high-risk pregnancies, including diabetic and postterm pregnancies, primarily owing to a high false-positive rate.[89–93] Thus, in the absence of fetal growth restriction, obstetric management decisions are not usually made on the basis of Doppler velocimetry findings alone. MCA peak systolic velocity provides a noninvasive evaluation of fetal anemia, including moderate to severe cases resulting from isoimmunization.[94] When severe anemia develops in a fetus, blood is preferentially shunted to the vital organs, such as the brain, which results in an increase in MCA peak systolic flow velocity.[94] This finding can help the perinatologist counsel affected patients about the need for cordocentesis and fetal blood transfusion. Doppler studies of other vessels (including the uterine artery, fetal aorta, ductus venosus, and fetal carotid arteries) have contributed to our knowledge of maternal-fetal physiology but as yet have resulted in few clinical applications.

Multiple Modalities to Assess Fetal Well-Being

All standard tests to assess antepartum fetal well-being (i.e., NST, BPP, CST) are evaluated according to their ability to predict the absence of fetal death during the 1-week period after the test. The false-negative rate (defined as a reassuring test result with a subsequent bad outcome) and false-positive rate (an abnormal result with a subsequent normal outcome) for each of these tests are listed in Table 6.6.[64,68,83] The false-negative rates for all three tests are relatively low. Because the NST has a high false-positive rate, some authorities consider it a screening test to identify fetuses requiring further assessment with either a BPP or a CST. No method of fetal assessment is perfect, and clinical judgment plays a large role in any management decision.

SPECIAL TECHNIQUES FOR ANTEPARTUM FETAL SURVEILLANCE

Perinatal Ultrasonography

Ultrasonography uses high-frequency sound waves (3.5 to 5 MHz for transabdominal transducers and 5 to 7.5 MHz for transvaginal transducers) that are directed into the body by a transducer, reflected by maternal and fetal tissue, detected by

a receiver, processed, and displayed on a screen. Increasing the wave frequency results in greater display resolution at the expense of diminished tissue penetration. Interpretation of images requires operator experience. Widespread clinical application of two-dimensional ultrasonography began in the 1960s after pioneering work by researchers in the United States and Great Britain.[95] Although no deleterious biologic effects have been associated with obstetric ultrasonography, the rates of false-positive and false-negative diagnoses based on the images are a major limitation.

The American College of Obstetricians and Gynecologists, the American College of Radiology, the American Institute of Ultrasound in Medicine, the National Institute of Child Health and Human Development, the Society of Maternal-Fetal Medicine, and the Society of Radiologists in Ultrasound have endorsed the following terminology for ultrasound examinations in the second and third trimesters: standard, specialized, and limited.[5] The **standard examination** involves determination of fetal number, presentation, amniotic fluid volume, cardiac activity, placental position, fetal biometry, and an anatomic survey. If technically feasible, the maternal cervix and adnexa should be evaluated. Most pregnancies can be evaluated adequately with this type of examination alone. If the patient's history, laboratory abnormalities, physical findings, or standard ultrasonographic results suggest an increased risk for a fetal malformation, then a **specialized examination** is performed.[38] Specialized examinations, which include fetal Doppler assessments, BPP, fetal echocardiogram, and additional biometric measurements, evaluate fetal structures in detail to identify and characterize any fetal malformations. Ultrasonographic markers of fetal aneuploidy (see later discussion) can be evaluated as well. In some situations, a **limited examination** may be appropriate to answer a specific clinical question, such as fetal viability, amniotic fluid volume, fetal presentation, placental location, and cervical length.[38]

Current debate centers on identifying those patients who would benefit from an ultrasonographic evaluation and determining what type of evaluation would be optimal. Advocates of the universal application of ultrasonography cite the advantages of more accurate dating of pregnancy (see earlier discussion) and earlier and more accurate diagnosis of multiple gestation, structural malformations, and fetal aneuploidy (see later discussion). Opponents of routine ultrasonographic examination view it as an expensive screening test that is not justified by published research, which suggests that routine ultrasonography does not change perinatal outcome significantly.[11,96,97] Although routine ultrasonography for all low-risk pregnant women is controversial, few would disagree that the benefits far outweigh the costs for selected patients. The ACOG has recommended that the benefits and limitations of ultrasonography should be discussed with all pregnant women.[5]

The indications for **first-trimester ultrasonography,** which is performed before 14 0/7 weeks' gestation, are different from those for **second- and third-trimester ultrasonography**[5]; most patients undergo a detailed fetal anatomic survey at 18 to 20 weeks' gestation to assess fetal growth and screen for structural defects. Placental location should be documented with the maternal bladder empty, because overdistention of the bladder or a lower uterine contraction can give a false impression of placenta previa. If placenta previa is identified at 18 to 22 weeks' gestation, serial ultrasonographic examinations should be performed to follow placental location. Only 5% of cases of placenta previa identified in the second trimester persist to term.[98] The umbilical cord should also be imaged and the number of vessels, placental insertion, and fetal insertion should be noted. Evaluation of the amniotic fluid volume should also be performed. In pregnancies at high risk for fetal cardiac anomalies or preterm birth, fetal echocardiography and cervical length measurements, respectively, should be performed.

Fetal anatomic surveys and EFW become less accurate with greater gestational age, especially in obese women or pregnancies complicated by oligohydramnios. However, fetal biometry and detailed anatomic surveys are still performed in late gestation, because certain fetal anomalies (e.g., achondroplasia, duodenal atresia) may become evident for the first time during this period. Transvaginal ultrasonographic measurement of cervical length (performed to identify women at risk for preterm birth) is of little use after 30 to 32 weeks' gestation.[99]

Screening for Fetal Chromosomal Abnormalities

Fetal chromosomal abnormalities are a major cause of perinatal morbidity and mortality, accounting for 50% of first-trimester spontaneous abortions, 6% to 12% of all stillbirths and neonatal deaths, and 10% to 15% of structural anomalies in live-born infants.[100] The most common aneuploidy encountered during pregnancy (autosomal trisomy) results primarily from nondisjunction during meiosis I. Women of advanced maternal age (> 35 years or older at EDD) are at higher risk for having a pregnancy complicated by fetal aneuploidy and are routinely offered noninvasive prenatal screening and an invasive diagnostic procedure (either amniocentesis or chorionic villus sampling [CVS]). However, because only 8% to 12% of all births occur in women 35 years of age and older, at most 20% to 25% of all cases of trisomy 21 (Down syndrome) would be identified if all women of advanced maternal age agreed to amniocentesis.[101] Klinefelter syndrome (47, XXY) is the most common sex chromosome aneuploidy with a prevalence of 1:500 males, and Turner syndrome (45, X) is the only viable monosomy. Many older women are now opting for serum analyte screening for fetal aneuploidy, which is equally accurate in older women.[102] All women, regardless of age, should be offered aneuploidy screening during early gestation.[100]

Fetal Aneuploidy Screening

Methods have been developed to help identify women at high risk for fetal aneuploidy. The major focus of attention has been the detection of Down syndrome, because it is the most common chromosomal abnormality manifesting at term and, unlike the less common disorders trisomy 13 and 18, its diagnosis can be very difficult to make with ultrasonography.

In all of these screening tests, one or more serum analytes are used to adjust the *a priori* risk for fetal aneuploidy in a given pregnancy, which depends primarily on maternal age.

First-trimester screening is performed between 10 0/7 and 13 6/7 weeks' gestation. A measurement of the nuchal translucency, the fluid-filled space on the posterior aspect of the fetal neck, is combined with serum markers, human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A), to calculate a specific risk estimate (Table 6.7). A nuchal translucency greater than 3.0 mm, or above the 99th percentile for the crown-rump length, is associated with an increased risk for aneuploidy and structural malformations, most often congenital heart defects.[103] First-trimester screening has a detection rate for Down syndrome of 82% to 87%, with a screen positive rate of 5%; the use of this screening method has increased significantly, given the benefits of being a single test performed in the first trimester with abnormal results predictive of aneuploidy and adverse outcomes (Table 6.8). However, tests that combine first- and second-trimester results have higher detection rates, and the measurement of nuchal translucency requires a specialized ultrasonographic examination with a credentialed sonographer and interpreting physician, which can limit its availability.[104]

TABLE 6.8 Relationship between First-Trimester Pregnancy-Associated Plasma Protein A Level at or below Fifth Percentile (0.42 MoM) and Risks for Adverse Pregnancy Outcomes

Adverse Outcome	Adjusted Odds Ratio	95% Confidence Interval
Spontaneous loss < 24 weeks	2.50	1.76–3.56
Fetal death ≥ 24 weeks	2.15	1.11–4.15
Preterm birth ≤ 37 weeks	1.87	1.61–2.17
Preterm birth ≤ 32 weeks	2.10	1.59–2.76
Preeclampsia	1.54	1.16–2.03
Gestational hypertension	1.47	1.20–1.82
Placental abruption	1.80	1.15–2.84
Fetal growth restriction	3.22	2.38–4.36

MoM, Multiple of the median.
Data from Dugoff L, Hobbins JS, Malone FD, et al. First-trimester maternal serum PAPP-A and free beta-subunit human chorionic gonadotropin concentrations and nuchal translucency are associated with obstetric complications: a population-based screening study (the FASTER Trial). *Am J Obstet Gynecol.* 2004;191:1446–1451.

TABLE 6.7 Detection Rate of Down Syndrome Screening Tests

Screening Test	Detection Rate (%)[a]	False-Positive Rate (%)[b]
Maternal age > 35 yr	30–40	10–15
First Trimester		
NT assessment	64–70	5–10
NT assessment, PAPP-A, and total or free β-hCG measurements	82–87	5–6
Second Trimester		
Triple screen (measurements of MS-AFP, total or free β-hCG, unconjugated estriol)	69–77	9
Quadruple screen (measurements of MS-AFP, total or free β-hCG, unconjugated estriol, inhibin A)	79–83	6
Combined First and Second Trimesters		
Integrated (NT assessment, PAPP-A measurement, quadruple screen)	93–96	1–2
Serum integrated (APP-A measurement, quadruple screen)	84–88	2–3
Stepwise sequential:	84–95	1
• If first-trimester test result positive, diagnostic test offered		
• If first-trimester test result negative, second-trimester test offered, and final risk assessment incorporates both first- and second-trimester results		
Contingent sequential:	88–94	1
• If first-trimester test result positive, diagnostic test offered		
• If first-trimester test result negative, no further testing		
• If first-trimester test result intermediate, second-trimester test offered, and final risk assessment incorporates both first- and second-trimester results		

β-hCG, Beta-human chorionic gonadotropin; *MS-AFP,* maternal serum level of alpha-fetoprotein; *NT,* nuchal translucency; *PAPP-A,* pregnancy-associated placental protein-A.
[a]Assuming a 5% false-positive rate.
[b]Assuming an 85% detection rate.
Data from references 128 and 130–132.

The quadruple ("quad") screen ideally should be performed between 16 and 18 (range 15 0/7 and 22 6/7) weeks' gestation to optimize screening for an open neural tube defect. It consists of measuring four maternal serum analytes: alpha-fetoprotein (MS-AFP), total or free β-subunit hCG (β-hCG), unconjugated estriol, and dimeric inhibin A. The quad screen has a detection rate for Down syndrome of 81%, with a screen positive rate of 5%, which is similar to first-trimester screening.[104] However, advantages of this method include: (1) it is a single test that does not require a specialized ultrasonographic examination; (2) it possesses the ability to screen for open fetal defects, such as open neural tube defects and abdominal wall defects; and (3) abnormal serum analyte measurements help predict risk for other adverse pregnancy outcomes, such as growth restriction, preterm delivery, stillbirth, and preeclampsia.

Screening tests that combine first- and second-trimester results, including integrated, sequential, or contingent screening, have a higher detection rate than first-trimester screening and the quad screen.[105] *Integrated* screening, which combines a first-trimester nuchal translucency measurement and PAPP-A with a second-trimester quad screen, results in the highest detection rate (96% with a 5% false-positive rate) of all the screening tests.[104] Integrated screening can also assess for open fetal defects, but does not assess all second-trimester serum markers; moreover, if nuchal translucency cannot be obtained, a lower Down syndrome detection rate of 88% with a 5% false-positive rate is observed.[104] *Sequential* screening differs from integrated screening by reporting first-trimester testing results, which offers a potentially earlier diagnosis of fetal abnormalities. Sequential screening has a Down syndrome detection rate of 95%, with a false-positive rate of 5%.[106]

Screening for aneuploidy by **analysis of fetal cell-free short DNA segments** released into maternal circulation from the placenta is a newly available technology (see later discussion); the DNA segments provide information about the three most common trisomies (Down syndrome, trisomy 18, and trisomy 13), fetal gender, Rh status in an Rh-negative mother, and some autosomal dominant genetic abnormalities.[107,108]

Aneuploidy screening in multifetal, versus singleton, pregnancies is not as accurate and is complicated by the number of fetuses and the zygosity. Whereas monozygous twins often have the same karyotype and thus an overall risk for aneuploidy similar to the mother's age-related risk, dizygous twins each carry a risk for aneuploidy, resulting in an increased risk.[105] Each fetus in a multifetal gestation can be evaluated for nuchal translucency, which has a Down syndrome detection rate of up to 75% with a 9% screen-positive rate.[109] In comparison, a quad screen has a 50% detection rate for Down syndrome in a twin gestation with a 5% false-positive rate.[110] Cell-free DNA is currently not recommended for multifetal pregnancies because of limited evidence regarding efficacy in this population.[111]

Ultrasonographic Screening for Fetal Aneuploidy

First-trimester screening for aneuploidy includes a measurement for thickened nuchal translucency (see earlier discussion), which is associated with an increased risk for aneuploidy and certain anomalies, such as cardiac defects, abdominal wall defects, and diaphragmatic hernia.[112] The presence of a cystic hygroma, which is a thickened nuchal translucency that extends the length of the fetus and contains septations (Fig. 6.8), is associated with a 50% likelihood of aneuploidy, most often Down syndrome, 45,X, and trisomy 18; even those with a normal karyotype will have a major structural malformation 50% of the time, often in the form of a cardiac anomaly, diaphragmatic hernia, skeletal dysplasia, or some other genetic syndrome. The presence of a cystic hygroma results in a healthy, full term infant less than 20% of the time.[113] Diagnosis of thickened nuchal translucency measurement or a cystic hygroma by first-trimester ultrasonographic examination should prompt genetic counseling, diagnostic testing for aneuploidy, and a targeted ultrasonographic examination

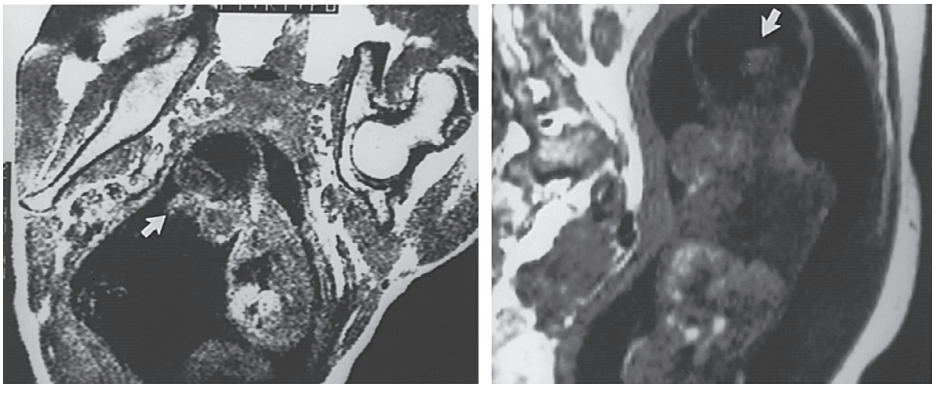

Fig. 6.8 Magnetic resonance images of a fetus with holoprosencephaly. **A,** Sagittal view showing the proboscis *(arrow)*. **B,** Coronal view showing the single ventricle and fused thalami *(arrow)*. and fetal echocardiogram in the second trimester.[105] An increased risk for Down syndrome has been associated with the absence of the nasal bone, although this assessment is not included as part of routine first-trimester ultrasound screening because the predictive value in high- or low-risk populations has been questioned.[114,115]

In the second trimester, major structural abnormalities, such as those associated with trisomy 13 or 18, can be detected more reliably by ultrasonographic examination. Although 50% of fetuses with Down syndrome appear structurally normal,[116] more than 30% have major structural abnormalities (e.g., endocardial cushion defect) that can be detected by ultrasonography.[116–118] The *genetic sonogram* is a second-trimester screen for Down syndrome using the identification of major structural malformations and minor ultrasonographic *soft markers* of aneuploidy (Table 6.9).

TABLE 6.9 Second-Trimester Serum Analyte (Marker) Screening and Adverse Pregnancy Outcome

Adverse Outcome	Marker	Odds Ratio
Spontaneous loss < 24 weeks	MS-AFP	7.8
Fetal death ≥ 24 weeks	Inhibin A	3.7
Preterm birth ≤ 32 weeks	Inhibin A	5.0
Preterm premature rupture of membranes	MS-AFP	1.9
Preeclampsia	Inhibin A	3.8
Gestational hypertension	Inhibin A	1.7
Placental abruption	MS-AFP	1.9
Placenta previa (confirmed at delivery)	MS-AFP	3.1
Fetal growth restriction	Inhibin A	3.0
Birth weight ≤ 5th percentile	Inhibin A	2.3
• Delivery < 37 weeks	Inhibin A	8.0
• Delivery < 32 weeks	Inhibin A	18.6

MS-AFP, Maternal serum level of alpha-fetoprotein.

Whereas major cardiac anomalies can be identified in the second trimester, duodenal atresia is typically not identified until the third trimester. Ultrasonographic soft markers do not necessarily represent malformations, but can signal development of fetal abnormalities, such as hydronephrosis developing into renal pyelectasis or an echogenic bowel progressing to intestinal atresia. Soft markers are also common in unaffected fetuses; as a consequence, their presence should prompt screening and testing for aneuploidy, and a targeted ultrasonographic examination if the findings are isolated.[105]

Second-trimester ultrasonographic markers (Table 6.10) are not part of standard algorithms to predict fetal aneuploidy risk; however, these markers can assist in modifying risk assessments for abnormalities. The clinical significance of isolated ultrasonographic soft markers for Down syndrome in a low-risk population is unclear.

Definitive Diagnosis of Fetal Chromosomal Abnormalities

Although an abnormal screening test result or the presence of ultrasonographic abnormalities may signal an increased risk for Down syndrome or other chromosomal abnormality, the majority of fetuses with such findings are chromosomally normal. To provide a definitive diagnosis, an invasive procedure is needed to obtain the fetal karyotype; generally amniocentesis or chorionic villus sampling (CVS) is used, although in rare cases a cordocentesis is performed.

All invasive procedures are associated with risks to the pregnancy. Risks common to all invasive procedures include the chance of bleeding, isoimmunization (especially in women who are Rh negative), and infection. All women who are Rh negative should receive $Rh_0(D)$ immune globulin before or after the procedure. Although the risk for vertical transmission of viral infections (e.g., hepatitis B, hepatitis C, human immunodeficiency virus) with invasive procedures is believed to be low,[119] every effort should be made to avoid invasive procedures in such patients, especially if there is a high viral load in the maternal circulation.

TABLE 6.10 Accuracy Measurements of Second-Trimester Ultrasonographic "Soft Markers" for Trisomy 21 (Down Syndrome) When Identified as Isolated Anomalies

Ultrasonographic Marker	Sensitivity (95% CI)	Specificity (95% CI)	Positive LR (95% CI)	Negative LR (95% CI)
Thickened nuchal fold	0.04 (0.02–0.10)	0.99 (0.99–0.99)	17 (8.0–38.0)	0.97 (0.94–1.00)
Choroid plexus cyst	0.01 (0.00–0.03)	0.99 (0.97–1.00)	1.00 (0.12–9.40)	1.00 (0.97–1.00)
Short femur length	0.16 (0.05–0.40)	0.96 (0.94–0.98)	2.7 (1.2–6.0)	0.87 (0.75–1.00)
Short humeral length	0.09 (0.00–0.60)	0.97 (0.91–0.99)	7.5 (4.7–12.0)	0.87 (0.67–1.10)
Echogenic bowel	0.04 (0.01–0.24)	0.99 (0.97–1.00)	6.1 (3.0–12.6)	1.00 (0.98–1.00)
Echogenic intracardiac focus	0.11 (0.06–0.18)	0.96 (0.94–0.97)	2.8 (1.5–5.5)	0.95 (0.89–1.00)
Renal pyelectasis (pelvicalyceal dilation)	0.02 (0.01–0.06)	0.99 (0.98–1.00)	1.9 (0.7–5.1)	1.00 (1.00–1.00)

The use of second-trimester genetic sonogram in guiding clinical management of patients at increased risk for fetal trisomy 21. *Obstet Gynecol.* 1996;87:948–952.

Amniocentesis

Amniotic fluid is composed of fetal urine, lung fluid, skin transudate, and water that is filtered across the amniotic membranes. It contains electrolytes, proteins, and desquamated fetal cells (amniocytes). Sampling of amniotic fluid (**amniocentesis**) can be used to measure various substances such as lecithin and sphingomyelin for assessing fetal lung maturity, to look for pathogenic bacteria for confirmation of an intra-amniotic infection, and to obtain fetal cells for determination of fetal karyotype or performance of specific genetic analyses.

Cell culture with karyotype analysis typically takes 10 to 14 days, although a small chance exists that the cells will fail to grow, resulting in an inconclusive result. Fluorescence *in situ* hybridization (FISH) does not require that the cells be cultured for any length of time, and its results can be obtained within a few days. This technique uses a series of chromosome-specific fluorescent probes to analyze the metaphase spread in fetal cells to determine fetal gender and detect common trisomies (21, 18, 13, X, and Y). It can also be used to identify chromosome deletions or duplications in pregnancies at risk for a specific genetic disorder because of a family history or suspicious ultrasonographic findings, such as the 22q11 deletion in DiGeorge syndrome.[120–122] Although FISH is highly specific (trisomy present on FISH testing is invariably present in the fetus), it is not particularly sensitive, with a false-negative rate of approximately 15%. For this reason, the American College of Medical Genetics (ACMG) and the American Society of Human Genetics (ASHG) recommend that all FISH results be confirmed by complete karyotype analysis.[122]

The most common indication for second-trimester amniocentesis is cytogenetic analysis of fetal cells, although on occasion it is performed to determine amniotic fluid AFP levels and acetylcholinesterase activity for the diagnosis of fetal open neural tube defects. Amniocentesis later in pregnancy is usually performed for nongenetic indications, such as (1) documentation of fetal pulmonary maturity before elective delivery before 39 weeks' gestation, (2) amnioreduction in pregnancies complicated by severe polyhydramnios, (3) to confirm preterm premature rupture of membranes (PROM) (amniodye test), or (4) to exclude intra-amniotic infection.

Genetic amniocentesis typically involves the insertion of a 22-gauge spinal needle through the maternal abdominal wall and into the uterine cavity at 15 to 20 weeks' gestation. The procedure is now commonly performed under ultrasonographic guidance, which allows the operator to choose the safest site, preferably away from the fetal face and umbilical cord and when possible without passage of the needle through the placenta. The greatest risk associated with amniocentesis is spontaneous abortion; however, the procedure-related pregnancy loss rate for genetic amniocentesis appears to be only 1 in 300 to 500.[123–126] Of interest, the pregnancy loss rate is not influenced by operator experience or needle placement through the placenta[126,127] but is higher in the presence of first-trimester bleeding or recurrent miscarriage, ultrasonographic demonstration of chorioamniotic separation, discolored amniotic fluid at the time of the procedure, and/or an unexplained elevation in MS-AFP.[125,128] Whether this risk is higher in twin pregnancies is not clear. Transient leakage of amniotic fluid can be seen in 1% to 2% of procedures. This leakage usually stops after 48 to 72 hours, infection is extremely rare (< 0.1% of cases), and the perinatal survival rate after mid-trimester fluid leakage may be as high as 90%.[100,129–133]

Compared with late second-trimester amniocentesis, early amniocentesis (before 15 weeks' gestation) is associated with significantly higher procedure-related pregnancy loss rates, ranging from 2.2% to 4.8%.[129–132] This rate is fourfold higher than that of late amniocentesis and twice as high as that of CVS. Early amniocentesis has also been shown to be associated with higher rates of rupture of membranes, club foot, and amniocyte culture failures (2% to 5%) than late amniocentesis.[129–134] For these reasons, amniocentesis before 15 weeks' gestation is not recommended.

If early karyotyping is desired, CVS is preferred over early amniocentesis (see later discussion). Amniocentesis in the third trimester is technically easier and is associated with fewer complications. If a late amniocentesis is being performed for any reason (e.g., to confirm fetal pulmonary maturity), consideration should be given to obtaining the karyotype if indicated, even though the pregnancy is too far along to be ended electively.

Amniocentesis in multiple gestations can be performed safely. Care must be taken to carefully map the fetal sacs so that the amniotic fluid for each fetus is sampled separately. A small amount of indigo carmine (3 to 5 mL) is typically inserted into the first sac after the fluid is sampled to ensure that the same sac is not sampled twice.

Chorionic Villus Sampling

Like that of amniocentesis, the goal of CVS is to provide fetal cells for genetic analysis, although in this case the cells are trophectoderm (placental) cells rather than amniocytes. The technique entails ultrasound-guided aspiration of chorionic villi by means of a 16-gauge catheter inserted transcervically or a 20-gauge spinal needle inserted transabdominally into the placenta. The 15 to 30 mg of villous material collected can be examined in two ways: (1) by direct cytogenetic analysis after an overnight incubation, which yields results in 2 to 3 days; and (2) by longer-term culture followed by cytogenetic analysis, which yields results in 6 to 8 days.[135] To provide rapid and accurate results, many centers report the results of both methods. The main advantage of CVS over amniocentesis is that it allows for fetal karyotyping results in the first trimester, thereby allowing decisions about pregnancy termination to be made earlier if chromosomal abnormalities are detected. Moreover, although rare, certain genetic disorders (e.g., osteogenesis imperfecta) can be diagnosed antenatally only through analysis of placental tissue.

CVS is best performed between 10 and 12 weeks' gestation. CVS performed before 10 weeks' gestation has been associated with limb reduction defects,[136,137] whereas no such

association exists if the procedure is performed after 66 days' gestation.[138] Transabdominal CVS can also be performed in the second or third trimester and is a reasonable alternative to cordocentesis for obtaining tissue for an urgent fetal karyotype.[139]

The most common complication of CVS is vaginal spotting, which occurs in 10% to 25% of patients within the first few days after the procedure. Fortunately, the bleeding is usually mild and resolves spontaneously with no long-term sequelae. The incidences of amnionitis (0.3%) and rupture of membranes (0.3%) after CVS do not differ significantly from those seen with late amniocentesis and are significantly lower than those reported after early amniocentesis.[138] As with amniocentesis, the most serious complication of CVS is spontaneous abortion. CVS appears to be associated with a higher risk for pregnancy loss than late amniocentesis; the procedure-related loss rate in CVS is reported as 1.0% to 1.5%.[138,140–145] This rate is significantly higher (0.6% to 0.8%) than that seen after late amniocentesis, with an adjusted odds ratio of 1.30 (95% confidence interval [CI], 1.17 to 1.52).[144] Factors that increase the procedure-related loss rate are operator inexperience, number of needle passes, and a history of bleeding before the procedure.[144] By contrast, the risk does not appear to be increased in twin gestations or with the anatomic approach used (i.e., transabdominal versus transcervical catheter placement).[143,146] Some investigators have suggested that the apparently higher pregnancy loss related to CVS (compared with amniocentesis) is a function of the earlier gestational age at which the procedure is performed.[123]

One complication unique to CVS involves the interpretation of the genetic test results. Because the fetus and placenta both arise from the same cell, it is assumed that the genetic complements of these two tissues are identical, but this is not always the case. **Confined placental mosaicism** refers to the situation in which the karyotype of the chorionic villus is a mosaic (i.e., it contains two or more populations of cells with different karyotypes, usually one normal and one trisomic) but the karyotype of the fetus is normal. The incidence of confined placental mosaicism may be as high as 1% to 2% with the direct cytogenetic analysis method, but most cases are not confirmed by the long-term tissue-culture method,[138,142] suggesting a methodologic error. For this reason, many centers report only the long-term culture results. On occasion, it may be necessary to repeat the fetal karyotype, either with a second CVS or with amniocentesis, to resolve the dilemma. The reverse situation, in which the CVS result is normal but the fetus has aneuploidy (a false-negative result), has also been reported[147] but is rare. It may occur from contamination with maternal cells or from inadvertent sampling of a twin placenta.

Cordocentesis

In cases in which pregnancy complications or fetal abnormalities are discovered late in gestation, **cordocentesis** (also known as percutaneous umbilical blood sampling) is an option for rapid evaluation of the fetal karyotype. Cordocentesis involves the insertion of a 22-gauge spinal needle through the maternal abdominal and uterine walls and into the umbilical vein, preferably at the insertion site on the placenta, under direct ultrasonographic guidance. Considerable training and expertise are needed to perform this procedure. Karyotype analysis results can be obtained in 24 to 48 hours.

The first cordocentesis was reported in 1983.[148] Although this procedure was originally considered superior to amniocentesis for a number of diagnostic indications, advances in laboratory analysis have allowed more information to be obtained through amniocentesis.[149] For example, cordocentesis was commonly used to obtain a sample of fetal blood for rapid karyotyping when a major structural anomaly or severe fetal growth restriction was identified late in pregnancy; however, this sample can be obtained as rapidly from amniocentesis or CVS samples using FISH analysis. Similarly, DNA analysis of amniocytes can rapidly and accurately determine the fetal Rh status and the presence of other red cell and platelet antigens,[150] which in the past was an absolute indication for cordocentesis. Now employed primarily for therapeutic indications, cordocentesis is most commonly used to transfuse fetuses with severe anemia from isoimmunization, parvovirus infection, or fetal-maternal hemorrhage (spilling of fetal blood cells into the maternal circulation). This intravascular route of fetal transfusion is preferred to the older technique of intraperitoneal transfusion.[151] Other rare indications for cordocentesis are to measure drug concentrations in the fetal circulation, to document response to pharmacologic therapy, and to administer drugs directly to the fetus (e.g., adenosine to treat resistant fetal tachydysrhythmia).[152]

When skilled operators perform cordocentesis, complications are infrequent and similar to those encountered with amniocentesis. Specifically, there is risk for bleeding, cord hematoma, infection, and preterm PROM. The risk for pregnancy loss as a result of the procedure is estimated to be 1.2% to 4.9%,[153] although fetuses with severe fetal growth restriction, hydrops, or major structural anomalies may be at higher risk compared with well-grown, structurally normal fetuses. Operator experience is an important determinant of success, as are logistical issues (e.g., volume of amniotic fluid, placental position, location of the cord insertion site within the placenta). A transient fetal bradycardia may occur during the procedure, often resulting from unintentional placement of the needle into one of the umbilical arteries and leading to arterial vasospasm. Although this bradycardia invariably resolves, if the fetus is at a favorable gestational age (> 24 weeks), the procedure should be performed at a facility with the capacity to perform an emergency cesarean delivery. There are no consistent data or recommendations regarding the benefits or risks associated with the use of prophylactic antibiotics, tocolysis, or maternal sedation during cordocentesis.

Other Tests

Three-Dimensional Ultrasonography

Compared with standard two-dimensional ultrasonography, three-dimensional (or four-dimensional, if fetal movements are included) ultrasonography allows for concurrent visualization of fetal structures in all dimensions for

improved characterization of complex anomalies. However, three-dimensional images are subject to interference from structures such as fetal limbs, umbilical cord, and placental tissue, and are greatly influenced by fetal movements; these movements make visualization of the fetal heart suboptimal.

In addition to rapid acquisition of images that can be later reconstructed and manipulated, three-dimensional compared with two-dimensional ultrasonography has the following potential advantages:

1. The ability to provide clearer images of soft tissue structures through surface rendering. Such images may improve the diagnosis of certain fetal malformations, especially craniofacial anomalies (e.g., cleft lip and palate, micrognathia, ear anomaly, facial dysmorphism, intracranial lesions), club foot, finger and toe anomalies, spinal anomalies, ventral wall defects, and fetal tumors.
2. The ability to provide more accurate measurements of the gestational sac, yolk sac, and crown-rump length and to obtain a midsagittal view for measuring nuchal translucency.
3. The ability to measure tissue volume. Preliminary data suggest that assessment of cervical volume may identify women at risk for cervical insufficiency,[154] and measurement of placental volume in the first trimester may determine fetuses at risk for fetal growth restriction.[155]

Despite these advantages, three-dimensional ultrasonography has been used primarily as a complementary technique rather than the standard technique for ultrasonographic imaging. In the future, technical improvements should provide higher-quality images, perhaps similar to those offered by computed tomography and magnetic resonance imaging (MRI).

Complementary Radiographic Imaging

Ultrasonography remains the first-line imaging modality during pregnancy. In certain situations, however, enhanced imaging may be required to better define a particular fetal anomaly. For example, radiographic imaging is superior to ultrasonography in evaluating the fetal skeleton and may provide valuable information in the evaluation of a fetus with a suspected bony dystrophy. At least 25 different forms of skeletal dysplasias are identifiable at birth, 11 of which are lethal in the peripartum period.[156] Although some of these forms can be identified from their unusual appearance on ultrasonography (e.g., cloverleaf skull and small thorax in thanatophoric dysplasia), the majority are difficult to identify. Timely radiographic imaging may allow an experienced pediatric radiologist to more thoroughly evaluate the fetal skeleton and determine the correct diagnosis. A simple maternal abdominal radiograph may be all that is required, because ossification is sufficient by 20 weeks' gestation to allow good visualization of the fetal bones.

Although computed tomography is best avoided in pregnancy because it exposes the fetus to ionizing radiation (albeit at small doses), MRI is regarded as safe. This latter technology relies on the interaction between an applied magnetic field and the inherent nuclear magnetism of atomic nuclei within the patient's tissues to generate a high-resolution anatomic image. Because MRI is particularly good at visualizing soft tissue rather than bony structures, it is uniquely suited to the evaluation of fetal intracranial defects and the soft tissues of the maternal pelvis (see Fig. 6.8).[157,158] Although fetal motion artifact has previously been a major limitation in the use of MRI, new ultrafast technology allows for rapid image acquisition and has largely overcome this problem.

Fetal Echocardiography

Cardiac anomalies are the most common major congenital defects encountered in the antepartum period. A four-chamber ultrasonographic view of the heart during the fetal anatomic survey at 18 to 20 weeks' gestation detects only 30% of congenital cardiac anomalies, although the detection rate can be increased to 60% to 70% if the outflow tracts are adequately visualized.[159] Owing to the number of congenital cardiac anomalies that would be missed, however, fetal echocardiography should be performed by a skilled and experienced sonologist at 20 to 22 weeks' gestation in all pregnancies at high risk for a fetal cardiac anomaly. Indications for fetal echocardiography include: (1) pregnancies complicated by pregestational diabetes mellitus, (2) a personal or family history of congenital cardiac disease (regardless of the nature of the lesion or whether it has been repaired), (3) maternal exposure to certain drugs (e.g., lithium, paroxetine),[160] and (4) conception by *in vitro* fertilization (but not if the pregnancy was conceived through the use of clomiphene citrate or ovarian stimulation/intrauterine insemination alone).[161]

Fetal Cells or DNA in the Maternal Circulation

To minimize the risks associated with invasive prenatal diagnosis (amniocentesis and CVS), improved noninvasive tests are being developed for fetal aneuploidy genetic testing. Fetal DNA, which has a short half-life (precluding contamination from a prior pregnancy) and accounts for 3% to 10% of all cell-free DNA in maternal serum (up to 20% if precclampsia or after major fetal-maternal hemorrhage), can be identified by high-throughput sequencing.[162] Available for use as early as 10 weeks' gestation, different molecular methods for analyzing the cell-free DNA offer similar detection rates of up to 99% when a result is obtained and a low false-positive rate of 0.5% in women at high risk for Down syndrome.[163] The positive predictive value of cell-free DNA screening is 93% for Down syndrome, 64% for trisomy 18, 44% for trisomy 13, and 39% for sex chromosome aneuploidy.[164] The positive predictive value is lower in low-risk women because of the lower prevalence of aneuploidy compared with women at high risk.[105] Disadvantages of cell-free DNA screening include a high false-positive rate in women at low risk for Down syndrome, and the potential for false-negative results[105]; as a consequence, this technology should not be used as a diagnostic test. Screening results for aneuploidy are reported as positive or negative by the performing laboratory, and the numerical risk for aneuploidy should be provided. Women with positive results should be offered further counseling and

cell-free DNA screening or diagnostic testing by chorionic villus sampling or amniocentesis.[105]

An alternative approach under investigation for definitive genetic testing is the isolation of trophoblast cells from the cervicovaginal discharge of women in early pregnancy.[165,166] These cells have been isolated from cervical canal lavage at 7 to 10 weeks' gestation[165] or with the use of a brush-type collection device at 5 to 12 weeks (the "genetic Pap smear").[166] Trophoblastic cells are found in 86% (195/227) of collected samples, and identified by immunocytochemistry with trophoblast-specific antibodies; the genetic analysis of these cells agree with those from placental tissue karyotyping via CVS in 95% (186/195) of cases.[166]

Refinement in these methods may allow for a simple, reliable, and noninvasive genetic test for fetal aneuploidy in an early, singleton pregnancy with no risk to the mother or fetus.

SPECIAL CIRCUMSTANCES REQUIRING ADDITIONAL FETAL SURVEILLANCE

Under certain circumstances, additional antenatal fetal surveillance may be required (see Box 6.2). If appropriate, early consultation with a specialist (e.g., a maternal-fetal medicine specialist, medical geneticist, pediatric surgeon, pediatric urologist, pediatric cardiologist, or infectious disease specialist) and delivery at a tertiary care center should be considered.

Abnormal Serum Analyte and Nuchal Translucency Screening with Normal Fetal Karyotype

Pregnancies with abnormal serum analyte screening in the first or second trimester are at increased risk for adverse outcomes, including preterm birth, preeclampsia, and stillbirth, *even if the karyotype is normal* (see Tables 6.8 and 6.9).[167–169] Such pregnancies therefore require more intensive fetal monitoring (Table 6.11), including serial growth evaluation and NST. Fetuses with a nuchal translucency measurement of 3.0 mm or more in the first trimester have a higher risk for congenital heart defects and other chest abnormalities, even with a negative aneuploidy screening test result and normal fetal chromosomes.[170,171] Women with such pregnancies should be offered a fetal echocardiogram at 20 to 22 weeks' gestation in addition to a routine targeted fetal anatomic survey at 18 to 20 weeks.

TABLE 6.11 Special Circumstances Requiring Additional Fetal Surveillance during Pregnancy

Pregnancy-Related Condition	Additional Testing Recommended	Gestational Age at Which Testing Should Be Started
Maternal Conditions		
Chronic hypertension	Growth scans q3-4 wk	24 weeks
	Weekly NST ± AFV	32 weeks
Diabetes mellitus:		
Pregestational diabetes	Growth scans q3-4 wk	24 weeks
	Weekly NST ± AFV	32 weeks
Gestational diabetes	Growth scans q3-4 wk	From diagnosis
	Weekly NST ± AFV	36 weeks
Maternal obesity (body mass index > 30 kg/m^2)	Weekly NST ± AFV	36 weeks
Advanced maternal age	Weekly NST ± AFV	38 weeks
Abnormal serum analyte screening result (MS-AFP > 2.0 MoM; pregnancy-associated placental protein-A [PAPP-A] < 0.4 MoM) with normal fetal karyotype	Growth scans q3-4 wk Weekly NST ± AFV	24 weeks 36 weeks
Prior unexplained preterm birth < 35 weeks	Weekly to biweekly cervical length measurements ± Weekly to biweekly fFN	16-18 weeks to 30-32 weeks 24 weeks to 32-34 weeks
Prior cervical cone biopsy	Weekly to biweekly cervical length measurements ± Weekly to biweekly fFN	16-18 weeks to 30-32 weeks 24 weeks to 32-34 weeks
Postterm pregnancy	Twice-weekly NST and AFV	41-42 weeks
Isoimmunization	Weekly middle cerebral artery Doppler velocimetry	18-20 weeks
Uteroplacental Conditions		
Chronic abruption	Growth scans q3-4 wk	From diagnosis
	Weekly NST ± AFV	28-32 weeks
Uterus didelphys	Weekly to biweekly cervical length measurements	16-18 weeks to 30-32 weeks
Preterm premature rupture of membranes	Daily NST	From diagnosis
	Growth scans q3-4 wk	From diagnosis
	Weekly AFV	From diagnosis

TABLE 6.11 Special Circumstances Requiring Additional Fetal Surveillance during Pregnancy—cont'd

Pregnancy-Related Condition	Additional Testing Recommended	Gestational Age at Which Testing Should Be Started
Unexplained oligohydramnios	Growth scans q3-4 wk	From diagnosis
	Weekly AFV	From diagnosis
	Weekly NST with AFV	32 weeks
	Weekly UA Doppler velocimetry	From diagnosis
Fetal Conditions		
Twin pregnancy:		
Dichorionic, diamniotic twin pregnancy	Biweekly AFV	18–20 weeks
	Growth scans q3-4 wk	24 weeks
	Weekly NST with AFV	32 weeks
	Weekly to biweekly cervical length measurements	16–18 weeks to 30–32 weeks
	± Weekly to biweekly fFN	22–24 weeks to 30–32 weeks
Monochorionic, diamniotic twin pregnancy	Weekly AFV	16–18 weeks
	Growth scans q3-4 wk	24 weeks
	Weekly NST with AFV	28–32 weeks
	Weekly to biweekly cervical length measurements	16–18 weeks to 30–32 weeks
	± Weekly to biweekly fFN	22–24 weeks to 30–32 weeks
Monochorionic, monoamniotic twin pregnancy	Weekly AFV	16–18 weeks
	Growth scans q3-4 wk	24 weeks
	Weekly to biweekly cervical length measurements	16–18 weeks to 30–32 weeks
	± Weekly to biweekly fFN	22–24 weeks to 30–32 weeks
	± Continuous fetal heart rate monitoring	24–26 weeks to delivery
Twin pregnancy complicated by demise of one twin	Weekly NST with AFV	From diagnosis
	Growth scans q3-4 wk	From diagnosis
Higher-order multiple pregnancy (≥ triplets)	Weekly AFV	16–18 weeks
	Growth scans q3-4 wk	24 weeks
	Weekly NST with AFV	28–32 weeks
	Weekly to biweekly cervical length measurements	16–18 weeks to 30–32 weeks
	± Weekly to biweekly fFN	22–24 weeks to 30–32 weeks
Fetal growth restriction:		
< 10th percentile	Growth scans q3-4 wk	From diagnosis
	Weekly NST with AFV	From diagnosis
< 5th percentile	Growth scans q3-4 wk	From diagnosis
	Weekly to twice-weekly NST with AFV	From diagnosis
	Weekly to twice-weekly UA Doppler velocimetry	From diagnosis
Major fetal structural anomaly	Growth scans q3-4 wk	24 weeks
	Weekly NST with AFV	32 weeks
	± Weekly UA Doppler velocimetry	32 weeks

AFV, Amniotic fluid volume; *biweekly,* every 2 weeks; *fFN,* fetal fibronectin; *MoM,* multiple of median; *MS-AFP,* maternal serum level of alpha-fetoprotein; *NST,* nonstress test; *UA,* umbilical artery.

Hydrops Fetalis

Hydrops fetalis ("edema of the fetus") is a rare pathologic condition that complicates approximately 0.05% of all pregnancies. It is an ultrasonographic diagnosis requiring the presence of an abnormal accumulation of fluid in more than one fetal extravascular compartment, including ascites, pericardial effusion, pleural effusion, subcutaneous edema, and/or placental edema. Polyhydramnios is seen in 50% to 75% of cases. Although classically seen in fetuses with severe anemia resulting from Rh isoimmunization, the introduction of $Rh_0(D)$ immune globulin has led to a substantial decrease in the incidence of immune hydrops. Indeed, 90% of hydrops fetalis cases are a result of nonimmune causes, such as maternal infection (e.g., with parvovirus B19, cytomegalovirus, syphilis), massive fetal-maternal hemorrhage, and fetal abnormalities (e.g., congenital cardiac defects, fetal thalassemia, twin-to-twin transfusion syndrome). Although the overall perinatal mortality rate in the setting of hydrops fetalis exceeds 50%, the prognosis depends on the underlying cause, severity, and gestational age.

Immune hydrops occurs when fetal erythrocytes express a protein that is not present on maternal erythrocytes. The maternal immune system can become sensitized and produce antibodies against these "foreign" proteins. These immunoglobulin (Ig) G antibodies can cross the placenta and destroy

fetal erythrocytes, leading to fetal anemia and high-output cardiac failure. Immune hydrops is typically associated with a fetal hematocrit less than 15% (normal fetal hematocrit is 50%). The most antigenic protein on the surface of fetal erythrocytes is the D antigen of the Rhesus protein complex, also known as Rh(D). Other antigens that can cause severe immune hydrops are Kell ("Kell kills"), Rh(E), Rh(c), and Duffy ("Duffy dies"). Antigens causing less severe hydrops are ABO, Rh(e), Rh(C), Ce, k, and s. Lewis a and b (Le^a, Le^b) incompatibility can cause mild anemia but not hydrops, because this condition primarily results in production of IgM antibodies, which do not cross the placenta ("Lewis lives"). For identification of women at risk for isoimmunization, every pregnant woman should undergo blood type and antibody screening at the first prenatal visit and again in the third trimester.

Sixty percent of cases of immune hydrops result from ABO incompatibility; however, only Rh(D) isoimmunization can be prevented. The Rh(D) antigen is expressed only on primate erythrocytes and becomes evident by 38 days of intrauterine life. A mutation in the Rh(D) gene on chromosome 1 results in lack of expression of Rh(D) antigen on circulating erythrocytes (Rh[D] negative). This mutation arose in the Basque region of Spain, and the difference in prevalence of Rh(D)-negative individuals between the races likely reflects the amount of Spanish blood in their ancestry: Caucasian, 15%; African-American, 8%; African, 4%; Native American, 1%; and Asian, less than 1%.[172] If the fetus of an Rh(D)-negative woman is Rh(D) negative, Rh(D) sensitization will not occur. However, 60% of Rh(D)-negative women have Rh(D)-positive fetuses, and exposure of these women to as little as 0.25 mL of Rh(D)-positive blood may induce an antibody response. Because the initial immune response is production of IgM, the index pregnancy is rarely affected. However, immunization in subsequent pregnancies triggers an IgG response that crosses the placenta and causes hemolysis. Risk factors for Rh(D) sensitization include a mismatched blood transfusion (95% sensitization rate), ectopic pregnancy (< 1%), abortion (3% to 6%), amniocentesis (1% to 3%), and pregnancy itself. Indeed, the sensitization rate is 16% to 18% after a normal pregnancy without Rh_0(D) immune globulin administration, 1.3% with Rh_0(D) immune globulin at delivery only, and 0.13% with anti-Rh_0(D) immune globulin at 28 weeks and again after delivery.[172,173] The risk for isoimmunization depends on the volume of fetal-maternal hemorrhage (Table 6.12). Passive immunization with Rh_0(D) immune globulin can destroy fetal erythrocytes before they evoke a maternal immune response, thereby preventing sensitization. Therefore, Rh_0(D) immune globulin should be given within 72 hours of potential exposure; 300 µg given intramuscularly is adequate for exposure to as much as 30 mL of fetal whole blood or 15 mL of fetal red blood cells.

Once isoimmunization has occurred, passive immunoglobulin is not useful. Such pregnancies should be observed closely for evidence of fetal compromise. Fetal hemolysis results in release of bile pigment into the amniotic fluid, which can be quantified as a change in optical density measured at a wavelength 450 nm. Traditionally, the extent of hemolysis had been measured with serial amniocenteses, with amniotic fluid optical density plotted against gestational age; increased density (upper 80% of zone 2 or zone 3 of the Liley curve) is associated with a poor prognosis,[174,175] and prompt intervention is indicated. Measurements of peak systolic velocity in the fetal MCA by means of noninvasive Doppler velocimetry have now emerged as the best tool to accurately identify fetuses with severe anemia requiring urgent intervention, regardless of the cause of the anemia.[94,173,176] The sensitivity of an elevated MCA peak systolic velocity (i.e., > 1.5 MoM for a given gestational age) for predicting moderate to severe anemia approaches 100%.[94] Depending on gestational age, these interventions may include immediate delivery or intrauterine blood transfusion.

TABLE 6.12 Fetal-Maternal Transfusion Volume and Risk for Rh(D) Isoimmunization in an Rh(D)-Negative Woman

Transfusion Volume	Incidence at Delivery (%)	Risk for Isoimmunization (%)[a]
Unmeasurable	50	Minimal
< 0.1 mL	45–50	3
> 5.0 mL	1	20–40
> 30 mL	0.25	60–80

[a]Without Rh_0(D) immune globulin.
Data from American College of Obstetricians and Gynecologists. Prevention of Rh D alloimmunization. ACOG Practice Bulletin No. 4. *Int J Gynaecol Obstet.* 1999;66:63–70 (reaffirmed 2009); Moise KJ. Red blood cell alloimmunization in pregnancy. *Semin Hematol.* 2005;42:169–178.

Postterm Pregnancy

Postterm pregnancy is defined as any pregnancy that continues to or beyond 42 weeks (294 days) from the first day of the last normal menstrual period or 14 days beyond the best obstetric estimate of the EDD, while a *late-term* pregnancy is defined as one between 41 0/7 weeks and 41 6/7 weeks of gestation.[177] The prevalence of postterm pregnancy depends on the patient population (e.g., percentage of primigravidas, incidence of pregnancy complications, frequency of spontaneous preterm births) and the local practice patterns (e.g., use of ultrasonographic assessment of gestational age, cesarean delivery rates, use of labor induction); the incidence of postterm pregnancy in the United States has steadily decreased over time to 0.35% in 2016.[178] Compared with delivery at 40 weeks, postterm pregnancies pose significant risks to both the mother (including higher risk for cesarean delivery, severe perineal injury, and postpartum hemorrhage) and the fetus (including stillbirth, fetal macrosomia, birth injury, and meconium aspiration syndrome).[93,179–182] A Cochrane review of 22 randomized control trials involving 9383 women determined that induction of labor at term is associated with a decreased risk for perinatal death, cesarean delivery, and meconium aspiration syndrome.[183] For this reason, induction of labor after 42 0/7 weeks and by 42 6/7 weeks' gestation

is recommended, while induction of labor between 41 0/7 weeks and 42 0/7 weeks' gestation can be considered.[184]

Postterm pregnancy is an indication for antenatal fetal surveillance,[93] although the efficacy of this approach has not been validated by prospective randomized trials.[185] Options for evaluating fetal well-being include NST with or without amniotic fluid volume assessment, BPP, CST, and a combination of these modalities. There is no consensus as to which of these modalities is preferred, and no single method has been shown to be superior.[93] The ACOG has recommended that antepartum fetal surveillance be initiated by 42 weeks' gestation at the latest, without making a specific recommendation about the type of test or frequency.[93] Many investigators would advise twice-weekly testing with some evaluation of amniotic fluid volume at least weekly. Doppler ultrasonography has no benefit in monitoring the postterm fetus and is not recommended for this indication.[89,90] Although the data are inconsistent, there is a suggestion that antenatal testing at 40 to 42 weeks' gestation may be associated with improvements in perinatal outcome. In one retrospective study, women with routine antenatal testing beginning at 41 weeks' gestation had lower rates of cesarean delivery for nonreassuring fetal test results than women in whom testing was started at 42 weeks (2.3% versus 5.6%, respectively; $P < .01$).[184] In addition, the group with delayed antenatal testing experienced three stillbirths and seven other neonatal major morbidity events, compared with none in the group who had antenatal testing from 41 weeks ($P < .05$).[184]

In the postterm period, evidence of fetal compromise (nonreassuring fetal test results) or **oligohydramnios** (e.g., low amniotic fluid volume) should prompt delivery.[93] Oligohydramnios, defined as amniotic fluid index of 5 cm or less or a single deepest pocket of 2 cm or less, has been associated with an increased risk for fetal demise and is an indication for delivery at or beyond 41 0/7 weeks' gestation. Recent studies concluded that use of a deepest vertical pocket of 2 cm or less to diagnose oligohydramnios, rather than an amniotic fluid index of 5 cm or less, was associated with a reduction of unnecessary interventions without an increase in adverse perinatal outcomes.[186,187] Oligohydramnios may result from uteroplacental insufficiency or increased renal artery resistance and may predispose to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, and meconium aspiration. Adverse pregnancy outcomes (nonreassuring FHR tracing, low Apgar score, and neonatal intensive care unit admission) are more common when oligohydramnios is present. Frequent screening of postterm patients for oligohydramnios is important, because amniotic fluid can become dramatically reduced within 24 to 48 hours.[188]

Intrauterine Fetal Demise

Intrauterine fetal demise (IUFD), also known as stillbirth, is defined in the United States as demise of the fetus after 20 weeks' gestation and before delivery.[189] The stillbirth rate in the United States was 5.96 per 1000 live births in 2013, with approximately half occurring before 28 weeks.[190] However, it remains a vastly underappreciated clinical problem, with antepartum stillbirths accounting for more perinatal deaths than either complications of prematurity or sudden infant death syndrome.[190] Risk factors for stillbirth include extremes of maternal age, chromosomal disorders, congenital malformations, antenatal infection, multiple pregnancy, prior unexplained IUFD, postterm pregnancy, fetal macrosomia, male fetus, umbilical cord and placental abnormalities, and underlying maternal medical conditions (e.g., chronic hypertension, pregestational or gestational diabetes mellitus, autoimmune disorders, inherited or acquired thrombophilia).[189,191,192]

Although older studies observed that approximately 50% of cases of IUFD were unexplained, an aggressive approach may identify the cause in up to 80% to 90% of cases (Table 6.13).[192–195] Pathologic examination of the fetus and the placenta/fetal membranes is the single most useful means of identifying a cause for the IUFD.[193,194] Early detection and appropriate management of underlying maternal disorders (e.g., diabetes, preeclampsia) may also reduce the risk. Genetic testing should be considered for determining the cause of stillbirth. Compared with karyotype testing, microarray analysis is more likely to yield a result because it does not require dividing cells to detect genomic abnormalities.[196] Some 6% to 10% of stillborn fetuses have an abnormal karyotype.[195] On occasion, amniocentesis may be recommended to salvage viable amniocytes for cytogenetic analysis before delivery. Fetal-maternal hemorrhage occurs in all pregnancies but is usually minimal (< 0.1 mL total volume); in rare instances, a significant hemorrhage may occur, leading to fetal demise. The Kleihauer-Betke (acid elution) test allows an estimate of the volume of fetal blood in the maternal circulation, and a maternal blood sample should be drawn within 6 to 8 hours of the purported bleeding episode because of rapid clearance of fetal cells from the maternal circulation.[197] Intra-amniotic infection resulting in fetal death is usually evident on clinical

TABLE 6.13 Causes of Intrauterine Fetal Demise

Maternal causes	Underlying medical conditions (diabetes mellitus, thyroid disease, antiphospholipid antibody syndrome)
	Preeclampsia
	Isoimmunization
	Illicit drug use (cocaine)
	Antepartum drug/toxin exposure
Uteroplacental causes	Placental abruption
	Placenta previa
	Vasa previa
	Fetomaternal hemorrhage
	Cord accident
Fetal causes	Fetal chromosomal/genetic anomalies
	Fetal structural abnormalities
	Intra-amniotic infection
	Complications of multiple pregnancies (including twin-to-twin transfusion syndrome)

examination. Placental membrane culture and autopsy examination of the fetus, placenta/fetal membranes, and umbilical cord may be useful. Fetal radiography or MRI may sometimes be valuable if autopsy is declined.[198,199]

The inability to identify fetal heart activity or the absence of uterine growth may suggest the diagnosis. Ultrasonography is the "gold standard" for confirming IUFD by documenting the absence of fetal cardiac activity. Other ultrasonographic findings in late pregnancy include Spalding's sign (overlapping of the cranial sutures), scalp edema, and soft tissue maceration, although these usually take a few days to develop. Every effort should be made to avoid cesarean delivery in the setting of IUFD. Thus, in the absence of a contraindication, expectant management is often recommended. Latency (the period from fetal demise to delivery) varies according to the underlying cause and gestational age. In general, the earlier the gestational age, the longer the latency period. Overall, more than 90% of women go into spontaneous labor within 2 weeks of fetal death. However, many women find the prospect of carrying a dead fetus distressing and want the pregnancy terminated as soon as possible. Management options include surgical dilation and evacuation or induction of labor with cervical ripening, if indicated. Disseminated intravascular coagulation develops in 20% to 25% of women who retain a dead singleton fetus for longer than 3 weeks because of excessive consumption of clotting factors.[200,201] Therefore, delivery should be effected within this period. Induction of labor with prostaglandins or oxytocin has been shown to be safe in the setting of an IUFD.

The death of one fetus in a twin gestation poses a particular challenge, and the risks are related to the type of placentation. In monochorionic twin gestations, the death of one twin puts the surviving co-twin at significant risk for major morbidity, including IUFD, neurologic injury, multiorgan system failure, thromboembolic events, placental abruption, and preterm birth.[202–204] The prognosis for the surviving twin depends on the cause of death, gestational age, chorionicity, and the time between death of the first twin and delivery of the second. However, there is some level of shared circulation in almost all monochorionic twin pregnancies, and death of one fetus in this setting raises the risk for death of its co-twin owing to profound hypotension and/or purported transfer of thromboplastic proteins from the dead fetus to the live fetus.[205] If it survives, the co-twin has a 20% risk for development of permanent neurologic injury (multicystic encephalomalacia), which may not be prevented by immediate delivery.[206,207] Dichorionic twin pregnancies do not share a circulation, and death of one twin may have little impact on the surviving twin. The dead twin may be resorbed completely or may become compressed and incorporated into the membranes *(fetus papyraceus)*. Disseminated intravascular coagulation in the surviving fetus and/or mother is rare.[208]

Regardless of type of placentation, management of the surviving twin should include regular fetal surveillance (kick counts, NST, BPP), and consideration of delivery in the setting of nonreassuring fetal test results or at a favorable gestational age.

FETAL THERAPY

Continued assessment of the fetus throughout pregnancy is critical to optimizing pregnancy outcomes. In most cases, evidence of fetal compromise prompts delivery. However, in certain situations, treatment may be available to improve or even correct the underlying problem *in utero*. These interventions can be noninvasive (e.g., administration of digoxin to the mother to treat a fetal supraventricular tachycardia) or invasive (e.g., placement of a vesicoamniotic shunt) and are summarized in Tables 6.14 and 6.15, respectively.[209–244] Some

TABLE 6.14 Noninvasive Treatment Options to Improve Perinatal Outcome

Clinical Condition	Treatment	Efficacy
Imminent risk for preterm birth < 34 weeks	Antenatal corticosteroids	Effective in decreasing respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis[209]
Pregestational diabetes mellitus	Strict glycemic control	Effective in decreasing rate of stillbirths and birth defects[210]
Phenylketonuria (autosomal recessive disorder caused by phenylalanine hydroxylase deficiency)	Dietary manipulation (low-phenylalanine diet)	Effective in decreasing birth defects and brain damage in affected fetuses[211]
Alloimmune thrombocytopenia	Maternal intravenous immunoglobulin ± corticosteroids	Data conflicting on effect of intravenous immunoglobulin on fetal platelets; steroids probably of no benefit[212,213]
Fetal thyrotoxicosis	Maternal propylthiouracil	Effective in decreasing fetal growth restriction and subsequent neurodevelopmental defects[214,215]
Congenital adrenal hyperplasia (usually caused by 21-hydroxylase deficiency)	Maternal dexamethasone	Effective in preventing virilization of female fetus if given before 8 to 9 weeks' gestation[216]
Fetal supraventricular tachycardia (SVT)	Maternal digoxin	Data conflicting on effect of digoxin to correct fetal SVT

TABLE 6.15 Invasive Treatment Options to Improve Perinatal Outcome

Clinical Condition	Treatment	Efficacy
Severe fetal anemia with or without hydrops fetalis	Intrauterine transfusion	Effective[217,218]
Fetal supraventricular tachycardia	Digoxin given directly to fetus by intramuscular injection	Effective
Severe obstructive uropathy	Vesicoamniotic shunting	Effective in preventing renal injury and improving survival[219]
Isolated fluid collection in the fetus (severe ascites, hydrothorax)	Fetoamniotic shunting	Effective[220]
Severe valvular stenosis	Fetal surgery (*in utero* valvuloplasty)	Investigational[221]
Fetal lung masses (congenital cystic adenomatous malformation, pulmonary sequestration)	Fetal surgery (*in utero* resection of lesion)	Investigational[222,223]
Congenital hydrocephalus	Fetal surgery (*in utero* shunting)	Investigational[224]
Congenital diaphragmatic hernia	Fetal surgery (*in utero* repair; tracheal occlusion)	Investigational[225,226]
Fetal neural tube defect	Fetal surgery (*in utero* repair)	Investigational[227–229]
Higher-order multiple pregnancy (≥ triplets)	Multifetal pregnancy reduction	Effective in improving perinatal outcomes with reduction to twins[230–233]
TTTS	Serial amnioreduction versus septostomy versus fetal surgery (endoscopic laser ablation, cord ligation)	Effective Laser ablation appears to give the best chance of intact survival in severe TTTS[234–239]
Preterm premature rupture of membranes	Serial amnioinfusion versus fetal surgery (laser coagulation, intra-amniotic amniopatch)	Investigational[240–242]
EXIT	To facilitate oxygenation at delivery before ligation of the umbilical cord when the infant's airway is obstructed; may facilitate transition to ECMO in infants with severe pulmonary or cardiac malformations	Case reports of success[243,244]

ECMO, extracorporeal membrane oxygenation; *EXIT, ex utero* intrapartum therapy; *TTTS,* twin-to-twin syndrome.

of these interventions have been subjected to rigorous clinical trials and have been shown to be effective, whereas others remain investigational. The intervention that has perhaps had the greatest effect on perinatal outcome is antenatal maternal administration of corticosteroids.

Antenatal Corticosteroids

Respiratory distress syndrome (RDS) refers to respiratory compromise presenting at or shortly after delivery as a result of a deficiency of pulmonary surfactant, an endogenous detergent that serves to decrease the surface tension within alveoli, thereby preventing alveolar collapse. Overall, neonatal RDS affects approximately 1% of live births, but not all infants are at equal risk. The pulmonary system is among the last of the fetal organ systems to become functionally mature. Thus, RDS is primarily, although not exclusively, a disease of preterm infants, with the incidence and severity highly dependent on gestational age. For example, RDS affects more than 80% of infants younger than 28 weeks' gestation and 10% to 15% of all infants weighing less than 2500 g.[245,246] RDS remains a major cause of perinatal morbidity and mortality in extremely preterm infants. In addition to gestational age, a number of other factors influence the risk for RDS in a given fetus. For reasons that are not clear, African-American ethnicity, female gender, preeclampsia, and intrauterine exposure to cigarette smoke are protective against the development of RDS.

In 1972, Liggins and Howie[247] demonstrated that the administration of a single course of two antenatal doses of a corticosteroid (betamethasone) reduced the incidence of RDS by 50%. A meta-analysis of 12 randomized controlled trials with more than 3000 participants concluded that antenatal administration of corticosteroids to women in preterm labor reduced the incidence of neonatal RDS by 40% to 60% and resulted in an improvement in overall survival.[209] In one study, a single course of antenatal corticosteroids resulted in a threefold rise in the chance of unaffected survival in neonates with a birth weight less than 1500 g.[248] Certain steroids cross the placenta and induce cellular differentiation at the expense of growth. Type II pneumocytes in the lungs differentiate and begin making pulmonary surfactant, which accounts for the decrease in risk for RDS, and endothelial cells lining the vasculature undergo cellular maturation and stabilization, which explains the concomitant drop in incidence of bleeding into the brain (intraventricular hemorrhage) or gastrointestinal tract (necrotizing enterocolitis).[249] Prednisone does not cross the placenta and therefore does not have a similar protective effect.

The National Institutes of Health and the ACOG have recommended that a single course of antenatal corticosteroids,

defined as either betamethasone (12 mg intramuscularly q24h × two doses) or dexamethasone (6 mg intramuscularly q12h × four doses), be given after 23 to 34 weeks' gestation to any pregnant women in whom delivery before 34 weeks' gestation is threatening.[250] More recently, the ACOG has recommended a course of corticosteroids for women with a singleton pregnancy in whom delivery is threatening between 34 0/7 weeks and 36 6/7 weeks' gestation, in the absence of chorioamnionitis and who have not received a previous course of antenatal corticosteroids.[251] Although the maximum benefit of antenatal corticosteroids is achieved 24 to 48 hours after the first injection, as little as 4 hours of treatment exerts some protective effect. This protective effect lasts for 7 days, after which further benefit is unclear. Multiple (three or more) courses of antenatal corticosteroids have been associated with fetal growth restriction, smaller head circumference, and (in animals) abnormal myelination of the optic nerves; consequently, multiple courses are not routinely recommended. A single repeat course of antenatal corticosteroids should be considered in women who are less than 34 0/7 weeks' gestation and at risk for preterm delivery within the next 7 days, at least 7 days after the prior dose.[251]

Fetal Surgery

Fetal surgery has been proposed in selected cases to prevent progressive organ damage or to restore normal anatomy and fetal development (see Chapter 7). The ideal case for fetal surgery consists of a singleton pregnancy before fetal viability (i.e., before 23 to 24 weeks' gestation) in which the fetus has a normal karyotype and an isolated malformation that, if untreated, will result in fetal or neonatal demise. A detailed understanding of the natural history of the malformation is essential when one is considering whether to recommend surgery. Fetal surgery should not be attempted if the natural history of the disorder is unknown or if the chances of survival without *in utero* treatment are greater than or equal to the risks associated with the procedure. The only two randomized controlled trials published to date in fetal surgery—one on tracheal occlusion for the management of congenital diaphragmatic hernia[226] and the other on prenatal versus postnatal repair of myelomeningocele[229]—found little significant benefit to *in utero* surgery. Moreover, although pediatric benefit with open maternal-fetal surgery for myelomeningocele repair has been observed, there are significant maternal risks, including the need for cesarean delivery with all future pregnancies (similar to that for women with a history of a classical cesarean delivery).[252] Repair of lesions that are not believed to be life threatening (e.g., cleft lip and palate) should be deferred until after delivery to minimize risks to the mother.

Before *in utero* surgery can be recommended, a thorough evaluation must be performed to (1) precisely characterize the defect, (2) exclude associated malformations, (3) perform a fetal karyotype analysis, and (4) eliminate the possibility that the condition can be treated using less aggressive technologies. Detailed counseling about the risks and benefits of the proposed procedure is required, and written informed consent is mandatory. Such a discussion must include a detailed review of the risks to both the fetus and the mother, including preterm PROM (28% to 100%), preterm labor and delivery (> 50%), maternal pulmonary edema (20% to 30%), placental abruption (5% to 10%), chorioamnionitis and sepsis (< 5%), and maternal death (rare).[226,228] Specific examples of fetal surgical procedures are summarized in Table 6.15.

KEY POINTS

- Accurate determination of gestational age is essential for the management of pregnancy complications and the effective use of antepartum fetal testing.
- Ultrasonography can be used to estimate gestational age, assess fetal growth, monitor amniotic fluid volume, and detect and characterize fetal anomalies.
- Appropriate fetal growth is strongly correlated with fetal health and can be assessed either clinically or with ultrasonography. Inappropriate fetal growth requires further evaluation.
- Fetal movement charts ("kick counts") can be used to confirm fetal well-being in both high- and low-risk populations. High-risk pregnancies may require additional fetal monitoring such as the nonstress test (NST), biophysical profile (BPP), or contraction stress test (CST).
- A fetal karyotype can be obtained by chorionic villus sampling, amniocentesis, or fetal blood sampling (cordocentesis).
- Doppler velocimetry has advanced our understanding of maternal-fetal physiology, but its role in confirming fetal well-being is unclear.
- Additional radiologic imaging (especially magnetic resonance imaging) may be used in selected cases to better define fetal malformations.
- A number of intrauterine therapies have been shown to improve perinatal outcome in selected cases, including antenatal corticosteroid administration, intrauterine transfusion, and fetal surgery (e.g., laser photocoagulation for twin-to-twin transfusion syndrome).
- The appropriate timing of delivery is a critical determinant of perinatal outcome. In general, delivery is indicated when the benefits of delivery to the fetus or mother outweigh the risks associated with continuing the pregnancy. Simply stated, delivery is indicated when the fetus is better off outside the uterus than inside. A number of variables should be considered in such a decision, the most important of which are gestational age and fetal well-being.

Anesthesia for Fetal Surgery and Other Intrauterine Procedures

Mark D. Rollins, MD, PhD

CHAPTER OUTLINE

The ability to treat underlying fetal conditions with medical procedures or surgery is a relatively recent development. Fetal therapy originated in 1963 with Sir William Liley's successful intraperitoneal blood transfusion to a fetus with erythroblastosis fetalis.[1] In 1981, following sheep and primate studies, the first successful human fetal surgery, a vesicostomy, was performed in a fetus with bilateral hydronephrosis secondary to a lower urinary tract obstruction.[2]

Advances in prenatal diagnosis, imaging, and surgical equipment have all contributed to the development of fetal surgery. Some fetal abnormalities are amenable to intrauterine fetal surgery, but the majority of anatomic malformations diagnosed *in utero* remain unsuitable for fetal intervention. Prenatal diagnosis of serious malformations (e.g., those that are uncorrectable and incompatible with normal postnatal life) allows the choice of pregnancy termination. Most correctable malformations are best managed after delivery, with antepartum recognition allowing time for the coordination of appropriate prenatal and postnatal care. Some defects, especially those that cause airway obstruction or irreversible end-organ damage, are suitable for intrapartum intervention. This allows the benefit of intervention while the uteroplacental unit remains functional and often eliminates any urgency that would be associated with undertaking the procedure in the postnatal period.

Guidelines for performing fetal surgery (Box 7.1) were originally developed more than 35 years ago but remain relevant today with only minimal modifications.[3,4] All fetal interventions should undergo multidisciplinary deliberation and planning. Potential maternal risks should be discussed as part of the consent process and a detailed maternal preoperative evaluation completed to ensure minimal risk to the mother. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics (AAP) recommend that fetal treatment centers include a multidisciplinary comprehensive consent and counseling process, oversight of fetal research, and participation in a data-sharing fetal intervention network.[5]

Fetal surgical interventions can be broadly categorized into three kinds of procedures, namely, minimally invasive procedures, open surgical procedures, and intrapartum procedures. A summary of fetal conditions, therapy, and intervention is detailed in Table 7.1.

Minimally invasive procedures involve either fetoscopic or image-guided percutaneous procedures, typically performed near mid-gestation. They entail a lower risk for preterm labor and delivery than open procedures because they do not require a hysterotomy, yet the risk for preterm premature rupture of membranes (PROM) remains.[6]

Open surgical procedures involve both a maternal laparotomy and hysterotomy with use of pharmacologic agents to maintain uterine relaxation. These procedures are typically performed near mid-gestation and entail greater maternal and fetal risks compared with the minimally invasive

BOX 7.1 Guidelines for Performing Fetal Procedures

1. Accurate diagnosis and staging is possible.
2. Other anomalies that would contraindicate fetal intervention are excluded.
3. Progression, severity, and prognosis of the condition are understood.
4. No effective postnatal therapy is currently available, and if not treated before birth, the anomaly would result in fetal death, irreversible organ damage, or other severe postnatal morbidity.
5. Intrauterine surgery has been proven feasible in animal models, with demonstrated reversal of the deleterious effects of the condition.
6. The maternal risk is acceptably low.
7. Interventions are performed in specialized multidisciplinary fetal treatment centers within strict protocols and approval of the local ethics committee, with informed consent obtained from the mother or parents.
8. There is access to high-level specialized medical care, including bioethical and psychosocial care and counseling.

Summarized from Harrison MR, Filly RA, Golbus MS, et al. Fetal treatment 1982. *N Engl J Med* 1982;307:1651-1652 and Sudhakaran N, Sothinathan U, Patel S. Best practice guidelines: Fetal surgery. *Early Hum Dev*. 2012;88:15-19.

techniques, including a significant risk for preterm PROM, preterm labor and delivery, uterine dehiscence, oligohydramnios, hemorrhage, pulmonary edema, and fetal mortality. In addition, after an open surgical procedure, a cesarean delivery is required for the pregnancy and all future deliveries owing to the location of the hysterotomy and the associated risks for uterine dehiscence or rupture.[7,8]

The third kind of procedure involves a modification of cesarean delivery to allow intrapartum fetal therapy while the fetus remains supported by placental gas exchange. These delivery techniques are termed ***ex utero* intrapartum therapy (EXIT) procedures**.[9] EXIT procedures are most often employed in order for gas exchange to continue across the placenta (placental bypass) while (1) securing the airway by endotracheal intubation, bronchoscopy, or tracheostomy in fetuses with congenital airway obstruction or neck mass or (2) performing invasive fetal procedures required before delivery. The EXIT procedure enables the prevention of asphyxia in neonates in whom securing an airway after birth can be problematic. The procedure can also be used as a bridge to extracorporeal membrane oxygenation (ECMO) for a fetus with cardiopulmonary disease at risk for postnatal cardiac failure or failure of adequate pulmonary gas exchange.[10,11]

TABLE 7.1 Fetal Conditions and Interventions

Fetal Condition	Therapy Rationale	Type	Intervention
Fetal anemia or thrombocytopenia	Prevention of heart failure and fetal hydrops	Fetal image guided	Intrauterine transfusion
Aortic stenosis, intact atrial septum, or pulmonary atresia	Prevention of fetal hydrops, myocardial dysfunction, and hypoplastic left (and right) heart	Fetal image guided	Percutaneous fetal valvuloplasty or septoplasty
Obstructive uropathy	Bladder decompression with reduction in renal dysfunction, pulmonary hypoplasia, oligohydramnios, and limb malformation	Fetal image guided or fetoscopy	Percutaneous vesicoamniotic shunting or fetoscopic laser ablation of urethral valves
Twin reversed arterial perfusion sequence	Prevention of high-output cardiac failure in the normal twin by stopping flow to the acardiac twin	Fetal image guided or fetoscopy	Umbilical radiofrequency ablation or fetoscopic cord coagulation
Twin-to-twin transfusion syndrome	Reduction of twin-to-twin blood flow and prevention of cardiac failure	Fetoscopy	Fetoscopic laser photocoagulation of placental vessels and/or amnioreduction
Congenital diaphragmatic hernia	Prevention of pulmonary hypoplasia	Fetoscopy	Fetoscopic tracheal occlusion
Myelomeningocele	Reduction in hydrocephalus and hindbrain herniation with improved neurologic function	Open	Closure of fetal defect *in utero*
Sacrococcygeal teratoma	Prevention of high-output cardiac failure, hydrops, and polyhydramnios	Fetal image guided or open	Ablation of tumor vasculature or open fetal tumor debulking
Congenital cystic adenomatoid malformation	Reversal of pulmonary hypoplasia and cardiac failure	Fetal image guided or open	Thoracoamniotic shunting or open fetal lobectomy
Fetal airway compression	Secured airway and/or circulatory support to prevent respiratory compromise at birth	Open intrapartum	*Ex utero* intrapartum therapy that allows stabilization while on uteroplacental circulation

Modified from Partridge EA, Flake AW. Maternal-fetal surgery for structural malformations. Best Pract Res Clin Obstet Gynaecol. 2012;26:669–682; Hoagland MA, Chatterjee D. Anesthesia for fetal surgery. *Paediatr Anaesth*. 2017;27:346–357.

INDICATIONS AND RATIONALE FOR FETAL SURGERY

Fetal Anemia and Intrauterine Transfusion

The rate of fetal anemia secondary to rhesus D (RhD) sensitization has decreased to 1 in 1000 pregnancies following the use of RhD immunoglobulin prophylaxis.[12] Fetal anemia can occur secondary to other red cell antigens, viral infections, homozygous thalassemia, maternal-fetal hemorrhage, and placental chorioangiomas.[13] Serial Doppler studies of the middle cerebral artery (MCA) peak velocity are used to diagnose fetal anemia.[14] A sample of fetal umbilical cord blood just before starting the intrauterine transfusion (IUT) is the most accurate test for fetal anemia. Before 18 weeks' gestation, intraperitoneal transfusion may be chosen for treatment of fetal anemia given that accessing the umbilical vein may not be possible. In this procedure, donor red blood cells are injected into the fetal peritoneal cavity and transported through the lymphatic system to the fetal circulation. With early diagnosis of severe cases, combining these two procedures with immunoglobulin therapy may provide added benefit.[15]

IUTs are frequently performed using a 20- or 22-gauge needle with local anesthesia at the needle insertion site. The needle is inserted percutaneously through the maternal abdomen and uterus under ultrasonographic guidance to access the umbilical vein (Fig. 7.1). The cord is often accessed near its placental insertion for stability, but a loop of umbilical cord or an intrahepatic portion of the cord can also be used. The volume of O-negative, cytomegalovirus (CMV)-negative, irradiated, leukocyte-depleted, packed red blood cells is determined based on the estimated fetal weight, gestational age, autologous hemoglobin, and hemoglobin of the sampled fetal blood.[16] Following an IUT, the fetal hemoglobin levels slowly decrease, and multiple IUTs are often required at 1- to 3-week intervals. Although the umbilical cord does not have pain receptors, if the needle is advanced into the fetus for intrahepatic vascular access, a fetal stress response will occur; fentanyl or another opioid should be administered to blunt this response.[17] An intramuscular paralytic agent can be administered to the fetus to decrease the chance of fetal movement dislodging the transfusion needle or sheering the cord vasculature.[18] Providers should be prepared for a possible emergent cesarean delivery at any point during the IUT if the fetus is of viable age. Rates of fetal demise following IUT range from 1% to 5%.[13] Increased risk for fetal demise is associated with fetal hydrops, early gestational age, not using fetal paralysis, operator inexperience, and severity of fetal anemia.[13] Other complications include transient fetal bradycardia (8%), emergent cesarean delivery (2%), intrauterine infection (0.3%), and rupture of membranes (0.1%).[19]

Obstructive Uropathy

Lower urinary tract obstruction (LUTO) occurs in approximately 1 in 5000 live births.[20] Congenital bilateral hydronephrosis results from fetal urethral obstruction at the bladder outlet, most commonly by either posterior urethral valves (typically male fetuses) or urethral atresia.[21] Other causes of fetal obstructive uropathy include obstruction at the ureteropelvic or vesicoureteric junction and a number of complex disorders in females (e.g., cloacal plate anomalies). These uropathies are typically evaluated by ultrasonography, which is often performed to investigate oligohydramnios from diminished fetal urine output. Magnetic resonance imaging (MRI) can also be used, but there is no evidence that it is superior. LUTO may lead to progressive renal dysplasia and dysfunction, bladder distention, and oligohydramnios, and ultimately result in devastating developmental consequences, such as limb and facial deformities, pulmonary hypoplasia, and even neonatal death (Fig. 7.2).[22] A disease severity classification system for LUTO based primarily on amniotic fluid index, renal imaging, and urinary biochemistries has recently been proposed.[23] Although postnatal correction relieves the obstruction, 25% to 30% of survivors develop end-stage kidney disease requiring dialysis by 5 years of age.[24] Early intrauterine intervention with placement of a vesicoamniotic shunt (VAS) allows drainage of urine from the fetal bladder into the amniotic cavity, thereby decompressing the urinary tract. In animal models, intrauterine relief of obstructive uropathy improves dysplastic renal histology, restores normal

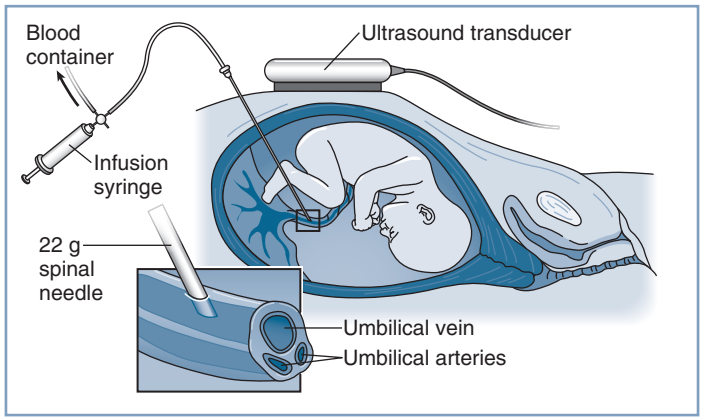

Fig. 7.1 Percutaneous intrauterine umbilical cord sampling and transfusion. (Courtesy of University of California, San Francisco Fetal Treatment Center.)

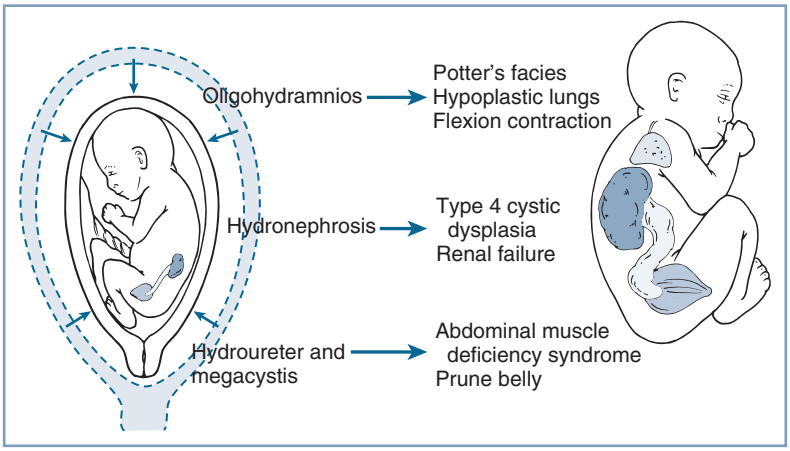

Fig. 7.2 Developmental consequences of fetal urethral obstruction. Obstructed fetal urinary flow results in hydronephrosis, hydroureter, megacystis, oligohydramnios, and pulmonary hyperplasia. (Redrawn from Harrison MR, Filly RA, Parer JT, et al. Management of the fetus with a urinary tract malformation. *JAMA*. 1981;246:635–639.)

urine flow and amniotic fluid volume, and results in improved lung growth and development.[25]

A VAS is a valveless, double-coiled catheter placed percutaneously with ultrasonographic guidance, with one coil remaining in the urinary bladder and the other in the amniotic space. Common problems associated with these catheters include: (1) difficult placement, occlusion, and displacement; (2) fetal trauma, iatrogenic abdominal wall defects, and amnioperitoneal leaking; and (3) preterm PROM, preterm labor, and chorioamnionitis.[20] In a recent meta-analysis of studies between 1990 and 2015, there was a perinatal survival improvement with VAS compared with conservative management (57.1% versus 38.8%, $P < .01$).[24] However, there was no difference in 2-year survival or postnatal renal function. A large multicenter, randomized controlled trial comparing the perinatal mortality and renal function of fetuses with LUTO treated by either VAS or conservative care suggested improved survival in fetuses receiving VAS treatment, but was unfortunately closed early secondary to poor enrollment.[26]

Fetal cystoscopy is a more recent treatment in which a trocar-assisted fetoscope enters the fetal bladder under ultrasonographic guidance and allows direct visualization of the fetal urethra. Although not a viable treatment for urethral atresia, fetal cystoscopy facilitates diagnosis and treatment of LUTO caused by posterior urethral valves (PUVs).[21] Once visualized, the PUVs are destroyed using guide wires and hydroablation or laser ablation. A two-center case-control study compared fetal cystoscopy ($n = 34$) with VAS ($n = 16$) and no intervention ($n = 61$) for cases between 1990 and 2013.[27] Both fetal cystoscopy and VAS improved the 6-month survival rate in severe LUTO. Compared with no intervention, a trend for normal renal function was present in the fetal cystoscopy group ($P = .06$) but not in the VAS group ($P = .33$). In just the subset of PUV cases ($n = 57$), fetal cystoscopy improved both 6-month survival and renal function, while VAS was only associated with improvement in the 6-month survival rate.

Current evidence supports the use of fetal intervention for LUTO in selected fetuses in an effort to restore amniotic fluid volume, prevent pulmonary hypoplasia, and decrease perinatal mortality. However, the effects on long-term renal function, bladder function, and other morbidities remain unclear.

Congenital Diaphragmatic Hernia

Approximately 1 in 2500 live-born infants has a congenital diaphragmatic hernia (CDH). Without fetal intervention, this anomaly causes significant morbidity and mortality from pulmonary hypoplasia and insufficiency. Survival rates have improved to greater than 70% over the past 25 years and are closely associated with the degree of pulmonary hypertension and respiratory insufficiency.[28,29] Significant mortality occurs despite optimal postnatal surgical management at tertiary care medical centers (i.e., procedures involving removal of the herniated viscera from the chest, administration of surfactant, ventilation techniques that minimize lung trauma, use of ECMO, and closure of the diaphragm). Intrauterine correction of CDH has the potential to prevent pulmonary hypoplasia and allow the fetal lung to develop before delivery.

Fetal lamb models of CDH demonstrated that parenchymal hypoplasia and associated pulmonary vascular changes could be reversed by correction *in utero*.[30] Primary open repairs of human CDH *in utero* have been undertaken only for fetuses with severe disease, with limited success but many lessons learned, including the development of minimally invasive approaches.[31]

Fetal lungs contribute to amniotic fluid volume by secreting more than 100 mL/kg/day of fluid that exits the trachea and mouth. Tracheal occlusion impedes the normal egress of fetal lung fluid and results in expansion of the hypoplastic lung, thereby inducing lung growth and cellular maturation in fetuses with CDH.[32] This occlusion technique, termed "*p*lug the *l*ung *u*ntil it *g*rows" (i.e., PLUG),[33] replaced primary repair *in utero* for the correction of the pulmonary hypoplasia

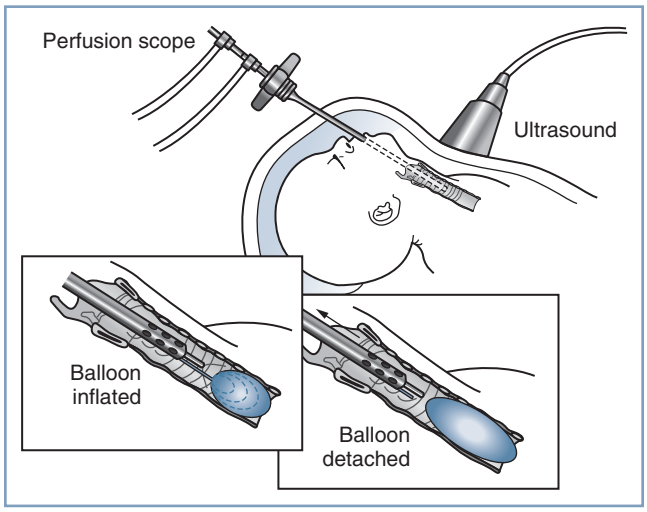

Fig. 7.3 Fetal tracheal occlusion using a balloon. (From Harrison MR, Albanese CT, Hawgood SB, et al. Fetoscopic temporary tracheal occlusion by means of detachable balloon for congenital diaphragmatic hernia. *Am J Obstet Gynecol.* 2001;185:730–733.)

TABLE 7.2 Postnatal Survival in Fetuses With Left-Sided Congenital Diaphragmatic Hernia and Intrathoracic Liver Herniation Based on Fetal Lung-to-Head Ratio

	POSTNATAL MANAGEMENT		FETOSCOPIC TRACHEAL OCCLUSION	
LHR (mm)[a]	Number of Fetuses	Survival Number (%)	Number of Fetuses	Survival Number (%)
0.4–0.5	2	0	6	1 (16.7)
0.6–0.7	6	0	13	8 (61.5)
0.8–0.9	19	3 (15.8)	9	7 (77.8)
1.0–1.1	23	14 (60.8)		
1.2–1.3	19	13 (68.4)		
1.4–1.5	11	8 (72.7)		
≥ 1.6	6	5 (83.3)		
Total	86	43 (50)	28	16 (57.1)

LHR, Lung-to-head ratio.
[a]LHR measurements in the table were obtained at 23 to 29 weeks' gestation.
Modified from Jani JC, Nicolaides KH, Gratacos E, et al. Fetal lung-to-head ratio in the prediction of survival in severe left-sided diaphragmatic hernia treated by fetal endoscopic tracheal occlusion (FETO). *Am J Obstet Gynecol.* 2006;195:1646–1650.

associated with CDH. It is a less extensive, palliative fetal surgical procedure that enhances lung growth to improve postnatal survival, with postponement of the definitive repair until after birth.[34] Once the trachea is occluded, fetal pulmonary fluid slowly accumulates and expands the lung, pushing the viscera out of the thorax. A small detachable balloon for endoluminal tracheal occlusion is placed in the trachea via percutaneous endoscopic endotracheal intubation and is either left in place until delivery or deflated earlier (Fig. 7.3).[35,36]

A prospective randomized trial (1999–2001) evaluated fetal tracheal occlusion for intrauterine treatment of severe CDH.[37] Inclusion criteria included (1) a gestational age of 22 to 28 weeks, (2) left-sided herniation of the liver into the hemithorax, and (3) a low lung-to-head ratio (LHR) (i.e., < 1.4). The LHR is a ratio of the contralateral lung cross-sectional area compared with head circumference and is correlated with the severity of pulmonary hypoplasia and survival for a given gestational age.[38] The trial was closed early ($n = 11$). Fetal tracheal occlusion resulted in no improvement in survival compared with the control group (77% versus 73%) and no reduction in morbidity at 90 days. The rates of preterm PROM and preterm delivery were higher in the fetal intervention group.[37] However, the survival rate was unexpectedly high in the control group. It is speculated that the LHR criterion of less than 1.4 was not sufficiently restrictive and allowed inclusion of fetuses in the study that were likely to survive with standard postnatal tertiary medical care. Table 7.2 notes improved survival for left-sided CDH fetuses treated *in utero* with an LHR < 1.0 compared with standard postnatal care.

Use of fetal endoscopic tracheal occlusion (FETO) began to focus on more severe cases of CDH with a high risk for death.[39] FETO intervention criteria for fetuses at high risk included both an LHR less than 1.0 and liver herniation into the hemithorax.[40] Owing to concern for tracheal damage by very early tracheal balloon placement,[41] the tracheal balloon is placed between 26 and 28 weeks' gestation and removed before birth by a second fetoscopic procedure near 34 weeks' gestation (if the fetus is still *in utero*).[42] This second procedure is performed to minimize the risk for preterm labor, avoid the need for the EXIT procedure (discussed later in the chapter), and possibly improve lung growth and minimize the reduction of type II alveolar cells associated with prolonged tracheal occlusion. Recently, a single institution, prospective observational cohort study compared treatment of left-sided severe CHD (LHR < 1.0 and liver herniation) with FETO to historic controls.[43] The FETO group had mean balloon placement and removal at 28 and 34 weeks' gestation, respectively. The FETO group had increased 2-year survival (67% versus 11%) and reduced need for ECMO. A recent meta-analysis examined five trials published between 2004 and 2012 that compared FETO to contemporary controls.[44] All studies included isolated severe CDH with an LHR ≤ 1.0 and liver herniation into the thorax. Survival outcome was improved with FETO (odds ratio 13). In all these studies, it is possible that the comparative results may represent selection bias or improvements in technique and clinical care over time. Although promising, there is currently inadequate evidence to recommend intrauterine fetal intervention to treat CDH as a routine clinical practice.[42]

In 2009, a randomized Tracheal Occlusion to Accelerate Lung growth trial (TOTAL) was started.[45] It compares postnatal CDH management to both late (30 to 32 weeks' gestation) FETO intervention for moderate lung hypoplasia

and also earlier FETO intervention (27 to 30 weeks' gestation) for severe lung hypoplasia. In both arms of the TOTAL trial, the balloon is removed in the 34th week of gestation. In addition, it is now appreciated that LHR depends on gestational age[46] and that a ratio of observed to expected LHR is a better expression of CDH severity and likelihood of survival.[47,48] This ratio is used as part of the ongoing TOTAL trial. Results of this trial will help determine if FETO should be offered and whether there is an optimal gestational age to intervene.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformations (CPAMs) are pulmonary tumors with cystic and solid components usually isolated to a single lung. These malformations were previously described as congenital cystic adenomatoid malformations (CCAMs). The incidence is approximately 1 in 25,000 pregnancies. A second-trimester ultrasonogram is reliable and accurate in detecting pulmonary lesions, with MRI and color Doppler ultrasonography facilitating differentiation between CPAM, bronchopulmonary sequestration, bronchogenic cysts, neurogenic cysts, and CDH.[49] The classification scheme for CPAM proposed by Stocker includes five subtypes, based on cyst size, characteristics of the epithelial lining, cyst wall thickness, and the presence of mucous cells, cartilage, and skeletal muscle.[50] Lesions are assessed by ultrasonography and can be divided by the presence of cysts either larger (macrocystic) or smaller (microcystic) than 5 mm in diameter.[49] Lesions can regress, resulting in minimal associated morbidity, or progressively enlarge, often resulting in fetal hydrops (fetal heart failure). The size and growth of the lesions, rather than their specific type, are the primary determinate of overall prognosis. Small lesions detected *in utero* or in the neonate are treated after birth by surgical excision of the affected pulmonary lobe. Large lesions can cause mediastinal shift, hydrops, polyhydramnios, and pulmonary hypoplasia and can interfere with fetal or neonatal survival. Fetuses with untreated lesions associated with hydrops have a survival rate of less than 5%.[51] In a retrospective single-institution review of 71 cases, the initial antenatal ultrasonographic ratio of CPAM volume-to-fetal head circumference (congenital pulmonary airway malformation volume ratio [CVR]) was evaluated for hydrops formation and postnatal outcomes.[52] Fetuses with a CVR less than 0.56 were noted to have no adverse postnatal outcomes, whereas a CVR greater than 0.56 had a positive predictive value for adverse postnatal outcomes of 33%. In addition, a CVR greater than 1.6 was associated with a greater risk for hydrops, and a CVR less than or equal to 1.6 with absence of a dominant cyst was associated with a < 3% risk for hydrops.[53]

Depending on size, location, and other characteristics, CPAMs can be managed with either fetal intervention or postnatal resection. Macrocystic lesions can be decompressed *in utero* by thoracocentesis or placement of shunt catheters between the cystic area and the amniotic cavity, resulting in sustained decompression and resolution of hydrops.[54] These *in utero* procedures are followed by postnatal surgery. However, not all lesions can be decompressed successfully with a shunt because the cysts are not always contiguous (i.e., in communication with each other) and can refill rapidly. In addition, thoracoamniotic shunts have associated risks, including malfunction, displacement, fetal hemorrhage, preterm PROM, preterm labor, and chorioamnionitis.[55] In a series of 68 fetuses with macrocystic CPAMs treated with thoracoamniotic shunts, the overall survival rate was 68% in hydropic and 88% in nonhydropic fetuses.[56] CPAMs inappropriate for drainage can be resected with open fetal surgery. Intrauterine pulmonary lobectomy for lesions associated with fetal hydrops has resulted in a 30-day postnatal survival rate of 50%, with tumor resection allowing for compensatory lung growth and resolution of hydrops.[57] Additional, less common options include resection while on placental circulation (EXIT procedure) or on postnatal ECMO, radiofrequency or laser ablation, and percutaneous ultrasound-guided sclerotherapy.[58] Maternal administration of betamethasone has been noted to improve fetal hydrops and overall outcome in selected fetuses with CPAM.[58-60] Thoracoamniotic shunts have also been successfully placed to decompress massive congenital pleural effusions caused by fetal chylothorax that otherwise would result in hydrops fetalis, pulmonary compression, and fetal or neonatal death.[61]

Sacrococcygeal Teratoma

With a prevalence of approximately 1 in 20,000 to 40,000, sacrococcygeal teratoma (SCT) is associated with perinatal demise in 25% to 37% of cases.[62] Management of these tumors requires serial ultrasonographic assessments, as some undergo rapid, substantial growth (i.e., 1000 cubic centimeters),[63] function as large arteriovenous fistulas, and result in high-output cardiac failure, hydrops fetalis, and placentomegaly. SCTs are staged using the Altman criteria,[64,65] which focuses on their location. Stage I tumors are based entirely outside the pelvis and are suitable for intervention; by contrast, Stage IV tumors are completely within the pelvis and not amenable to fetal resection. Tumor size is estimated based on a tumor volume-to-fetal weight ratio, with large SCTs considered > 0.12 cm^3/g[66]; rapid growth (>150 cm^3/week) is associated with adverse outcomes, including tumor rupture and hemorrhage, as well as intrapartum dystocia.[64,67] Fetuses with lesions diagnosed before 30 weeks' gestation have a poor prognosis (< 7% survival) but may benefit from *in utero* intervention.[64] Current surgical techniques do not allow complete resection of lesions that deeply invade the pelvis; however, *in utero* radiofrequency ablation, embolization, and thermocoagulation of the tumor or feeding vessels can reduce the tumor burden and resolve hydrops. Large multicenter studies are needed to determine which therapies deliver the most definitive, optimal benefits (Fig. 7.4A).[64,68] During open fetal tumor resection (Fig. 7.4B), catheterization of a fetal limb or umbilical cord vein may be needed to allow for blood or fluid administration.

Some SCT cases are accompanied by "maternal mirror" or Ballantyne syndrome, a hyperdynamic state (i.e., hypertension, peripheral and pulmonary edema) in which the maternal physiology mimics the abnormal circulatory physiology

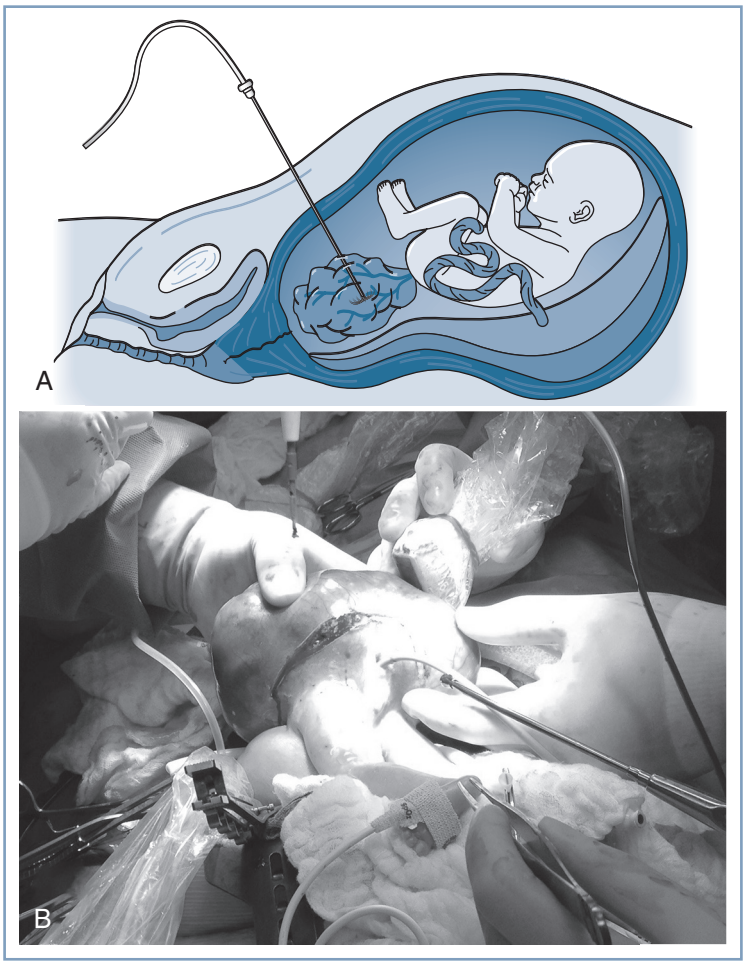

Fig. 7.4 *In utero* fetal treatment of sacrococcygeal teratoma (SCT). (A) Radiofrequency ablation treatment of an SCT. (B) Open fetal surgery for *in utero* vascular ablation and tumor resection of SCT. Note pulse oximeter on fetal foot, placement of rectal temperature probe, and use of ultrasound to monitor blood flow in SCT. (**A** from Van Mieghem T, Al-Ibrahim A, Deprest J, et al. Minimally invasive therapy for fetal sacrococcygeal teratoma: case series and systematic review of the literature. *Ultrasound Obstet Gynecol.* 2014;43:611–619. **B** courtesy of author Mark Rollins during his affiliation with the UCSF Fetal Treatment Center.)

of the hydropic fetus.[69] This syndrome is associated with a substantial increase in fetal mortality and maternal morbidity and requires aggressive management similar to that used for preeclampsia with severe features, a disease from which it must be distinguished. Platelet count, aspartate aminotransferase, alanine aminotransferase, and haptoglobin are typically unaffected in maternal mirror syndrome and may serve as diagnostic clues. Unfortunately, maternal mirror syndrome does not resolve quickly, even with rapid correction of the fetal pathophysiology, and severe life-threatening maternal complications including pulmonary edema occur in about 20% of cases.[69,70]

Myelomeningocele

Although not lethal, a myelomeningocele (MMC) is the most common form of spina bifida and characterized by a protrusion of the meninges and spinal cord through a congenital defect in the vertebrae and overlying muscles and skin (Fig. 7.5A). MMC has an incidence of about 1 in 3000 live births and can result in lifelong morbidity and disability, including paraplegia, bowel and bladder incontinence, hydrocephalus, Arnold-Chiari II malformation, and impaired cognition.[71] Neonates with MMC have become less common owing to maternal folate supplementation and detection by ultrasonography and alpha-fetoprotein screening of maternal blood, which has allowed for earlier consideration of pregnancy termination.

The specific cause of MMC remains unknown but includes a variety of genetic factors, maternal nutrition factors, maternal co-morbidities, and environmental factors.[72] Animal models demonstrated improved neonatal neurologic function with fetal closure of the defect *in utero.*[73] These outcomes support a "two-hit" disease model in which the pathology is produced by both failure of the fetal neural tube to form, combined with prolonged exposure to the uterine amniotic fluid.[73,74]

The 5-year mortality rate of MMC is approximately 8% for live births; if it is not corrected *in utero,* surgical closure must be performed within a few days after birth.[75] With postnatal

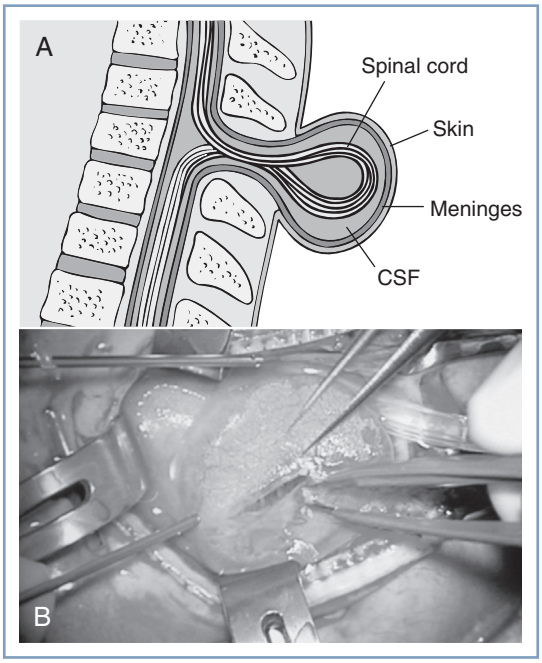

Fig. 7.5 Myelomemingocele (MMC). (A) Spine with myelomeningocele. (B) Myelomeningocele repair during open *in utero* fetal surgery. Note the cystic membrane covering the deficit has been incised and meninges are visible inside the cystic cavity. The absorbable copolymer staples used during creation of the hysterotomy are visible along the uterine edges. (**A** Modified from Kerr LM, Huether SE. Alterations of neurologic function in children. In McCance KL, Huether SE, Brashers VL, Rote NS, eds. *Pathophysiology: The Biologic Basis for Disease in Adults and Children,* 7th ed. St. Louis, MO: Elsevier; 2014:660–688. **B** courtesy of author Mark Rollins during his affiliation with the UCSF Fetal Treatment Center.)

MMC repair, ventriculoperitoneal shunting is required in nearly all neonates with thoracic level lesions, approximately 85% of lumbar level lesions, and approximately 70% of sacral lesions.[72] Despite successful shunting, permanent deficits such as central hypoventilation, vocal cord dysfunction, and oromotor and swallowing dysfunction can still occur from the associated Arnold-Chiari malformation. In addition, lifelong complications also include fecal and urinary incontinence, orthopedic abnormalities, neurocognitive abnormalities, and lower-extremity paralysis. Cognitive and motor deficits are directly related to spinal lesion level; higher-level defects are associated with more severe brain dysmorphology.[72]

The purpose of *in utero* surgery for MMC is to improve function later in life. Primarily performed through an open fetal surgical technique, *in utero* MMC repair involves removing the cystic membrane covering the deficit and separating the meninges from the fetal skin and soft tissues (see Fig. 7.5B). The fetal dura is then closed over the neural placode, followed by closure of the paraspinal myofascial flaps and, finally, the mobilized skin. If the defect is too large for primary closure, an acellular human dermis graft is used.

A randomized, prospective, multicenter clinical trial completed between 2003 and 2010 examined the risks and benefits of open fetal surgery versus standard postnatal surgery for MMC repair in 183 patients.[76] *In utero* repair reduced the need for ventriculoperitoneal shunt placement (40% versus 82%, $P < .001$) and improved motor function at 30 months of age, as assessed by ability to walk without orthotic devices (42% versus 21%, $P = .01$). However, *in utero* repair also increased the risk for chorionic membrane separation, oligohydramnios, preterm birth, and a partial or complete uterine dehiscence (Table 7.3).[8,76] Two perinatal deaths occurred in each group; expected future data from the trial will assess long-term outcomes from both interventions.

Although the vast majority of *in utero* MMC repairs use an open technique, a few centers have employed a minimally invasive endoscopic repair approach that includes intrauterine trocar insertion followed by partial evacuation of amniotic fluid and carbon dioxide insufflation of the amniotic cavity for improved fetal visualization and manipulation.[77] A biocompatible patch or primary closure is used to cover the neural defect following release of the placode, and then the fetal skin layer is closed. A 2012 study of 19 patients undergoing endoscopic intrauterine MMC repair observed high maternal and fetal complication rates[78]; three procedures were aborted because of severe hemorrhage, and in an additional three cases, the fetus died intraoperatively. A 2016 phase I trial of endoscopic fetal repair in 10 MMC patients resulted in 2 of the 10 procedures aborted because of loss of uterine access, 1 fetal and 1 neonatal demise, and PROM in 100% of the cases.[79] Six of the seven neonates who had successful *in utero* MMC repairs had reversal of hindbrain herniation (although three required shunting), and a functional motor level that was the same or better than the anatomic level of the defect.

Although endoscopic MMC repairs have comparable shunt rates to open MMC repairs and can diminish uterine thinning or dehiscence,[76] they have been associated with longer operative times, increased membrane complications, earlier gestational age at time of birth, more persistent CSF leakage, and increased perinatal demise.[71,78–80] Although promising, further optimization of the endoscopic approach will be needed before widespread clinical use.[71,74] Additional minimally invasive fetal treatment techniques being examined include the use of tissue engineering methods and the infusion of stem cells.[73]

Twin-to-Twin Transfusion Syndrome

An abnormal connection of chorionic blood vessels in the placenta between two monochorionic twins can result in twin-to-twin transfusion syndrome (TTTS). One-third of twin pregnancies are monozygotic, and 75% of monozygotic twins are monochorionic diamniotic (MCDA). TTTS typically complicates about 10% of these MCDA pregnancies, or about 1 per 5000 births in general.[81] Twin screening for TTTS starts at the end of the first trimester, with recognition typically occurring between 15 and 26 weeks' gestation.[82] Intertwin transfusion is common between monochorionic twins and is usually balanced by the presence of arterioarterial (AA) and venovenous (VV) connections; the presence of AA connections is associated with a ninefold reduction in TTTS.[83] By contrast, unidirectional and imbalanced blood flow

TABLE 7.3 Maternal and Fetal or Neonatal Complications for MOMS Trial Patients*

	Prenatal ($n = 78$)	Postnatal ($n = 80$)	P
Maternal Outcomes			
Chorioamniotic membrane separation	20 (26%)	0	< .001
Pulmonary edema	5 (6%)	0	.03
Oligohydramnios	16 (21%)	3 (4%)	.001
Placental abruption	5 (6%)	0	.03
Spontaneous rupture of membranes	36 (46%)	6 (8%)	< .001
Spontaneous labor	30 (38%)	11 (14%)	< .001
Blood transfusion at delivery	7 (9%)	1 (1%)	.03
Hysterotomy site thin, or partial or complete dehiscence noted at delivery	27 (36%)	N/A	
Fetal Outcomes			
Fetal bradycardia during repair	8 (10%)	0	.003
Mean gestational age at birth (weeks)	34.1 ± 3.1	37.3 ± 1.1	< .001
Mean birth weight (g)	2383 ± 688	3039 ± 469	< .001
Respiratory distress syndrome	16 (21%)	5 (6%)	.008

*The table lists maternal and fetal/neonatal complications that were significantly different ($P < .05$) between the prenatal and postnatal repair groups in the Management of Myelomeningocele Study (MOMS). Other outcomes were evaluated, but only those that were different between the two groups are included. Data for each group are shown as both an absolute number and as a percentage.
Modified from Adzick NS, Thom EA, Spong CY, et al. A randomized trial of prenatal versus postnatal repair of myelomeningocele. *N Engl J Med.* 2011;364:993–1004.

through arteriovenous (AV) chorionic vessels results in TTTS. In normal fetoplacental vasculature, the umbilical artery branches at the placenta surface, traverses, and then descends into the tissue, where it further branches into capillary divisions for gas and nutrient exchange. The arterial system is "paired" with venous vasculature, which returns blood to the umbilical cord. In TTTS, the umbilical artery similarly descends into the placenta and cotyledon, but rather than connecting with a paired vein from the same twin, it connects with a vein that transports blood to the other twin.[82,84] The pathophysiology of TTTS is complex, dynamic, and related to various hemodynamic, humoral, biochemical, and functional changes in the two fetuses.

The twin serving as the recipient demonstrates polycythemia, polyuria, polyhydramnios, and hypertrophic cardiomyopathy; this twin is at risk for hydrops fetalis and fetal death. The twin serving as the donor is typically hypovolemic, growth restricted, and pressed against the endometrium in an oligohydramniotic sac (hence the designation "stuck" or "pump" twin) and often has a velamentous cord insertion. This twin is at risk for neonatal renal failure, tubular dysgenesis and dysfunction, and high cardiac output hydrops fetalis.

The diagnosis of TTTS requires two criteria: (1) the presence of an MCDA pregnancy; (2a) the presence of oligohydramnios, defined as a maximal vertical pocket (MVP) of < 2 cm in one amniotic sac, and (2b) the presence of polyhydramnios, defined as MVP of > 8 cm in the other amniotic sac.[81] The most commonly used staging system describing the severity of TTTS was published by Quintero and is displayed in Table 7.4. Serial fetal echocardiographic assessments, using a myocardial performance index, can assess and monitor the severity of TTTS in the recipient twin.[85] Although the donor twin typically has normal cardiac function, the recipient twin can develop ventricular hypertrophy, atrioventricular valve regurgitation, ventricular diastolic and systolic dysfunction, and right ventricular outflow tract obstruction.

Fetuses with TTTS are at risk for neurologic injury with white matter lesions and long-term disability, preterm PROM, and preterm delivery. If TTTS remains at Stage I or resolves, the overall survival rate is about 85%[81]; however, if TTTS progresses, the overall mortality rate of one or both fetuses can increase to more than 80% if untreated.[86]

A variety of therapeutic management techniques have been developed to treat TTTS: (1) serial amnioreduction, which can control polyhydramnios, thereby reducing the risk for preterm labor, reducing hydrostatic pressure in the amniotic cavity, and potentially improving placental blood flow; (2) ultrasound-guided needle septostomy, which can equalize amniotic pressures between the amniotic sacs; (3) selective feticide, which can improve the survival of the other fetus; and (4) selective fetoscopic laser photocoagulation (SFLP) of the vascular anastomoses between the twins.

In a retrospective review of 223 twin sets with TTTS, amnioreduction resulted in an overall birth survival rate of 78%, with 65% of recipient twins and 55% of donor twins alive at 1 month of age.[87] In a prospective randomized trial comparing serial amnioreduction to septostomy, there was no difference in the rate of survival between the two techniques[88]; consequently, septostomy is rarely used because it offers no survival benefit, and the creation of a single amniotic sac can increase the risk for umbilical cord entanglement. Selective fetoside of one twin is reserved for the most severe cases of TTTS and uses techniques described in the section on twin reversed arterial perfusion sequence later in the chapter.

The laser used for SFLP is typically inserted through a fetoscope to allow visualization of the vascular anastomoses to be ablated. The fetoscope enters the maternal abdomen and uterus through a 3-mm percutaneously inserted cannula that allows passage into the recipient twin's amniotic sac (Fig. 7.6). Maternal anesthesia is commonly managed with either neuraxial blockade or local anesthetic infiltration from skin to myometrium. The fetoscope placement is guided by ultrasonography and ideally positioned at 90 degrees to the placental vascular surface. The location of the abnormal vascular connections (vascular equator) is determined by tracing vessels visualized by the fetoscope from each fetus and determining their connections and cessations. In addition, Doppler ultrasonographic imaging can be used to determine the magnitude and direction of vessel blood flow. A vessel traveling from one fetus, inserting into a cotyledon, and then exiting and traveling to the cord root of the other fetus is considered nonfunctional, pathologic, and a target for photocoagulation.[89] Arteries always travel over veins, allowing the two vessels to be distinguished. Nonselective laser ablations of vessels were initially performed, until lower fetal survival rates were demonstrated when compared with selective techniques. After completion of the SFLP, amniotic fluid may be removed to reduce the degree of polyhydramnios and decrease the risk for preterm labor.

A 2004 randomized multicenter trial demonstrated the benefits of SFLP compared with amnioreduction for treatment of severe TTTS diagnosed between 15 and 26 weeks' gestation.[90] Rates of at least one twin survival were significantly higher in the laser treatment group at both 28 days (76% versus 56%, $P < .01$) and 6 months of life (76% versus 51%, $P < .01$). In addition, neurologic outcomes were better in the SFLP group. A systematic review and meta-analysis of 34 studies examining TTTS treated with laser therapy published between 1995 and 2014 noted that treatment of TTTS with laser ablation resulted in improved survival rates over

TABLE 7.4 Staging of Twin-to-Twin Transfusion Syndrome Severity

Stage	Parameter	Ultrasonographic Criteria
I	Amniotic fluid	MVP < 2 cm in donor twin amniotic sac and MVP > 8 cm in recipient twin amniotic sac
II	Fetal bladder	Unable to visualize the fetal bladder in the donor twin during 1 hour of observation
III	Flow velocity change in UA, UV, or DV	Absent or reversed UA diastolic flow waveform Pulsatile UV flow waveform Reversed DV a-wave flow waveform
IV	Fetal hydrops	Presence of hydrops in either twin
V	Fetal demise	Absent fetal cardiac activity

MVP, Maximal vertical pocket of amniotic fluid; *UA,* umbilical artery; *UV,* umbilical vein; *DV,* ductus venosus.

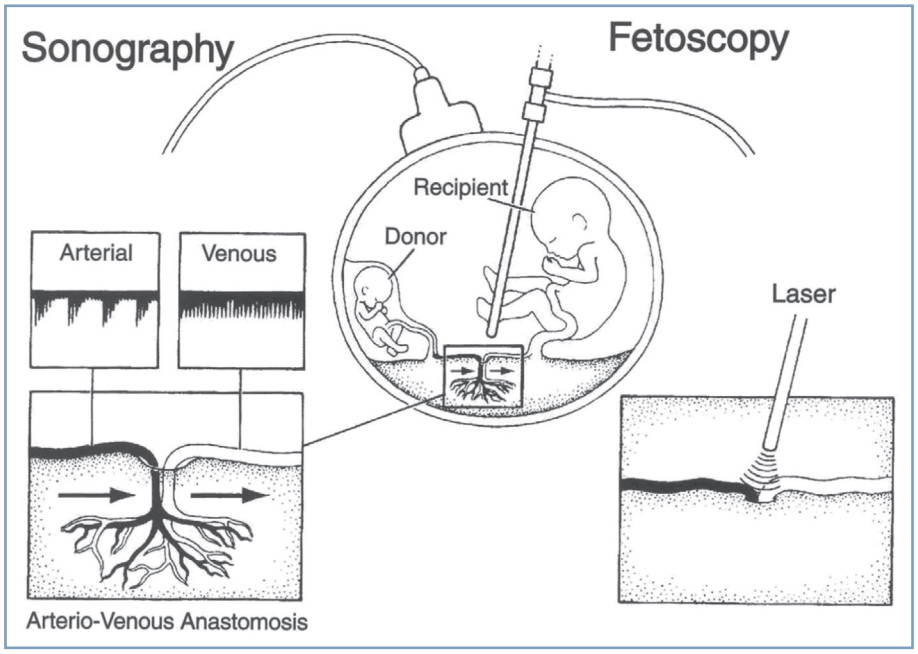

Fig. 7.6 *In utero* fetoscopic laser ablation for twin-to-twin transfusion syndrome. Under ultrasound guidance, a fetoscope is inserted percutaneously into the recipient twin's amniotic sac. Using both ultrasonographic guidance and fetoscopic visualization, intertwin vessels are identified and ablated with the laser. (From Graves CE, Harrison MR, Padilla BE. Minimally invasive fetal surgery. *Clin Perinatol.* 2017;44:729–751.)

time; the most recent studies (2011 to 2014) demonstrate a 62% mean survival rate for both twins and an 88% survival rate for at least one twin.[91]

A variation of the SFLP technique requires laser ablation of abnormal vasculature in a specific sequence. First, ablation occurs at the donor-to-recipient AV anastomoses, then at the recipient-to-donor AV anastomoses, then at the AA superficial anastomoses, and finally at the VV superficial anastomoses. The order of the procedure is designed to reduce the chance of hemodynamic compromise and hypotension during the procedure in the donor twin.[92] Although associated with longer operative times, the use of the sequential technique has been associated with improved dual neonatal survival and decreased fetal demise in cohort studies.[93]

In an effort to reduce both recurrent TTTS and the twin anemia-polycythemia sequence that can subsequently develop, the Solomon technique photocoagulates a line across the surface of the placenta at the vascular equator following SFLP.[94,95] A randomized controlled trial of the Solomon technique, compared with SFLP, noted a significant decrease in both of these adverse outcomes;[96] however, no difference in long-term (2-year) survival without neurodevelopmental impairment was observed.[97] Major neurologic abnormalities in long-term survivors of TTTS following SFLP range from 5% to 18%.[81]

The most common complications of SFLP are preterm PROM with subsequent preterm labor and delivery, and intrauterine infection. Other possible complications include placement of the trocar through the placenta, hemorrhage, and possible membrane perforation resulting in limb entrapment and ischemia. Overall, trial results and meta-analyses provide evidence that SFLP results in superior outcomes compared with amnioreduction for the treatment of TTTS, but further research is needed to optimize the timing and technical aspects of the various interventions.

Twin Reversed Arterial Perfusion Sequence

In monozygotic twins, one twin can perfuse the other by retrograde blood flow though AA anastomoses. Twin reversed arterial perfusion (TRAP) sequence affects 1% of monozygotic twins, 1 in 35,000 pregnancies, and 1 in 30 triplet pregnancies. Inadequate perfusion of the recipient twin via retrograde anastomotic flow results in the development of a lethal set of anomalies that include acardia and acephalus. The normal ("pump") twin perfuses both itself and the nonviable twin and is at risk for high-output congestive heart failure, polyhydramnios, and preterm birth. If untreated, TRAP sequence is associated with a 55% risk for intrauterine death of the pump twin.[98] Diagnosis is confirmed with ultrasonographic demonstration of reverse flow to the acardiac twin via the umbilical artery. Cardiovascular failure in the pump twin is the indication for intervention, and early diagnosis is beneficial for optimal treatment. The mortality risk of the pump twin is related to the high-output cardiac failure, preterm delivery, and the size ratio of the acardiac twin to the pump twin.[98]

The goal of therapy is to interrupt the vascular communication between the two twins. In contrast to the treatment of TTTS, treatment of TRAP sequence results in the death of the anomalous nonviable fetus. Ultrasound-guided bipolar or radiofrequency coagulation of the umbilical cord and/or placental vascular anastomoses is the most viable therapeutic option.[99] Alternative therapies include use of endoscopic laser coagulation, *sectio parva* (selective cesarean delivery of one of multiple fetuses), percutaneous thrombosis of the acardiac twin's umbilical cord with coils or other thrombogenic material, and alcohol-impregnated suture cord ligation. Although these procedures are typically done after 16 weeks' gestation, earlier intervention may be beneficial, as approximately 30% of pump twins suffer demise before intervention.[100] A recent meta-analysis and review of the literature noted the survival rate of the pump twin was about 80% for most techniques, except when performed by ligation of the cord, the placement of cord coils, or the injection of intrafetal alcohol.[99] A significant inverse association between gestational ages at treatment and at birth has been observed; when an intervention was performed at 13 or 27 weeks' gestation, the mean gestation at birth was 38 and 34 weeks, respectively.[99]

TRAP intervention procedures are typically performed with either infiltration of local anesthesia at the ablation device insertion site or the administration of neuraxial anesthesia. The procedures are guided by ultrasonography, and absence of flow to the nonviable acardiac twin is confirmed with Doppler imaging at the end of the procedure and again 12 to 24 hours later. The most common complication is preterm PROM. Additional research is needed to determine optimal timing and method of intervention.

Congenital Heart Defects

Congenital heart abnormalities are the leading cause of mortality from birth defects and occur in approximately 1% of live births.[101] Fetal valvuloplasty for aortic stenosis with evolving hypoplastic left heart syndrome is the most common, minimally invasive intervention performed for a congenital heart defect. The procedure uses an angioplasty balloon placed over a percutaneously inserted guide wire, with technical success as high as 77%. The valvuloplasty allows improved left ventricular function, augmented aortic and mitral valvular growth, and progression to live birth in 90% of cases.[102,103] Although 40% to 50% of successful fetal valvuloplasty cases enable biventricular circulation present at birth,[102,103] approximately 40% of cases result in aortic regurgitation and minimal left ventricular growth.

Additional closed fetal cardiac interventions include: (1) septoplasty for hypoplastic left heart syndrome with an intact or highly restrictive atrial septum; (2) pulmonary valvuloplasty for evolving hypoplastic right heart syndrome with pulmonary atresia or stenosis without a ventricular septal defect; and (3) fetal pericardiocentesis to treat aneurysms or congenital cardiac tumors.[104]

Open fetal cardiac surgery for severe hypoplastic left heart syndrome has also been described using maternal-placental support.[105] Fetal intrapericardial teratomas have been successfully resected with *in utero* open fetal surgery or while on placental support during an EXIT procedure.[106] Correction of

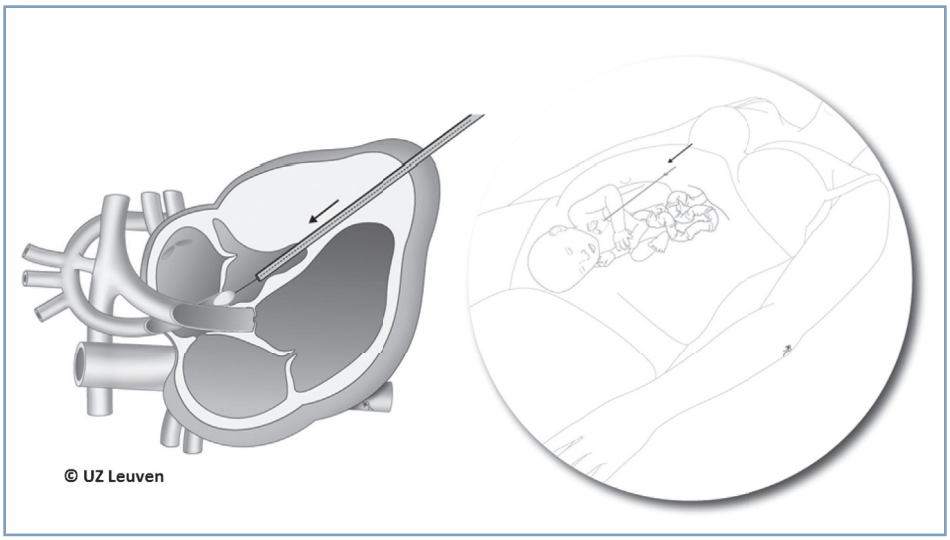

Fig. 7.7 Percutaneous fetal aortic valvuloplasty for evolving hypoplastic left heart syndrome. The needle is inserted percutaneously through the maternal abdomen and uterus, and enters the apex of the fetal heart in alignment with the left ventricular outflow tract. A guide wire and a coronary dilation balloon catheter are advanced through the aortic valve, which is then dilated. (From Van Mieghem T, Baud D, Devlieger R, et al. Minimally invasive fetal therapy. *Best Pract Res Clin Obstet Gynaecol.* 2012;26:711–725.)

complex congenital cardiac defects, either open or closed, requires careful anesthetic and pharmacologic strategies for myocardial protection. Maternal anesthesia is typically provided by spinal anesthesia, whereas fetal anesthesia is administered via an intramuscular injection of opioid and muscle relaxant, as detailed later in the chapter.

Complications of fetal cardiac interventions include fetal bradycardia, pericardial effusion, ventricular thrombosis, preterm delivery, and fetal demise.[104] Procedures are typically performed at mid-gestation, with the fetus manipulated, if possible, with the left chest anterior so that a linear path can be established through the maternal abdomen to the apex of the fetal left ventricle (Fig. 7.7).[103]

SURGICAL BENEFITS AND RISKS

The primary goal of intrauterine fetal surgery is to improve neonatal outcomes compared with interventions performed after a preterm or term delivery. The intrauterine environment supports rapid wound healing[107] (i.e., without scarring before mid-gestation), provides adequate nutritional and respiratory needs, and limits robust immune responses to interventions (through a minimally developed fetal immune surveillance system). However, continued refinement of surgical and anesthetic techniques, with appropriate attention to reducing maternal and fetal risks, and conducting appropriate clinical trials for each intervention, must occur before fetal surgery can be performed more routinely for specific congenital anomalies.

Serious maternal morbidity from intrauterine fetal surgery is relatively uncommon, but maternal welfare must always be emphasized; for example, pulmonary edema may occur because of the absorption of significant amounts of crystalloid during uterine irrigation.[7] Moreover, although fetal surgical procedures do not affect future fertility, open procedures involve a hysterotomy through the upper uterine segment and a requirement for cesarean delivery in subsequent pregnancies. The fetal risks of intrauterine surgery remain relatively high and include central nervous system injuries, membrane separation, PROM, placental abruption, preterm labor and delivery, blood loss, chorioamnionitis, postoperative amniotic fluid leaks with oligohydramnios, and fetal demise.[7] Preterm delivery accounts for significant morbidity and mortality. Chorioamniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise.[108] Improved techniques for sealing the membranes are being devised, including different surgical patching techniques, sealants, and intra- or extra-amniotic platelet or cryoprecipitate injections.[109]

ANESTHETIC MANAGEMENT

Fundamental considerations for the anesthetic management of fetal surgery are similar to those for nonobstetric surgery during pregnancy (see Chapter 17). Maternal safety is paramount. Anesthesiologists should participate in preoperative maternal assessment and exclude women when their perioperative risk is not acceptably low given the potential fetal benefit. To ensure both maternal and fetal safety, the anesthesiologist must understand the physiologic impact of pregnancy on anesthetic management (see Chapter 2) and serve as an active member of the multidisciplinary team. Imaging studies should be reviewed for placental location, anatomic information about the congenital lesion, and estimated fetal weight.

Unlike other surgical procedures performed during pregnancy in which the fetus is an innocent bystander (e.g., maternal appendectomy), fetal surgery involves two surgical patients. This requires the anesthesiologist to balance the anesthetic needs of both patients, as well as control uterine tone throughout the perioperative period. Complete uterine relaxation is necessary during open fetal surgical procedures.

Maternal analgesia and anesthesia can be provided by local infiltration, intravenous sedation, neuraxial anesthesia, general anesthesia, or a combination of these techniques, depending on the procedure, location of the placenta, and maternal co-morbidities. Fetal analgesia and anesthesia can be achieved via placental transfer of anesthetic agents given to the mother, via direct fetal intravenous (peripheral fetal vein or umbilical vein) or intramuscular administration of agents, or by a combination of these methods. An appropriate method of fetal monitoring and the potential requirement for fetal intravenous access and volume resuscitation during open surgical cases should be determined preoperatively. The operative team should be prepared for emergency situations such as maternal hemorrhage, need for intrauterine fetal resuscitation (e.g., fetal epinephrine administration), and/or delivery and resuscitation of the viable neonate.

Anesthesia for Minimally Invasive and Percutaneous Procedures

Local anesthetic infiltration of the maternal abdominal wall is sufficient to reduce maternal discomfort for many percutaneous procedures (e.g., amniocentesis, cordocentesis, intrauterine blood transfusion, needle aspiration of cysts, shunt placement into the fetal bladder or thorax, SFLP for TTTS). Supplemental maternal analgesia and anxiolysis can be achieved by maternal administration of an opioid, a benzodiazepine, and/or a low-dose propofol infusion, and may reduce fetal mobility via placental transfer of drug. However, neuraxial anesthesia is often used to minimize maternal movement, enable positioning, and provide sensory coverage for multiple percutaneous instrumentation sites or a mini-laparotomy. General anesthesia is rarely necessary for minimally invasive procedures unless the placental location, fetal position, and/or the potential need for uterine exteriorization (e.g., certain MMC repair approaches) are valid concerns.

Fetal movement may be hazardous for the fetus in cases of intrauterine transfusion, cord blood sampling, or thoracic shunt placement, because displacement of the needle or catheter may lead to trauma, bleeding, or compromise of the umbilical circulation. Placental transfer of maternally administered opioids and benzodiazepines can reduce, but not necessarily eliminate, fetal movement. A randomized controlled trial of the use of a maternal remifentanil infusion (0.1 μg/kg/min) demonstrated improved fetal immobility and operating conditions during fetoscopic surgery, when compared with maternal administration of diazepam.[110] Fetal immobility can be safely achieved with direct fetal intramuscular or umbilical venous administration of rocuronium (2.5 mg/kg IM, 1 mg/kg IV) or vecuronium (0.2 mg/kg IM, 0.1 mg/kg IV) using ultrasonographic guidance. The onset of fetal paralysis occurs in 2 to 5 minutes, with an approximate duration of 1 to 2 hours.[111] For procedures that can cause noxious stimulation to the fetus, such as shunt catheter placement or cardiac septoplasty, an opioid (e.g., fentanyl 10 to 20 μg/kg) can be administered to the fetus intramuscularly or intravenously.[17] When general anesthesia is employed, placental transfer of a volatile halogenated agent is usually sufficient to immobilize and anesthetize the fetus; however, a muscle relaxant is frequently administered directly to the fetus if fetal immobility is critical to the procedure.

The surgical team should be prepared to immediately administer appropriate fetal weight-based intramuscular doses of atropine (20 μg/kg) and epinephrine (10 μg/kg), and perform an emergent cesarean delivery if the gestational age is compatible with extrauterine viability. The anesthesiologist should be prepared to provide maternal general anesthesia if required.

Tocolysis typically is unnecessary after cordocentesis or intrauterine transfusion. For more invasive percutaneous procedures (e.g., shunt catheter placement, fetoscopic techniques), some fetal surgery groups administer prophylactic perioperative tocolytic agents such as indomethacin or nifedipine to the mother.[112]

Anesthesia for Open Fetal Surgery

When corrective fetal surgery or an intrauterine procedure requires surgical access through a hysterotomy, general anesthesia is typically administered. Unique considerations for open fetal procedures include the need for profound uterine relaxation, intraoperative fetal monitoring, fetal anesthesia or analgesia, and postoperative maternal analgesia and uterine tocolysis (Box 7.2). In addition, significant maternal and fetal blood loss may occur, and the anesthesiologist must be prepared to provide maternal and fetal resuscitation. A high concentration of a volatile halogenated agent is typically administered to provide both maternal and fetal anesthesia as well as uterine relaxation. Adequate uterine relaxation may require greater than twice the minimum alveolar concentration (MAC) of a volatile halogenated agent. Some centers use supplemental intravenous anesthesia (SIVA) or other agents (e.g., nitroglycerin) to augment the uterine relaxation provided by a reduced concentration of the halogenated agent.[112]

Preoperatively, the mother receives agents for aspiration prophylaxis and uterine tocolysis (e.g., rectal/oral indomethacin), and a high lumbar epidural catheter is placed for postoperative analgesia. The patient is placed in the supine position with left uterine displacement. A final assessment of the fetus is performed, and the availability of all appropriate personnel, equipment, resuscitation medications, and blood products is confirmed before induction. Medications to provide fetal analgesia (e.g., fentanyl 10 to 20 μg/kg), immobility (e.g., vecuronium 0.2 mg/kg), and resuscitation (e.g., atropine 20 μg/kg, epinephrine 10 μg/kg) are prepared in sterile, labeled syringes; each syringe should contain a single weight-based unit dose. Cross-matched blood should be available for maternal transfusion. In addition, O-negative, cytomegalovirus (CMV)-negative, irradiated, leukocyte-depleted,

BOX 7.2 Perioperative Considerations for Open Fetal Surgery

Preoperative Considerations

- Complete maternal history and physical examination
- Fetal workup to exclude other anomalies and imaging studies to determine fetal lesion, placental location, and estimated fetal weight
- Maternal counseling by multidisciplinary team and preoperative team meeting
- Emergent delivery plan determined if needed based on gestational age
- High lumbar epidural catheter placed and tested
- Prophylactic premedications for aspiration and tocolysis
- Blood products available for potential maternal and fetal transfusion
- Sequential compression devices on lower extremities for thrombosis prophylaxis
- Fetal resuscitation drugs and fluid transferred sterilely to scrub nurse in unit doses

Induction and Intraoperative Considerations

- Left uterine displacement and standard monitors
- Fetal assessment before induction
- Preoxygenation for 3 minutes before induction
- Rapid sequence induction and intubation
- Maintain maternal F_{IO_2} > 50% and end-tidal CO_2 28 to 32 mm Hg
- Forced air warmer to maintain maternal normothermia
- Ultrasonography to determine fetal and placental positioning
- Urinary catheter placed; additional large-bore IV access placed; possible arterial line
- Prophylactic antibiotics administered
- Blood pressure maintained (± 10% baseline with intravenous phenylephrine, ephedrine, and/or glycopyrrolate)
- Before hysterotomy, high concentrations of volatile anesthetic agent (2 to 3 MAC) administered to achieve uterine relaxation. Alternative SIVA technique relies on intravenous remifentanil and propofol infusions, combined with 1 to 1.5 MAC volatile anesthetic agent
- Consider intravenous nitroglycerin boluses or infusion if uterine relaxation not adequate
- Maintain good communication with fetal monitoring personnel
- Intramuscular administration of fetal opioid and neuromuscular blocking agent by surgeons
- Placement of fetal monitors. Intrauterine temperature and fetal pulse oximetry if needed
- Fluid restriction to < 2 L total to reduce risk for maternal pulmonary edema
- Intravenous loading dose of magnesium sulfate once uterine closure begins
- Decrease volatile agent once magnesium sulfate load is complete
- Administer maternal anesthetic and opioids as needed
- Activate epidural catheter for postoperative analgesia
- Monitor neuromuscular blockade carefully because of magnesium sulfate administration
- Extubate trachea when patient is fully awake

Early Postoperative Considerations

- Complete a postoperative debrief
- Continue tocolytic therapy
- Patient-controlled epidural analgesia
- Monitor uterine activity and fetal heart rate
- Ongoing periodic fetal evaluation

maternally cross-matched blood should be available for fetal transfusion.

After administration of 100% oxygen and denitrogenation of the lungs, a rapid-sequence induction of general anesthesia with cricoid pressure and endotracheal intubation is performed. Fetal heart rate (FHR), umbilical cord blood flow, and fetal cardiac function are often monitored with ultrasonography during induction. End-tidal carbon dioxide concentration should be maintained at 28 to 32 mm Hg, which is normocarbic for pregnancy. Initially, anesthesia is maintained with approximately 1 MAC of a volatile halogenated agent or intravenous anesthetic agents while further preparations for surgery are undertaken, including (1) obtaining additional maternal vascular access, (2) prophylactic antibiotic administration, (3) urinary bladder catheterization, and (4) ultrasonographic assessment of fetal presentation and placental location. For open procedures with a high risk for significant fetal blood loss (e.g., resection of a fetal mass), a fetal intravenous catheter should be placed after hysterotomy to provide access for blood and fluid transfusions. An arterial catheter should be placed for maternal blood pressure monitoring if uterine tocolysis with a nitroglycerin infusion is planned or if maternal hemodynamic instability occurs. Total intraoperative maternal intravenous fluids are restricted (less than 2 L) to reduce the risk for postoperative pulmonary edema. Some fetal surgery centers administer colloid as a portion of the fluids to better maintain maternal blood pressure and/or choose to limit fluids even further (less than 500 mL). No clinical trials have proven a benefit of further fluid restriction in this setting.

A final discussion (surgical time-out) should occur before skin incision. Mean maternal arterial blood pressure is typically maintained within 10% of baseline values and greater than 65 mm Hg. A phenylephrine infusion provides titratable blood pressure control with minimal changes in the fetal acid-base status.[113] Bolus doses of ephedrine and/or glycopyrrolate also can be administered to maintain maternal heart rate near baseline and improve cardiac output.[114] Maternal administration of a nondepolarizing muscle relaxant is usually not required owing to the profound depth of anesthesia provided by the volatile agent, but may be used to improve operative conditions. The intrauterine

location and position of the fetus is confirmed with ultrasonography just before hysterotomy to optimize the incision location.

Before hysterotomy, it is desirable to achieve an increased end-tidal concentration (2 to 3 MAC) of the volatile halogenated agent to provide both fetal anesthesia and uterine relaxation. The uterus is assessed both visually and by palpation for contractions or increased tone. Further tocolysis can be achieved with intravenous nitroglycerin as an infusion or in bolus doses (100 μg).[115] Because the use of high levels of volatile anesthetic is associated with fetal cardiac dysfunction and abnormal umbilical artery blood flow, a combination of volatile anesthetic (1 to 1.5 MAC) and intravenous propofol and remifentanil infusions (SIVA technique) is used at some institutions.[112,116,117] For circumstances in which volatile halogenated agents or general anesthesia must be avoided (e.g., family history of malignant hyperthermia), a neuraxial anesthetic can be administered and combined with an intravenous infusion of nitroglycerin to achieve uterine relaxation.[115] This technique does not have any clear advantage for fetal outcome and may be associated with more morbidity, as nitroglycerin administration during open fetal surgery has been associated with maternal pulmonary edema.[118]

Fetal well-being is periodically assessed with ultrasonography to monitor FHR, umbilical artery blood flow, and cardiac contractility. In certain open cases, a sterile pulse oximetry probe may be attached to a fetal digit or limb. An opioid and a muscle relaxant are administered to the fetus intramuscularly, either before or after uterine incision with ultrasonographic guidance or direct vision, respectively. Some anesthesiologists also administer intramuscular fetal atropine at this time in an effort to prevent opioid-induced fetal bradycardia. Further studies are needed to determine the optimal anesthetic technique for ensuring maternal and fetal cardiovascular stability, optimal uteroplacental perfusion, and adequate fetal anesthesia to cause immobility and blockade of the fetal stress response.

A small uterine incision is created remote from the location of the placenta. A stapling device with absorbable synthetic copolymer (Lactomer) staples is used to extend the incision, seal the membranes to the endometrium, and prevent excessive bleeding.[119] During surgery, the exposed fetus and uterus are bathed with warmed fluids. The intrauterine temperature is closely monitored to prevent fetal circulatory compromise associated with hypothermia.[120]

At the conclusion of the fetal procedure, when uterine closure is initiated, a loading dose of maternal magnesium sulfate is administered (4 to 6 g intravenously over 20 minutes), followed by an intravenous infusion of 1 to 2 g per hour. As magnesium potentiates neuromuscular relaxation, close monitoring of twitch recovery is needed if a nondepolarizing muscle relaxant was administered. The volatile halogenated agent can be significantly decreased or discontinued after the magnesium sulfate bolus has been administered. The epidural analgesia can be initiated, and maternal anesthesia is maintained with additional opioid and intravenous anesthetics as appropriate.

Postoperative concerns include maternal and fetal pain, preterm PROM, preterm labor, infection, and a variety of potential fetal complications, including heart failure, intracranial hemorrhage, constriction of the ductus arteriosus from indomethacin, and demise. Maternal analgesia can be maintained with an epidural infusion of a dilute solution of local anesthetic and opioid for several days. Effective analgesia may help prevent postoperative preterm labor.[121] Intravenous opioids can also be used to provide postoperative maternal analgesia; however, decreased FHR variability may occur.

Postoperative preterm labor is the "Achilles heel" of fetal surgery.[7] Tocolysis is typically provided by an infusion of magnesium sulfate for at least 24 hours, although supplemental agents may include indomethacin, nifedipine, or terbutaline. Magnesium most likely competes with calcium at voltage-operated calcium channels, indomethacin blocks the synthesis of prostaglandins, and beta-adrenergic agonists activate adenylate cyclase in the uterine muscle, thereby reducing intracellular calcium levels. Not infrequently, two tocolytic agents are required to create uterine quiescence. Uterine activity and FHR are monitored closely during the first 2 to 3 postoperative days. The fetus is evaluated postoperatively by ultrasonography, and if indomethacin is used, periodic fetal echocardiography is performed to determine if premature closure of the ductus arteriosis has occurred.

Patients recovering from open fetal surgery should remain near the fetal treatment center after hospital discharge. These patients are at high risk for preterm PROM, preterm labor, infection, and uterine rupture.[7,119] Unless preterm labor occurs, cesarean delivery is typically planned at 37 weeks' gestation.

Anesthesia for the *Ex Utero* Intrapartum Treatment Procedure

Initially described as a method to remove the iatrogenic airway obstruction created for intrauterine treatment of CDH, the EXIT procedure has evolved into a technique useful for a number of fetal disorders that compress the airway and/or render neonatal tracheal intubation difficult or impossible. It is also useful when resuscitation and surgical intervention are required immediately before birth, while the fetus is still supported by the placental circulation. Cases appropriate for an EXIT procedure include cervical masses, severe craniofacial anomalies, lung masses, mediastinal masses, severe congenital cardiac lesions, and CDH with anticipated respiratory compromise. The use of an EXIT procedure may also assist the transition to ECMO for pulmonary insufficiency or the stabilization of conjoined twins before separation.[10,11] Similar to open fetal surgery procedures, sustained uterine relaxation and delay of placental separation are necessary for a successful EXIT procedure.

Anesthesia for EXIT procedures is most commonly performed with the use of general anesthesia, with many considerations similar to those detailed earlier for open fetal surgery.[112,119] Preparation for fetal monitoring, airway management, fetal/neonatal resuscitation, and postdelivery care should be completed before entering the operating room.

Fetal heart ultrasonography, a sterile pulse oximeter probe, and an end-tidal carbon dioxide indicator or gas analyzer are frequently used for fetal monitoring during the procedure. Unit doses of atropine (20 μg/kg) and epinephrine (10 μg/kg), as well as supplemental fetal anesthetic agents (for subsequent fetal intramuscular injection) are prepared and transferred in a sterile manner to the scrub nurse (see later discussion). A sterile ventilation bag with an air/oxygen source and manometer is available for the fetus, along with multiple endotracheal tube sizes and devices for fetal tracheal intubation, including a rigid and flexible bronchoscope.[122] Catheters for intravenous access as well as crystalloid and blood (O-negative, CMV-negative, leukocyte-depleted, irradiated, maternally cross-matched) should be available for fetal volume resuscitation if needed.

A maternal epidural catheter may be placed preoperatively for postoperative analgesia. Maternal anesthetic considerations should include large-bore intravenous access, availability of uterotonic agents and cross-matched blood, and the ability to quickly obtain invasive maternal monitoring if needed.

Techniques of induction and tracheal intubation do not differ from those typically used for cesarean delivery. Although techniques for maintenance of anesthesia vary between medical centers, administration of 2 to 3 MAC of a volatile halogenated agent is often needed to achieve and maintain adequate uterine relaxation. Occasionally, nitroglycerin administered as a bolus dose (50 to 100 μg) or as an infusion may also be required to maintain appropriate uterine relaxation. Fetal anesthesia from the halogenated agent transferred across the placenta is typically supplemented by direct fetal intramuscular administration of an opioid (e.g., fentanyl 5 to 15 μg/kg or morphine 0.1 mg/kg) and a paralytic agent (e.g., rocuronium 1 to 3 mg/kg). Some practitioners also administer intramuscular atropine (20 μg/kg) to prevent fetal bradycardia. Intramuscular agents can be administered to the fetus either before uterine incision with ultrasonographic guidance or after uterine incision under direct visualization. Significant variability in serum fentanyl concentrations has been documented in umbilical cord blood during EXIT procedures,[123] and similar variability may exist with muscle relaxants and other agents.

Following exposure of the uterus, the placental location and edges are determined by intraoperative ultrasonography. Similar to open fetal procedures, the uterine incision is extended with a stapling device to minimize blood loss. The fetal head and shoulders are delivered in preparation for tracheal intubation. In an effort to maintain fetoplacental circulation, warmed fluids are continuously irrigated into the uterine cavity, and care is taken to avoid manipulation of the umbilical cord. The warmed irrigant maintains fetal euthermia and helps prevent decreased uterine volume, placental separation, and spasm of the cord vessels. The fetus is initially monitored with (1) a pulse oximeter probe placed on the fetal hand, (2) periodic cardiac ultrasonography, and (3) direct visualization. For more extensive procedures, such as fetal thoracotomy, or when there is fetal bradycardia suggestive of umbilical cord compression, the fetus can be delivered from the uterus and placed on the maternal chest and abdomen to facilitate the procedure.

The duration of the fetal procedure can range from a few minutes (e.g., bronchoscopy or intubation) to several hours (e.g., neck or thoracic mass resection, tracheostomy, or central intravascular cannulation). Although the majority of procedures require less than 1 hour, the anesthetic technique is capable of providing maternal, fetal, and uteroplacental stability over several hours.[124] Once surgery is completed and the trachea secured, surfactant is administered if indicated. Fetal oxyhemoglobin saturation is typically 40% to 70% at this time,[125] but increases significantly to above 90% with ventilation of the fetal lungs.

Upon umbilical cord clamping, the maternal anesthetic technique is altered by reducing or eliminating the volatile anesthetic agent to help achieve uterine tone and diminish the risk for postpartum hemorrhage. Typically, a combination of an opioid, propofol, and nitrous oxide are used to maintain anesthesia. Oxytocin is administered, as well as other uterotonic agents if needed to achieve uterine tone. Finally, epidural analgesia is initiated.

If general anesthesia with a halogenated agent is contraindicated (e.g., history of malignant hyperthermia) an alternative technique for EXIT procedures involves the use of neuraxial anesthesia combined with intravenous infusions of propofol, remifentanil, and nitroglycerin to maintain uterine relaxation.[126] Large doses of intravenous nitroglycerin are often required to achieve adequate uterine relaxation; if significant doses are to be used for a prolonged period, an arterial catheter is recommended and the patient should be observed for evidence of pulmonary edema. Fetal analgesia and immobility can be achieved with fetal administration of intramuscular drugs (see earlier discussion). Maternally administered intravenous remifentanil undergoes significant transfer across the placenta and may serve as an adjuvant for fetal analgesia and immobility.[110]

Fetal Response to Surgical Stimulation

The subjective phenomenon of pain has not been, and perhaps cannot be, assessed adequately in human fetuses. Pain is a multidimensional, subjective, psychological construct that can exist in the absence of physical stimuli (e.g., phantom limb pain), and it includes emotional and affective components that require higher-level cortical processing. As such, although pain is commonly associated with noxious physical stimuli, it is more than nociception or a simple reflex activity associated with a withdrawal response.[127] Attempts have been made to correlate pain with surgical stress; however, the physiologic responses are not equivalent. The stress response is mediated primarily in the spinal cord, brainstem, and/or basal ganglia, without involvement of the cortex.

In studies of intrauterine blood transfusion in the human fetus, surgical needling of the intrahepatic vein (in contrast to the insensate umbilical cord) is associated with evidence of a stress response, including increases in plasma beta-endorphin and cortisol concentrations and decreases

in the middle cerebral artery pulsatility index (determined by Doppler imaging).[128] These responses can be blunted by the fetal administration of fentanyl 10 μg/kg.[17] Human fetuses elaborate pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 16 to 18 weeks' gestation.[129,130] Immature skin nociceptors likely begin to emerge at 10 weeks' gestation and are present by 17 weeks' gestation.[131] In internal organs, nociceptors develop slightly later. Peripheral nerve fibers that control movement grow into the spinal cord at about 8 weeks' gestation. When these fibers connect with nociceptors is unknown, but one human study suggests that nociceptive nerve fibers do not enter the spinal cord before about 19 weeks' gestation.[132] The cerebral cortex develops after the fetal spinal cord and brainstem. Thalamocortical connections to the somatosensory cortex are significantly developed at 24 to 30 weeks' gestation.[127,130]

The developing cerebral cortex consists of transient fetal zones where neuronal proliferation, cell migration, apoptosis, axonal outgrowth, and synaptogenesis occur according to a highly specific timetable. Originating as a smooth layer without sulci and gyri, the cerebral cortex, like the thalamus, has no internal cellular organization. The cortical subplate is a temporary structure that serves as a waiting and organizing zone for various afferents destined for the cortex. It develops at about 13 weeks' gestation and recedes after 32 to 34 weeks' gestation.

Studies of fetal electroencephalograms (EEGs) at 24 weeks' gestation demonstrate electrical activity only 2% of the time, predominantly in 20-second bursts, with periods of inactivity lasting up to 8 minutes. At 30 weeks' gestation, EEGs begin showing patterns of wakefulness and sleep, but these are not concordant with fetal behavior. By 34 weeks' gestation, electrical activity is present 80% of the time, with more distinct wakefulness and sleep cycles similar to adult patterns.[133]

Two studies using near-infrared spectroscopy in preterm infants demonstrated differences in cerebral oxygenation over the somatosensory cortex with noxious and non-noxious stimulation.[134,135] This appears to indicate that noxious information is at least transmitted to the infant cortex by 25 weeks' gestation. Similarly, preterm neonates also have demonstrated cortical evoked potentials after a heel lance.[136]

The exact onset of fetal *sentience,* the capacity to feel pain, is unknown. Because of this uncertainty, it seems best to err on the side of administering adequate fetal anesthesia.[130] Altogether, clinical observations of fetal and neonatal behavior, information about the development of mechanisms of pain perception, and studies of fetal and neonatal responses to noxious stimuli provide a compelling physiologic and philosophic rationale for the provision of adequate fetal anesthesia, especially after 24 to 26 weeks' gestation. Noxious stimulation during fetal life causes a stress response, which could have both short- and long-term adverse effects on the developing central nervous system. Although the link between the stress response and pain is not always predictable, the threshold for pain relief is typically below that for stress response ablation, and the stress response to noxious stimulation is clear evidence that the fetal nervous system is reactive.[137] Administration of fetal anesthesia has been the standard practice worldwide since the inception of fetal surgery more than 35 years ago.[2,138]

Effects of Anesthesia on the Fetus

With maternal administration of general anesthesia, volatile agents readily cross the placenta to the fetus. The fetal level of halogenated anesthetic agent depends on both the inspired maternal concentration as well as the duration of administration. Based on data from cesarean delivery, after 10 minutes of general anesthesia, fetal levels of both isoflurane and halothane reach approximately 70% of maternal levels.[139] Of interest, studies in sheep models have shown a lower fetal-to-maternal ratio of volatile agents at 10 minutes, demonstrating that the fetal concentrations remain lower than maternal concentrations for significant periods of time (Fig. 7.8). Significant levels of maternal inhaled anesthetics (2 to 3 MAC) can affect fetal cardiac function and blood flow. A retrospective analysis of cardiac imaging from both open fetal cases and EXIT procedures noted severe left ventricular systolic dysfunction in the fetus with use of high concentrations of desflurane.[116] Echocardiographic findings from 100 open fetal MMC cases under desflurane anesthesia noted intraoperative ventricular dysfunction in 60% of cases, tricuspid regurgitation in 35%, and mitral valve regurgitation in 19%, with serious cardiovascular events in 7% of cases.[140] In another review of open fetal surgery for MMC repair utilizing a volatile anesthetic agent (2 to 3 MAC), 34 of 37 fetuses developed intraoperative umbilical artery flow abnormalities.[117] Brief fetal exposure to deep maternal inhalation

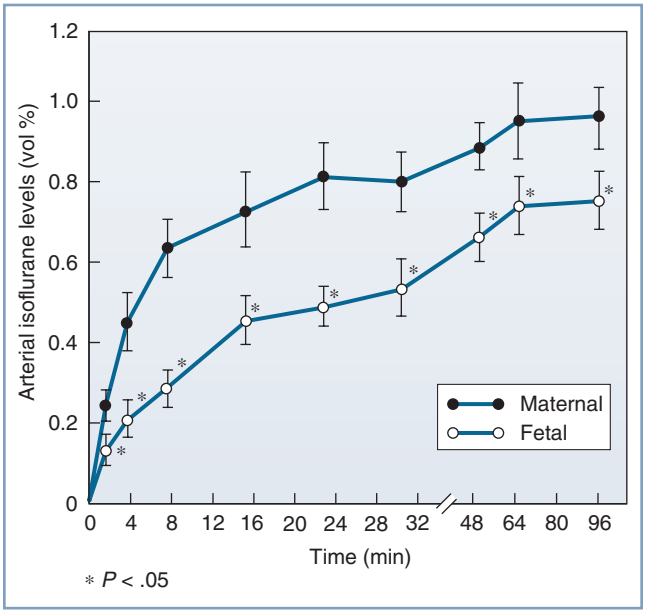

Fig. 7.8 Maternal and fetal arterial isoflurane concentrations in sheep during maternal administration of 2.0% isoflurane (mean ± SE). (From Biehl DR, Yarnell R, Wade JG, Sitar D. The uptake of isoflurane by the foetal lamb *in utero*: effect on regional blood flow. *Can Anesth Soc J.* 1983;30:581–586.)

anesthesia (2 to 3 MAC) does not appear to result in significant fetal hypoxia, hypercarbia, or acidosis even after exposures of 2 hours if maternal arterial pressure is maintained.[141] However, others have seen acidosis after 45 minutes of fetal exposure to anesthesia.[142]

Another concern is that anesthetic agents may result in neuronal apoptosis in the developing fetal brain (see Chapter 10). Initial evidence was found in 2003, when an anesthetic consisting of midazolam, nitrous oxide, and isoflurane was shown to alter neurons in the developing brain of 7-day-old rats and to cause long-term impairment of brain function.[143] Evidence for neuronal apoptosis in the developing brain after exposure to a wide range of anesthetic agents, such as halogenated agents, propofol, and benzodiazepines, has since been demonstrated in a variety of animal studies.[144] It is not currently known if anesthetic agents similarly affect human fetuses or neonates. Nonetheless, in December 2016, the U.S. Food and Drug Administration (FDA) issued a communication warning that "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains."[145] Currently no specific anesthetic agent (e.g., volatile agents, propofol, ketamine, benzodiazepines) is known to be safer than another.[146] There does not appear to be any association between the use of general anesthesia for emergent cesarean delivery and future learning disability.[144] The long-term neurocognitive effect of anesthetic exposure and surgical stimuli on fetuses during fetal surgery remains an area for future research.

Fetal Monitoring

Maternal and fetal anesthesia, uterine incision, fetal manipulation, and surgical stress may adversely affect uteroplacental and fetoplacental circulation by several mechanisms. Maternal hypotension, increased uterine activity, and maternal hyperventilation and hypocarbia impair uteroplacental and/or umbilical blood flow. Fetal manipulation may affect fetal cardiac output, regional distribution of cardiac output, and umbilical blood flow. Direct compression of the umbilical cord, inferior vena cava, and mediastinum also adversely affect fetal circulation. Current methods of intraoperative fetal monitoring include FHR monitoring, pulse oximetry, ultrasonography (including echocardiography and Doppler assessment of umbilical cord blood flow), and blood gas and acid-base analysis.

Plethysmography combined with pulse oximetry is very useful, particularly for the EXIT procedure. It remains unclear whether pulse oximetry or FHR monitoring is a more sensitive method of detecting changes in umbilical cord flow. Bradycardia has been found to be a late sign of fetal compromise in fetal lambs subjected to umbilical cord compression.[147] However, bradycardia can also precede oxyhemoglobin desaturation during human fetal surgery.[148]

Ultrasonography is a crucial intraoperative fetal monitoring device. The FHR can be determined with visualization of the heart or with Doppler assessment of umbilical cord blood flow. Both absent and reversed umbilical artery diastolic flow are associated with increased perinatal morbidity and mortality in obstetric patients, but the implications during fetal surgery remain unclear. Fetal cardiac contractility and volume also can be assessed qualitatively by echocardiography. Unfortunately, the sterile transducer often cannot be positioned continuously because its location interferes with surgery. When prolonged fetal bradycardia, oxyhemoglobin desaturation, and/or significant changes in fetal cardiac function and umbilical artery blood flow are noted, maneuvers should be done to improve uterine perfusion and relieve umbilical cord compression.[112] These maneuvers can include improving maternal blood pressure, cardiac output, and oxygenation through administration of vasoactive agents, fluids, and supplemental oxygen, as well as maximizing uterine relaxation. In severe cases requiring administration of fetal resuscitation drugs and fluids, *ex utero* fetal resuscitation including advanced cardiac life support (ACLS) may be necessary.

THE FUTURE OF FETAL THERAPY

Successful diagnosis and management of complex congenital anomalies and other fetal conditions amenable to prenatal intervention rely on well-organized, multidisciplinary, professional, and comprehensive fetal treatment programs to innovate new techniques, challenge dogma, and ensure ongoing success. More collaborative clinical investigation among international research centers will drive improvement, variety, and availability of fetal interventions, assist in the miniaturization of invasive techniques, and decrease maternal and fetal risk.

Although the rationale for prenatal fetal therapy seems straightforward, many issues remain problematic. Questions remain regarding the manner in which fetal development is modulated by intrauterine intervention. Other questions revolve around maternal and fetal rights, safety, efficacy, long-term outcomes, cost-effectiveness, and societal resource allocation. Societal expectations and the availability of therapy must be balanced against the budgetary constraints in contemporary health care. In addition, there is concern about the sensitivity, specificity, and appropriate use of diagnostic testing. Fetal therapy raises complex social, ethical, and legal issues that go beyond those customary for therapeutic interventions.[149] The ethical framework for the transition from innovation to clinical trials to offering fetal surgery as a standard of care must be managed thoughtfully and responsibly. A bioethics committee with representatives from both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists has provided recommendations for medical institutions offering fetal surgery.[5]

Fetal therapy must be evaluated carefully in properly conducted trials and undertaken only with great caution and informed maternal consent. Publication in scientific journals and open communication with colleagues nationally and internationally facilitates the moral obligation of researchers to report all results to allow peer review of the merits and liabilities of fetal surgery. The principal concept

of *primum non nocere* argues that it is unethical to undertake human trials until a procedure is appropriately tested in animals.[150] Training programs are necessary to safely expand access and services from academic fetal centers to smaller facilities. Fetuses that may benefit from invasive therapy must be carefully distinguished from those that will not. Intervention should be undertaken only when there is a reasonable probability of long-term benefit and minimal maternal risk.

KEY POINTS

- Most fetal malformations diagnosed *in utero* are not suitable for antenatal intervention. Fetal surgery is a reasonable option for anomalies that cause harm to the fetus before adequate development necessary for extrauterine survival (particularly lung maturity).
- Maternal safety is a primary consideration and must be weighed against potential long-term benefit to the fetus and neonate.
- Local or neuraxial anesthesia is normally suitable for percutaneous or minimally invasive procedures. Open intrauterine procedures typically require administration of general anesthesia.
- Anesthetic considerations for intrauterine fetal surgery are similar to those for nonobstetric surgery in pregnant women. However, in addition to maintaining adequate maternal anesthesia and uteroplacental blood flow, fetal surgery typically requires (1) provision of analgesia for the fetus, (2) more intensive intraoperative fetal monitoring, and (3) intraoperative uterine relaxation.
- Randomized controlled trials have demonstrated improved outcomes with use of fetoscopic laser ablation to treat twin-to-twin transfusion syndrome and intrauterine open fetal repair to treat myelomeningocele.
- Preterm premature rupture of membranes and preterm labor after surgery are significant barriers to optimal outcomes with fetal surgery.
- There are many medical, social, ethical, and legal considerations regarding the efficacy and safety of intrauterine fetal surgery. Careful evaluation of fetal benefits and maternal risks is fundamental to the decision as to when and whether fetal intervention is appropriate.

Intrapartum Fetal Assessment and Therapy

Elizabeth G. Livingston, MD

CHAPTER OUTLINE

Accurate fetal assessment in labor remains challenging despite the application of new technologies. An elevated cesarean delivery rate and persistent cases of fetal/neonatal neurologic injury indicate the need to further optimize fetal/neonatal outcomes while minimizing unnecessary maternal interventions.

FETAL RISK DURING LABOR

The fetus is at risk during labor and delivery. Worldwide, intrapartum stillbirths account for almost 1.3 million perinatal deaths per year, with a range of 10% to 50% of all stillbirths in developed and developing countries, respectively.[1] Obstetric care can influence the intrapartum stillbirth rate.[1] With each percentage increase in cesarean delivery rate up to 15%, intrapartum stillbirth rates decrease by 1.61/1000.[2]

Experimental models support the hypothesis that intrapartum events can have long-term neurologic sequelae for the offspring. Fetal monkeys subjected to hypoxia *in utero* suffer neurologic injuries similar to those seen in children who presumably suffered asphyxia *in utero*.[3–5] Work with rodent, rabbit, piglet, and sheep models have shown similar patterns of damage.[6–10]

Some fetuses appear to be at greater risk for adverse intrapartum events than others. Older studies report that high-risk mothers constitute 20% of the pregnant population, but their offspring represent 50% of the cases of perinatal morbidity and mortality.[11] Various methods for identification of high-risk pregnancies have been published.[12,13] High-risk pregnancies include, but are not limited to, women with (1) **medical complications** (e.g., hypertension, preeclampsia, diabetes, autoimmune disease, hemoglobinopathy); (2) **fetal complications** (e.g., fetal growth restriction, nonlethal anomalies, preterm delivery, multiple gestation, post-datism, hydrops); and (3) **intrapartum complications** (e.g., abnormal vaginal bleeding, maternal fever, meconium-stained amniotic fluid, oxytocin augmentation of labor). Owing to inadequate sensitivity, poor positive predictive values, and the inability to modify risk factor–related outcomes, high-risk scoring systems have not been proven to improve pregnancy outcomes.[14,15] In one study, more than half of infants with asphyxia had no clinical risk factors.[16] However, scoring systems may be useful in the management of low-risk parturients who do not warrant continuous monitoring during labor.[13,15] One European strategy for identifying high-risk parturients integrates the analysis of the fetal heart rate (FHR) tracing at the time of admission; if the FHR tracing is abnormal, patients receive intensive monitoring.[17] A meta-analysis of this approach failed to demonstrate outcome improvement, but did increase cesarean delivery rates.[18,19]

The magnitude of risk for intrapartum fetal neurologic injury is a matter of some dispute. In 2014, the American College of Obstetricians and Gynecologists (ACOG) Task Force on Neonatal Encephalopathy concluded that 70% of these types of fetal neurologic injuries result from events that occur before the onset of labor.[20] Examples of antepartum events that may cause fetal neurologic injury include congenital anomalies, chemical exposure, infection, and fetal thrombosis/coagulopathy. Only 4% of cases of neonatal encephalopathy result solely from intrapartum hypoxia, an incidence of approximately 1.5/1000.[20] The Task Force criteria are consistent with clinical findings in a case series of neurologically impaired infants with intrapartum compromise.[21] An additional case series of sentinel events (i.e., uterine rupture,

BOX 8.1 Neonatal Encephalopathy and Association with Peripartum Intrapartum Events

Definition of Neonatal Encephalopathy

Syndrome of disturbed neurologic function in the earliest days of life in an infant born at ≥ 35 weeks' gestation

Neonatal signs consistent with an acute peripartum or intrapartum event:

1. Apgar scores less than 5 at 5 minutes and 10 minutes of life
2. Evidence of metabolic acidosis in umbilical cord arterial blood obtained at delivery (i.e., pH < 7.00, base deficit > 12 mmol/L)
3. Neuroimaging evidence of acute brain injury seen on brain magnetic resonance imaging or magnetic resonance spectroscopy consistent with hypoxemia-ischemia
4. Presence of multisystem organ failure consistent with hypoxic-ischemic encephalopathy

Type and timing of contributing factors that are consistent with an acute peripartum or intrapartum event:

1. Sentinel hypoxic or ischemic event occurring immediately before or during labor and delivery (i.e., uterine rupture, abruption, amniotic fluid embolus)
2. Fetal heart rate monitor patterns consistent with an acute peripartum or intrapartum event
3. Type and timing of brain injury pattern based on imaging studies consistent with an etiology of an acute peripartum or intrapartum event
4. No evidence of other proximal or distal factors that could be contributing events

Developmental outcome is spastic quadriplegia or dyskinetic cerebral palsy.

Modified from the American College of Obstetricians and Gynecologists. Executive summary: Neonatal encephalopathy and neurologic outcome, 2nd ed. Report of the American College of Obstetricians and Gynecologists' Task Force on Neonatal Encephalopathy. *Obstet Gynecol.* 2014;123:896–901.

cord prolapse, placental abruption, amniotic fluid embolus) during labor described a high rate of hypoxic-ischemic encephalopathy in surviving infants.[22] Although a low percentage of neonatal encephalopathy is caused by intrapartum hypoxia, approximately 25% of fetuses may have antepartum and intrapartum risk factors for neurologic injury.[20,23] Box 8.1 lists findings that suggest an acute intrapartum hypoxic-ischemic event contributed to neonatal encephalopathy.

The ability of obstetricians to recognize and treat pregnancies at risk for hypoxia during labor is an evolving science. With the current understanding of pathophysiology and the contemporary technology used clinically, the extent to which obstetricians can prevent intrapartum injury remains unclear.[24–26] Obstetricians need clear pathophysiology-based definitions of intrapartum injury. Improved monitoring technologies and standardized interpretation will enhance ascertainment of the fetus at risk.[27] Research may result in the development of new strategies and interventions that can specifically identify and correct reversible pathophysiology.

Efforts to understand placental physiology and pathophysiology are central to efforts to support the health of the pregnant woman and her fetus, both antepartum and intrapartum. The fetus depends on the placenta for the diffusion of nutrients and for respiratory gas exchange. Many factors affect placental transfer, including concentration gradients, villus surface area, placental permeability, and placental metabolism (see Chapter 4). Maternal hypertensive disease, congenital anomalies, and intrauterine infection are examples of conditions that may impair placental transfer.

One of the most important determinants of placental function is uterine blood flow.[28] A uterine contraction results in a transient decrease in uteroplacental blood flow. A placenta with borderline function before labor may be unable to adequately maintain gas exchange to prevent fetal asphyxia during labor. The healthy fetus may compensate for the effects of hypoxia during labor.[28] The compensatory response includes (1) decreased oxygen consumption, (2) vasoconstriction of nonessential vascular beds, and (3) redistribution of blood flow to the vital organs (e.g., brain, heart, adrenal glands, placenta).[28–30] Humoral responses (e.g., release of epinephrine from the adrenal medulla, release of vasopressin and endogenous opioids) may enhance fetal cardiac function during hypoxia.[28,31] Prolonged or severe hypoxia overwhelms these compensatory mechanisms, resulting in fetal injury or death.

INTRAPARTUM FETAL ASSESSMENT

Electronic Fetal Heart Rate Monitoring

There is need for a sensitive yet specific method for determination of fetal health during labor and delivery. Most contemporary methods include assessment of the FHR. The FHR can be monitored intermittently with a simple DeLee or Pinard stethoscope. Alternatively, either Doppler ultrasonography or a fetal electrocardiography (ECG) electrode can be used to monitor the FHR intermittently or continuously.

Experimental models have provided insight into the regulation of the FHR. Both neuronal and humoral factors affect the intrinsic FHR. Parasympathetic outflow by means of the vagus nerve decreases the FHR, whereas sympathetic activity increases FHR and cardiac output.[31] Baroreceptors respond to increased blood pressure, and chemoreceptors respond to decreased Pao_2 and increased $Paco_2$ to modulate the FHR through the autonomic nervous system. Cerebral cortical activity and hypothalamic activity affect the FHR through their effects on integrative centers in the medulla oblongata (Fig. 8.1).[31] Both animal studies and clinical observations have helped establish a correlation between FHR and perinatal outcome.

An electronic monitor simultaneously records the FHR and uterine contractions. Use of an electronic monitor allows determination of the **baseline rate** and **patterns** of the FHR and their relationship to uterine contractions. External or internal techniques can assess the FHR and uterine contractions (Fig. 8.2). Doppler ultrasonography detects the changes in ventricular wall motion and blood flow in major vessels

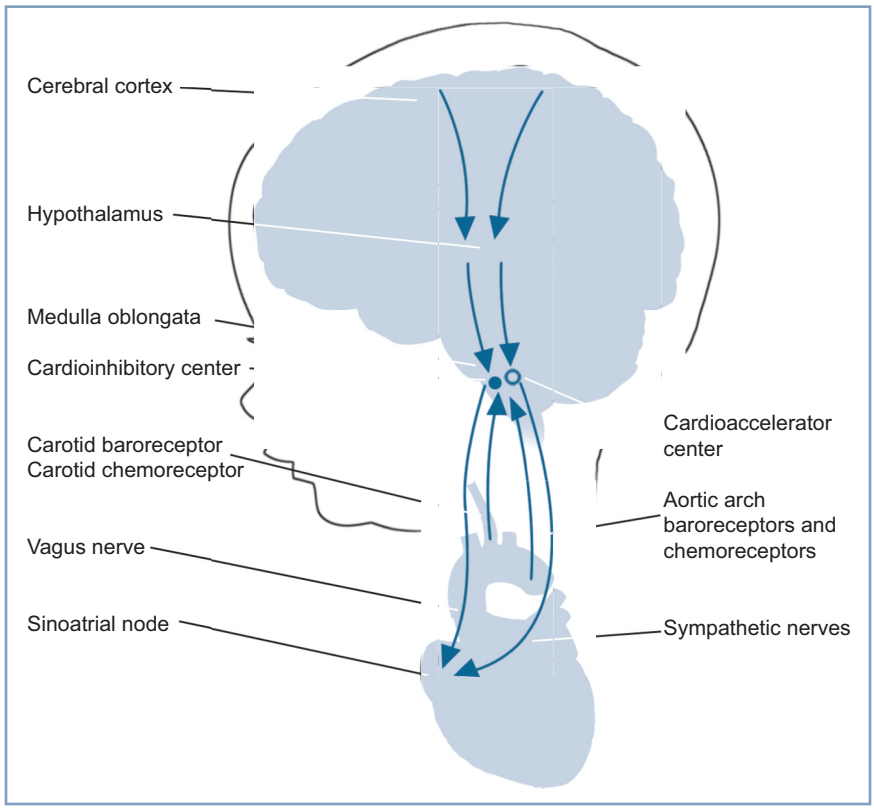

Fig. 8.1 Regulation of fetal heart rate. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

during each cardiac cycle. The monitor calculates the FHR by measuring the intervals between fetal myocardial contractions. Alternatively, an ECG lead attached to the fetal scalp enables the cardiotachometer to calculate the FHR by measuring each successive R-R interval. Both external and internal methods allow continuous assessment of the FHR.

The FHR is superimposed over the uterine contraction pattern. Uterine contractions can be monitored externally with a tocodynamometer or internally with an intrauterine pressure catheter. The tocodynamometer allows determination of the approximate onset, duration, and offset of each uterine contraction. A normal pattern of uterine contractions in labor is five or less in a 10-minute period, averaged over 30 minutes; tachysystole is defined as more than five contractions in a 10-minute period.[32] An intrauterine pressure catheter may be used to measure the relative strength, and the onset and offset, of each uterine contraction with greater precision than an external monitor. Such information may be used to distinguish among early, variable, and late FHR decelerations. Additionally, the intrauterine pressure catheter may be useful for obese parturients where the tocodynamometer lacks sensitivity. In a randomized controlled trial, internal tocodynamometry did not improve labor or neonatal outcome in a general population compared with external contraction measurements.[33] The FDA has approved a new device ("LaborView", OBMedical, Newberry, FL) utilizing electrohysterography, a technique that measures uterine electrical activity across the maternal wall, which may decrease the need for intrauterine pressure catheter placement.[34]

The following features of the FHR pattern can be assessed: (1) **baseline** measurements, (2) **variability** (the extent to which the rate changes both instantaneously and over longer periods), (3) **accelerations**, and (4) **decelerations** and their association with uterine contractions.

Baseline Fetal Heart Rate

A normal baseline FHR is defined as 110 to 160 beats per minute (bpm) and is determined by assessing the mean heart rate over a 10-minute period rounded to increments of 5 bpm.[32,35] In general, term fetuses have a lower baseline FHR than preterm fetuses because of greater parasympathetic nervous system activity. Laboratory studies suggest that bradycardia (caused by increased vagal activity) is the initial fetal response to acute hypoxemia. After prolonged hypoxemia, the fetus may experience tachycardia as a result of catecholamine secretion and sympathetic nervous system activity.[36] Changes in baseline FHR may also be caused by fetal anatomic or functional heart pathology, maternal fever and/or intrauterine infection, or maternally administered medications, such as beta-adrenergic receptor agonists (e.g., terbutaline) or the anticholinergic agent atropine.

Fetal Heart Rate Variability

Fetal heart rate variability is the fluctuation in the FHR of two cycles or greater per minute.[32,35] Previously, FHR variability was divided into *short term* (from one beat, or R wave, to the next) and *long term* (occurring over the course of 1 minute), but this distinction is no longer made because in

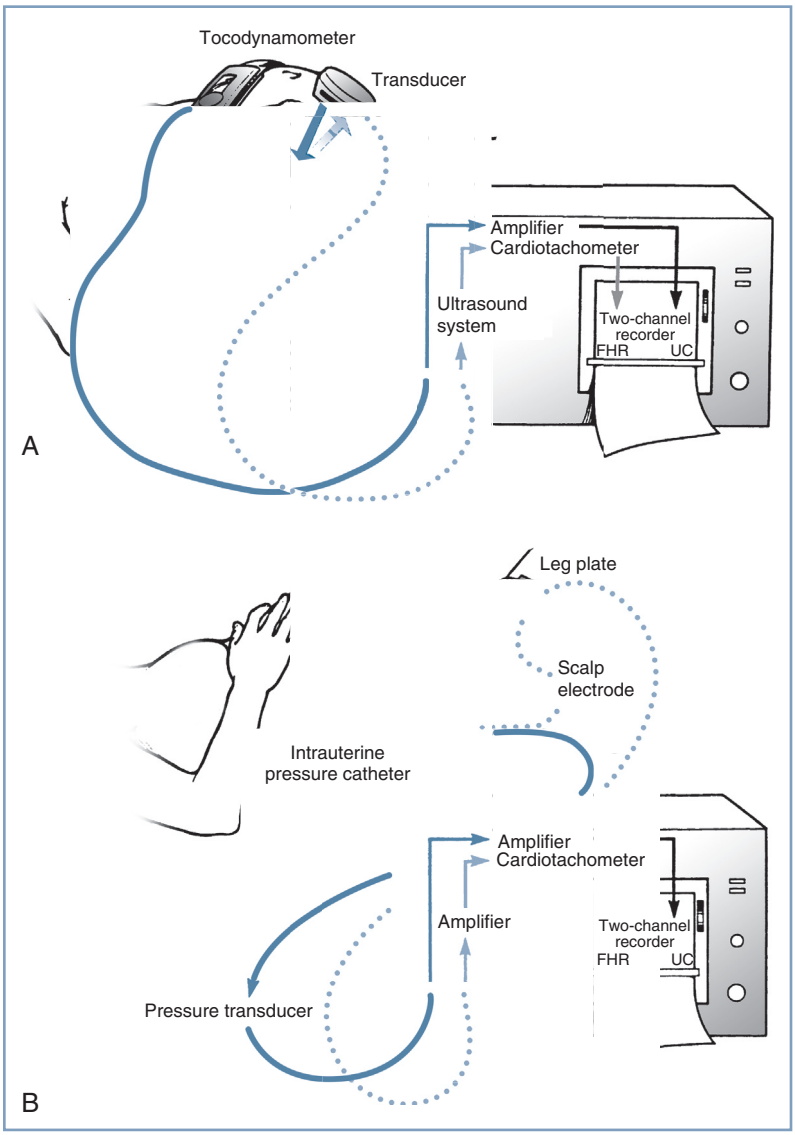

Fig. 8.2 Electronic fetal monitoring apparatus. (A) Instrumentation for external monitoring. Contractions are detected by the pressure-sensitive tocodynamometer, amplified, and then recorded. The fetal heart rate (FHR) is monitored with the Doppler ultrasound transducer, which emits and receives the reflected ultrasound signal that is then counted and recorded. (B) Techniques used for direct monitoring of FHR and uterine contractions (UC). Uterine contractions are assessed with an intrauterine pressure catheter connected to a pressure transducer. This signal is then amplified and recorded. The fetal electrocardiogram (ECG) is obtained by direct application of the scalp electrode, which is then attached to a leg plate on the mother's thigh. The signal is transmitted to the monitor, where it is amplified, counted by the cardiotachometer, and recorded. (Drawing by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

clinical practice variability is visually assessed as a unit (Fig. 8.3). The presence of normal FHR variability reflects the presence of normal, intact pathways from—and within—the fetal cerebral cortex, midbrain, vagus nerve, and cardiac conduction system (see Fig. 8.1).[31] Variability is greatly influenced by the parasympathetic tone, by means of the vagus nerve. Maternal administration of atropine, which readily crosses the placenta, can eliminate some variability. In humans, the sympathetic nervous system appears to have a lesser role in influencing variability.[31] Maternal administration of the beta-adrenergic receptor antagonist propranolol has little effect on FHR variability.[31]

During hypoxemia, fetal myocardial and cerebral blood flows increase to maintain oxygen delivery.[28,37,38] With severe hypoxemia, however, fetal blood flow cannot increase sufficiently to maintain oxygen delivery. The decompensation of cerebral blood flow and oxygen delivery results in a loss of FHR variability.[31] The absence of variability in an anencephalic fetus also suggests that the presence of FHR variability reflects the integrity of the central nervous system (CNS). In animal models, perfusion of the CNS with calcium results in depolarization of electroencephalographic (EEG) activity, which abolishes FHR variability.

Clinically, the presence of normal FHR variability predicts early neonatal health, as defined by an Apgar score of greater than 7 at 5 minutes.[39] In a case series of monitored fetal deaths, no fetus had normal variability immediately before demise.[31] However, in a cohort of 500 deliveries, presence or absence of variability was not associated with neonatal acidosis.[40] The differential diagnosis of decreased variability includes fetal hypoxia, fetal sleep state, fetal neurologic abnormality, and decreased CNS activity that results from exposure to drugs such as opioids.

Accelerations

Accelerations are abrupt changes in the FHR from baseline. Beyond 32 weeks' gestation, an acceleration is defined by a peak of at least 15 bpm above baseline and lasting at least 15 seconds. (Before 32 weeks' gestation, a peak of 10 bpm above the baseline, lasting at least 10 seconds, is required.)[32,35] While

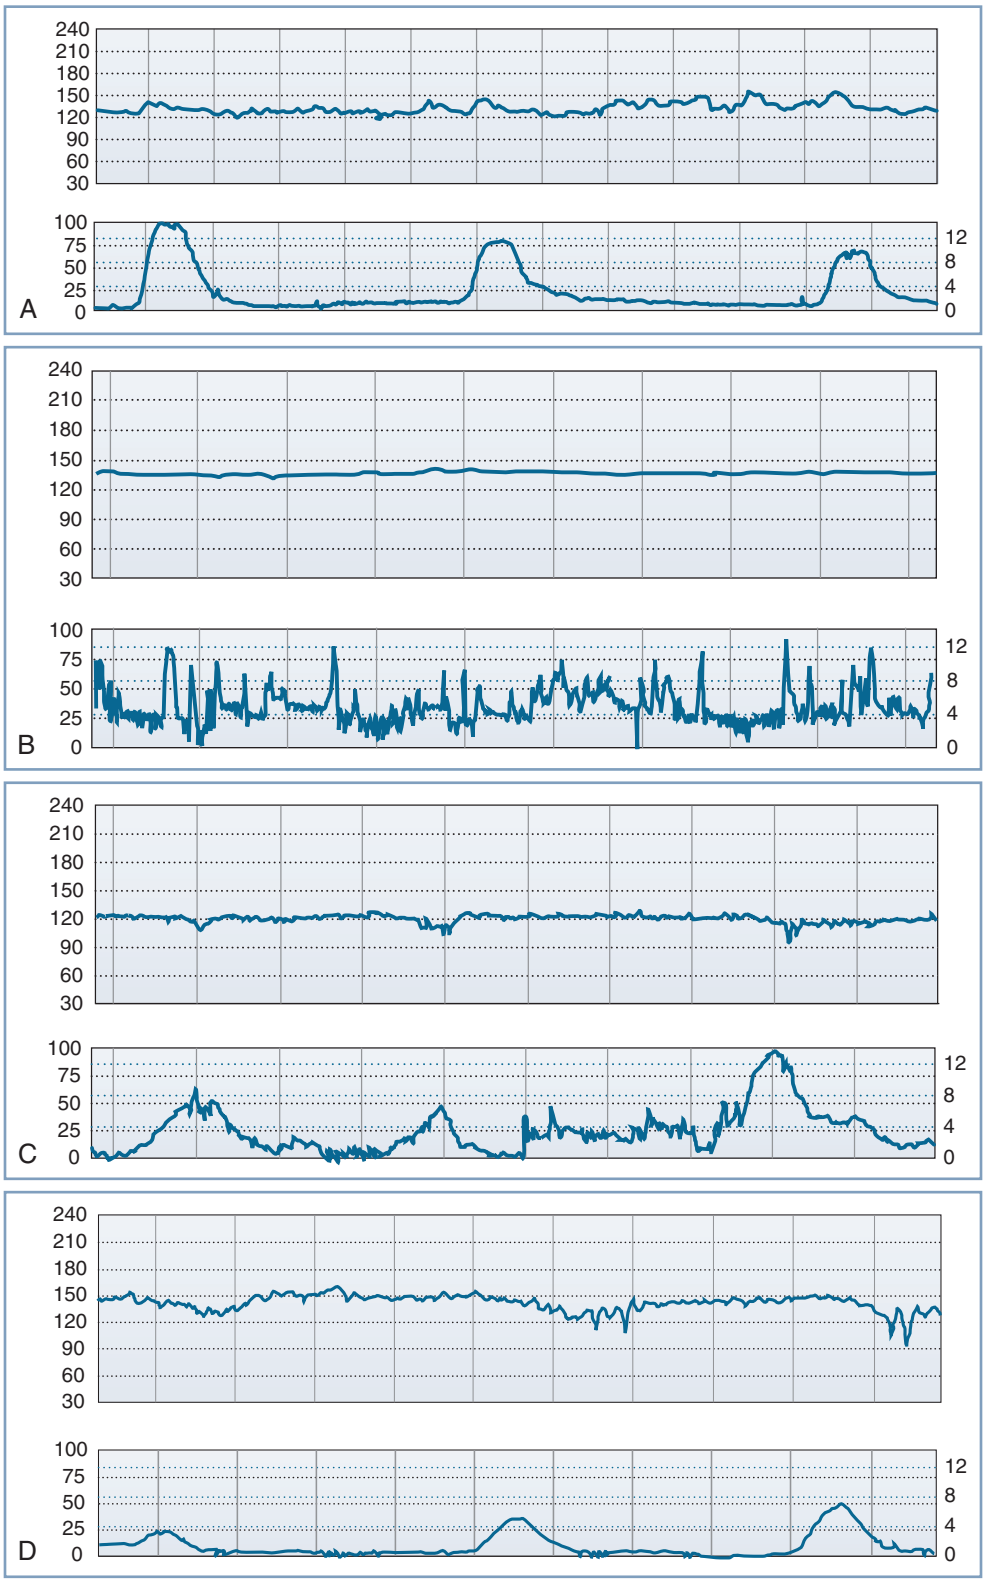

Fig. 8.3 (A) Normal intrapartum fetal heart rate (FHR) tracing. The infant had Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. (B) Absence of variability in a FHR tracing. Placental abruption was noted at cesarean delivery. The infant had an umbilical arterial blood pH of 6.75 and Apgar scores of 1 and 4, respectively. (C) Early FHR decelerations. After a normal spontaneous vaginal delivery, the infant had Apgar scores of 8 and 8, respectively. (D) Late FHR decelerations. The amniotic fluid surrounding this fetus was meconium-stained. Despite the late FHR decelerations, the variability remained acceptable. The infant was delivered by cesarean delivery and had an umbilical venous blood pH of 7.30. Apgar scores were 9 and 9, respectively.

Continued

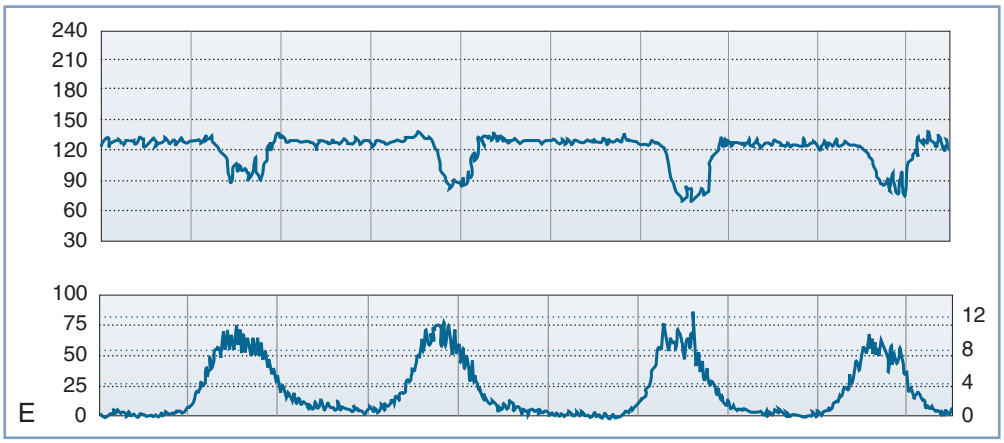

Fig. 8.3, cont'd (E) Variable FHR decelerations. A tight nuchal cord was noted at low-forceps vaginal delivery. The infant had Apgar scores of 6 and 9, respectively. Numerical scales: *Left upper panel margin,* FHR in beats per minute; *left lower panel margin,* uterine pressure in mm Hg; *right lower panel margin,* uterine pressure in kilopascals (kPa).

an acceleration that extends for 2 minutes is considered prolonged, at 10 minutes it is considered a baseline change.[32,35] During the antepartum period, the heart rate of the healthy fetus accelerates in response to fetal movement. Antepartum FHR **accelerations** signal fetal health, and their presence indicates a reactive nonstress test. During the intrapartum period, the significance of the presence or absence of FHR accelerations is less clear.[36,41] Whereas intrapartum accelerations may indicate a vulnerable umbilical cord in some cases, their presence most commonly precludes the existence of significant fetal metabolic acidosis.

Decelerations

Decelerations include early, late, or variable decelerations. **Early decelerations** occur simultaneously with uterine contractions and usually are less than 20 bpm below baseline. The onset and offset of each deceleration coincides with the onset and offset of the uterine contraction (see Fig. 8.3). In animal models, head compression can precipitate early decelerations.[36] In humans, early decelerations are believed to result from reflex vagal activity secondary to mild hypoxia. Early decelerations are not ominous.

Late decelerations begin 10 to 30 seconds after the beginning of uterine contractions, and end 10 to 30 seconds after the end of uterine contractions. Late decelerations are smooth and repetitive (i.e., they occur with each uterine contraction). Animal studies suggest that late decelerations represent a response to hypoxemia. The delayed onset of the deceleration reflects the time needed for the chemoreceptors to detect decreased oxygen tension and mediate the change in FHR by means of the vagus nerve.[36,42] Late decelerations may also result from decompensation of the myocardial circulation and myocardial failure. Unfortunately, clinical and animal studies suggest that late decelerations may be an oversensitive indication of fetal asphyxia.[36,39] However, the combination of late decelerations and decreased or absent FHR variability is an accurate, ominous signal of fetal compromise.[39,43,44]

Variable decelerations vary in depth, shape, and duration. They often are abrupt in onset and offset. Variable decelerations result from baroreceptor- or chemoreceptor-mediated vagal activity or possible transient hypoxemia.[45,46] Experimental models and clinical studies suggest that **umbilical cord occlusion,** either partial or complete, results in variable decelerations. During the second stage of labor, variable decelerations may result from compression of the fetal head. In this situation, dural stimulation leads to increased vagal discharge.[47] The healthy fetus can typically tolerate mild to moderate variable decelerations (not below 80 bpm) without decompensation. With prolonged, severe variable decelerations (less than 60 bpm) or persistent fetal bradycardia, it is difficult for the fetus to maintain cardiac output and umbilical blood flow.[47]

Some practitioners additionally characterize decelerations as "atypical" when they demonstrate "shoulders," "overshoot," "biphasic" or "W pattern," "slow return," or absent variability at the nadir. The 2008 National Institute for Child and Human Development (NICHD) Consensus guidelines do not categorize atypical decelerations separately from other decelerations.[35] There is controversy whether these atypical patterns indicate additional hazard for the fetus.[48,49]

Sinusoidal and **saltatory** patterns are two unusual FHR tracing results that may indicate fetal compromise. The sinusoidal FHR pattern is a regular, smooth, wavelike pattern that may signal fetal anemia.[50] Occasionally, maternal administration of an opioid can lead to a sinusoidal FHR pattern. The saltatory pattern consists of excessive swings in variability (more than 25 bpm) and may signal the occurrence of acute fetal hypoxia; there is a weak association between this pattern and low Apgar scores.[51]

Limitations of Electronic Fetal Heart Rate Monitoring

Despite laboratory and early clinical data suggesting that FHR monitoring accurately reflects fetal health, controversy exists

regarding the ability of this assessment tool to improve fetal and neonatal outcomes. FHR monitoring was first introduced some 40 years ago and now is utilized in over 85% of monitored deliveries.[32] Retrospective reports of continuous FHR monitoring associate its use with a lower incidence of intrauterine fetal demise, neonatal seizures, and neonatal death.[52–54] By contrast, the only consistent finding from multiple case-control studies and more than a dozen prospective, randomized trials of electronic FHR monitoring (with control arms that employed intermittent FHR auscultation[55-57]) is an increased rate of operative delivery. Meta-analyses of these trials and a large U.S. birth cohort found a decreased incidence of 1-minute Apgar scores less than 4 and a decreased incidence of neonatal seizures with the use of continuous FHR monitoring.[55–59]

It remains unclear why prospective studies have not confirmed greater benefit of the use of continuous electronic FHR monitoring during labor; the intensity of intrapartum assessment and care may be partially responsible. In prospective trials, women were randomly assigned to receive intermittent FHR auscultation and were monitored by dedicated nursing staff who provided intensive intrapartum care. By contrast, the historical cohort studies compared patients who received continuous electronic FHR monitoring and intensive intrapartum care with patients who had intermittent FHR auscultation with *nonintensive* nursing care. There are no published studies that have randomly assigned a group of patients to receive no FHR monitoring; however, the continued high rate of intrapartum stillbirth in unmonitored births in the developing world suggests that FHR assessment may be beneficial.

Consistent with the results of the prospective trials, the ACOG endorses the use of either intermittent auscultation or continuous electronic FHR monitoring during labor. In high-risk patients, ACOG guidelines recommend that the obstetrician or nurse review the electronic FHR tracing every 15 minutes during the first stage of labor and every 5 minutes during the second stage.[32] For low-risk patients, the intervals may be lengthened to 30 minutes for the first stage and 15 minutes for the second stage.[32,60] The optimal interval for intermittent FHR monitoring has not been studied, but the intervals of 15 to 30 minutes in the active phase and every 5 minutes in the second stage have some indirect support.[58,61] Adherence to these standards for intermittent auscultation may be difficult to achieve in the clinical setting; in one study, only 3% of parturients met this standard.[62] A Cochrane review compared use of handheld Doppler/intermittent cardiotocography to use of Pinard (nonelectronic device) and demonstrated no improvement in neonatal outcome but an increase in operative delivery.[63]

Several hypotheses to account for the apparent failure of intrapartum FHR monitoring to reduce the incidence of cerebral palsy have been proposed, and include the following:

- A large proportion of asphyxial damage begins before the onset of labor;
- Catastrophic, "sentinel" events (e.g., cord prolapse, placental abruption, uterine rupture) may not allow sufficient time for intervention before neurologic damage occurs;
- A larger proportion of very-low-birth-weight (VLBW) infants survive and thus contribute to the number with cerebral palsy;
- Infection is associated with abnormal FHR patterns and the subsequent development of cerebral palsy, and it is unclear if early intervention offers any benefit in such cases;
- The amount of asphyxia required to cause permanent neurologic damage approximates the amount that causes fetal death, leaving a narrow window for intervention.[64] The number of patients in whom cerebral palsy develops from intrapartum asphyxia is probably quite small.[64]

Limitations of FHR monitoring include a poor positive predictive value in distinguishing between abnormal FHR tracings and abnormal outcomes. Because of this imprecision, the ACOG recommended that abnormal FHR tracings be described with the term *nonreassuring fetal status* rather than *fetal distress* or *birth asphyxia*.[65] In one population-based case-control study of children with cerebral palsy, FHR tracings were retrospectively reviewed. While a markedly higher incidence of abnormal FHR tracings were found in children with cerebral palsy than in controls, there was a 99.8% false-positive rate of abnormal tracings.[66] Later case-control studies have yielded similar results.[16,67] A 2006 meta-analysis of 12 trials including 37,000 women suggested a decrease in seizures with electronic fetal monitoring (EFM) but with no change in neonatal mortality or cerebral palsy.[58] Calculations suggested that EFM resulted in one cesarean delivery for every 58 women monitored and that 661 women would need to be monitored to prevent one neonatal seizure.[58]

While poor specificity of EFM is a documented concern, inadequate sensitivity is also an issue. A 2017 report noted that 20% of fetuses born with acidemia do not have an abnormal FHR tracing even with expert retrospective evaluation.[26] A case-control study of infants with hypoxic-ischemic encephalopathy (HIE) showed that FHR monitoring the hour before delivery was poorly predictive of neurologic injury.[25]

Further limitations of continuous FHR monitoring include: (1) poor intra-observer and inter-observer agreement despite the use of trained observers, especially when FHR patterns are observed; (2) the required continual presence of a nurse or physician to assess the FHR tracing; (3) the inconvenience to the patient (e.g., confinement to bed and the application of monitor belts or a scalp electrode); and (4) the need to maintain the FHR tracings as legal documents.[68–70]

Despite little evidence for its efficacy, Parer and King suggested that obstetricians continue to rely on electronic FHR monitoring for the following three reasons: (1) professional obstetric organizations (e.g., the ACOG) advise some form of monitoring during labor, (2) electronic FHR monitoring is logistically easier and less expensive than one-on-one nursing care during labor, and (3) individual (often anecdotal) experiences cause "many obstetricians [to] believe that in their own hands FHR monitoring is … efficacious."[71]

In 2008 the National Institute of Child Health and Human Development (NICHD) sponsored a workshop that resulted in the publication of updated definitions, interpretation, and research guidelines for intrapartum electronic FHR monitoring.[35] The published report proposed a three-tier system for the categorization of FHR patterns.[35] The ACOG has described this system in a 2009 Practice Bulletin with suggested options for management.[32,72]

- **Category I (normal):** Strongly predictive of *normal* fetal acid-base status at the time of observation.
- **Category II (indeterminate):** Not predictive of *abnormal* fetal acid-base status, but without adequate evidence to classify as normal or abnormal.
- **Category III (abnormal):** Predictive of *abnormal* fetal acid-base status at the time of observation and thus requiring prompt evaluation (Box 8.2).[32,35]

BOX 8.2 Three-Tiered Fetal Heart Rate Interpretation System

Category I Tracings Include All of the Following:
- Baseline rate: 110–160 beats per minute (bpm)
- Baseline FHR variability: moderate
- Accelerations: present or absent
- Late or variable decelerations: absent
- Early decelerations: present or absent

Category II Tracings Include:
- All tracings not categorized as Category I or Category III
- Baseline FHR
  - Bradycardia not accompanied by absent baseline variability
  - Tachycardia
- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability not accompanied by recurrent decelerations
  - Marked baseline variability
- Accelerations
  - Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate variability
  - Prolonged deceleration ≥ 2 minutes but < 10 minutes
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with other characteristics such as slow return to baseline, overshoots, or shoulders

Category III Tracings Include Either:
- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

Modified from Macones GA, Hankins GD, Spong CY, et al. The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring. *Obstet Gynecol.* 2008;112:661–666.

In a large population review, 78% of tracings were Category I, 22% of tracings were Category II, and Category III was present 0.004% of the time.[73] Whereas only 0.2% of Category I tracings had low Apgar scores and NICU admissions, this increased to 0.7% with Category II tracings, suggesting a greater association with increased short-term morbidity.

An overriding concern with the three-tier system is the number and heterogeneity of patients with Category II tracings.[74] A five-tier system has been proposed to offer better sensitivity than the three-tier system; however, the ability of both classification systems to predict fetal acidemia appears equivalent.[75]

Methods for Improving the Efficacy of Electronic Fetal Heart Rate Monitoring

Several technologies have been employed to enhance the value of electronic FHR monitoring. To facilitate continual FHR assessment, many labor and delivery units transmit the tracings from the bedside to the nurses' station. Presumably, this practice facilitates a more rapid response to worrisome FHR tracings.

Computerized analysis may assist in the interpretation of FHR tracings. While commercially available programs with sound or light alerts have been developed, are consistent with expert analysis, and demonstrate accuracy at identifying fetal acidemia, randomized controlled trials have not shown improvement over visual interpretation of tracings.[76-79]

Continuous FHR monitoring requires the patient to wear FHR and uterine contraction monitoring devices and to remain within several feet of the monitor. An alternative is the use of telemetry, which transmits the FHR from the patient to the monitor and consequently allows ambulation. The low-risk patient who wishes to ambulate probably does not require continuous electronic FHR monitoring.

Electronic archiving allows for the electronic storage and retrieval of FHR tracings and eliminates the need for long-term storage of the paper record. The FHR tracing is a medico-legal document, and if it is lost, the plaintiff's lawyer may allege that the tracing was discarded intentionally because it was detrimental to the defendant.[80]

Supplemental Methods of Fetal Assessment

A normal electronic FHR monitor tracing is more than 99% accurate in predicting a 5-minute Apgar score higher than 7. Unfortunately, an abnormal FHR tracing has a false-positive rate of more than 99%.[32] Adding other fetal assessment tools may help identify the compromised fetus with greater specificity and allow appropriate intervention.

An older method used to confirm or exclude the presence of fetal acidosis when FHR monitoring suggests the presence of fetal compromise is the **fetal scalp blood pH determination.** Suggested indications include the presence of decreased or absent FHR variability or persistent late or variable FHR decelerations. The obstetrician inserts an endoscope into the vagina, makes a small laceration in the fetal scalp (or buttock), and uses a capillary tube to collect a sample of fetal capillary blood (Fig. 8.4). Data suggesting a lack of benefit of fetal

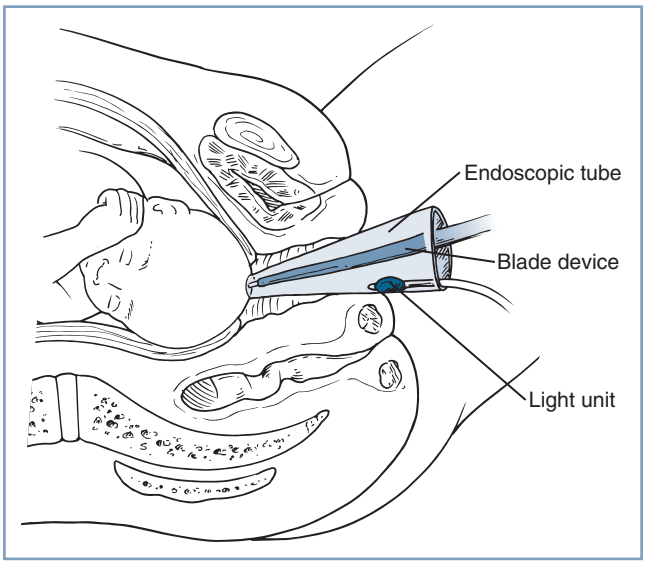

Fig. 8.4 Technique of obtaining fetal scalp blood during labor. (Redrawn from Creasy RK, Parer JT. Perinatal care and diagnosis. In Rudolph AM, ed. *Pediatrics.* 16th ed. New York, NY: Appleton-Century-Crofts; 1977:121.)

blood sampling beyond FHR interpretation, the technical challenges of obtaining a sample, and the requirement for having readily available instrumentation to conduct the test, have led most U.S. centers to abandon this technique.[81] An alternative method, which remains in use in Europe, analyzes the fetal blood sample for the presence of lactate. Sampling of lactate requires a smaller amount of blood and is therefore more frequently successful.[82] While some data suggest fetal blood sampling may decrease operative deliveries, there is no evidence to suggest improvement in fetal outcomes.[76]

An alternative to fetal scalp blood sampling is **fetal scalp stimulation** (although fetal scalp blood sampling is a form of fetal scalp stimulation). The fetal scalp can be digitally stimulated during vaginal examination or squeezed with an Allis clamp. The heart rate of a healthy, nonacidotic fetus accelerates in response to scalp stimulation; FHR acceleration is associated with a fetal pH of at least 7.19.[83,84]

Vibroacoustic stimulation is another method for assessing a worrisome FHR tracing. Advocates of this technique contend that application of an artificial larynx to the maternal abdomen results in FHR acceleration in a healthy fetus and improves the specificity of FHR monitoring.[85] Used primarily in antepartum testing situations, there is less evidence for intrapartum use.[86] A meta-analysis of intrapartum stimulation tests (i.e., fetal scalp blood pH determination, Allis clamp scalp stimulation, vibroacoustic stimulation, and digital fetal scalp stimulation) found the tests to be equivalent at predicting fetal acidemia, with digital fetal scalp stimulation having the greatest ease of use.[85]

The intrapartum use of **umbilical artery velocimetry** has been applied as an adjunct to FHR monitoring, but has demonstrated poor correlation with fetal outcomes.[87] However, middle cerebral artery (MCA) Doppler evaluation, alone or in conjunction with umbilical artery Doppler evaluation, has been suggested to have a good negative predictive value as a screening test for at-risk fetuses.[87]

Just as the antenatal use of the **biophysical profile (BPP)** decreases the false-positive rate of a positive nonstress test before labor, the BPP has been proposed as a potential tool to assist with intrapartum management.[88,89]

The presence of **meconium-stained amniotic fluid** has long been associated with an increased risk for infant depression at birth. Moderate to thick meconium is associated with lower Apgar scores, lower umbilical arterial blood pH, an increased incidence of neonatal seizures, and higher rates of cesarean delivery and admission to an intensive care nursery.[90] Although approximately 4% to 22% of all deliveries are complicated by meconium-stained amniotic fluid, few of these infants experience neonatal depression. The odds ratio for complications increases with meconium, but the majority of infants with neonatal complications have clear fluid.[90] Meconium-stained fluid has a poor positive predictive value and poor sensitivity in predicting adverse neonatal outcomes.[90] The physiology associated with the passage of meconium is incompletely understood. Ultrasonographic imaging suggests that the fetus regularly passes rectal contents into the amniotic fluid throughout gestation.[90] However, meconium-stained amniotic fluid is more common in pregnancies complicated by postdatism or fetal growth restriction. Putative triggers for the passage of meconium include umbilical cord compression and hypoxia. The presence of meconium combined with an abnormal FHR tracing or another risk factor (e.g., fetal growth restriction, postdatism) appears to be associated with an increased likelihood of neonatal depression.[90]

Among the newborns with meconium-stained amniotic fluid, approximately 3% to 12% develop significant neonatal respiratory compromise termed **meconium aspiration syndrome.**[90] Antenatal risk factors for this syndrome include moderate or thick meconium (suggesting recent passage and lower amniotic fluid volume) and abnormal FHR tracings.[90] The lung injury likely originates from intrapartum fetal hypoxia.[90] Oropharyngeal suctioning at delivery has not proved beneficial; randomized controlled trials have suggested that vigorous neonates do not need aggressive airway cleansing with endotracheal intubation (see Chapter 9).[91,92] Aggressive management of postdate pregnancies has led to a decreased incidence of meconium-stained amniotic fluid over the past decade.[90]

Additional Technologies for Fetal Assessment

Because FHR monitoring provides only an *indirect* measure of fetal oxygenation and acid-base status, alternative technologies such as **ST waveform analysis of fetal electrocardiography (ECG)** have been proposed to enhance assessment of fetal oxygenation. Animal and human studies indicate that fetal hypoxia induces changes in the ECG morphology of the ST segment and T wave collected by a fetal spiral electrode. In early European trials, a device utilizing computerized analysis of ST waveform collected from the fetal electrocardiographic tracing (STAN S31, Neoventa Medical, Mölndal, Sweden)

showed promise in reducing the risk for neonatal hypoxic encephalopathy.[93,94] A 2015 randomized controlled trial of more than 11,000 parturients in the United States did not demonstrate an improvement in neonatal outcomes or a decrease in cesarean delivery rates with use of STAN S31 versus conventional monitoring.[95] A meta-analysis of studies showed a decrease in the use of fetal scalp sampling and fewer operative vaginal births with use of STAN S31 but likewise no improvement in neonatal outcomes or cesarean delivery rates.[96] Explanations of outcome differences with STAN in American and European trials include use of three-tier (American) versus four-tier (European) classification systems for FHR tracings. Also, the American trial encouraged intervention based on clinical suspicion without an abnormal ST signal.[97] Need for electrode placement, early application of the STAN monitor before suspected fetal compromise, and unclear benefit of the technique have led to limited use in the United States.

Reflectance pulse oximetry was adapted for assessment of fetal oxygenation. The United States Food and Drug Administration (FDA) approved the Nellcor N-400 fetal pulse oximeter (Nellcor Puritan Bennett, Pleasanton, CA) for use in the setting of a term, singleton fetus at more than 36 weeks' gestation with a vertex presentation and a nonreassuring FHR pattern after rupture of membranes.[98,99] The most commonly used probes are held in place against the fetal head or cheek with pressure from the cervix. A reliable pulse oximetry signal can be obtained in 60% to 70% of cases. Fetal pulse oximetry used in conjunction with FHR monitoring appeared to reduce the rate of cesarean delivery for a nonreassuring FHR tracing; however, this reduction was offset by an increased rate of cesarean delivery for dystocia.[100–102] A meta-analysis of four randomized trials of fetal pulse oximetry showed similar results.[103] The absence of an effect on the overall cesarean delivery rate prompted the ACOG to withhold an endorsement of fetal pulse oximetry.[99]

Research Technologies for Fetal Assessment

Transcutaneous Po_2, Pco_2, and pH monitors have been developed to provide a more direct fetal assessment.[95,96,104–106] These monitors, however, are limited by technical difficulties in application of the probe(s), drift of baseline measurements, artifactual measurements, and difficulty in establishing diagnostic criteria for intervention. None of these monitors are in routine clinical use for fetal assessment in labor.

Proton magnetic resonance spectroscopy (^{1}H MRS) can obtain metabolic information from the brains of humans and animals, and early investigations have suggested an ability to assess fetal brain oxygenation.[107–109] ^{1}H MRS has proved useful in the evaluation of hypoxic-ischemic encephalopathy and metabolic disorders in pediatric patients. Although these measurements can be correlated with the level of tissue oxygenation, the clinical utility of this technique as a means of fetal assessment remains unclear.[110]

Near-infrared spectroscopy (NIRS) has the potential to measure fetal tissue oxygenation directly.[111] Transabdominal NIRS has been used in research settings to assess placental oxygenation.[112] NIRS can detect changes in the ratio of reduced to oxygenated cytochrome-*c* oxidase in the brain and in the ratio of oxygenated to deoxygenated hemoglobin in the blood perfusing the brain. This technique can also measure the total amount of hemoglobin in the tissue, which provides an estimate of tissue blood perfusion.[111] Current NIRS technology is limited by a frequent inability to obtain interpretable measurements (approximately 20% of the time) and the need to correlate the measurements with long-term neurodevelopmental outcomes. Therefore, NIRS remains a research rather than a clinical tool at this time.[111]

INTRAPARTUM FETAL THERAPY

The ACOG has suggested that intrapartum management be based on the three-tier evaluation framework.[72] A Category I tracing requires only periodic re-evaluation. Category III tracings should prompt preparation for delivery if improvement of the FHR tracing is not accomplished in a timely manner. Currently, Category II tracings should be evaluated as suggested earlier by assessment of the presence of moderate variability and spontaneous or provoked accelerations, which suggest a nonacidotic fetus.[72]

The identification of potential intrapartum fetal compromise with a Category II tracing should prompt a careful assessment of maternal, placental, and fetal factors. Clinical history, physical findings, laboratory findings, and fetal monitoring (e.g., FHR, ultrasonography) should be used in an attempt to identify the etiology.[113,114]

Correctable **maternal factors** that may contribute to fetal compromise include pathologic states that result in hypoxemia or decreased oxygen delivery to the placenta. **Respiratory failure** caused by long-standing diseases (e.g., asthma) can be determined from the history and physical findings, whereas additional laboratory measurements may be necessary to diagnose pneumonia or pulmonary edema as an underlying cause. **Decreased oxygen delivery** to the placenta may result from acute (e.g., sepsis, hypotension) or chronic conditions. **Decreased uteroplacental perfusion** can result from reduced maternal cardiac output (e.g., cardiovascular disease) or chronic vascular disease (e.g., chronic hypertension, diabetes). Dehydration from prolonged labor is a more subtle cause of diminished uteroplacental perfusion.

Attention to the etiology of fetal hypoxemia and institution of appropriate treatments may mitigate fetal compromise. Administration of supplemental oxygen may enhance fetal oxygenation, even in the previously normoxemic mother; however, whether maternal oxygen therapy improves fetal outcome remains unclear.[115,116]

Uterine hypertonus or **frequent uterine contractions (tachysystole),** which may result in decreased uteroplacental perfusion, are known risks of oxytocin or prostaglandin compounds used for the induction of labor. Uterine contractions constrict the uterine spiral arteries, decreasing oxygen delivery to the placenta. A rare cause of fetal compromise is **uterine rupture,** which may result from uterine hyperstimulation,

TABLE 8.1 Various Intrauterine Resuscitative Measures for Category II or Category III Tracings or Both

Goal	Associated Fetal Heart Rate Abnormality*	Potential Intervention(s)†
Promote fetal oxygenation and improve uteroplacental blood flow	Recurrent late decelerations Prolonged decelerations or bradycardia Minimal or absent fetal heart rate variability	Initiate lateral positioning (either left or right) Administer maternal oxygen Administer intravenous fluid bolus Reduce uterine contraction frequency
Reduce uterine activity	Tachysystole with Category II or III tracing	Discontinue oxytocin or cervical ripening agents Administer tocolytic medication (e.g., terbutaline)
Alleviate umbilical cord compression	Recurrent variable decelerations Prolonged decelerations or bradycardia	Initiate maternal repositioning Initiate amnioinfusion If prolapsed umbilical cord is noted, elevate the presenting fetal part while preparations are underway for operative delivery

*Evaluation for the underlying suspected cause(s) is also an important step in management of abnormal FHR tracings.
†Depending on the suspected underlying cause(s) of FHR abnormality, combining multiple interventions simultaneously may be appropriate and potentially more effective than doing individually or serially (Simpson KR, James DC. Efficacy of intrauterine resuscitation techniques in improving fetal oxygen status during labor. *Obstet Gynecol.* 2005;105:1362–1368).
From American College of Obstetricians & Gynecologists: Practice Bulletin No. 116: Management of intrapartum fetal heart rate tracings. *Obstet Gynecol.* 2010;116:1232–1240.

particularly in the setting of a uterine scar. **Placental abruption,** which may result in a partial or complete cessation of oxygen transfer to the fetus, can be associated with chronic or acute diseases. Long-standing vascular diseases, produced by chronic hypertension or smoking, and acute factors such as cocaine abuse and abdominal trauma, can precipitate a placental abruption.

The treatment of uteroplacental causes of fetal compromise includes correction of uterine hypertonus or tachysystole by cessation of oxytocin infusion (Table 8.1). Oxytocin has a plasma half-life of 1 to 6 minutes, and consequently, it may take several minutes for the hypertonus to be relieved. Alternatively, a tocolytic agent (e.g., terbutaline, nitroglycerin, magnesium sulfate) may be administered.[113,114,117] Normal maternal circulation should be maintained by avoiding aortocaval compression with position change, expanding intravascular volume, and giving a vasopressor (e.g., phenylephrine, ephedrine) if indicated.[118]

Fetal factors may contribute to fetal hypoxemia and acidosis. **Umbilical cord prolapse** through the cervix causes cord compression and often results in sudden fetal bradycardia. In the vast majority of circumstances, treatment of a prolapsed cord consists of manual elevation of the fetal head until emergency cesarean delivery can be accomplished. Only rarely should the umbilical cord be returned into the uterus and expectant care be attempted.[119] Reports from the developing world indicate that, in some cases, expeditious vaginal delivery may produce acceptable neonatal outcome.[120] Alternative methods to decompress a prolapsed umbilical cord include the use of the Trendelenburg position or an infusion of 500 to 700 mL of 0.9% saline into the maternal bladder until delivery can be expedited.[119,121,122]

Umbilical cord prolapse is not the only cause of **umbilical cord compression.** Much more commonly, such compression occurs within the uterus and manifests as variable FHR decelerations or bradycardia. **Oligohydramnios** is a risk factor for this type of cord compression, and a **change in maternal position** or the use of **saline amnioinfusion** may be therapeutic. Amnioinfusion presumably restores the natural cushion of amniotic fluid, and studies suggest that it reduces the frequency of severe variable decelerations and the incidence of cesarean delivery, and increases the umbilical cord blood pH in women with preterm premature rupture of membranes (PROM), oligohydramnios, or variable decelerations during labor.[123,124] A 2012 Cochrane systematic review concluded that there was no advantage between *prophylactic* intrapartum amnioinfusion in patients with oligohydramnios and *therapeutic* amnioinfusion in patients with both oligohydramnios and FHR abnormalities.[125]

Initial studies suggested that in patients with thick, meconium-stained amniotic fluid, amnioinfusion might decrease the incidence of meconium aspiration syndrome and fetal acidosis.[126] A meta-analysis of studies, however, suggests no benefit of amnioinfusion in the setting of meconium unless decelerations resulting from oligohydramnios are present.[126,127]

Saline amnioinfusion requires a dilated cervix, ruptured membranes, and the placement of an intrauterine catheter. Equipment that allows simultaneous saline amnioinfusion and measurement of intrauterine pressure is preferred. Either normal saline or lactated Ringer's solution may be infused as a bolus or as a continuous infusion.[128] The ideal rate of infusion has not been determined, but a commonly used regimen consists of a bolus of as much as 800 mL (infused at a rate of 10

to 15 mL/min), followed by either a continuous infusion at a rate of 3 mL/min or repeated boluses of 250 mL, as needed.[128] The necessity of either an infusion pump or a fluid warmer has not been demonstrated.[128] Alleviation of abnormal FHR patterns generally requires 20 to 30 minutes.[128]

Although most studies suggest that amnioinfusion is safe for the mother and fetus, some complications have been reported. Overdistention of the uterus, a higher rate of maternal infection, and maternal respiratory distress, including cases of fatal amniotic fluid embolism, have occurred.[129,130] A causal relationship between amniotic fluid embolism and amnioinfusion has yet to be determined. Overdistention of the uterus may be controlled with proper documentation of fluid loss from the uterus during infusion, the provision of amnioinfusion by gravity instead of an infusion pump, and the use of ultrasonography to evaluate the fluid volume.[128]

Maternal fever may increase fetal oxygen consumption. Obstetricians should treat maternal fever with acetaminophen, a cooling blanket, and antibiotics as indicated to maintain maternal and fetal euthermia. **Hyperglycemia** also increases fetal oxygen consumption, so administration of a large bolus of a glucose-containing solution is contraindicated.

Fetal cardiac failure results in inadequate umbilical blood flow and fetal hypoxemia and acidosis. **Fetal anemia** caused by maternal isoimmunization, fetal hemoglobinopathy, or fetal hemorrhage results in diminished fetal oxygen-carrying capacity. There are few options for the treatment of fetal cardiac failure or anemia during labor.

Standardization of FHR tracing interpretation and staged levels of intervention based on likely etiology of the FHR abnormalities will assist in guiding obstetric management. If intrapartum assessment suggests the presence of fetal compromise and fetal therapy is unsuccessful, the obstetrician should affect an expeditious, atraumatic delivery.

KEY POINTS

- A normal FHR tracing accurately predicts fetal well-being. An abnormal tracing is not specific in the prediction of fetal compromise. Exceptions include the fetus with prolonged bradycardia or the fetus with late FHR decelerations and absence of variability; both suggest a high likelihood of fetal hypoxia/acidemia.
- Large, prospective, randomized studies have not confirmed that continuous electronic FHR monitoring confers substantial clinical benefit over intermittent FHR auscultation as performed by dedicated labor nurses.
- The specificity of FHR monitoring may be improved by the use of fetal scalp stimulation and fetal vibroacoustic stimulation.
- Neither fetal pulse oximetry nor fetal ST segment analysis reduce the rate of cesarean delivery.
- When a Category II FHR tracing occurs, fetal resuscitation *in utero* may be attempted with interventions that include maternal position change, treatment of uterine tachysystole, intravenous fluid bolus, administration of supplemental oxygen, and/or saline amnioinfusion.

Neonatal Assessment and Resuscitation

Susan W. Aucott, MD, Jamie D. Murphy, MD

CHAPTER OUTLINE

The transition from intrauterine to extrauterine life represents the most important adjustment that a neonate will make. This transition occurs uneventfully after most deliveries and is dependent on the anatomic and physiologic condition of the infant, the ease or difficulty of the delivery, and the extrauterine environmental conditions. When the transition is unsuccessful, prompt assessment and supportive care must be initiated immediately.

At least one person skilled in neonatal resuscitation should be present at every delivery.[1] The resuscitation team may include personnel from the pediatric, anesthesiology, obstetric, respiratory therapy, and nursing services. The composition of the team varies among institutions, but there should be some form of 24-hour coverage in all hospitals that provide labor and delivery services.[1] A multidisciplinary team should participate in the process of ensuring that appropriate personnel and equipment are available for neonatal resuscitation.[1]

All personnel working in the delivery area should receive basic training in neonatal resuscitation to ensure prompt initiation of care before the arrival of the designated resuscitation team. The 2015 American Heart Association (AHA) Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care led to the publication of updated guidelines for neonatal resuscitation.[2] Changes in these guidelines reflected a review of scientific evidence by members of the American Academy of Pediatrics (AAP), the AHA, and the International Liaison Committee on Resuscitation. These guidelines have been incorporated into the Neonatal Resuscitation Program (NRP), which is the standardized training and certification program administered by the AAP. The NRP, which was originally sponsored by the AAP and the AHA in 1987, is designed to be appropriate for all personnel who attend deliveries. To ensure the implementation of current guidelines for neonatal resuscitation, the AAP recommends that at least one NRP-certified practitioner attend every delivery.[2–4]

Both the American Society of Anesthesiologists (ASA) and the American College of Obstetricians and Gynecologists (ACOG) have published specific goals and guidelines for neonatal resuscitation (Box 9.1).[5] The ASA has emphasized that a single anesthesiologist should not be expected to assume responsibility for the concurrent care of both the mother and her child. Rather, a second anesthesia provider or a qualified individual from another service should assume responsibility for the care of the neonate, except in an unforeseen emergency.

Although the anesthesia provider is not usually the primary provider of neonatal resuscitation, he or she may be asked to provide assistance in cases of difficult airway management or when the neonatal resuscitation team has not yet arrived. The anesthesia provider should be prepared to provide assistance, provided that doing so does not compromise the care of the mother. Written hospital policies should identify the personnel responsible for neonatal resuscitation, and obstetric anesthesia providers should also maintain a high level of skill in neonatal resuscitation.

TRANSITION FROM INTRAUTERINE TO EXTRAUTERINE LIFE

Circulation

At birth, the circulatory system changes from a fetal circulation pattern (which is in parallel), through a transitional

BOX 9.1 Optimal Goals for Anesthesia Care in Obstetrics: Neonatal Resuscitation

Personnel other than the surgical team should be immediately available to assume responsibility for resuscitation of the depressed neonate. The surgeon and anesthesiologist are responsible for the mother and may not be able to leave her to care for the neonate, even when a neuraxial anesthetic is functioning adequately. Individuals qualified to perform neonatal resuscitation should demonstrate:

- Proficiency in rapid and accurate evaluation of the neonate's condition, including Apgar scoring
- Knowledge of the pathogenesis of a depressed neonate (acidosis, drugs, hypovolemia, trauma, anomalies, and infection) as well as specific indications for resuscitation
- Proficiency in neonatal airway management, laryngoscopy, endotracheal intubation, airway suctioning, artificial ventilation, cardiac massage, and maintenance of thermal stability

In larger maternity units and those functioning as high-risk centers, 24-hour in-house anesthesia, obstetric, and neonatal specialists are usually necessary.

Modified from a joint statement from the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists. Optimal goals for anesthesia case in obstetrics. Approved by the American Society of Anesthesiologists in October 2008. (See Appendix C for full document.)

circulation, to an adult circulation pattern (which is in series) (Fig. 9.1).[6] In the fetus, blood from the placenta travels through the umbilical vein and the ductus venosus to the inferior vena cava and the right side of the heart. The anatomic orientation of the inferior vena caval–right atrial junction favors the shunting (i.e., streaming) of this well-oxygenated blood through the foramen ovale to the left side of the heart. The blood is then pumped through the ascending aorta, where branches that perfuse the upper part of the body (e.g., heart, brain) exit proximal to the entrance of the ductus arteriosus.[7] Desaturated blood returns to the heart from the upper part of the body via the superior vena cava. The anatomic orientation of the superior vena caval–right atrial junction favors the streaming of blood into the right ventricle. Because fetal pulmonary vascular resistance is higher than systemic vascular resistance (SVR), approximately 90% of the right ventricular output passes through the ductus arteriosus and enters the aorta distal to the branches of the ascending aorta and aortic arch; therefore, blood that is less well-oxygenated perfuses the lower body, which has a lower oxygen consumption than the heart and brain. Deoxygenated blood from the fetus returns to the placental circulation via the umbilical arteries.

At the time of birth and during the subsequent period of circulatory transition, the amount of blood that shunts through the foramen ovale and ductus arteriosus diminishes,

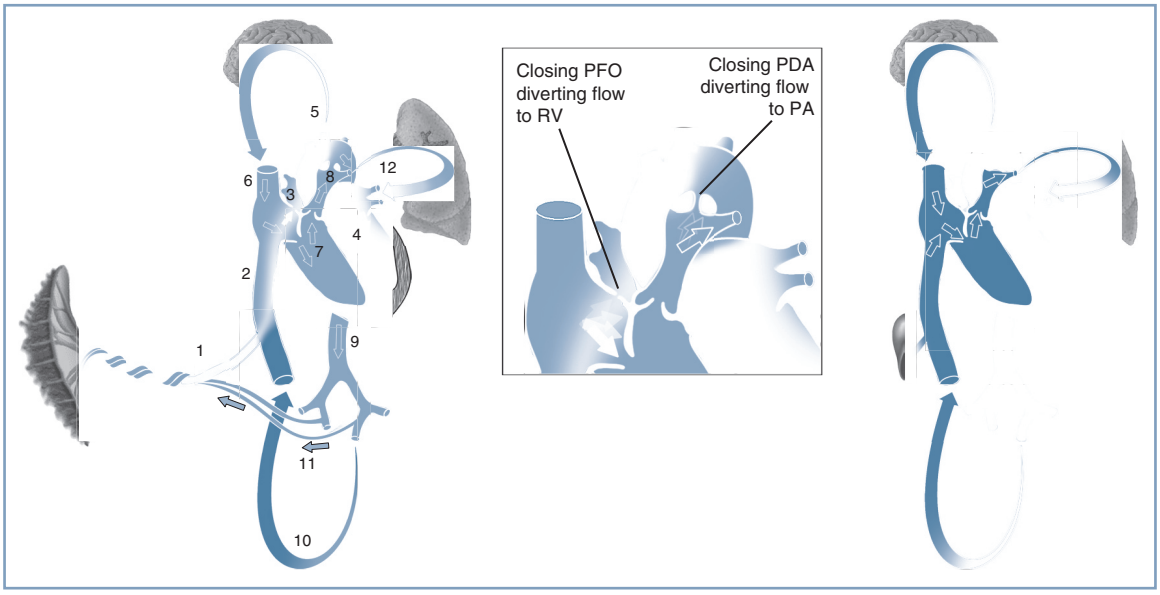

Fig. 9.1 Modification of blood flow patterns from the fetal *(left),* via the transitional *(center),* to the neonatal *(right)* circulation. In the fetal circulation, oxygenated blood *(white)* from the placenta travels through the umbilical vein *(1)* into the ductus venosus and the inferior vena cava *(2).* The majority of oxygenated blood passes through the patent foramen ovale *(PFO)* from the right atrium to the left atrium *(3)* and ventricle *(4),* and distributes this blood to the brain *(5).* The deoxygenated blood *(blue)* from the brain and upper extremities enters the superior vena cava, mixing with a small portion of the oxygenated blood in the right atrium, before entering the right ventricle *(RV, 7).* The mostly deoxygenated blood is transported into the pulmonary artery, where the majority is diverted through the patent ductus arteriosus *(PDA, 8)* into the descending aorta *(9),* thereby bypassing the lungs. Some blood enters the lower body *(10),* but the majority returns to the placenta via the umbilical arteries *(11).* A small amount of blood from the pulmonary artery enters the lungs *(12).* During the transitional circulation, which occurs over a few days, the PFO closes, diverting blood from the right atrium to the right ventricle. Closure of the PDA diverts deoxygenated blood through the pulmonary arteries to the lungs. The neonatal circulation separates the oxygenated and deoxygenated blood flow pathways. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

and flow becomes bidirectional. Clamping the umbilical cord (or exposing the umbilical cord to room air) results in increased SVR. Concurrently, expansion of the lungs and increased alveolar oxygen tension and pH result in decreased pulmonary vascular resistance and greater flow of pulmonary artery blood through the lungs.[8,9] Increased pulmonary artery blood flow results in improved oxygenation and higher left atrial pressure; the latter leads to a diminished shunt across the foramen ovale. Increased Po_2 and SVR and decreased pulmonary vascular resistance result in a constriction of the ductus arteriosus.[10,11] Together, these changes in vascular resistance result in functional closure of the foramen ovale and the ductus arteriosus. This process does not occur instantaneously, and arterial oxygen saturation (Sao_2) remains higher in the right upper extremity (which is preductal) than in the left upper extremity and the lower extremities until blood flow through the ductus arteriosus is minimal.[12] Differences in Sao_2 are usually minimal by 10 minutes and absent by 24 hours after birth. Provided there is no interference with the normal drop in pulmonary vascular resistance, both the foramen ovale and the ductus arteriosus close functionally as the infant transitions to an adult circulation.

Persistent pulmonary hypertension of the newborn (previously referred to as persistent fetal circulation) can occur when the pulmonary vascular resistance remains elevated at the time of birth. Factors that may contribute to this problem include hypoxia, acidosis, hypovolemia, and hypothermia.[9,13] Maternal use of nonsteroidal anti-inflammatory drugs may also cause premature constriction of the ductus arteriosus in the fetus and thus predispose to persistent pulmonary hypertension of the newborn.[14]

Respiration

Fetal breathing movements have been observed *in utero* as early as 11 weeks' gestation. These movements increase with advancing gestational age but undergo a marked reduction within days of the onset of labor. They are stimulated by hypercapnia and maternal smoking, and are inhibited by hypoxia and central nervous system (CNS) depressants (e.g., barbiturates). Under normal conditions, this fetal breathing activity results only in the movement of pulmonary dead space.[15]

The fetal lung contains a liquid composed of an ultrafiltrate of plasma, which is secreted by the lungs *in utero*[16]; the volume of this lung liquid is approximately 30 mL/kg. Partial reabsorption of this liquid occurs during labor and delivery, and approximately two-thirds is expelled from the lungs of the term neonate by the time of delivery.[17] Preterm infants and infants requiring cesarean delivery without labor may have a greater amount of residual lung liquid after delivery owing to a reduced catecholamine surge at delivery that promotes sodium channel transport; this residual lung liquid leads to difficulty in the initiation and maintenance of normal breathing patterns, and is the presumed cause of **transient tachypnea of the newborn (TTN).**[18]

The first breath occurs approximately 9 seconds after delivery. Air enters the lungs as soon as the intrathoracic pressure begins to decrease. This air movement during the first breath is important, because it establishes the neonate's functional residual capacity (Fig. 9.2).

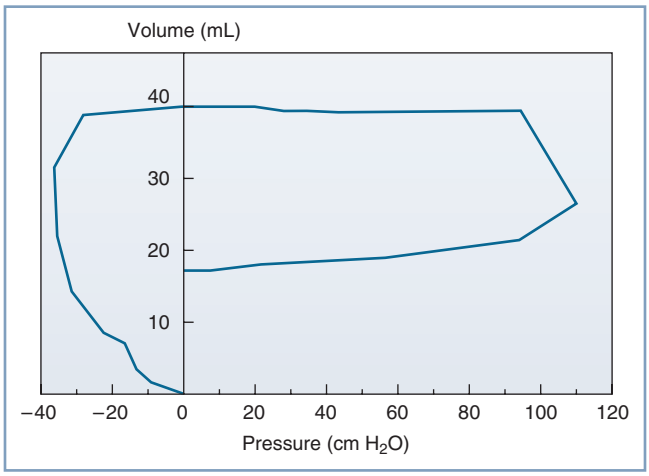

Fig. 9.2 Typical pressure-volume loop of the neonate's first breath. The intrathoracic pressure decreases to –30 to –40 cm H_2O, drawing air into the lungs. The expiratory pressure is much greater than the inspiratory pressure. (Modified from Milner AD, Vyas H. Lung expansion at birth. *J Pediatr.* 1982;101:879–886.)

Lung inflation is a major physiologic stimulus for the release of lung surfactant into the alveoli.[19] Surfactant, which is necessary for normal breathing, is present within the alveolar lining cells by 20 weeks' gestation[20] and within the lumen of the airways by 28 to 32 weeks' gestation. However, significant amounts of surfactant do not appear in terminal airways until 34 to 38 weeks' gestation unless its production has been stimulated by chronic stress or maternal corticosteroid administration.[21] Stress during labor and delivery can lead to the passage of meconium into the amniotic fluid and gasping efforts by the fetus, which may result in the aspiration of amniotic fluid into the lungs.[22]

Catecholamines

Transition to extrauterine life is associated with a catecholamine surge, which may be necessary for the process to be successful. In chronically catheterized sheep, catecholamine levels begin to rise a few hours before delivery and may be higher at the time of delivery than at any other time during life.[23] Catecholamines have an important role in the following areas: (1) the production and release of surfactant, (2) the transition to active sodium transport for absorption of lung fluid, (3) the mediation of preferential blood flow to vital organs during the period of stress that occurs during every delivery, and (4) thermoregulation of the neonate.

Thermal Regulation

Thermal stress challenges the neonate in the extrauterine environment. Neonates raise their metabolic rate and release norepinephrine in response to cold; this response facilitates the oxidation of brown fat, which contains numerous mitochondria. The oxidation results in **nonshivering thermogenesis,** the major mechanism for neonatal heat regulation.[24]

This process may lead to significant oxygen consumption, especially if the neonate has not been dried and placed in an appropriate thermoneutral environment, for example with a radiant warmer. Thermal stress is an even greater problem in infants with low fat stores, such as preterm infants or infants who are small for gestational age. An alternative method to eliminate heat loss from evaporation is to provide an occlusive wrap rather than drying the infant. For infants born at less than 28 weeks' gestation, the use of polythene wraps or bags is recommended to minimize heat loss.[25,26] The maintenance of a neutral thermal environment (i.e., 34° to 35°C) is recommended. However, in the neonate with a perinatal brain injury, mild hypothermia therapy through selective head or whole-body cooling is initiated in the first 6 hours of life and may be neuroprotective in the setting of hypoxia-ischemia.[27,28] Hyperthermia may worsen neurologic outcomes and should be avoided.[2,29] Hypothermia therapy, via selective head cooling or whole-body hypothermia, is continued for 72 hours after initiation. Consequently, if an infant is delivered at a center where hypothermia therapy is unavailable, passive cooling can be initiated by turning the radiant warmer off while awaiting infant transfer.

Administration of epidural analgesia during labor is associated with an increase in maternal and fetal temperature, which might result in an increase in the frequency of neonatal sepsis evaluations.[30] However, a number of variables (e.g., preeclampsia/hypertension, gestational age, birth weight, meconium aspiration, respiratory distress at birth, hypothermia at birth, and group B beta-hemolytic streptococcal colonization of the maternal birth canal) have been observed to be strong predictors of the performance of neonatal sepsis evaluations, whereas maternal fever and epidural analgesia have not.[31] Confounding variables may influence the findings of these types of association studies; patients who choose either to receive or not receive epidural analgesia may be inherently different. The incidence of actual neonatal sepsis is not different in term infants whose mothers either did or did not receive epidural analgesia.

In infants not requiring immediate resuscitation, providing skin-to-skin contact with the mother can allow for appropriate thermal regulation, enhance breast-feeding, and reduce maternal stress. This practice must be associated with close monitoring to prevent the infant from slipping off the mother, and to detect sudden unexpected postnatal collapse (SUPC). Although rare, SUPC can be a fatal event in an otherwise healthy appearing infant, and requires adequate personnel to provide observation, monitoring, and treatment.[32]

BOX 9.2 Risk Factors Suggesting a Greater Need for Neonatal Resuscitation

Antepartum Risk Factors

- Maternal diabetes
- Hypertensive disorder of pregnancy
- Chronic hypertension
- Fetal anemia or isoimmunization
- Previous fetal or neonatal death
- Bleeding in second or third trimester
- Maternal infection
- Maternal cardiac, pulmonary, renal, thyroid, or neurologic disease
- Polyhydramnios
- Oligohydramnios
- Premature rupture of membranes
- Fetal hydrops
- Postterm gestation
- Multiple gestation
- Discrepancy between fetal size and dates (i.e., last menstrual period)
- Drug therapy (e.g., lithium carbonate, magnesium, adrenergic-blocking drugs)
- Maternal substance abuse
- Fetal malformation
- Diminished fetal activity
- No prenatal care
- Maternal age > 35 years

Intrapartum Risk Factors

- Emergency cesarean delivery
- Forceps or vacuum-assisted delivery
- Breech or other abnormal presentation
- Preterm labor
- Precipitous labor
- Chorioamnionitis
- Prolonged rupture of membranes (> 18 hours before delivery)
- Prolonged labor (> 24 hours)
- Macrosomia
- Category II or III fetal heart rate patterns
- Use of general anesthesia
- Uterine tachysystole with fetal heart rate changes
- Maternal administration of opioids within 4 hours of delivery
- Meconium-stained amniotic fluid
- Prolapsed umbilical cord
- Placental abruption
- Placenta previa
- Significant intrapartum bleeding

Modified from *Textbook of Neonatal Resuscitation*, 6th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2011:216.

ANTENATAL ASSESSMENT

Approximately 10% of neonates require some level of resuscitation.[2] The need for resuscitation can be predicted before labor and delivery with approximately 80% accuracy on the basis of a number of antepartum factors (Box 9.2).

Preterm delivery increases the likelihood that the neonate will require resuscitation. When a mother is admitted with either preterm labor or premature rupture of membranes, plans should be made for neonatal care in the event of delivery. The antenatal assessment of gestational age is based on the presumed date of the last menstrual period, the fundal height, and ultrasonographic measurements of the fetus. Unfortunately, it may be difficult to assess gestational age accurately, because menstrual dates may be

unknown or incorrect, the fundal height may be affected by abnormalities of fetal growth or amniotic fluid volume, and ultrasonographic assessment of fetal age is less precise after mid-pregnancy. The assessment of gestational age is most accurate in patients who receive prenatal care in early pregnancy and enables the health care team to plan for the neonatal needs and to appropriately counsel the parents regarding neonatal morbidity and mortality. These plans and expectations must be formulated with caution and flexibility, because the antenatal assessment may not accurately predict neonatal size, maturity, and/or condition at delivery.

A variety of **intrauterine insults** can impair the fetal transition to extrauterine life. For example, neonatal depression at birth can result from acute or chronic uteroplacental insufficiency or acute umbilical cord compression. Chronic uteroplacental insufficiency, regardless of its etiology, may result in fetal growth restriction. Fetal hemorrhage, viral or bacterial infection, meconium aspiration, and exposure to opioids or other CNS depressants also can result in neonatal depression. Although randomized trials have not confirmed that fetal heart rate (FHR) monitoring improves neonatal outcome, a nonreassuring FHR tracing is considered a predictor of the need for neonatal resuscitation.[33]

Studies have evaluated the use of fetal pulse oximetry for the evaluation of fetal well-being during labor. This technique involves the transcervical insertion of a flexible fetal oxygen sensor until it rests against the fetal cheek. A randomized trial found that use of fetal pulse oximetry in conjunction with FHR monitoring led to a reduction in the number of cesarean deliveries performed for a nonreassuring FHR tracing.[34] However, this decrease was offset by an increased number of cesarean deliveries performed for dystocia, raising the concern that the presence of the probe might predispose to dystocia. As a consequence, the ACOG has recommended further study before fetal pulse oximetry is used routinely in clinical practice.[35] A meta-analysis of five trials concluded that there was some benefit to fetal pulse oximetry in the presence of a nonreassuring FHR tracing, but the use of fetal pulse oximetry did not lead to an overall reduction in the cesarean delivery rate.[36]

Infants with **congenital anomalies** (e.g., tracheoesophageal fistula, diaphragmatic hernia, CNS and cardiac malformations) may need resuscitation and cardiorespiratory support. Improved ultrasonography allows for the antenatal diagnosis of many congenital anomalies and other fetal abnormalities (e.g., nonimmune hydrops). Obstetricians should communicate knowledge or suspicions regarding these entities to those who will provide care for the neonate in the delivery room to allow the resuscitation team to make specific resuscitation plans.

In the past, infants born by either elective or emergency cesarean delivery were considered more likely to require resuscitation than infants delivered vaginally. Evidence suggests that repeat cesarean deliveries and those performed for dystocia—in patients without FHR abnormalities—result in the delivery of infants at low risk for neonatal resuscitation, especially when the cesarean deliveries are performed with neuraxial anesthesia.[3,4,37] Of interest, infants born by elective repeat cesarean delivery are at higher risk for subsequent respiratory problems (e.g., TTN) than infants born vaginally. In addition, infants born by cesarean delivery after a failed trial of labor are at a higher risk for neonatal sepsis than similar infants born vaginally.[38] Emergency cesarean delivery is considered a risk factor for the need for neonatal resuscitation.

NEONATAL ASSESSMENT

Apgar Score

Resuscitative efforts typically precede the performance of a thorough physical examination of the neonate. Because NRP instructions require simultaneous assessment and treatment, it is important that the neonatal assessment be both simple and sensitive. In 1953, Virginia Apgar, an anesthesiologist, described a simple method for neonatal assessment that could be performed while care is being delivered.[39] She suggested that this standardized and relatively objective scoring system would differentiate between infants who require resuscitation and those who need only routine care.[40]

The Apgar score is based on five parameters that are assessed at 1 and 5 minutes after birth. Further scoring at 5- or 10-minute intervals may be done if initial scores are low. The parameters are: heart rate, respiratory effort, muscle tone, reflex irritability, and color. A score of 0, 1, or 2 is assigned for each of these five entities (Table 9.1). A total score of 8 to 10 is normal, a score of 4 to 7 indicates moderate impairment, and

TABLE 9.1 Apgar Scoring System

	SCORE		
Parameter	**0**	**1**	**2**
Heart rate (bpm)	Absent	< 100	> 100
Respiratory effort	Absent	Irregular, slow, shallow, or gasping respirations	Robust, crying
Muscle tone	Absent, limp	Some flexion of extremities	Active movement
Reflex irritability (nasal catheter, oropharyngeal suctioning)	No response	Grimace	Active coughing and sneezing
Color	Cyanotic	Acrocyanotic (trunk pink, extremities blue)	Pink

Modified from Tabata BK. Neonatal resuscitation. In: Rogers MC, ed. *Current Practice in Anesthesiology*, 2nd ed. St. Louis, MO: Mosby; 1990:368.

a score of 0 to 3 signals the need for immediate resuscitation. Dr. Apgar emphasized that this system does not replace a complete physical examination and serial observations of the neonate for several hours after birth.[41]

The Apgar score is widely used to assess neonates, although its value has been questioned. The scoring system may help predict mortality and neurologic morbidity in *populations* of infants, but Dr. Apgar cautioned against the use of the Apgar score to make these predictions in an *individual* infant. She noted that the risk for neonatal mortality was inversely proportional to the 1-minute score.[41] In addition, the one-minute Apgar score was a better predictor of mortality within the first 2 days of life than within 2 to 28 days of life.

Several studies have challenged the notion that a low Apgar score signals perinatal asphyxia. In a prospective study of 1210 deliveries, Sykes et al.[42] noted a poor correlation between the Apgar score and the umbilical cord blood pH. Other studies, including those of low-birth-weight infants, have found that a low Apgar score is a poor predictor of neonatal acidosis, although a high score is reasonably specific for excluding the presence of severe acidosis.[43-49] By contrast, the fetal biophysical profile has a good correlation with the acid-base status of the fetus and the neonate (see Chapter 6).[50] The biophysical profile includes performance of a nonstress test and ultrasonographic assessment of fetal tone, fetal movement, fetal breathing movements, and amniotic fluid volume.[50]

Additional studies have suggested that Apgar scores are poor predictors of long-term neurologic impairment.[51,52] The Apgar score is more likely to predict a poor neurologic outcome when the score remains 3 or less at 10, 15, and 20 minutes. However, when a child has cerebral palsy, low Apgar scores alone are not adequate evidence that perinatal hypoxia was responsible for the neurologic injury.

The ACOG Task Force on Neonatal Encephalopathy and Cerebral Palsy published criteria for defining an intrapartum event sufficient to cause cerebral palsy.[53] An Apgar score of 0 to 3 beyond 5 minutes of age is not included in the list of "essential criteria"; rather, it is one of five criteria that "collectively suggest an intrapartum timing (within close proximity to labor and delivery…) but are nonspecific to asphyxial insults."[53–58]

In summary, the usefulness of the Apgar score is still being debated more than 50 years after its inception.[59,60] The Apgar scoring system is used throughout the world, but its limitations must be kept in mind. Low Apgar scores alone do not provide sufficient evidence of perinatal asphyxia; rather, Apgar scores can be low for a variety of reasons. Preterm delivery, congenital anomalies, neuromuscular diseases, antenatal drug exposure, manipulation at delivery, and subjectivity and error may influence the Apgar score.

Umbilical Cord Blood Gas and pH Analysis

Umbilical cord blood gas and pH measurements reflect the fetal condition immediately before delivery and can be obtained routinely after delivery or measured only in cases of neonatal depression. These measurements may be a more objective indication of a neonate's condition than the Apgar score. However, there is a delay between obtaining the samples and completing the analysis; during this interval, decisions must be made on the basis of clinical assessment. The ACOG[61] has recommended that cord blood gas measurements be obtained in circumstances of cesarean delivery for fetal compromise, low 5-minute Apgar score, severe growth restriction, abnormal FHR tracing, maternal thyroid disease, intrapartum fever, and/or multiple gestation.

The fetus produces carbonic acid (from oxidative metabolism) and lactic and beta-hydroxybutyric acids (primarily from anaerobic metabolism). Carbonic acid, which is often called *respiratory acid,* is cleared rapidly by the placenta as carbon dioxide when placental blood flow is normal. However, metabolic clearance of lactic and beta-hydroxybutyric acids requires hours; thus, these acids are called *metabolic* or *fixed acids.* In the fetus, metabolic acidemia is more ominous than respiratory acidemia because the former reflects a significant amount of anaerobic metabolism.

The measured components of umbilical cord blood gas analysis are pH, Pco_2, Po_2, and bicarbonate (HCO_3^-). HCO_3^- is a major buffer in fetal blood. The measure of change in the buffering capacity of umbilical cord blood is reflected in the delta base, which is also known as the base excess or deficit; this value can be calculated from the pH, Pco_2, and HCO_3^-. Ideally, blood samples from both the umbilical artery and vein are collected. Umbilical artery blood gas measurements represent the fetal condition, whereas umbilical vein measurements reflect the maternal condition and uteroplacental gas exchange. Unfortunately, it may be difficult to obtain blood from the umbilical artery, especially when it is small, as it is in very low-birth-weight (VLBW) infants. Caution should be used in the interpretation of an isolated umbilical venous blood pH measurement, which can be normal despite the presence of arterial acidemia.

Proper blood sampling and handling are necessary. The measurements should be accurate, provided that (1) the umbilical cord is double-clamped immediately after delivery[62–64]; (2) the samples are drawn, within 15 minutes of delivery,[65] into a syringe containing the proper amount of heparin[66]; and (3) the samples are analyzed within 30 to 60 minutes.[65,67] The Po_2 measurement is more accurate if residual air bubbles are removed from the syringe.

Historically, a normal umbilical cord blood pH measurement was believed to be 7.2 or higher.[68] However, investigators have challenged the validity of this number, given the lack of distinction between umbilical arterial and venous blood despite clear differences in their normal measurements.[69] One study noted that the median umbilical arterial blood pH in vigorous infants (those with 5-minute Apgar scores of 7 or higher) was 7.26, with a measurement of 7.10 representing the 2.5th percentile.[70] Published studies suggest that the lower limit of normal umbilical arterial blood pH measurements may range from 7.02 to 7.18 (Table 9.2).[42,71–80] A number of factors may also influence the umbilical arterial blood pH measurement. A fetus subjected to the stress of labor has lower pH than one born by cesarean delivery without labor.[77] Offspring of nulliparous women tend to have

TABLE 9.2 Studies Reporting Umbilical Cord Arterial Blood Gas Measurements[a]

Study	Sample Size	pH	P_{CO_2} (mm Hg)	Bicarbonate (mmol/L)	Base Deficit (mmol/L)	P_{O_2} (mm Hg)
Huisjes and Aarnoudse (1979)[74]	852	7.20 ± 0.09 (7.02–7.38)

a lower pH than offspring of parous women, a difference that is likely related to a difference in the duration of labor.[81]

Some studies have suggested that preterm infants have a higher incidence of acidemia; however, later studies have observed that term and preterm infants have similar umbilical cord blood gas and pH measurements.[72,73,81] Preterm infants often have low Apgar scores despite the presence of normal umbilical cord blood gas and pH measurements; therefore, the assessment of umbilical cord blood may be especially helpful in the evaluation of preterm neonates.

Physicians should use strict definitions when interpreting umbilical cord blood gas and pH measurements. Terms such as *birth asphyxia* should be avoided in most cases.[53] *Acidemia* refers to an increase in the hydrogen ion concentration in the blood. *Acidosis* occurs when there is an increased hydrogen ion concentration in tissue. *Asphyxia* is a clinical situation that involves hypoxia (i.e., a decreased level of oxygen in tissue), damaging acidemia, and metabolic acidosis.

When acidemia is present, the type—respiratory, metabolic, or mixed—must be identified (Table 9.3). Metabolic acidemia is more likely to be associated with acidosis than respiratory acidemia and is clinically more significant. Similarly, mixed acidemia with a high P_{CO_2}, an extremely low HCO_3^-, and a high base deficit is more ominous than a mixed acidemia with a high P_{CO_2} but only a slightly reduced HCO_3^- and a low base deficit. Mixed or metabolic acidemia (but not respiratory acidemia) is associated with an increased incidence of neonatal complications and death.[81] In their study of 3506 term neonates, Goldaber et al.[82] noted that an umbilical arterial blood pH measurement less than 7.00 was associated with a significantly higher incidence of neonatal death. All neonatal seizures in their study occurred in infants with an umbilical arterial blood pH less than 7.05. By contrast, a short-term outcome study failed to show a good correlation between arterial blood pH and the subsequent health of an infant.[49] In the previously discussed large study reported by Casey et al.,[59] umbilical arterial blood pH of 7.0 or less was a poorer predictor of the relative risk for neonatal death during the first 28 days of life than a 5-minute Apgar score of 3 or less. However, 6264 infants were excluded from their study because umbilical

arterial blood gas measurements could not be obtained, and these infants had a higher incidence of neonatal death than those for whom blood gas measurements were available (4.5 per 1000 versus 1.2 per 1000, respectively). In a separate review of 51,519 term deliveries, Yeh et al.[83] found an increased risk for adverse outcomes in infants with a pH less than 7.10, with the lowest risk in infants with a pH between 7.26 and 7.30; however, 75% of infants with neurologic morbidity had a normal pH. Thus, it is important to remember that neonates may suffer multiorgan system damage, including neurologic injury, even in the absence of low pH and Apgar scores.

According to the ACOG Task Force, an umbilical arterial blood pH less than 7.0 and a base deficit greater than or equal to 12 mmol/L at delivery are considered one part of the definition of an acute intrapartum hypoxic event sufficient to cause cerebral palsy.[53] The base deficit and bicarbonate (the metabolic component) values are the most significant factors associated with morbidity in neonates with an umbilical arterial blood pH less than 7.0. Ten percent of infants with an umbilical arterial base deficit of 12 to 16 mmol/L have moderate to severe complications, which increases to 40% when the deficit is greater than 16 mmol/L.[61]

Abnormal FHR patterns and umbilical cord blood gas measurements are not consistently correlated with poor neonatal outcomes.[33] In a longitudinal study that evaluated outcomes at 6.5 years of age, Hafstrom et al.[84] found that infants with an umbilical arterial blood pH less than 7.05 but a normal examination at birth had outcomes that did not differ from those for matched infants with a normal umbilical arterial blood pH.

As Virginia Apgar emphasized in 1962, the most important components of neonatal assessment are a careful physical examination and continued observation for several hours.[41] Additional information can be gained from the antenatal history, Apgar scores, and umbilical cord blood gas and pH measurements, provided that clinicians are aware of the proper methods of interpretation as well as the limitations of these methods of assessment.

Respiration and Circulation

There are some similarities between the initial assessment of the neonate and the initial assessment of an adult who requires resuscitation. In both situations, the physician should give immediate attention to the ABCs of resuscitation (i.e., airway, breathing, circulation).

The normal neonatal respiratory rate is between 30 and 60 breaths per minute. Breathing should begin by 30 seconds and be regular by 90 seconds of age. Failure of the neonate to breathe by 90 seconds of age represents either primary or secondary apnea. During *primary apnea,* but not secondary apnea, tactile stimulation can initiate breathing efforts. In addition, although heart rate may be low with both periods of apnea, a reduction in blood pressure occurs only during secondary apnea. Therefore, during evaluation of the apneic neonate, aggressive resuscitation must be initiated promptly if tactile stimulation does not result in the initiation of spontaneous breathing.

Assessment of the adequacy of respiratory function requires comprehensive observation for signs of neonatal respiratory distress. These signs include cyanosis, grunting, flaring of the nares, retracting chest motions, and unequal breath sounds. The adequacy of respiratory function can also be assessed by the estimation of Sao_2. Pulse oximetry provides accurate estimates of Sao_2 during periods of stability but may overestimate values during rapid desaturation.[85] In addition, the Sao_2 (Spo_2) measurements may fluctuate in the delivery room as a result of the ongoing transition from the fetal to the neonatal circulation, and it may take more than 10 minutes to achieve a preductal Sao_2 greater than 95% in a healthy term infant. Overall, the newer-generation pulse oximeters reliably provide continuous noninvasive Sao_2 measurements and are useful for neonatal monitoring.[86–88]

When cyanosis persists beyond 5 to 10 minutes, or supplemental oxygen is needed, the pulse oximeter sensor should be applied to the neonate's right upper extremity, which receives preductal blood flow (see earlier discussion); because CNS blood flow is also preductal, right upper extremity Sao_2 measurements provide a more accurate assessment of CNS oxygenation.[12] Sensor placement can be difficult on skin that is wet and covered with vernix caseosa; therefore, it may be easier to place the sensor over the right radial artery, especially in preterm infants.[89]

Neonatal arterial blood sampling is technically difficult and thus rarely obtained in the delivery room. Cannulation of the umbilical artery is useful in infants who will require frequent blood sampling. This procedure often requires the use of microinstruments (especially in preterm and VLBW infants) and the ability to monitor the infant when obscured from view by surgical drapes; therefore, this procedure is usually performed in the neonatal intensive care unit (NICU).

The normal neonatal heart rate may be greater than 160 beats per minute (bpm) in the very early preterm neonate, but it should be within the range of 120 to 160 bpm by 28 weeks' gestational age. Clinical determination of the heart rate can be done by lightly grasping the base of the umbilical cord to feel the arterial pulsations or by listening to the apical heartbeat. These methods have been found to be less reliable than an ECG.[90] Additionally, several studies have found the ECG to be more accurate than pulse oximetry.[87,91–94]

Measurement of arterial blood pressure is not a priority during the initial assessment and resuscitation of the neonate.[2] However, observation for signs of abnormal circulatory function is considered essential. These signs include cyanosis, pallor, mottled coloring, prolonged capillary refill time, and weakness or absence of pulses in the extremities. One of the causes of abnormal circulatory function is hypovolemia, which should be anticipated in cases of bleeding from the umbilical cord or the fetal side of the placenta or whenever a neonate does not respond appropriately to resuscitation. The hypovolemic neonate may exhibit not only signs of abnormal circulatory function but also tachycardia and tachypnea (neonatal hypovolemia usually does not accompany placental abruption, which may cause maternal bleeding or other conditions associated with fetal asphyxia).

TABLE 9.4 Stages of Neonatal Hypoxic-Ischemic Encephalopathy

Stage I	Stage II	Stage III
Irritable	Lethargic/obtunded	Coma
Normal respirations	Depressed respirations	Apnea
Hypertonic	Hypotonic	Flaccid
Increased reflexes	Decreased reflexes	Absence of reflexes
No seizures	Occasional seizures	Status epilepticus or nearly isoelectric electroencephalogram
Good outcome	Moderate outcome	Poor outcome

Modified from Eicher DJ, Wagner CL. Update on neonatal resuscitation. *J S C Med Assoc.* 2002;98:114–120.

Neurologic Status

The initial neonatal neurologic assessment requires only simple observation. The neonate should demonstrate evidence of vigorous activity, including crying and active flexion of the extremities. Signs of possible neurologic abnormalities include apnea, seizures, hypotonia, and unresponsiveness. Neonates should be assessed for physical signs of hypoxic-ischemic encephalopathy (Table 9.4). The stages of hypoxic-ischemic encephalopathy are associated with different outcomes: stage I, good; stage II, moderate; and stage III, poor.[95] Although detailed neurologic assessment is performed after the neonate is transferred to the NICU, assessment of tone, baseline heart rate, respirations, and reflex activity is part of both the Apgar scoring system and the assessment for hypoxic-ischemic encephalopathy and is made initially in the delivery room.

Gestational Age

When assessing a very small neonate whose gestational age appears to be lower than that of viability, the evaluator must consider whether it is appropriate to initiate and maintain resuscitation efforts. The neonatal gestational age is often assessed with the use of the scoring systems described initially by Dubowitz et al.[96] and subsequently modified by Ballard et al,[97] using physical and neurologic criteria.

The Ballard score is most accurate when used to estimate gestational age at 30 to 42 hours, rather than during the first several minutes after birth, and is less accurate in very small preterm infants.[98,99]

Another commonly used criterion for the estimation of gestational age is birth weight. Normal values for birth weight are published and readily available.[100] Although birth weight may help physicians estimate the gestational age of an otherwise healthy preterm infant, physicians cannot rely on birth weight to provide an accurate estimate of gestational age in an infant who suffered from fetal growth restriction or who is large for gestational age.

Because of the potential for inaccurate gestational age estimation in the delivery room, it is best not to use scoring systems to guide decisions regarding the initiation or continuation of neonatal resuscitation immediately after delivery. In most circumstances, the neonate's response to resuscitative efforts is the best indicator as to whether further intervention is warranted.

NEONATAL RESUSCITATION

The equipment and medications needed for neonatal resuscitation are listed in Box 9.3. Equipment, supplies, and medications should be checked regularly to ensure that all components are available and functional.

Although previously published guidelines recommended suctioning of the mouth and nose after delivery of the head, current guidelines do *not* recommend routine intrapartum oropharyngeal and nasopharyngeal suctioning for infants born with either clear or meconium-stained amniotic fluid to avoid inducing bradycardia.[2,101]

Timing of cord clamping may vary by the gestational age and vigor of the infant. Current evidence supports a delay in cord clamping for 1 minute after the delivery of term and preterm infants not requiring resuscitation.[2] In preterm infants, delayed cord clamping is associated with improved blood pressure and a lower incidence of intraventricular hemorrhage[102]; no alterations in Apgar scores or need for delivery room resuscitation have been observed with this practice.[103] In nonvigorous infants, the benefits of delayed cord clamping may be outweighed by the need to promptly initiate resuscitation.

After delivery is complete, the neonate is transferred to the resuscitation area. The availability of sterile blankets allows the individual performing the delivery to remain sterile while transferring the infant; this issue is especially important during cesarean deliveries. The timing of delivery should be noted, assessment and appropriate resuscitative measures should be continued, and Apgar scores should be assigned at the appropriate intervals (Fig. 9.3).

Maintaining normal temperature during stabilization for non-asphyxiated infants is essential. The physician or nurse should place the infant beneath an overhead radiant warmer and promptly dry the skin of infants delivered at greater than 28 weeks' gestation. The infant who is delivered preterm at less than 28 weeks' gestation should be placed in a polythene bag or wrapping to prevent heat loss.[25,26] Additional methods to prevent hypothermia include increasing the room temperature and using a thermal mattress. Hypothermia can result in increased oxygen consumption and metabolic acidosis[104] and leads to a significantly higher mortality rate among preterm infants.[105]

Selective cerebral hypothermia[106] or whole-body hypothermia[27,28] may protect against brain injury in the asphyxiated

BOX 9.3 Equipment and Drugs Needed for Neonatal Resuscitation

Suction Equipment
- Bulb syringe
- Mechanical suction and tubing
- Suction catheters: 5F or 6F, 8F, and 10F or 12F
- 8F feeding tube and 20 mL syringe
- Meconium aspiration device

Bag-and-Mask Equipment
- Neonatal resuscitation bag with a pressure-release valve or pressure manometer and valve to deliver positive end-expiratory pressure (the bag must be capable of delivering 90% to 100% oxygen) or a pressure limiting T-piece resuscitator
- Face masks, term and preterm newborn sizes (masks with cushioned rim preferred)
- Air source with tubing
- Oxygen with flowmeter (flow rate up to 10 L/min) and tubing (including portable oxygen cylinders)
- Blender to mix air and oxygen to adjust oxygen delivery

Intubation Equipment
- Laryngoscope with straight blades: No. 0 (preterm) and No. 1 (term)
- Extra bulbs and batteries for laryngoscope
- Tracheal tubes: 2.5, 3.0, 3.5, and 4.0 mm ID
- Stylet (optional)
- Scissors
- Tape or securing device for tracheal tube
- Alcohol sponges
- CO_2 detector (optional)
- Laryngeal mask airway (optional)

Medications
- Epinephrine 1 : 10,000 (0.1 mg/mL), 3- or 10-mL ampules
- Isotonic crystalloid (normal saline or lactated Ringer's solution) for volume expansion, 100 or 250 mL
- Sodium bicarbonate 4.2% (5 mEq/10 mL), 10-mL ampules
- Normal saline, 30 mL
- Dextrose 10%, 250 mL
- Normal saline "fish" or "bullet" (optional)
- Feeding tube: 5F (optional)
- Umbilical vessel catheterization supplies:
  - Sterile gloves
  - Scalpel or scissors
  - Povidone-iodine solution
  - Umbilical tape
  - Umbilical catheters: 3.5 F, 5 F
  - Three-way stopcock
- Syringes: 1, 3, 5, 10, 20, and 50 mL
- Needles: 25, 21, and 18 gauge, or puncture device for needleless system

Miscellaneous
- Gloves and appropriate personal protection
- Radiant warmer or other heat source
- Firm, padded resuscitation surface
- Clock (timer optional)
- Warmed linens
- Stethoscope
- Tape: ½ or ¾ inch
- Cardiac monitor and electrodes and/or pulse oximeter with probe
- Oropharyngeal airways
- Polythene wrap or bags (for infants < 28 weeks' gestation)

ID, internal diameter.
Modified from *Textbook of Neonatal Resuscitation*, 6th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2011:216.

infant. The use of intentional hypothermia therapy requires an NICU with defined protocols and multidisciplinary support. When assessing an infant for hypothermia therapy, the radiant warmer can be turned off to allow passive cooling. With further assessment, if the criteria for hypothermia therapy are not met, the infant can be warmed slowly. Hyperthermia should be avoided in all infants.[2]

The neonate should be positioned in a way that allows the airway to remain open, with the head in the "sniffing" position (the neck flexed on the chest and the head extended on the neck, thereby aligning the oropharynx, pharynx, and hypopharynx). Suctioning of the mouth and nose with a bulb syringe may be necessary if secretions accumulate.

The neonate with a normal respiratory pattern, heart rate, and color requires no further intervention. Often the neonate has a normal respiratory pattern and heart rate but may not be pink. Acrocyanosis often persists for several minutes after delivery and does not require intervention. However, an evaluation for choanal atresia can be performed at this time with the gentle insertion of a small suction catheter through each nostril into the nasopharynx. Vigorous nasal suctioning should be avoided because it can cause trauma to the nasal mucosa and result in progressive edema and airway obstruction. The neonate is an obligate nasal breather; thus, choanal atresia is a potentially lethal anomaly that requires immediate attention. If this anomaly is present (as evidenced by failure of nasal passage of the catheter), the neonate should have an oral airway or endotracheal tube inserted and an evaluation performed for repair of the obstruction. The classic clinical presentation for choanal atresia is an infant with cyanosis and respiratory distress at rest who becomes pink when crying.

Tactile stimulation should be used if the neonate does not breathe immediately; this consists of gently rubbing the back and flicking the soles of the feet. Tactile stimulation does not trigger respiratory efforts during secondary apnea in the neonate. Therefore, if the neonate does not begin to breathe spontaneously after tactile stimulation, the evaluator should begin positive-pressure mask ventilation. If the neonate has an abnormally slow heart rate (i.e., less than 100 bpm), positive-pressure ventilation should be performed until the heart rate rises to the normal range. Overzealous tactile stimulation (e.g., slapping the back) is not useful; it

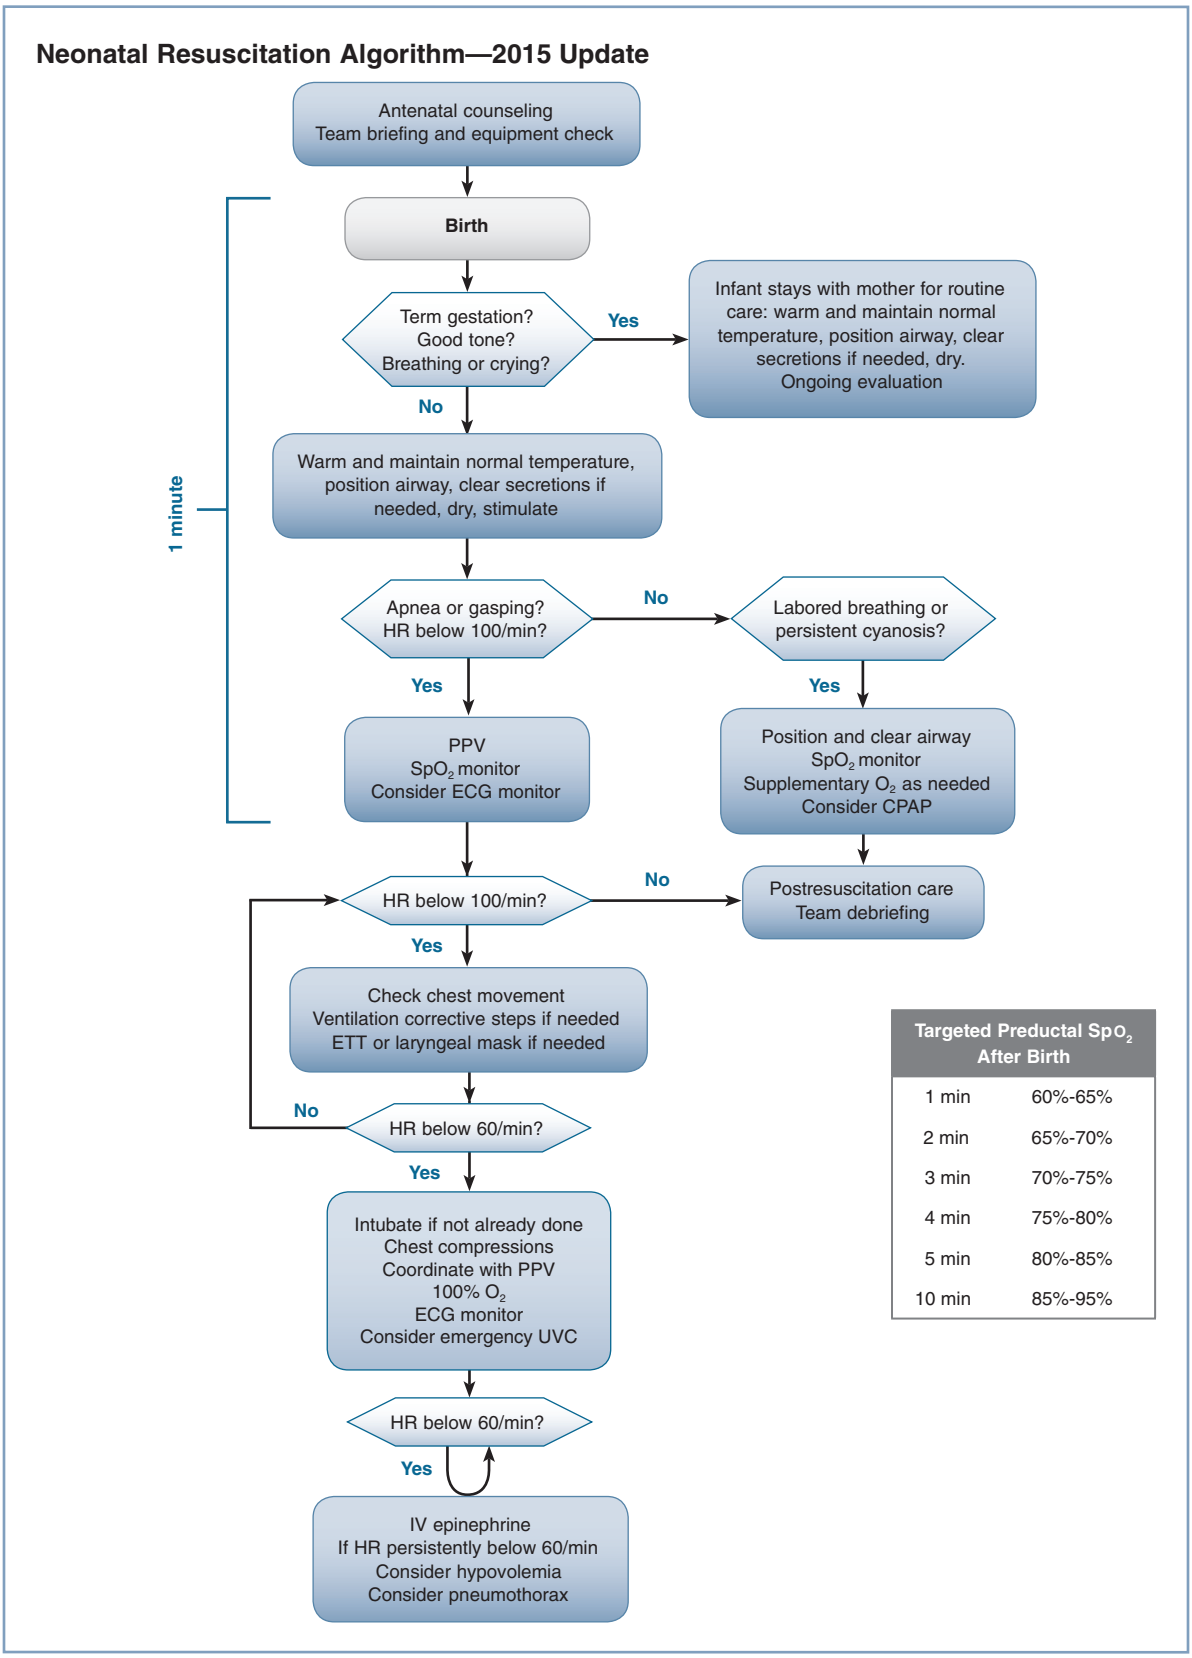

Fig. 9.3 Algorithm for resuscitation of the newly born infant. *HR,* heart rate; *PPV,* positive-pressure ventilation; *Spo_2,* oxygen saturation. (From Wyckoff MH, Aziz K, Escobedo MB, et al. Part 13: Neonatal Resuscitation: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 2015;132:S543–S560 with permission from the American Heart Association.)

provides no advantage over the more moderate methods and can cause traumatic injury. Infants with labored breathing or persistent cyanosis may benefit from continuous positive airway pressure.

High concentrations of oxygen (as opposed to ambient air) can raise production of oxygen free radicals, which have been linked to hypoxia-reoxygenation injury.[107] Additionally, an association between neonatal oxygen supplementation and childhood cancer has been noted with supplemental oxygen exposure for 3 minutes or longer.[108] In two studies, term or near-term infants were randomly assigned to receive neonatal resuscitation with either room air or 100% oxygen; no major outcome differences were observed.[109,110] Subsequently a pooled meta-analysis of five trials, consisting of 1032 term or near-term infants, showed a significantly lower mortality rate with no evidence of harm when resuscitation was performed initially with room air rather than 100% oxygen.[111] The current guidelines for neonatal resuscitation for term infants recommend the use of room air for assisted ventilation. A meta-analysis detected no significant differences in neurodevelopmental outcomes at 12 to 24 months of age between infants resuscitated with either room air or 100% oxygen,[112] with a recent publication showing more adverse outcomes using 100% oxygen.[113]

For preterm infants, several randomized trials have compared high oxygen (65% or greater) and low oxygen (21% to 30%) concentration with no benefit in survival or outcomes such as intraventricular hemorrhage or bronchopulmonary dysplasia,[114–120] with infants generally requiring 30% oxygen when stabilized. As a result, the current guidelines recommend resuscitation with 21% to 30% oxygen with titration as needed. Sao_2 measurements of 85% to 92% are thought to be adequate and appropriate for neonates of less than 35 weeks' gestation.

Positive-pressure ventilation must be performed correctly to ensure that it is effective and does not cause barotrauma. A ventilation bag with a volume of 250 to 500 mL may be used. The circuit must contain a safety pop-off pressure valve (e.g., at 35 cm H_2O), a visible pressure gauge, or both. An oxygen flow rate of 5 to 10 L/min is adequate. Alternatively, a T-piece, which is a valved mechanical device, may be used; it allows more consistent delivery of target inflation pressures and long inspiratory times. The mask must be of appropriate size and shape to ensure a good seal around the nose and mouth. A variety of masks should be available to accommodate infants of all sizes and gestational ages. For the infant with excessive occipital scalp edema (e.g., *caput succedaneum*), placing a small roll under the shoulders to alleviate hyperflexion of the neck may be helpful.

During the first assisted breath, positive pressure at 30 cm H_2O in term infants should be maintained for 4 to 5 seconds at the end of inspiration to overcome the surface tension of the lungs and open the alveoli.[121] The neonatal response to a large, rapid inflation of the lungs is a sharp inspiration of its own (Head's paradoxical reflex).[122] Subsequent breaths should be delivered at a rate of 40 to 60 breaths per minute, with intermittent inspiratory pauses to prevent the development of atelectasis. The maximum pressure generated should range between 20 and 30 cm H_2O, with an inspiration-to-expiration ratio of approximately 1 : 1. In preterm infants, whose lungs may be more easily injured, initial inflation pressures of 20 to 25 cm H_2O may be adequate. If mask ventilation is needed for longer than 2 to 3 minutes, the stomach should be emptied with an orogastric catheter. Distention of the stomach with air can compromise respiratory function in the neonate. This maneuver should be performed with care, because pharyngeal stimulation can result in bradycardia and apnea.[123]

The adequacy of respiratory resuscitation can be monitored from observation of its effect on heart rate; an increase in heart rate is the first consistently reliable sign of effective oxygenation. By contrast, changes in color occur slowly, are difficult to assess, and are a relatively poor index of successful resuscitation.

When the neonate's heart rate is higher than 100 bpm, positive-pressure ventilation can be stopped, and the infant can be reevaluated for spontaneous respiratory effort. If the neonate does not begin to breathe and if an opioid effect is the suspected etiology, administration of **naloxone** is *not* recommended. Naloxone can worsen the neurologic damage caused by asphyxia[124,125] and can precipitate acute neonatal opioid withdrawal, including seizure activity in cases of maternal opioid abuse. Assisted ventilation should be continued until resolution of the opioid effect rather than attempting to reverse it with naloxone.

If positive-pressure mask ventilation does not improve oxygenation (as reflected by an increase in heart rate), prompt tracheal intubation is indicated. Tracheal intubation must be performed gently to avoid damage to the delicate neonatal neck and airway. The size of the neonate's head is large relative to that of its body; therefore, the neonate is in the optimal position when it lies supine. In most cases, it is not necessary to elevate or hyperextend the neonate's head during laryngoscopy. The neonatal larynx is more anterior than that of the adult, and visualization often is easier when cricoid pressure is applied. The practitioner should hold the laryngoscope and apply cricoid pressure with the same hand. The thumb and first two fingers hold the base of the laryngoscope, the third finger rests on the mandible, and the fourth finger applies cricoid pressure. This technique promotes gentleness during airway manipulation. The distance from the gums to the larynx often is surprisingly short. A common mistake is to advance the laryngoscope blade too deeply—past the larynx and into the esophagus. When this error occurs, the larynx falls into view if the laryngoscope blade is withdrawn slowly.

The diameter of the endotracheal tube should be large enough to allow adequate ventilation and insertion of a suction catheter (if needed) but small enough to avoid causing trauma and subsequent subglottic stenosis. The ratio of internal diameter to gestational age should be less than 0.1 (e.g., 3.0 mm tube/35 weeks' gestation = 0.09).[126,127]

After tracheal intubation, positive-pressure ventilation should be resumed by means of an appropriate circuit, as described earlier for mask ventilation. Assessment of proper

tube placement is accomplished by listening for breath sounds in both axillae. Exhaled CO_2 detection is the recommended method for confirming placement of the tube in the trachea.[2,128] False-negative results can occur in situations in which the infant is correctly intubated, with the tube in the trachea, but pulmonary blood flow is poor or absent. This may lead to unnecessary extubation in critically ill infants. As noted previously, the Fio_2 should be reduced as soon as possible, especially in the preterm neonate. The use of a pulse oximeter and an oxygen blender allows more targeted delivery of supplemental oxygen to the preterm infant immediately after birth. If the neonate is to remain intubated, a chest radiograph should be obtained to confirm the exact position of the endotracheal tube. The skill and experience required for correct tracheal intubation and effective bag-and-mask ventilation may be lacking in providers who are inexperienced with neonatal resuscitation; as a consequence, the laryngeal mask airway (LMA) has been evaluated as a potential alternative airway device for neonatal resuscitation.[129–131] The LMA is blindly inserted into the pharynx, and a cuff is inflated to provide a low-pressure seal around the larynx. When evaluated in term infants requiring resuscitation at delivery, use of the LMA was found to be highly successful and without complications.[129,130] The current neonatal resuscitation guidelines state that the LMA is an acceptable alternative means of establishing an airway in infants born at 34 weeks' gestation and greater and weighing more than 2000 g; it can be used by appropriately trained providers when bag-and-mask ventilation is ineffective or attempts at tracheal intubation have been unsuccessful.[2]

One cause of unequal breath sounds and eventual circulatory collapse is a tension pneumothorax. Some physicians have recommended that providers of neonatal resuscitation be skilled in needle aspiration of a tension pneumothorax.[1] This maneuver is accomplished by placement of a 22- or 25-gauge needle in the second intercostal space in the midclavicular line (on the side where no breath or heart sounds are heard). Air will rush out of the needle hub, thereby reducing the tension pneumothorax.

In the vast majority of resuscitations, the neonate responds to ventilatory support. Chest compressions are needed in only 0.03% of deliveries.[132] Chest compressions are indicated when the heart rate is less than 60 bpm despite adequate ventilation with supplemental oxygen for 30 seconds.[133]

The preferred method for providing chest compressions is with the thumbs of both hands and the hands encircling the chest.[2,133] Pressure is applied over the sternum just below an imaginary line drawn between the nipples; pressure applied over the lower part of the sternum or xiphoid can injure the abdomen. The sternum should be compressed to approximately one-third the anteroposterior dimension of the chest, and the compression depth must be adequate to produce a palpable pulse.[2,134–136] The compression time should be slightly shorter than the release time, particularly to improve blood flow in the very young infant.[137] Ventilation is compromised if the chest is compressed simultaneously with the administration of positive-pressure ventilation. The recommended ratio of compressions to breaths is 3:1.[138,139] This pattern is given at a rate of 120 events per minute, with 90 chest compressions and 30 breaths administered each minute. Respirations, heart rate, and color should be rechecked every 30 seconds. Compressions should be resumed until the heart rate is 60 bpm or higher. Positive-pressure ventilation with supplemental oxygen titrated to Sao_2 should be continued until the heart rate is higher than 100 bpm.

Medications are rarely required during neonatal resuscitation because most neonates who require resuscitative measures respond well to satisfactory oxygenation and ventilation alone.[140] However, a variety of pharmacologic agents should be available in the delivery room (see Box 9.3). **Epinephrine** (0.01 to 0.03 mg/kg or 0.1 to 0.3 mL/kg of a 1:10,000 solution) should be administered if the heart rate remains lower than 60 bpm after 30 seconds of adequate ventilation and chest compressions.[2] Intravenous administration is the preferred route (via an umbilical venous line). While intravenous access is being established, intratracheal administration through an endotracheal tube may be considered; however, a larger dose of epinephrine (0.05 to 0.1 mg/kg) may be required. Administration of epinephrine is especially important if the heart rate is zero, and may require repeated dosing to be effective.[141] Epinephrine raises the heart rate (the major determinant of neonatal cardiac output) and restores coronary and cerebral blood flow.[142]

Sodium bicarbonate is not recommended during resuscitation. Because of its high osmolarity, this agent can cause hepatic injury at any gestational age and cerebral hemorrhage in the preterm infant[143,144]; it may also compromise myocardial and cerebral function.[145,146] It should be given only during prolonged resuscitation and when adequate ventilation and circulation have been established. Arterial blood gas measurements and serum chemistry determinations should guide the use of sodium bicarbonate, which generally occurs after stabilization.

Atropine is not recommended for use during neonatal resuscitation. Epinephrine is considered the drug of choice for the treatment of bradycardia.

Calcium administration is not recommended for neonatal resuscitation, unless it is given specifically to reverse the effect of magnesium (which may have crossed the placenta from the mother to the fetus). Evidence suggests that calcium administration causes cerebral calcification and decreases survival in stressed neonates.[147]

Volume expanders must be given strictly according to recommended dosage. A continuous infusion is dangerous in the neonate, because it can easily result in the administration of an excessive fluid volume. Fluid overload can cause hepatic capsular rupture, brain swelling in the asphyxiated infant, or intracranial hemorrhage in the preterm infant. Fluids and medications can be administered either intravenously (most commonly through the umbilical vein) or, if necessary, intraosseously.

The cannulation of the umbilical vein involves insertion of a soft catheter into the cut end of the vein (Fig. 9.4). The catheter is advanced until blood return is noted, but no more than

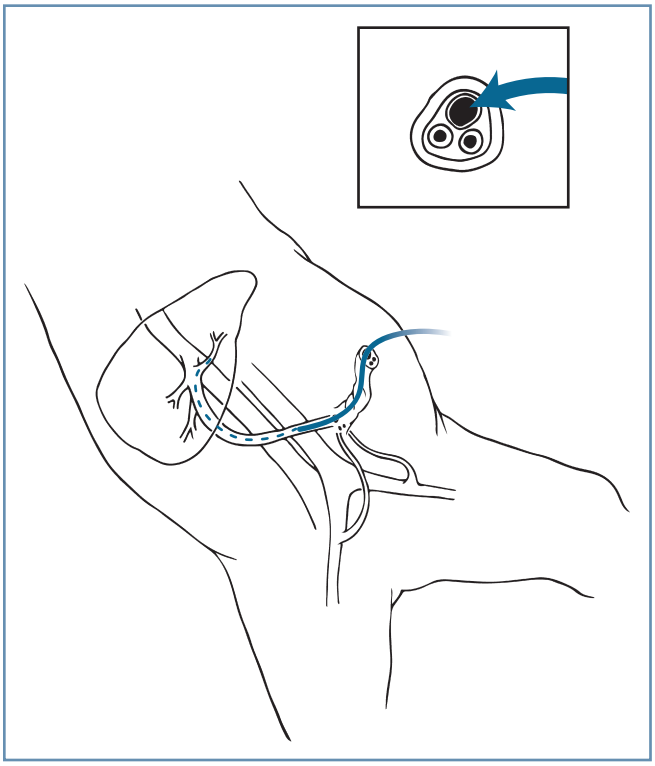

Fig. 9.4 Cannulation of the umbilical vein. A 3.5F or 5F umbilical catheter with a single end-hole and a radiopaque marker should be used. For emergency use, the catheter should be inserted into the vein of the umbilical stump until the tip of the catheter is just below the skin level but free flow of blood is present. If the catheter is inserted farther, there is a risk for infusing solutions into the liver and possibly causing damage. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

2 cm past the abdominal surface. If ongoing vascular access is required during the neonate's hospital course, the soft umbilical catheter can be advanced through the ductus venosus into the inferior vena cava. Care must be taken to avoid leaving the tip in an intermediate location because of possible hepatic damage if a high-osmolarity substance is injected. Other complications of umbilical venous catheterization are hemorrhage and sepsis. The prolonged absence of vascular access in critically ill neonates can lead to hypoglycemia, which in association with hypoxia, can increase the risk for adverse neonatal outcomes.[148]

Intraosseous access is accomplished by insertion of a 20-gauge needle into the proximal tibia approximately 1 cm below the tibial tuberosity.[149] This technique may be easier to perform for practitioners who have little experience with intravenous or umbilical neonatal catheterization. Absorption from the neonatal bone marrow into the general circulation occurs almost immediately.[150,151] This rapid absorption results from the preponderance of red bone marrow over yellow bone marrow; yellow bone marrow is less vascular and is the dominant form of marrow after 5 years of age. Complications related to this technique are rare and include tibial fracture (which occurs more often in older children)[152] and osteomyelitis. The risk for infection is proportional to the duration of intraosseous infusion[153–155]; therefore, the needle should be removed after 1 to 2 hours and, if necessary, a more conventional route of access should be established. Current guidelines state that intraosseous access should be used for medication administration or volume expansion when venous access is difficult to achieve.[2]

Volume expanders should be considered when the infant demonstrates signs of shock, such as pale skin, poor perfusion, and weak pulse, or has not shown adequate response to other resuscitative measures. **Normal saline** and **lactated Ringer's solution** are the preferred volume expanders, given initially at 10 mL/kg over 5 to 10 minutes, with doses repeated as necessary after reassessment for ongoing hypovolemia. Intravascular volume should be assessed through evaluation of heart rate, capillary refill time, and color. If heavy blood loss is suspected, O-negative packed red blood cells may be used according to the same dosage regimen.[2] Red blood cells replete the oxygen-carrying capacity as well as the intravascular volume. O-negative blood should be available at all times for emergency use during neonatal resuscitation. Placental blood has been used for neonatal volume expansion,[156] but this practice is discouraged in most institutions because of the risks for infection or transfusion of clotted blood. Albumin administration is not recommended, because it carries a risk for infectious disease and has been associated with higher mortality.[157]

SPECIAL RESUSCITATION CIRCUMSTANCES

Meconium-Stained Amniotic Fluid

Meconium is present in the intestinal tract of the fetus after approximately 31 weeks' gestation. Meconium-stained amniotic fluid is present in 10% to 15% of all pregnancies; the incidence is higher in postterm pregnancies. Intrapartum passage of meconium may be associated with fetal stress and hypoxia.[158,159]

Meconium aspiration syndrome (MAS) is defined as respiratory distress in a neonate whose airway was exposed to meconium and whose chest radiograph exhibits characteristic findings, including pulmonary consolidation and atelectasis.[160] Treatment of MAS often involves the use of positive-pressure ventilation and is associated with a 5% to 20% incidence of pneumothorax from pulmonary air leaks,[161] and can be associated with persistent pulmonary hypertension of the newborn. Historically, the death rate from MAS was as high as 6 per 10,000 live infants.[162] The use of ECMO and inhaled nitric oxide for the treatment of pulmonary hypertension associated with MAS has been shown to reduce mortality rates.[163–165]

In an attempt to reduce inhalation of meconium from the pharynx and thus prevent or reduce the severity of MAS, the practice of suctioning the mouth and pharynx after delivery of the head, and subsequent intubation to remove meconium from the trachea, was common practice.[162,166,167] However, studies have documented that airway suctioning at birth does not prevent MAS and its associated mortality[168,169]; these studies indicated that MAS was primarily a result of intrauterine events such as asphyxia or sepsis. Hypoxia induces

pathologic changes in the pulmonary vasculature, which results in pulmonary hypertension and respiratory distress after birth. The pulmonary damage is independent of meconium aspiration; therefore, it is not prevented by the suctioning of meconium. A prospective study designed to assess the efficacy of routine tracheal suctioning of meconium to prevent MAS indicated little or no benefit to this practice.[170]

Amnioinfusion—the instillation of saline into the amniotic cavity—has been used successfully for reduction of cord compression in the presence of oligohydramnios during labor. It has also been proposed as a potential treatment to reduce the incidence of MAS in infants born to women with thick meconium staining of the amniotic fluid. Potential benefits include (1) the reduction of cord compression, thus alleviating fetal compromise and acidemia that contribute to MAS; and (2) the dilution or washing out of the meconium in the amniotic fluid. A large multicenter randomized trial found no difference in rates of MAS or other neonatal disorders with the use of amnioinfusion.[171,172] Thus, the routine practice of amnioinfusion for meconium-stained fluid alone is not recommended.[173]

Current guidelines do not recommend routine intrapartum oropharyngeal and nasopharyngeal suctioning before delivery of the infant's head,[2,174] given that a large multicenter randomized trial showed no benefit to this practice in term-gestation infants.[175] After stabilization of the infant, meconium may be gently cleared from the mouth and nose by means of a bulb syringe or a large suction catheter (e.g., 12F to 14F).

Preterm Infant

The preterm neonate, especially the VLBW infant, is at higher risk for problems with multiple organ systems simply because of immaturity. During resuscitation, the physician should give special attention to the effect of prematurity on the lungs and the brain. Before the addition of surfactant and high-frequency ventilation to the therapeutic armamentarium of the neonatologist, neonatal respiratory distress syndrome caused by surfactant deficiency was the overwhelming obstacle to the attempted salvage of the very preterm infant.

Between 1970 and 2005, the proportion of infants weighing less than 1500 g at delivery rose from 1.17% to 1.5%; the proportion has stabilized at 1.45%.[176] The survival rate of these 500- to 1500-g infants has increased to approximately 85%.[176] Of these, 5% to 10% have what is characterized as cerebral palsy, and 25% to 50% exhibit behavioral and cognitive deficits that lead to important school problems (see Chapter 10).[177,178] These VLBW infants constitute a tiny proportion of the birth population, but they are at the highest risk for development of cerebral palsy; infants weighing less than 1500 g at birth account for 25% of cases of this disorder.[54]

Markers for brain injury affecting preterm infants are intraventricular hemorrhage (IVH) arising from the germinal matrix and periventricular leukomalacia. The brain injury may occur either as a consequence of the IVH and its sequelae or as an associated finding. The incidence of IVH in preterm infants declined from 35% to 50% in the late 1970s and early 1980s to approximately 15% in the mid-1990s.[179] Despite the decreased incidence of IVH, which is directly related to prematurity,[178] the overall burden of disability has sharply increased in recent years owing to the proportion of very preterm infants who are surviving.[179] Periventricular leukomalacia, which is the classic neuropathology associated with hypoxic-ischemic cerebral white matter injury in the preterm infant, commonly accompanies IVH.[180]

The fragility of the immature subependymal germinal matrix predisposes the preterm infant to the development of IVH. The hemorrhage originates from the endothelial cell–lined vessels that course through the germinal matrix in free communication with the venous circulation (i.e., the capillary-venule junction). The hemorrhage can expand into the adjacent lateral ventricle. The mechanism of damage to these endothelial cells and to the integrity of these capillaries has been investigated in animal models[181] and in human neonates by means of Doppler velocimetry.[182] The pathogenesis of IVH is multifactorial; different combinations of factors are relevant in different patients.[183,184] The three major categories in the pathogenesis of IVH are intravascular, vascular, and extravascular. **Intravascular factors** include fluctuating cerebral blood flow (CBF), which can result from respiratory disturbances in the ventilated preterm infant with neonatal respiratory distress syndrome[182,185]; increases in CBF[181,186]; increases in cerebral venous pressure[187]; decreases in CBF followed by reperfusion; and platelet and coagulation disturbances.[188] **Vascular factors** include the tenuousness of the capillary integrity of the germinal matrix and the vulnerability of the matrix capillaries to hypoxic-ischemic injury.[189] **Extravascular factors** include deficient vascular support, excessive fibrinolytic activity, and a possible postnatal decrease in extravascular tissue pressure.[190]

Of special interest in the discussion of antepartum and intrapartum care and neonatal resuscitation are the possible interventions that may prevent or lessen the severity of IVH. The best way to prevent germinal matrix IVH is to prevent preterm birth. Infection and inflammation are the most commonly identified causes of preterm birth at the lowest relevant gestational age.[191] Antenatal *treatment* of infections has not been proven to prevent preterm labor or premature rupture of membranes[54]; however, *prevention* of infection, if possible, may be an important way to reduce the risk for IVH. Another intervention that lowers the incidence of IVH is the transportation of the preterm mother while the fetus is still *in utero* to a center that specializes in the care of high-risk neonates.[1]

Various antenatal pharmacologic interventions have been evaluated for the prevention of IVH. Clinical trials of antenatal maternal administration of phenobarbital[192,193] and vitamin K[194,195] have yielded conflicting results, and their routine use is not currently recommended.[54]

Corticosteroids are currently the most beneficial antenatal pharmacologic intervention for the prevention of IVH. This effect was first noticed when obstetricians began giving betamethasone and dexamethasone to pregnant women to help accelerate fetal lung maturity. The mechanism behind this

protection is thought to be improved neonatal cardiovascular stability, which results in less hypotension and less need for blood pressure treatment in these infants.[196] Antenatal betamethasone administration leads to lower placental vascular resistance and higher placental blood flow.[197] This improvement in placental blood flow may decrease impairment of the preterm infant's cerebral autoregulation. In addition, corticosteroids may stimulate the maturation of the germinal matrix. Recommendations regarding timing of steroid administration have been published by the ACOG, which recommends corticosteroid administration for pregnant women between 24 0/7 weeks' and 33 6/7 weeks' gestation who are at risk to deliver, while corticosteroid administration can be considered for at-risk pregnancies as early as 23 0/7 weeks' gestation. A repeat course can be considered when there is risk for delivery within 7 days and the woman is less than 34 0/7 weeks' gestation and the previous course of corticosteroids occurred more than 14 days previously[198] (see Chapter 33).

Multiple studies have demonstrated a lower incidence of cerebral palsy in infants of mothers given magnesium sulfate for the treatment of preeclampsia or for tocolysis[199,200]; subsequent studies have observed a similar benefit when magnesium has been given specifically for fetal neuroprotection.[201–203] An ACOG committee opinion[204] recommends the administration of magnesium sulfate to mothers in preterm labor. Maternal magnesium sulfate administration does not result in a decreased incidence of IVH, although the incidence of high-grade (grade III or IV) lesions may be reduced.[205] Although some investigators have suggested that antenatal exposure to magnesium sulfate results in a higher risk for adverse neonatal outcomes,[206] others have observed no association between umbilical cord blood magnesium concentration and the need for delivery room resuscitation when magnesium sulfate was administered for neuroprotection in anticipation of a preterm birth.[207]

Postnatal interventions that may prevent IVH include the avoidance of overly rapid infusion of volume expanders or hypertonic solutions such as sodium bicarbonate.[143,208] The establishment of adequate ventilation is the most beneficial immediate intervention that helps preserve cerebrovascular autoregulation in the preterm infant. The prevention of hypoxemia and hypercarbia is essential, because they are both linked to pressure-passive cerebral circulation, which in turn leads to the development of IVH.[208]

Perlman et al.[209] found that, among infants who exhibit fluctuating CBF velocity, treatment with **pancuronium,** which corrects this fluctuation, reduced both the incidence and severity of IVH.[209] Other clinical trials have evaluated the efficacy of other pharmacologic agents for the correction of fluctuating hemodynamic disturbances. Studies of **meperidine**[210] and **fentanyl**[211] have shown some benefit, but the side effects and need for prolonged ventilation associated with these agents must be weighed against any potential benefits.

If the use of antepartum and intrapartum pharmacologic prophylaxis against IVH becomes part of preterm delivery management, the practice of obstetric anesthesia for preterm patients will be directly affected. For example, the conventional wisdom is that preterm infants are more sensitive than term infants to the effects of maternally administered agents such as analgesics[212] and that this effect is inherently deleterious. However, if this effect is found to protect the preterm infant brain from factors that may lead to IVH (e.g., hemodynamic instability), perhaps obstetric anesthesia providers will no longer attempt to avoid the placental transfer of pharmacologic agents but will deliberately administer these agents to the mother with the intent that they reach the fetus.

Congenital Anomalies

Occasionally, neonatal resuscitation is complicated by congenital anomalies of the airway or diaphragm. These anomalies may manifest as respiratory distress, which resolves only when appropriate resuscitation techniques are used. For example, neonates are obligatory nose breathers. The diagnosis and management of choanal stenosis and atresia include placement of an oral airway or endotracheal tube until a definitive surgical procedure can be performed.

Other congenital anomalies that cause upper airway obstruction include (1) micrognathia, as in Pierre Robin sequence; (2) macroglossia, as in Beckwith-Wiedemann syndrome or glycogen storage disease type II; (3) laryngeal webs; (4) laryngeal atresia; (5) stenosis or paralysis at the level of the vocal cords; (6) subglottic stenosis; (7) subglottic webs; (8) tracheal agenesis; and (9) tracheal rings. Obstruction also can occur as a result of tumors such as subglottic hemangiomas. The presence of a cleft palate may lead to difficulty with manual ventilation. In an infant with micrognathia or macroglossia, airway patency may be maintained if the neonate is kept in the prone position, which reduces posterior movement of the tongue into the pharynx. If macroglossia is extreme, use of an oral airway or a small nasogastric or orogastric suction catheter may be necessary to prevent complete obstruction of the pharynx by the tongue.

When respiratory distress and difficulty with bag-and-mask ventilation are encountered, laryngoscopy should be performed. The cause of the obstruction may be evident if it is supraglottic in location. Some supraglottic entities (e.g., laryngeal webs) may be treated successfully by passing an endotracheal tube through the obstruction and into the trachea. Subglottic lesions may require tracheostomy. The help of an otolaryngologist may be invaluable during resuscitation of a neonate with congenital airway obstruction. If there is antepartum evidence of such a condition (e.g., laryngeal stenosis), it is best to have an otolaryngologist present at the time of delivery.[213] If obstruction is discovered after delivery, the resuscitator should not hesitate to call for surgical assistance.

Fetal neck masses such as cervical teratoma and lymphangioma can lead to extrinsic airway compression. The resulting distortion of the airway can result in airway obstruction, and it may be difficult—if not impossible—to secure an airway in a timely fashion at delivery. These masses often are diagnosed before delivery because of the associated occurrence of polyhydramnios resulting from esophageal compression. In these rare cases, a multidisciplinary team should be assembled

before delivery to assist in securing the airway. Liechty et al.[214] described a way of providing the time necessary to secure an airway, known as the **ex utero intrapartum treatment (EXIT) procedure** (see Chapter 7). An EXIT procedure delivers the fetal head and shoulders, but keeps the lower torso and umbilical cord intact within the uterus, thereby maintaining placental perfusion and oxygenation. The fetus can be given additional agents intramuscularly (e.g., fentanyl, muscle relaxant, and atropine) to provide fetal analgesia and to prevent movement and breathing. The FHR and Sao_2 are monitored continuously via a pulse oximeter probe attached to the fetal hand. The pediatric surgeon can then perform direct laryngoscopy, rigid bronchoscopy, or tracheostomy if necessary. After establishment of the airway, the delivery of the infant is completed.

The EXIT procedure has been considered an option for fetuses with a number of congenital anomalies.[215,216] A common indication for the EXIT procedure is an intrinsic airway obstruction. Intrinsic airway obstruction of the larynx or upper trachea (e.g., laryngeal web, subglottic cyst, tracheal atresia) can lead to retention of bronchial secretions and subsequent pulmonary distention; this constellation of findings is often classified as **congenital high airway obstruction syndrome (CHAOS).**[215] Use of the EXIT procedure resulted in the first long-term survival of a child with this syndrome.[217]

Indications for EXIT procedures continue to evolve and now include conditions such as severe congenital heart disease, in which the need for emergency ECMO at birth is anticipated. The EXIT procedure allows for the placement of arterial and venous cannulas before umbilical cord clamping, thereby avoiding an unstable period between the termination of placental perfusion and the institution of ECMO.[215] Other possible indications for the EXIT procedure include the resection of congenital cystic adenomatoid malformations and as a first step in separation procedures for conjoined twins with cardiovascular involvement.

Anesthetic considerations for the mother during an EXIT procedure include those relevant to general anesthesia for the mother undergoing cesarean delivery or other surgical procedures during pregnancy (see Chapters 7, 17, and 26). Anesthetic technique is dependent upon several variables including but not limited to the anticipated surgical approach, maternal medical history, and patient preference. Anesthetic management of EXIT procedures focuses on achieving maximal uterine muscle relaxation and maintaining uteroplacental perfusion and maternal hemodynamics while minimizing fetal cardiac dysfunction.[218]

Uterine relaxation is often achieved through the use of volatile anesthetics, as well as adjuvant medications including nitroglycerin, beta-adrenergic receptor agonists, and magnesium sulfate. Several volatile halogenated agents have been used for the EXIT procedure, including isoflurane, desflurane, and sevoflurane.[215] To achieve maximal uterine muscle relaxation, high doses of a volatile agent can be required (up to 2 to 3 minimum alveolar concentration [MAC]). Prolonged neonatal exposure to volatile agents at the time of cesarean delivery can be associated with decreased 1-minute Apgar scores secondary to respiratory depression and hypotonia.[219] In addition, fetal exposure to high-dose volatile anesthetic agents has been associated with fetal hypoxia and acidosis as well as fetal cardiac dysfunction, including ventricular dysfunction and bradycardia.[220] For this reason, combination techniques that lower volatile agent requirements are often employed to optimize relaxation while balancing fetal risk. In 2010, Boat et al. retrospectively examined the records of 39 patients undergoing EXIT procedures with high-dose desflurane (2 to 3 MAC) or supplemental intravenous anesthesia (SIVA) with propofol, remifentanil, and desflurane (1 to 1.5 MAC). The SIVA group achieved adequate uterine relaxation at lower MAC of desflurane (1 to 1.5 MAC) and had a lower incidence of fetal left ventricular dysfunction when compared with the high-dose volatile agent group.[221]

In addition to volatile anesthesic agents, intravenous agents including nitroglycerin, magnesium sulfate, and beta-adrenergic receptor agonists have been utilized to optimize uterine relaxation. Nitroglycerin is most commonly the adjuvant of choice as it allows for quick titration and is rapidly metabolized to allow for quick return of uterine tone after delivery of the neonate.[220] Careful titration is essential to avoid maternal hypotension and possible decreases in uteroplacental perfusion. Magnesium sulfate and beta-adrenergic receptor agonists are much less frequently utilized during EXIT procedures because of their prolonged effects on uterine tone and increased fetal side-effect profile. Neonates exposed to magnesium sulfate can present with hypotonia and lethargy upon delivery, while those exposed to beta-adrenergic receptor agonists can present with fetal tachycardia and metabolic derangements.[218]

Maintenance of uterine muscle relaxation is often complicated by vasodilation, which can lead to maternal hypotension, decreased uteroplacental blood flow, and decreased fetal cardiac output.[221] To maintain mean arterial pressure and ensure adequate uteroplacental perfusion, vasopressor administration is often required. Ephedrine and phenylephrine are the two most commonly used vasopressor agents in obstetric and fetal surgery. While both agents are considered safe for the mother and fetus, some studies suggest that phenylephrine results in higher umbilical artery blood pH and base excess than ephedrine. However, human studies have shown no difference in Apgar scores or umbilical blood flow when the two drugs were compared.[221]

Intraoperative monitoring including continuous fetal pulse oximetry and heart rate monitoring is critical throughout the EXIT procedure. Decreased baroreceptor activity and vasoconstrictive responses to hypovolemia make the fetus particularly susceptible to heat and evaporative fluid losses, as well as hypovolemia and hypoperfusion during exposure on the surgical field.[221] Effort should be made to maintain fetal temperature during the course of the procedure, including higher operating room temperatures and limiting exposure of fetal parts, not critical to the procedure, to the outside environment. Fetal blood should be immediately available at the time of the procedure and fetal hemoglobin and blood gases measured as indicated.

Esophageal atresia and **tracheoesophageal fistula** occur in 1 of 3000 births.[222] There are many variations of these anomalies, the most common being esophageal atresia with a distal tracheoesophageal fistula (80% to 90% of cases). Neonates with a tracheoesophageal fistula are at increased risk for the pulmonary aspiration of gastric contents through the fistula into the lung. When the presence of a tracheoesophageal fistula is not known antepartum, it should be suspected if bubbling secretions are observed during spontaneous or bag-and-mask ventilation. Once a tracheoesophageal fistula is suspected, bag-and-mask ventilation should be discontinued, because its use may contribute to overdistention of the gastrointestinal tract with air, possibly leading to difficulty in ventilation from impingement of the enlarged stomach on the diaphragm. A suction catheter should be placed in the esophageal pouch to facilitate the removal of oral secretions. If mechanical ventilation is necessary, an endotracheal tube should be inserted with the tip distal to the entrance of the fistula. This positioning can be accomplished by performing an intentional right mainstem bronchial intubation followed by slowly withdrawing the tube until breath sounds are auscultated on the left; a lack of breath sounds over the stomach should then be confirmed. Percutaneous gastrostomy placement may be necessary during resuscitation to facilitate decompression of the gastrointestinal tract.

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 3000 live births.[223] The mortality rate from CDH is 30% to 60%. In 80% to 90% of cases, the CDH occurs on the left side and is the result of herniation of the gut through the posterolateral defect of Bochdalek. During formation of the lung, herniation of the gut into the thoracic cavity results in hypoplasia of the lung tissue and pulmonary vasculature. This hypoplasia may be unilateral, but often it is bilateral because of the shift in mediastinal structures to the other side. CDH should be suspected when a neonate has respiratory difficulty and a scaphoid abdomen; this abnormal abdominal shape results from the presence of abdominal contents in the thorax.

During resuscitation of the neonate with CDH, bag-and-mask ventilation is contraindicated because it allows further distention of the gut, which would further impinge on the lung. Tracheal intubation is recommended, followed by the placement of a nasogastric or orogastric tube to ensure decompression of the gastrointestinal tract. Ventilation should consist of low-positive-pressure breaths to decrease the risk for causing a pneumothorax on the side contralateral to the CDH. If a pneumothorax does occur, it must be evacuated promptly. In the neonate, evacuation is accomplished initially by placement of a 22-gauge needle into the second intercostal space in the midclavicular line and aspiration of air with an attached stopcock and syringe. Severe pulmonary hypertension often accompanies CDH. Maintenance of euthermia, normoxia, and adequate systemic blood pressure promotes pulmonary artery blood flow.

Whenever congenital anomalies of the respiratory tract are noted, the presence of other anomalies should be suspected. It is important to evaluate the neonate promptly for cardiac malformations, especially if appropriate resuscitative efforts are not successful. Echocardiography is used to evaluate cardiac structures and function.

ETHICAL CONSIDERATIONS

The current neonatal resuscitation guidelines address the ethical considerations of non-initiation or discontinuation of resuscitation in the delivery room.[2] Extremes of prematurity (< 23 weeks' confirmed gestation) and severe congenital anomalies (e.g., anencephaly, confirmed trisomy 13 or 18) are examples of circumstances when non-initiation of resuscitation is considered appropriate. Because intrapartum confirmation of pertinent information may not be possible, it is recognized that initiation of resuscitation may occur and that its discontinuation may then be appropriate after further information has been obtained and discussion with family has occurred. In some cases, a trial of therapy may be appropriate, which does not always mandate continued support. In situations or conditions in which there is a high rate of survival and acceptable morbidity (i.e., ≥ 25 weeks' gestation and most congenital malformations), resuscitation is generally indicated. For those situations with a poor prognosis, including unlikely survival and potentially high morbidity (i.e., 23 to 25 weeks' gestation), the parents' desires as to initiation of resuscitation should be supported (Table 9.5).[224,225]

TABLE 9.5 Guidelines for Withholding or Discontinuing Resuscitation

Conditions with high survival, acceptable risk for morbidity	≥ 25 weeks' gestational age Most congenital malformations	Resuscitation nearly always indicated
Conditions with poor prognosis, high risk for morbidity	23 to 25 weeks' gestational age	Parental desires about initiating/continuing resuscitation should be supported
Conditions with almost certain death or unacceptably high morbidity	< 23 weeks' gestational age Birth weight < 400 g Anencephaly Chromosomal abnormalities incompatible with life (e.g., trisomy 13)	Resuscitation not indicated

TABLE 9.6 Neurobehavioral Tests for Neonates

Neurobehavioral Test	Items Tested	Focus	Uses
Brazelton (Neonatal Behavioral Assessment Scale)	45 individual tests taking 45 minutes	Early cortical function	Evaluates prenatal influences, effects of maturity, maternal medications, effects of difficult delivery
Scanlon (Early Neonatal Behavior Scale)	26 observations taking 6–10 minutes	Early cortical function	Evaluates effects of maternal medications
Amiel-Tison (Neurologic and Adaptive Capacity Score)	20 criteria taking 3–4 minutes	Motor tone	Differentiates drug-induced depression from depression related to asphyxia, trauma, or neurologic disease

Discontinuation of resuscitation of an infant with cardiopulmonary arrest may be appropriate if spontaneous circulation has not occurred in 15 minutes. After 10 minutes of asystole, survival itself and survival without severe disabilities are very unlikely.[224,226–230]

NEUROBEHAVIORAL TESTING

It is difficult to detect subtle neurobehavioral differences among neonates during the assignment of Apgar scores or the performance of the initial neurologic examination; therefore, investigators have developed and studied methods of documenting neonatal neurobehavioral status (Table 9.6). In the past, the neonate was considered incapable of exhibiting higher cortical function. However, investigators have noted that the term neonate is able to sense and respond to a variety of stimuli in a well-organized fashion.[231–233]

In 1973, Brazelton[234] described the Neonatal Behavioral Assessment Scale (NBAS) with the following four variables as key determinants of neonatal neurobehavior: (1) various prenatal influences (e.g., infection); (2) the maturity of the infant, especially its CNS; (3) the effects of analgesics and anesthetics administered to the mother before and during delivery; and (4) the effects of difficulties encountered during delivery (e.g., trauma). The NBAS was developed as a tool to detect neurobehavioral abnormalities that resulted from any of these four variables.

This scale consists of 47 individual tests with 27 evaluating behavior and 20 evaluating elicited or provoked responses. The 47 tests can be completed in approximately 45 minutes. The NBAS evaluates the ability of the neonate to perform complex motor behaviors, to alter the state of arousal, and to suppress meaningless stimuli. The goal is to provide an extensive evaluation of neonatal cortical function and to detect subtle differences among groups of infants. Habituation (i.e., the ability to suppress the response to meaningless, repetitive stimuli) is considered an excellent indicator of normal early cortical function.[231]

In 1974, Scanlon et al.[235] described the Early Neonatal Behavioral Scale (ENNS), which consisted of tests that were easy to perform and score quantitatively during the neonatal period. The ENNS was developed primarily for the evaluation of the effects of maternal medications (e.g., analgesic and anesthetic agents) on neonatal neurobehavior. The ENNS consists of (1) 15 observations of muscle tone and power, reflexes (e.g., rooting, sucking, Moro), and response to stimuli (e.g., light, sound, pinprick); (2) 11 observations of the infant's state of wakefulness; (3) an assessment of the ability of the neonate to habituate to repetitive stimuli; and (4) an overall general assessment of neurobehavioral status. This test can be performed in 6 to 10 minutes.

In 1982, Amiel-Tison et al.[236] described the Neurologic and Adaptive Capacity Score (NACS) to differentiate neonatal depression secondary to maternally administered drugs from depression caused by asphyxia, birth trauma, or neurologic disease. Whereas the ENNS concentrates on the infant's habituation ability, the NACS emphasizes motor tone as a key indicator of drug-induced abnormal neurobehavior. The basis for this emphasis on neonatal motor tone is explained as follows: unilateral or upper body hypotonus may occur as a result of either birth trauma or anoxia, but global motor depression is more likely a result of anesthetic- or analgesic-induced depression. A total of 20 criteria are tested in the areas of adaptive capacity, passive tone (e.g., scarf sign), active tone (e.g., assessment of the flexor and extensor muscles of the neck), primary reflexes (e.g., Moro), and alertness. The total possible score is 40, and a score of 35 to 40 is considered normal. The NACS can be performed in 3 to 4 minutes.

Amiel-Tison et al.[236] examined interobserver reliability and assessed the correlation of results between the NACS and ENNS. The interobserver reliability was 93% for the NACS and 88% for the ENNS. Approximately 92% of infants with high scores on the ENNS scored equally well on the NACS. However, the reliability of the NACS has been questioned[237,238]; Halpern et al.[239] examined 200 healthy term infants with the NACS and found poor interobserver reliability. In contrast, in 2002 Amiel-Tison[240] reported her later experience with the NACS and documented good interobserver reliability.

Anesthesiologists have used neurobehavioral testing to document the effects of analgesic and anesthetic agents and techniques on neonatal neurobehavior (see Table 9.6); the AAP[241] and the U.S. Food and Drug Administration (FDA)[242,243] have recommended that these investigations be performed. A number of studies have demonstrated transient, serum concentration–dependent depression of neonatal neurobehavior with the maternal administration of systemic agents (e.g., meperidine, diazepam).[244–246] However, in a NBAS examination that controlled for patient and labor

and delivery characteristics, only decreased habituation was observed in neonates born to mothers who had received intravenous meperidine.[247] Similarly, maternal administration of intravenous fentanyl appears to minimally affect neonatal NACS examinations.[248]

As is the case with many studies of systemic agents, studies of epidural anesthesia are often confounded by variables that are difficult to control, such as different patient populations, varied durations of labor, and multiple drug administrations. Scanlon et al.[235] introduced the ENNS in a study of the effect of maternal epidural anesthesia on neonatal neurobehavior. The researchers concluded that epidural anesthesia was associated with lower ENNS scores because of decreased muscle strength and tone. In this study, all patients who had received epidural anesthesia were considered part of one group, although nine patients had received lidocaine and 19 had received mepivacaine. Further investigation showed that epidural lidocaine, even when administered in larger doses for cesarean delivery, does not affect ENNS scores.[249] The difference in ENNS scores between the epidural and non-epidural groups noted in the earlier study[235] was most likely related to the use of mepivacaine rather than lidocaine.[250] As was observed with lidocaine, epidurally administered bupivacaine, 2-chloroprocaine, and etidocaine—when given for cesarean delivery—do not affect ENNS scores.[249,251] Kuhnert et al.[252] assessed NBAS scores in a group of infants exposed to either epidural lidocaine or 2-chloroprocaine. Although the investigators observed subtle changes in neurobehavior in the group of infants whose mothers had received lidocaine, they concluded that other variables (e.g., mode of delivery) are more likely to affect performance on neurobehavioral testing.

Sepkoski et al.[253] compared NBAS scores between two groups of vaginally delivered infants. In one group, the mothers had received epidural bupivacaine, and in the other group, the mothers had received no anesthesia or analgesia. The infants in the epidural group showed less alertness, less orientation ability, and less motor function maturity than the infants in the control group. However, variables such as duration of labor, incidence of oxytocin administration, and incidence of instrumental delivery were not similar in the two groups. Earlier, Abboud et al.[254] performed ENNS examinations on vaginally delivered infants whose mothers had received epidural bupivacaine. In this study, epidural administration of bupivacaine did not affect the ENNS scores. The maternal doses of epidural bupivacaine and the maternal venous and umbilical cord blood bupivacaine concentrations were similar to those noted by Sepkoski et al.[253] Abboud et al.[254] also noted normal ENNS scores for infants whose mothers had received epidural lidocaine or 2-chloroprocaine.

Critics of the ENNS and NACS claim that the evaluations are unable to demonstrate subtle differences in neurobehavior that would be detected by the more comprehensive NBAS.[255] However, although some differences have been observed in NBAS performance among groups of infants exposed or not exposed to local anesthetics, confounding variables have prevented clear conclusions as to cause and effect.

Hodgkinson et al.[256] observed that the subarachnoid administration of tetracaine for cesarean delivery did not adversely affect ENNS performance. Other studies have indicated that NACS performance is not significantly affected by the maternal epidural administration of opioids[257–262] or epinephrine (in combination with a local anesthetic).[263–266]

The effects of general anesthetic agents on neonatal neurobehavior have been evaluated by the ENNS and NACS. In a prospective, randomized study, Abboud et al.[267] assessed NACS performance at 15 minutes, 2 hours, and 24 hours of age in infants whose mothers received general, epidural, or spinal anesthesia for cesarean delivery. Women who underwent general anesthesia received thiopental 4 mg/kg followed by enflurane 0.5% with nitrous oxide 50% in oxygen. Although the NACS was lower at both 15 minutes and 2 hours of age in the infants in the general anesthesia group than in the infants in the neuraxial anesthesia groups, no difference in NACS results was noted at 24 hours of age.

Hodgkinson et al.[256] used the ENNS to evaluate outcomes among three groups of infants, all of whom were delivered by elective cesarean delivery. One group of women received general anesthesia with thiopental 4 mg/kg followed by 50% nitrous oxide. A second group received general anesthesia with ketamine 1 mg/kg followed by 50% nitrous oxide. A third group received spinal anesthesia with tetracaine 6 to 8 mg. The ENNS evaluations were conducted at 4 to 8 hours of age and again at 24 hours. During the 4- to 8-hour examination, infants in the spinal anesthesia group scored significantly higher on multiple components of the ENNS than did infants in either of the general anesthesia groups. At 24 hours, infants in the spinal anesthesia group scored significantly higher than those in the thiopental group in alertness, total decrement score, and overall assessment. Similarly, infants in the spinal anesthesia group scored higher than those in the ketamine group in alertness and overall assessment. No significant differences existed between the scores of the thiopental group infants and the ketamine group infants.[256] Palahniuk et al.[268] observed similar results in a study that compared groups of infants whose mothers received either epidural anesthesia or general anesthesia for elective cesarean delivery. Infants whose mothers had received thiopental and nitrous oxide scored significantly lower in the alertness component of the ENNS than infants whose mothers had received epidural lidocaine with epinephrine.

Stefani et al.[269] observed that subanesthetic maternal doses of enflurane or nitrous oxide did not affect neonatal neurobehavior (as assessed by ENNS and NACS) at 15 minutes, 2 hours, and 24 hours of age. Abboud et al.[270] obtained similar results from NACS examinations of infants whose mothers had received subanesthetic doses of isoflurane.

The long-term effects of perinatal exposure to either general or neuraxial anesthesia at the time of cesarean delivery compared with vaginal delivery appear limited. In a population-based birth cohort, Sprung et al.[271] found that children exposed to either general or regional anesthesia during cesarean delivery were not more likely to develop learning disabilities than children who were delivered

vaginally. Some controversy does exist, however, regarding the issue of repeated or lengthy use of general anesthesia, specifically in the third trimester of pregnancy. In 2017 the FDA issued a drug safety communication warning about the use of general anesthetics and sedation drugs in pregnant women and young children.[272] The statement reported that:

> *"Published studies in pregnant animals and young animals have shown the use of general anesthetic and sedation drugs for more than 3 hours caused widespread loss of nerve cells in the brain. Studies in young animals suggest these changes result in long-term effects on the animals' behavior or learning. Studies have also been conducted in children, some of which support findings from previous animal studies, particularly after repeated or prolonged exposure to these drugs early in life. All the studies in children had limitations, and it is unclear whether any negative effects seen in children's learning or behavior were due to the drugs or to other factors, such as the underlying medical condition that led to the need for the surgery or procedure."*

This statement focused on repeated or prolonged exposure, defined as greater than 3 hours, and was based primarily on animal studies with limited human data. Further research is needed to determine the true extent of neurologic impact in these cases. It is important to remember that the risks and benefits of exposure must be weighed with the indications for exposure. The ACOG, ASA, and FDA all agree that "anesthesia and sedation drugs are necessary for infants, children, and pregnant women who require surgery or other painful and stressful procedures, especially when they face life-threatening conditions requiring surgery that should not be delayed."[272] Patients should be appropriately counseled regarding the concerns or potential risk associated with prolonged exposure to anesthesia and sedative drugs, and decisions should be balanced with the benefits of such exposure.

In summary, subtle changes in neonatal neurobehavior may result from factors such as antepartum maternal drug exposure. Parent-infant bonding and the ability of the infant to breast-feed may be adversely affected by these neurobehavioral changes.[231] These transient effects may seem trivial to some observers but important to others. With regard to the long-term neurologic outcome of individual infants, performance during neurobehavioral assessment may aid the observer in the formulation of a prognosis. However, as demonstrated with Apgar scores, the prognostic value of an isolated test score is likely to be lower than the prognostic value of multiple factors considered together during the overall assessment of an individual infant.

KEY POINTS

- The anesthesia provider attending the mother should not be responsible for resuscitation of the neonate. However, all anesthesia providers should be prepared to provide assistance during neonatal resuscitation when it is needed.
- Adverse conditions at birth (e.g., hypoxia, acidosis, profound hypovolemia, hypothermia) may impair the transition from intrauterine to extrauterine life. Impaired transition may manifest as persistent pulmonary hypertension of the newborn.
- The Apgar scoring system gives the practitioner a standard guide for assessing the need for neonatal resuscitation.
- No single factor should be considered prognostic of poor neurologic outcome. A combination of factors, including severe metabolic acidemia and Apgar scores of 3 or less beyond 5 minutes, are included among the criteria that suggest the occurrence of intrapartum hypoxia of sufficient severity to cause long-term neurologic impairment. However, not all infants who fulfill these criteria suffer permanent neurologic injury.
- Severe mixed or metabolic acidemia—but not respiratory acidemia alone—is associated with a higher incidence of neonatal complications and death.
- During evaluation of the apneic neonate, assisted ventilation should be initiated promptly if tactile stimulation does not result in the initiation of spontaneous breathing.
- Air rather than 100% oxygen should be used for initial neonatal resuscitation in term infants, and 21% to 30% oxygen should be administered in preterm infants. If necessary, the administration and titration of supplemental oxygen should be guided by pulse oximetry.
- ECG monitoring of the heart rate rather than clinical assessment of the heart rate provides a more accurate evaluation of response to resuscitation.
- Meconium-exposed neonates no longer require nasopharyngeal and oropharyngeal suctioning before delivery of the thorax or endotracheal tube suctioning after delivery. Meconium-stained fluid may represent evidence of fetal compromise; thus, the infant may be more likely to require neonatal resuscitation.
- In most circumstances, decisions about the initiation or continuation of resuscitation in the delivery room should be based on the neonate's response to resuscitative efforts rather than an estimation of gestational age. Parental desires should be considered when the prognosis for infant survival is poor.

Fetal and Neonatal Neurologic Injury

Tania F. Esakoff, MD, Sarah J. Kilpatrick, MD, PhD, Arvind Palanisamy, MBBS, MD, FRCA

CHAPTER OUTLINE

The detection and diagnosis of fetal and neonatal brain injury have been advanced by improvements in functional imaging and the identification of potential biochemical markers. Evidence indicates that inflammatory mediators play an important role in the pathophysiology of fetal brain injury. Maternal administration of magnesium sulfate before anticipated early preterm birth reduces the risk for cerebral palsy in surviving infants. Induced hypothermia is beneficial for the treatment of neonatal hypoxic-ischemic encephalopathy. Of specific concern to anesthesia providers are rodent and nonhuman primate data that suggest that fetal exposure to anesthetic agents may have harmful effects on neurogenesis and synapse formation in the developing brain. Overall, however, little progress has been made in reducing the incidence of neonatal brain injury and cerebral palsy.

FETAL BRAIN DEVELOPMENT

Generation of the various cell types that populate the developing brain, and the subsequent layering and organization, is a precisely regulated process encoded by genetic programs and modified by epigenetic influences.[1–4] Contrary to previous dogma, it is now well established that the brain continuously evolves during ontogeny and that these processes are susceptible to subtle changes in the internal and external milieu. Although such neurodevelopmental processes occur throughout the human lifespan, the process is most robust and dynamic during the perinatal period.[5] Much of our understanding of the processes that drive fetal brain development comes from studies in rodents and nonhuman primates.[6] With recent advances in neuroimaging, it is now possible to study brain anatomy and assess neurobehavioral changes in the human fetus.[7]

When pathways leading to orderly brain development are deconstructed, three major events appear critical to the establishment of functional synapses. **Neuronal proliferation, migration,** and **cellular differentiation** occur in a preordained fashion to establish early neural circuitry. These processes often overlap and occur at different rates in different brain regions. **Neurogenesis,** a term that encompasses both neuronal proliferation and subsequent survival, begins with neural stem/progenitor cells in neurogenic niches such as the subventricular zone and the subgranular zone of the dentate gyrus. These neural progenitor cells undergo mitosis to generate immature neurons that migrate in a radial fashion and laminate the cortex in an "inside-out" fashion.[8] Interneurons, which compose 10% to 15% of the total neuronal cells in the brain, originate from the ganglionic eminences in the developing brain.[9] These newly generated interneurons, which play an indispensable role in circuit inhibition, migrate in a tangential manner to populate distinct brain areas. Both forms of migration are guided by cell-intrinsic mechanisms and by structural scaffolds and humoral mediators such as **gamma-aminobutyric acid** (**GABA**) and **glutamate.**[10,11]

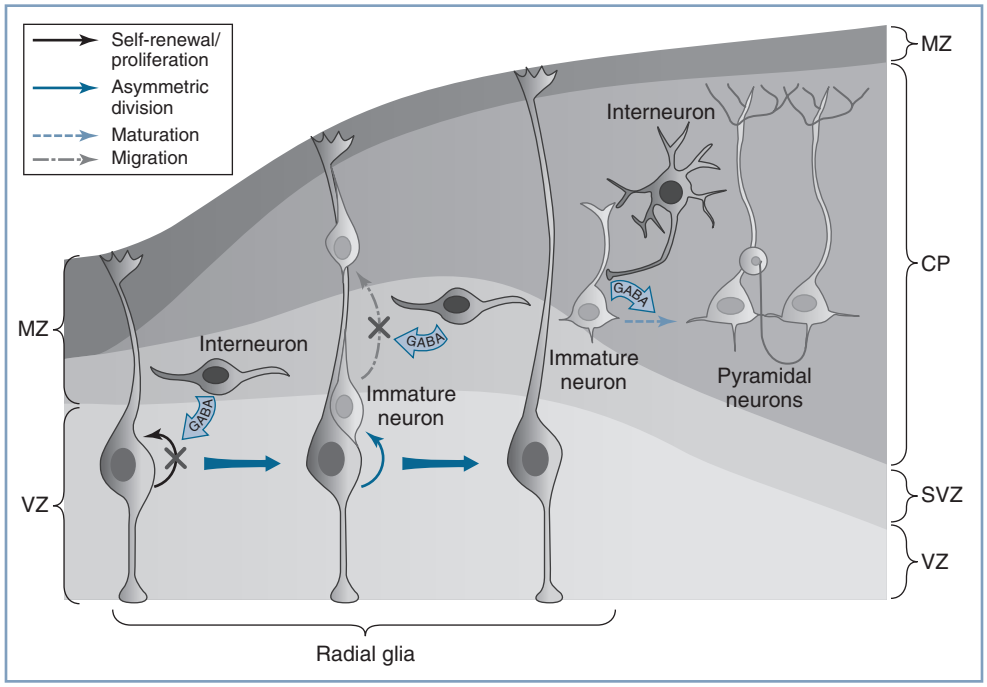

Fig. 10.1 Gamma-aminobutyric acid's (GABA) role in regulating embryonic cortical development. During corticogenesis, interneurons migrating in the subventricular zone (SVZ) can release GABA and activate GABAergic receptors on the radial glia, depolarizing these progenitors and decreasing their proliferation. Radial glia generate immature pyramidal neurons through asymmetric division, and the migration of these immature neurons along the radial fibers is decreased by GABA signaling. As young neurons assume their position in the cortex and begin to mature, GABA-mediated depolarization by the interneurons is required for the development of dendritic arbors and excitatory synaptic inputs from other pyramidal neurons. *MZ,* marginal zone; *VZ,* ventricular zone; *SVZ,* subventricular zone; *CP,* cortical plate. (From Wang DD, Kriegstein AR. Defining the role of GABA in cortical development. *J Physiol.* 2009;587:1873–1879.)

In humans, neurogenesis starts and peaks at 5 and 25 weeks' gestation, respectively, while neuronal migration is completed between 30 and 36 weeks' gestation.[12] Between 20 and 40 weeks' gestation, these processes are followed by the generation of an array of supporting glial cells, such as astrocytes and oligodendrocytes. Concurrently, synapse formation begins as early as the 10th week of gestation and continues to increase gradually at a rate of approximately 4% per week until the end of the second trimester. After this phase, a robust and exponential increase in synapse formation (almost 40,000 synapses/min) occurs between 28 weeks' and term gestation.[13] These processes, in conjunction with the onset of myelination, result in a fivefold increase in brain volume and the appearance of morphologic features of the mature brain such as sulci and gyri. By 24 weeks' gestation, the fetus has all the neural machinery necessary to perceive pain.[14] Many clinicians recommend that appropriate measures should be taken to provide fetal analgesia during fetal surgical procedures from this point onward.[15]

Although the ontogeny of neurotransmitter systems is less well studied, a wealth of animal and human data indicates that these systems appear very early in life, before the phase of active synaptogenesis.[12] The presence of these neuromodulatory substances before synapse formation lends credence to the view that they serve a trophic role during early brain development, a role that is distinct from their predominant role of facilitating synaptic neurotransmission in the mature brain. Among these neurotransmitters, GABA remains the most widely studied (Fig. 10.1).[16] Although GABA has an inhibitory action in the mature brain, GABA serves an excitatory role during fetal brain development. The major mechanism for this role reversal is the differential expression of chloride ion transporters NKCC1 and KCC2; these transporters increase the intracellular concentration of chloride in developing neurons.[17] On stimulation of **GABA receptors** that are expressed in neural progenitor cells and immature neurons, chloride ions are actively extruded, causing membrane depolarization rather than the hyperpolarization seen in mature neurons. This depolarizing effect of GABA decreases DNA synthesis and inhibits proliferation of neural progenitor cells,[18] causes concentration- and time-dependent effects on neuronal migration,[11] and plays a major role in activity-dependent synapse formation.[19]

The ***N*-methyl-D-aspartate (NMDA)-subtype glutamate receptors** originate later than the GABA receptors and remain functionally silent because of magnesium ion–induced channel blockade; thus, they play a limited role during early brain development. Dopaminergic, cholinergic, and serotonergic systems develop concomitantly and appear fully functional by the second trimester.[12] Pharmacologic interventions (e.g., ethanol, antiepileptic drugs) that act directly or indirectly on these powerful neuromodulator systems induce long-lasting impairment of fetal brain development, mainly owing to impaired neurogenesis and/or altered neuronal

migration.[20–22] Alteration of this excitation-inhibition balance is purported to be responsible for an array of childhood neurodevelopmental disorders.

Experimental studies reveal that the fetal **blood-brain barrier** is morphologically well developed and functionally competent at term.[23] Convincing evidence confirms that the endothelial tight junctions of the blood-brain barrier are as effective in the term fetus as in the adult, although the exact time that blood-brain barrier competency is established in the human fetus is unknown. In rodents, data suggest that the fetal blood-brain barrier is established between embryonic days 11 and 17 (term gestation is 22 days), a time period that corresponds to approximately the late second and early third trimesters in humans.

CEREBRAL PALSY

History, Definitions, and Significance

In 1861, John Little, an orthopedic surgeon, first described cerebral palsy in a report to the Obstetrical Society of London. Described as a neonatal neurologic disorder associated with difficult labor or birth trauma, the disorder was known as Little's disease until William Osler coined the term *cerebral palsy* in 1888.[24] A precise definition and classification of cerebral palsy has proved elusive. In the foreword to the "Report on the Definition and Classification of Cerebral Palsy," published in 2007 in *Developmental Medicine and Child Neurology,* Peter Baxter[24] wrote, "This [supplement] illustrates the difficulties inherent in trying to agree what we mean by the terms we use and that a classification that suits one purpose, such as a diagnostic approach, may not always be ideal for others, such as therapy issues. Defining and classifying cerebral palsy is far from easy. We do need a consensus that can be used in all aspects of day-to-day care and for future research on cerebral palsy."

Today, **cerebral palsy** is defined as a nonprogressive disorder of the central nervous system (CNS) present since birth that includes some impairment of motor function or posture.[24] *Intellectual disability* (formerly known as *mental retardation*) may be present but is not an essential diagnostic criterion. Various forms of cerebral palsy exist, with differences in pathology, pathophysiology, and potential relationships with intrapartum events. The literature on cerebral palsy is difficult to review and understand. Data from individual studies are difficult to compare because of variations in the duration of follow-up, birth weight classifications, inclusion criteria for congenital abnormalities, and exclusion criteria for various causes of death. Terms such as *hypoxic-ischemic encephalopathy of the newborn, newborn asphyxia, birth asphyxia,* and *asphyxia neonatorum* are difficult to distinguish. Some authorities, including the American College of Obstetricians and Gynecologists (ACOG), have argued that the term *birth asphyxia* should be abandoned.[25]

Intrapartum events continue to receive the blame for some cases of cerebral palsy. It is a widely believed theory that an intrapartum reduction in fetal oxygen delivery may cause cerebral palsy, and early reports in primates demonstrated that perinatal asphyxia could cause brain injury.[26] Continuous electronic fetal heart rate (FHR) monitoring, which has largely replaced intermittent FHR auscultation during labor, is believed to prompt the delivery of at-risk fetuses and thus reduce asphyxial events. However, despite a higher incidence of cesarean delivery, no reduction in the incidence of cerebral palsy has been observed since the widespread implementation of continuous electronic FHR monitoring during labor.[27,28] Further, among patients with new-onset late FHR decelerations, an estimated 99% of tracings would be false positive "if used as an indicator for subsequent development of cerebral palsy."[29]

Large randomized trials have not demonstrated better fetal and neonatal outcomes with continuous electronic FHR monitoring than with intermittent FHR auscultation.[30,31] In an editorial citing observations made by Schifrin and Dame,[32] Friedman[33] opined, "The absence of either suggestive or overtly ominous fetal heart rate patterns is reliably reassuring." Unfortunately, there is little objective evidence that reassuring FHR tracings exclude the subsequent occurrence of cerebral palsy. In a 1993 review of published FHR monitoring studies, Rosen and Dickinson[34] could not identify FHR patterns that were consistently associated with neurologic injuries. These investigators concluded, "We do not advocate the abandonment of the use of electronic fetal monitoring, but we do believe that it is yet to be proved to be of value in predicting or preventing neurologic morbidity." A more focused application of FHR monitoring may ultimately be found useful. For example, fetal inflammatory changes, which can be associated with neurologic injury, may be associated with characteristic FHR findings.[35]

More recently, research has focused on whether expert, algorithm-assisted FHR interpretation has the potential to improve standard clinical care by leading to earlier recognition of nonreassuring FHR tracings.[36] Although use of the algorithm identified more infants with acidemia (base deficit > 12 mM/L) than standard monitoring (46% versus 30%), less than 50% of the acidemic infants were identified.[36] Thus, the current application of electronic FHR monitoring provides incomplete data that should be evaluated in the clinical context in which it is used.

Despite significant limitations in the use of intrapartum electronic FHR monitoring, there is no doubt that it will continue to be used for the foreseeable future. In a review of medicolegal issues in FHR monitoring, Schifrin and Cohen[37] noted that despite its limitations, "Monitoring deserves credit for reducing intrapartum death, one of the original rationales for its development."

A 2008 workshop (sponsored by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, the ACOG, and the Society for Maternal-Fetal Medicine [SMFM]) updated the definitions of various types of FHR tracings to simplify interpretation for providers.[38] As a result, a three-category system was developed. Category I FHR tracings provide reassuring evidence of fetal well-being and strongly predict *normal* fetal acid-base status at the time of observation. Category III tracings are the most ominous;

these tracings predict *abnormal* fetal acid-base status at the time of observation and require prompt evaluation. Most FHR tracings are category II (indeterminate). Category II tracings are *not* predictive of *abnormal* fetal acid-base status, but they do not provide sufficient evidence to be classified as either normal or abnormal; these tracings require continued surveillance and reevaluation (see Chapter 8).

Intrapartum events are responsible for some cases of cerebral palsy[39]; however, these cases are few. After exclusion of infants with significant congenital anomalies, intrapartum events—including asphyxial insults—likely account for only 5% to 8% of all cases of cerebral palsy at all gestational ages.[40,41] In 1999, the International Task Force on Cerebral Palsy published a consensus statement summarizing criteria that are necessary and suggestive of an intrapartum etiology for neurologic abnormalities (Box 10.1).[42] In 2010, a proposed evidence-based neonatal workup to confirm or refute allegations of intrapartum asphyxia was published.[43]

BOX 10.1 Criteria to Define an Acute Intrapartum Hypoxic Event as Sufficient to Cause Cerebral Palsy

Essential Criteria (All Four Must Be Met)

1. Evidence of metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH < 7 and base deficit ≥ 12 mmol/L)[a]
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks' gestation
3. Cerebral palsy of the spastic quadriplegic or dyskinetic type[b]
4. Exclusion of other identifiable etiologies, such as trauma, coagulation disorders, infectious conditions, and genetic disorders

Criteria That Collectively Suggest an Intrapartum Event—within Close Proximity to Labor and Delivery (e.g., 0 to 48 hours)—but Are Nonspecific to Asphyxial Insults

1. A sentinel (signal) hypoxic event occurring immediately before or during labor
2. A sudden and sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal
3. Apgar scores of 0 to 3 beyond 5 minutes
4. Onset of multisystem involvement within 72 hours of birth
5. Early imaging study showing evidence of acute nonfocal cerebral abnormality

[a]Buffer base is defined as the amount of buffer in blood available to combine with nonvolatile acids. A buffer base of 34 mmol/L is equivalent to a whole blood base deficit of 12 mmol/L.

[b]Spastic quadriplegia and, less commonly, dyskinetic cerebral palsy are the only types of cerebral palsy associated with acute hypoxic intrapartum events. Spastic quadriplegia is not specific to intrapartum hypoxia. Hemiparetic cerebral palsy, hemiplegic cerebral palsy, spastic diplegia, and ataxia are unlikely to result from acute intrapartum hypoxia.

From Nelson KB, Grether JK. Potentially asphyxiating conditions and spastic cerebral palsy in infants of normal birth weight. *Am J Obstet Gynecol.* 1998;179:507–513.

Epidemiology and Etiology

The causes of cerebral palsy are not known, but the varying forms suggest a multifactorial etiology. The Collaborative Perinatal Project still represents one of the largest studies of the antecedent factors associated with cerebral palsy.[44] The investigators in this study evaluated the outcomes of 54,000 pregnancies among patients who delivered at 12 university hospitals between 1959 and 1966. They evaluated more than 400 variables in a univariate analysis,[44] which identified potential risk factors that were then subjected to a more rigorous multivariate analysis.[45] Maternal age, parity, socioeconomic status, smoking history, maternal diabetes, duration of labor, or use of anesthesia was not associated with cerebral palsy in the univariate analysis. The factors most strongly associated with cerebral palsy in the multivariate analysis were (1) maternal mental retardation, (2) birth weight ≤ 2000 g, and (3) fetal malformations. Other factors associated with cerebral palsy included (1) breech presentation (but not vaginal breech delivery), (2) severe proteinuria (> 5 g/24 h) during the second half of pregnancy, (3) third-trimester bleeding, and (4) gestational age ≤ 32 weeks. There was a slight association between cerebral palsy and fetal bradycardia, chorioamnionitis, and low placental weight. However, only 37% of the cases of cerebral palsy occurred in patients with one or more of these identified risk factors.

Rosen and Dickinson[46] reviewed studies from Europe, Australia, and the United States that were published between 1985 and 1990 and included data from 1959 to 1982. The incidence of cerebral palsy ranged from 1.8 to 4.9 (composite rate of 2.7) cases per 1000 live births. The incidence of certain conditions in infants with cerebral palsy was as follows: birth weight < 2500 g, 26%; diplegia, 34%; hemiplegia, 30%; quadriplegia, 20%; and extrapyramidal forms, 16%.

Two more recent studies from Australia reexamined the risk factors for cerebral palsy. A large epidemiologic study from 1998 noted an incidence of neonatal encephalopathy of 3.8 per 1000 term births.[47] The investigators identified preconception and antepartum factors that were associated with neonatal encephalopathy (Box 10.2). In the second study from 2011, the greatest risks for cerebral palsy included (1) preterm birth, (2) fetal growth restriction, (3) perinatal infection, and (4) multiple gestation.[48] Upper respiratory tract and gastrointestinal infections during pregnancy and instrumental (forceps or vacuum) vaginal delivery were not associated with cerebral palsy.[48] Evidence suggests that intrapartum factors alone are associated with neonatal encephalopathy in < 5% of cases.[47,49] These data, along with the recognition that most patients with identified risk factors do not have children with cerebral palsy, have led the majority of investigators to agree that most cases of cerebral palsy cannot be predicted and that the identification of pregnancy-related conditions contributes minimally to the identification of patients at risk for having a child with cerebral palsy.

BOX 10.2 Risk Factors for Neonatal Encephalopathy

Preconception Factors
- Increasing maternal age
- Mother unemployed, unskilled laborer, or stay-at-home
- No private health insurance
- Family history of seizures
- Family history of neurologic disorders
- Infertility treatment

Antepartum Factors
- Maternal thyroid disease
- Severe preeclampsia
- Bleeding in pregnancy
- Viral illness in pregnancy
- Postdates pregnancy
- Fetal growth restriction
- Placental abnormalities

Information compiled from Badawi N, Kurinczuk JJ, Keogh JM, et al. Antepartum risk factors for neonatal encephalopathy: the Western Australia case-control study. *BMJ.* 1998;317:1549–1553.

In 2000, the ACOG and the American Academy of Pediatrics (AAP) convened the Neonatal Encephalopathy and Cerebral Palsy Task Force. The resulting landmark report,[50] which was released in 2003, was reviewed and endorsed by many groups. The Task Force extended the earlier international consensus statement regarding the requirements for establishing a causal relationship between intrapartum events and cerebral palsy (see Box 10.1).[42] The consensus statement led to several medicolegal conclusions[50]:

1. The only types of cerebral palsy associated with intrapartum hypoxia are spastic quadriplegia and, less commonly, dyskinesia.
2. Intellectual disability, learning disorders, and epilepsy should not be ascribed to birth asphyxia unless accompanied by spastic quadriplegia.
3. No statements about severity should be made before an affected child is 3 to 4 years of age, because mild cases may improve and dyskinesia may not be evident until then.
4. Intrapartum hypoxia sufficient to cause cerebral palsy is always accompanied by neonatal encephalopathy and seizures.

Phelan et al.[51] subsequently confirmed that fetuses that experienced a sudden and sustained deterioration of the FHR, and that subsequently were found to have cerebral palsy, demonstrated characteristics consistent with the ACOG/AAP Task Force criteria for intrapartum asphyxial injury.

Peripartum Asphyxia and Cerebral Palsy

Asphyxia may be defined as insufficient exchange of respiratory gases.[52] Although accurate, this definition does not include an index of severity or have any predictive value. Unfortunately, most studies have not used a uniform definition of *birth asphyxia.*[53]

In 1953, Dr. Virginia Apgar, an anesthesiologist, introduced her scoring system to identify newborn infants in need of resuscitation and to assess the adequacy of subsequent resuscitation efforts.[54] Although the Apgar score has also been used to identify infants at risk for cerebral palsy, only a weak association has been found.[55] In the Collaborative Perinatal Project, only 1.7% of children with a 1-minute Apgar score ≤ 3 developed cerebral palsy.[56] Among infants who weighed more than 2500 g at delivery, the incidence of cerebral palsy was 4.7% if the 5-minute Apgar score was 0 to 3 and 0.2% if the 5-minute Apgar score was at least 7. Among infants who weighed < 2500 g with the same 5-minute Apgar scores, the incidence of cerebral palsy was 6.7% and 0.8%, respectively. Among all infants, a higher incidence of cerebral palsy was observed if the Apgar score remained ≤ 3 for longer than 5 minutes. The incidence of early neonatal death increased among those infants with prolonged neonatal depression.

Most infants who subsequently manifest evidence of cerebral palsy have a normal 5-minute Apgar score. In the Collaborative Perinatal Project, only 15% of the infants in whom cerebral palsy later developed had a 5-minute Apgar score ≤ 3.[56] It should also be noted that preterm delivery is independently associated with a low Apgar score.

Although most cases of cerebral palsy are not attributed to intrapartum insults, intrapartum asphyxia does occur and can have serious consequences. However, the degree of asphyxia necessary to produce irreversible CNS injury is unclear. In some cases, an intrapartum insult that might have otherwise been innocuous might be superimposed on subclinical chronic fetal compromise and result in permanent injury.

Umbilical cord blood gas measurements are often used to diagnose suspected asphyxia. However, the definition of *normal* umbilical cord blood gas and pH measurements remains unclear.[52] In one study of 15,073 *vigorous* neonates (arbitrarily defined as having a 5-minute Apgar score of ≥ 7) conducted between 1977 and 1993, the median umbilical arterial blood gas measurements (with the 2.5th percentile in parentheses) were as follows: pH 7.26 (7.10), Po_2 17 (6) mm Hg, Pco_2 52 (74) mm Hg, and base excess –4 (–11) mmol/L.[52] Only small differences in median pH and other measurements were present when infants were grouped according to gestational age. These data suggest that umbilical arterial blood pH in vigorous neonates can be as low as 7.10, and base excess may be as low as –11 mmol/L.

Although intrapartum events are most likely associated with a minority of cerebral palsy cases, clinical studies have attempted to define the associated extent and duration of perinatal asphyxia. Fee et al.[57] defined asphyxia as an umbilical arterial blood pH of < 7.05 with a base deficit > 10 mmol/L; they concluded that this threshold was a poor predictor of adverse neurologic outcomes. Goodwin et al.[58] defined asphyxia as an umbilical arterial blood pH < 7.00; with the use of this definition, hypoxic-ischemic encephalopathy and abnormal neurologic outcome were associated with acidemia. Goldaber et al.[59] also observed greater neonatal morbidity

and mortality among term infants (birth weight > 2500 g) with an umbilical arterial blood pH < 7.00.

Low et al.[60,61] also studied complications of intrapartum asphyxia in term and preterm infants. They developed a complication score that expressed the magnitude of neonatal complications. Among term infants, the frequency and severity of newborn complications increased with the severity and duration of metabolic acidosis at birth. Importantly, respiratory acidosis at birth did not predict complications in newborns. Similar results were noted for preterm infants delivered between 32 and 36 weeks' gestation. In contrast, in infants delivered before 32 weeks' gestation, complications were similar in the control and asphyxia (defined as umbilical arterial blood buffer base < 30 mmol/L) groups. When this scoring system was used in term infants, the threshold for moderate or severe newborn complications was an umbilical arterial blood base deficit of 12 mmol/L.[61]

Relatively few studies have followed neurodevelopmental examinations for a sufficient duration to make meaningful conclusions about peripartum predictors of neurologic injury. Nagel et al.[62] performed such examinations in 30 children in whom umbilical arterial blood pH was < 7.00 at delivery, 28 of whom survived the neonatal period. Evaluation at 1 to 3 years of age detected three children who had experienced an episode of hypertonia. Most of the children exhibited no major problems, with only one child displaying mild motor developmental delay. Another study examined neonatal complications (neonatal death, grade 3 or 4 intraventricular hemorrhage, gastrointestinal dysfunction, and neonatal seizures) in 35 newborns with an umbilical arterial blood pH < 7.00 at delivery, three of whom died during the neonatal period.[63] An umbilical arterial blood base deficit ≥ 16 mmol/L and a 5-minute Apgar score < 7 had a sensitivity and specificity for predicting adverse neonatal outcomes of 79% and 81%, respectively.

Because metabolic acidosis may be a predictor of complications in newborns, the severity of intrapartum acidosis could be an important variable. Gull et al.[64] studied a small cohort of 27 patients with terminal bradycardia who were delivered vaginally. Not surprisingly, the umbilical arterial blood base deficit was greater in infants with end-stage bradycardia than in controls. The loss of short-term FHR variability for more than 4 minutes during terminal bradycardia correlated with the development of metabolic acidosis.

The relationship between umbilical arterial blood base excess values and the timing of hypoxic injury has been estimated in human and animal studies.[65] In a 2010 systematic review and meta-analysis, an umbilical cord arterial blood pH < 7.00 was significantly associated with important, biologically plausible, adverse neonatal outcomes (i.e., neonatal mortality, hypoxic ischemic encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, cerebral palsy).[66] Unfortunately, this relationship does not consider the role of previous or repetitive hypoxic episodes before the episode in question and therefore cannot accurately pinpoint the time of injury. Fortunately, the human fetus is quite robust, and episodes of intrauterine asphyxia usually yield a normal neonate. Blumenthal[67] concluded that there is a fine threshold between normality and death from asphyxia.

The increased presence of nucleated red blood cells in the umbilical circulation at delivery has been proposed as a marker of the occurrence and timing of intrauterine asphyxia.[68] However, data from these investigations demonstrated considerable variability and were influenced by birth weight and gestational age.[69] In 2014, the ACOG concluded that biomarkers predictive of long-term outcome after a hypoxic insult have not been identified, and that it is likely that a battery of such markers, in conjunction with clinical and imaging findings, rather than a single biomarker, would better predict outcome.[25]

Chorioamnionitis, Fever, and Cerebral Palsy

An association between cerebral palsy and chorioamnionitis has been demonstrated in preterm and term infants.[70,71] Intra-amniotic infection and inflammation show direct evidence of causality between the intrauterine process and white matter injury.[72] An elevated maternal temperature is one sign of chorioamnionitis, but alone it is insufficient for the diagnosis. Other signs include, but are not limited to, maternal and fetal tachycardia, foul-smelling amniotic fluid, uterine tenderness, and maternal leukocytosis. The diagnosis remains unproven until confirmed by placental culture or histologic examination.

The mechanism by which chorioamnionitis is associated with cerebral palsy is unclear; however, inflammatory cytokines may play a role (see later discussion).[73,74] A landmark meta-analysis published in 2000 reported that both clinical and histologic chorioamnionitis were strongly associated with an increased risk for cerebral palsy and periventricular leukomalacia in both preterm and term infants.[75] In a 2010 meta-analysis, both histologic (pooled odds ratio [OR], 1.83; 95% confidence interval [CI], 1.17 to 2.89) and clinical chorioamnionitis (OR, 2.42; 95% CI, 1.52 to 3.84) were again found to be significantly associated with cerebral palsy.[76]

Several studies have demonstrated a tendency for maternal temperature to rise after administration of epidural analgesia during labor (see Chapter 23). The mechanism of epidural analgesia–associated maternal pyrexia remains unclear but appears to be inflammatory in nature.[77] Epidural analgesia has been blamed for the common obstetric practice of antibiotic administration to mothers with fever but no other evidence of chorioamnionitis. This practice may lead to unnecessary neonatal sepsis evaluations and antibiotic exposure.[78] Rather than treat all women with pyrexia for presumed chorioamnionitis, Mayer et al.[79] correctly noted that physicians should make an effort to differentiate true chorioamnionitis from incidental maternal fever. These investigators found that additional signs of chorioamnionitis were present in all cases in which the diagnosis was later confirmed by culture or pathologic examination. Neuraxial anesthesia is not a risk factor for cerebral palsy.[44]

PATHOPHYSIOLOGY OF FETAL ASPHYXIA

Intrauterine Hypoxemia and the Fetal Brain

The fetus is exclusively dependent on the placenta for oxygen and nutrients; thus, acute and chronic conditions that affect the placenta or the umbilical cord can deprive the fetus of one or more of these vital resources. Recent evidence from experimental animal models and humans suggests that both hypoxemic and inflammatory pathways interact and augment fetal brain damage.

The spectrum of neurologic injury in neonates depends on the duration and gestational age at hypoxemic-ischemic insult. Acute hypoxemia during the early- to mid-gestational period in sheep affects the predominant neurodevelopmental events such as neurogenesis and neuronal migration. Such hypoxemia causes the death of cerebellar Purkinje cells and hippocampal pyramidal neurons, and impaired neuronal migration.[80] In contrast, acute hypoxemia in late gestation appears to spare the hippocampus and cerebellum but causes neuronal death in the cerebral cortex and striatum.[81] Furthermore, acute perinatal anoxia causes long-term changes in dendritic arborization and synaptic connectivity.[82,83]

Experimental models of chronic hypoxemia, based on restriction of placental mass or blood flow, demonstrate an array of completely different effects on the fetal brain. Chronic placental insufficiency relatively spares the fetal brain compared with other organ systems, although it results in reduced fetal brain weight. Overall, neurons appear to survive chronic and mild hypoxemia; even minor behavioral changes appear to resolve fully by adulthood in animal models. It is not known whether these effects are mediated by hypoxemia per se, or by other accompanying conditions such as chronic reduction of fetal nutrient supply or altered maternal-fetal endocrine status.

Dysregulation of neuronal calcium transport appears to be the initial pathway by which cerebral hypoxemia causes perinatal neuronal injury.[84] Hypoxia-induced changes in the NMDA receptor increase cellular permeability to calcium; such increases in intracellular calcium trigger a variety of downstream effects, ultimately resulting in generation of free radicals, peroxidation of lipid membranes, and nuclear fragmentation. It has long been recognized that developing oligodendroglia are highly vulnerable to excitotoxic injury in preterm infants.[85] Altered maturation or premature oligodendrocyte death can occur in areas of severe hypoxia-ischemia as a result of upregulation of inflammatory cytokines by activated microglia, elevated glutamate levels, or depleted levels of the antioxidant glutathione. It is highly likely that a combination of these mechanisms, modified by the nature and duration of insults and gestational age, determines the ultimate neurobehavioral phenotype.

Maternal Inflammation and Fetal Brain Injury

Although the development of the fetal brain is encoded by genetic programming, such programs remain highly susceptible to environmentally induced epigenetic modifications and appear closely intertwined with maternal immune and endocrine systems. Recent experimental and epidemiologic studies reveal that maternal infection and inflammation early in pregnancy can cause an array of neurodevelopmental abnormalities in offspring such as schizophrenia and autism.[86–89] Among maternal infections, chorioamnionitis is the best characterized and thoroughly investigated model of perinatal neuroinflammation. Human registry studies have confirmed an association between histological chorioamnionitis and cerebral palsy.[90] Although the exact contribution of maternal inflammation to perinatal brain injury is obscured because of the association of chorioamnionitis with preterm delivery and hypoxic-ischemic encephalopathy, inflammatory experimental models have revealed much information on cytokine induction, their transport across the placenta and amniotic fluid, and subsequent activation of the fetal immune system.

The exact mechanism by which maternal inflammation triggers a fetal immune response is likely multifactorial (Fig. 10.2). Despite the presence of circulating immune cells as early as 7 weeks' gestation in humans, antigen presentation is suboptimal because of reduced expression of the major histocompatibility complex class II on antigen-presenting cells. Furthermore, the T-cells are relatively immature. Therefore, maternally derived humoral mediators seem credible candidates to initiate and perpetuate an inflammatory cascade across the placenta. This idea has gained traction with the identification of maternal interleukin-6 (IL-6) in the fetal circulation as early as the second trimester, suggesting the possibility of transplacental transfer of proinflammatory cytokines.[91] Proinflammatory mediators such as IL-6 cause significant impairment of placental blood flow and fetal hypoxemia in animal models, dysregulate the barrier function of both the placenta and the immature fetal blood-brain barrier, trigger production of acute-phase proteins from the fetal liver, promote T-cell entry into the immature brain parenchyma, and disrupt the orderly patterning of the fetal cerebral cortex.[86,88,92–95] The role of inflammatory mediators in this phenomenon is reinforced by the direct correlation that exists between plasma levels of IL-6 and the severity of functional deficits in offspring.[96,97] In addition to IL-6, cytokines such as IL-1β, IL-7, and IL-13 are upregulated in the fetal brain after a prenatal immune insult, a phenomenon that suggests collective activation of the innate fetal immune response.[98]

Both microglia (the major resident macrophages in the developing brain) and the complement system have been implicated as amplifiers of this immune response. During normal fetal development, microglia invade and colonize the fetal brain during the first and second trimesters[99] and are readily activated by proinflammatory mediators such as IL-1β. Activated microglial cells either cause a direct cytotoxic effect on oligodendrocytes and impair myelination or produce long-lasting alterations in neuronal-glial crosstalk, resulting in impaired synaptic function and subsequent neurodevelopmental disorders.[3,86,100]

At the cellular level, numerous mechanisms are involved in propagating the prenatal immune response. Intrauterine

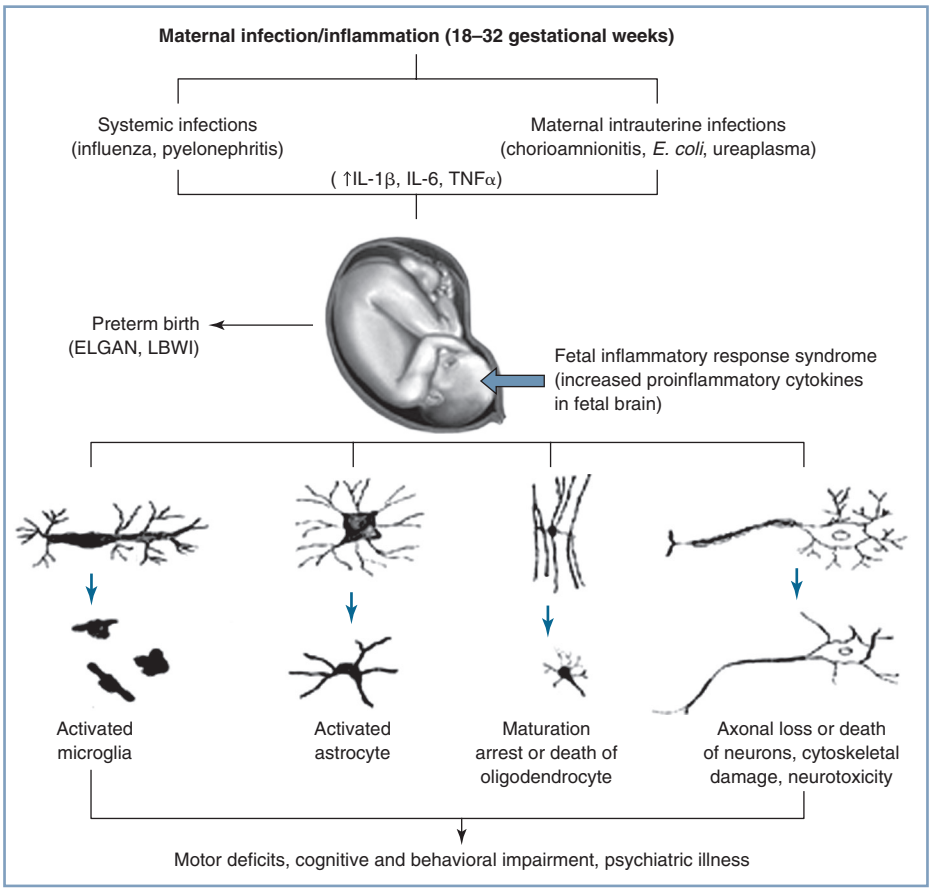

Fig. 10.2 Probable mechanisms of fetal brain injury with *in utero* exposure to maternal inflammation. *IL,* interleukin; *TNF,* tissue necrosis factor; *LBWI,* low-birth-weight infant; *ELGAN,* extremely low gestational age neonate. (From Burd I, Balakrishnan B, Kannan S. Models of fetal brain injury, intrauterine inflammation, and preterm birth. *Am J Reprod Immunol.* 2012;67:287–294.)

inflammation is linked to the metabolic demand of the fetal brain; in infants born before 30 weeks' gestation, chorioamnionitis was associated with significantly increased total carotid artery blood flow (92 versus 63 mL/kg/min) and oxygen delivery (13.7 versus 10.1 mL/kg/min) compared with a control cohort without chorioamnionitis.[101] Whether the increase in oxygen delivery contributes to, or is a consequence of, fetal brain injury is unclear, but emerging evidence suggests an enhanced susceptibility of the developing brain to oxidative stress.[102]

Collectively, robust experimental evidence suggests that prenatal inflammation alters fetal brain development at the molecular, cellular, and circuit levels. These findings are reinforced by epidemiologic studies that show a strong correlation between maternal infection/inflammation and neurodevelopmental disorders such as schizophrenia and autism.[87,103,104]

Animal Models of Fetal Asphyxia

Much of our knowledge of the fetal response to insufficient exchange of respiratory gases has been gained using animal models. However, the limitations of these models must be acknowledged. Raju[105] reviewed the various animal models of fetal brain injury. At birth, sheep and guinea pig brains are much closer to maturity than the human brain. In this regard, rat pup and human brains are more similar to each other because they both undergo significant extrauterine development (Fig. 10.3).[106] Nonetheless, the importance of this distinction has been challenged. Previously, investigators relied mainly on morphologic milestones (e.g., the brain growth spurt) to compare species at different stages of development. A computerized method attempted to more accurately compare observations among 10 species (including humans) by evaluating the mathematical relationships of more than 100 developmental events and factors (e.g., evolutionary, genetic, neurochemical, neuroanatomic).[107] Although all events have not been catalogued for any one species, the iterative process allows information to be added to improve the theoretic model and is freely available online.[a] This method is not completely understood or accepted but may explain some of the variability observed among various models of developmental brain injury.

One advantage of the chronically instrumented fetal lamb is that it is similar in size to the human fetus, thus facilitating

[a]Translating Time across Developing Mammalian Brains: http://www.translatingtime.net/.

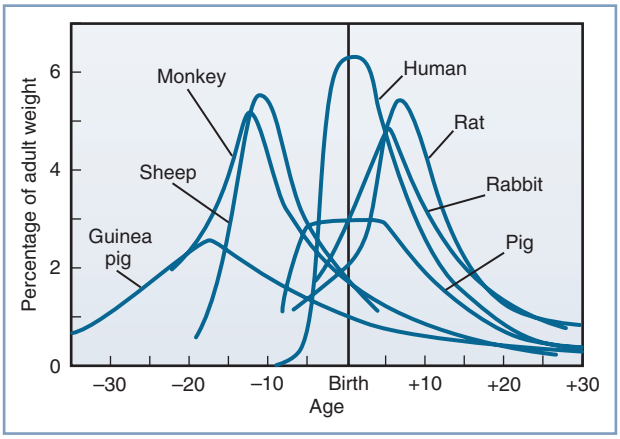

Fig. 10.3 Brain growth spurts of seven mammalian species expressed as first-order velocity curves of the increase in weight with age. The units of time for each species are as follows: guinea pig (days); rhesus monkey (4 days); sheep (5 days); pig (weeks); human (months); rabbit (2 days); rat (days). Rates are expressed as a percentage of adult weight for each unit of time. (Modified from Dobbing J, Sands S. Comparative aspects of the brain growth spurt. *Early Hum Dev*. 1979;3:79–83.)

the placement of electrodes and vascular catheters in both the fetus and the mother. Investigators may obtain measurements while the mother (and fetus) remains anesthetized or from awake animals that have recovered from surgery. Studies of animals with continuous instrumentation allow the assessment of fetal breathing movements, gross body movements, brain electrical activity (electroencephalogram), and blood gas and pH measurements. Blood concentrations of glucose, lactate, and various hormones can also be determined. Microdialysis techniques have been used to evaluate neurotransmitter release within the fetal brain *in vivo* in acute, exteriorized, and chronic preparations.[108,109] Other studies have measured fetal cerebral blood flow *in vivo* during episodes of hypoxemia[110] and during maternal infusion of ethanol.[111] Together, these studies have enhanced the understanding of the fetal brain response to pathophysiologic insults *in utero*. Ultimately, these insights may lead to improved diagnoses, treatment, and prevention of fetal brain injury.

Studies have used a variety of methods to produce fetal hypoxemia and acidemia in fetal lambs. Each method attempts to mimic one or more clinically relevant situation(s), including (1) decreased concentration of maternal inspired oxygen for several hours[112] or days[113]; (2) decreased uterine blood flow, which may be accomplished by placement of an adjustable clamp on the common iliac artery[114]; (3) decreased umbilical blood flow, either by total obstruction[115] or by means of a slow, progressive obstruction[116]; (4) selective uteroplacental embolization[117]; (5) maternal hemorrhage[118]; and (6) a combination of two insults, such as hypoxemia plus hypotension.[119]

Care must be exercised in the application of knowledge gained from hypoxia-ischemia studies conducted on nonfetal models (e.g., rat pups) to the problem of insufficient intrauterine gas exchange. The fetus and the fetal brain exist in a relatively hypoxemic environment. Despite preferential streaming of the most highly oxygenated blood to the brain and heart, the average Po_2 measured in the carotid artery of fetal lambs at term is approximately 22 mm Hg.[120] Further, unlike adult conditions in which global anoxia (i.e., cardiac arrest) or focal ischemia (i.e., stroke) is the clinical correlate, fetal asphyxia typically involves diminution, but not absence, of delivery of oxygen, with variable degrees of respiratory or metabolic acidosis. A complete loss of cerebral blood flow rarely occurs, except as a terminal event. Of course, prolonged hypoxemia and decreased oxygen delivery can lead to acidemia and myocardial failure, followed by ischemia and rapid fetal demise. Fetal hypoxemia may result from the compromise of any or all of the steps involved in maternal-fetal oxygen transport (Box 10.3).[121] The impact of repeated hypoxic-ischemic insults should not be underestimated, and numerous clinical scenarios can be envisioned whereby this might occur (e.g., repetitive umbilical cord occlusion, chronic abruption). Moreover, brief insults that may be harmless could cause damage if repeated, as has been demonstrated in adult rats[122] and in fetal lambs.[123]

The neuropathology of intrauterine asphyxia depends, to some extent, on gestational age. In fetal lambs exposed to sustained hypoxemia with developing acidemia, immature fetuses demonstrated a predominantly periventricular

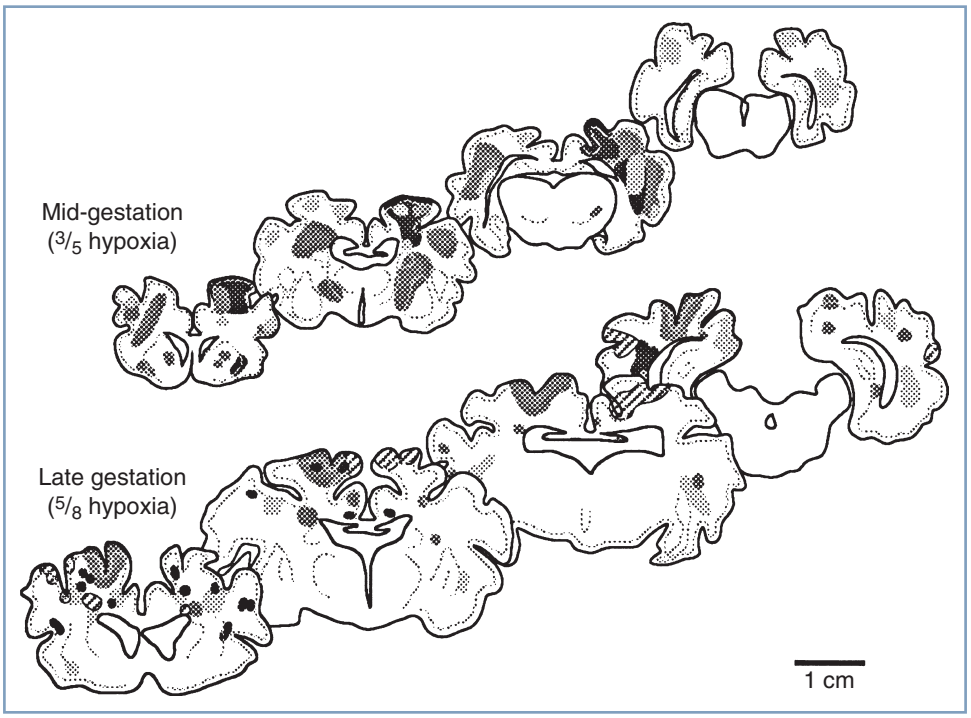

Fig. 10.4 Composite diagram showing distribution of hypoxic injury in mid-gestational *(top)* and near-term *(bottom)* fetal lambs at 3 days after 8 hours of arterial hypoxemia. Hypoxemia was produced by placing the pregnant ewe in a chamber with reduced ambient oxygen. Each shading pattern represents an individual animal. The severity of injury is not indicated in this diagram. (From Penning DH, Grafe MR, Hammond R, et al. Neuropathology of the near-term and midgestation ovine fetal brain after sustained in utero hypoxemia. *Am J Obstet Gynecol.* 1994;170:1425–1432.)

injury, whereas mature fetuses had a primarily cortical injury, although there was some overlap (Fig. 10.4).[124] This finding is consistent with injury patterns in humans. It is not surprising that the biophysical and biochemical responses to hypoxemia vary between preterm and term fetuses. Matsuda et al.[112] observed that the development of metabolic acidemia, reduced fetal breathing and body movements, and an altered sleep state were much less pronounced in mid-gestational fetal lambs subjected to hypoxemia than in fetal lambs at term.

Neuropathology of Fetal Asphyxia

The mechanism and timing of an asphyxial insult can affect the resulting fetal or neonatal pathology. Acute, complete asphyxia must be distinguished from incomplete, brief, or intermittent asphyxia or chronic hypoxemia. *Complete asphyxia* may occur in the setting of a total placental abruption or umbilical cord occlusion (as may occur with a uterine rupture or umbilical cord prolapse), which if unrecognized and not treated rapidly leads to fetal demise. *Incomplete asphyxia* may occur in any setting in which oxygen delivery to the fetus is inadequate to meet all of its needs (e.g., brief and/or repeated episodes of partial umbilical cord occlusion, placental embolization, or incomplete placental abruption). This latter category of asphyxia presumably contributes to the largest proportion of cases of cerebral palsy attributed to antepartum events. In these cases, the insult is not severe enough to lead to immediate fetal death but can profoundly affect fetal brain growth and development. Ongoing studies are attempting to determine whether there is a period *in utero* when the fetus is especially vulnerable to neurologic injury.

Using a primate model to perform seminal research on perinatal brain injury, Myers[26] identified two patterns of injury based on whether the fetus suffered complete or partial asphyxia. True complete asphyxia was demonstrated in fetal monkeys at term subjected to varying durations (0 to 25 minutes) of complete asphyxia. These fetuses were resuscitated when possible, a procedure that often required the use of cardiac massage and epinephrine, and postmortem examinations revealed extensive pathology in brainstem areas. In humans, such a severe intrauterine insult would most likely be incompatible with extrauterine survival. If survival did occur, the infant would show obvious encephalopathy and multiorgan system dysfunction at birth. The second pattern (i.e., partial asphyxia) is more relevant to the discussion of human cerebral palsy. In studies of fetal monkeys subjected to partial asphyxia,[125] some animals demonstrated cortical necrosis, subcortical white matter damage, and basal ganglia damage. Although these two studies form the core of our knowledge of perinatal brain injury in primates, there were relatively few animals in each experimental group, and considerable variation in response occurred. Some animals suffered no injury, whereas others could not be resuscitated. Volpe[126] emphasized that the variation in neuropathology

after intrauterine asphyxia depends on the fetal gestational age and proposed a framework for these variations. The principal sites of injury in preterm fetuses are the white matter (especially periventricular white matter) and the basal ganglia, whereas older fetuses demonstrate injury primarily in the gray matter of the cortex and cerebellum.

Cerebral white matter injury is a term that encompasses the full spectrum of periventricular leukomalacia. *Diffuse noncystic white matter injury* is currently the predominant form of brain injury in children born prematurely.[127] The incidence of *cystic necrotic white matter injury* has declined markedly in the past several decades. The primary reason for white matter injury in preterm infants is the vulnerability of premyelinating oligodendrocytes to hypoxia-ischemia and inflammation.[127,128] Preterm infants have impaired cerebral blood flow autoregulation, particularly in vascular end zones and border zones.[129] Premyelinating oligodendrocytes are more susceptible to oxidative stress than mature cells because they lack antioxidant enzymes.[128]

Approximately one-third of preterm infants born between 24 and 32 weeks' gestation have evidence of diffuse white matter injury on magnetic resonance imaging (MRI).[130] These lesions cause disrupted white matter maturation and associated long-term neurodevelopmental consequences as these children grow.[127]

Fetal Adaptive Responses

The fetus takes advantage of several adaptive responses for survival and growth in the relatively hypoxemic intrauterine environment; these adaptive changes to intrauterine hypoxemia vary between immature and mature fetuses. Fetal responses to asphyxia may be categorized as an alteration of fetal metabolism or maximization of fetal oxygen transport (Box 10.4).[121] Richardson[131] defined the *oxygen margin of safety* as the extent to which fractional oxygen extraction can increase and fetal arterial Po_2 can decrease before tissue oxygen supplies are inadequate. Regardless of the etiology of decreased oxygen delivery to the fetus, fetal oxygen consumption is maintained by increasing oxygen extraction until oxygen delivery is approximately 50% of normal.[132] Lower levels of tissue oxygen tension result in progressive metabolic acidemia and a terminal decrease in oxygen consumption.[131]

Fetal Cerebral Metabolism
- Increased oxygen extraction
- Use of alternative energy sources
- Decreased growth
- Altered behavioral state

Fetal Cerebral O_2 Transport
- Redistribution of cerebral blood flow

Modified from Richardson B. The fetal brain: metabolic and circulatory responses to insufficient exchange of respiratory gases. *Clin Invest Med.* 1993;16:103–114.

Alterations in substrate use may affect the fetal response to insufficient exchange of respiratory gases. Unlike the adult brain, the fetal brain can use ketone bodies and lactate as alternative energy sources.[133] In gravid ewes, a reduction in uterine blood flow results in reduced fetal glucose consumption.[133] Current opinion holds that hyperglycemia should be avoided in adult humans at risk for ischemia.[134] Hyperglycemia may exacerbate metabolic acidosis by providing substrate for anaerobic metabolism, which increases lactic acid production. However, Vannucci and Mujsce,[135] citing experiments in neonatal rat pups, suggested that the immature brain may respond differently and that glucose administration may actually reduce hypoxic-ischemic brain injury. These investigators did not consider earlier work by Blomstrand et al.,[136] who studied the effects of hypoxia in the anesthetized, exteriorized fetal lamb. In that study, hyperglycemia accelerated the loss of somatosensory-evoked potentials, the onset of metabolic acidosis, and the reduction of cerebral oxygen consumption. Until these different observations are reconciled, the maintenance of normoglycemia *in utero* appears prudent.

During chronic hypoxemia, the fetus may also restrict the use of energy derived from oxidative metabolism to maintain essential cellular processes. This may lead to decreased somatic growth and fetal growth restriction. Using an ovine model of asphyxia, Hooper[137] detected decreased incorporation of tritiated [^{3}H]-thymidine (which reflects decreased DNA turnover and, presumably, decreased cell division) in fetal tissue. The decrease in incorporation of tritiated [^{3}H]-thymidine was not uniform in all tissues. The rates of DNA synthesis were maintained in most fetal tissues (including the fetal brain) but were greatly reduced in the lung, the skeletal muscle, and the thymus gland.

The fetus can conserve additional energy by decreasing breathing and gross body movements. Rurak and Gruber[138] demonstrated a 17% reduction in oxygen consumption in fetal lambs that were paralyzed by a neuromuscular blocking agent. Perceptible fetal movements represent an index of fetal health. Many obstetricians instruct their patients to count episodes of fetal activity for specified periods and to consult them if fetal movements are decreased or absent (see Chapter 6). Fetal hypoxemia results in decreases in both activity and rapid eye movement (REM) sleep in fetal lambs. REM sleep states are associated with an increased cerebral metabolic rate for oxygen ($CMRo_2$).[110] Thus, during periods of fetal stress, reductions in fetal body movements or REM sleep lead to a significant decline in fetal energy expenditure.

Oxygen deprivation typically results in a change in and/or redistribution of fetal cardiac output.[139] The magnitude of these changes depends on the mechanism and severity of oxygen deprivation. Sheldon et al.[140] demonstrated that experimental fetal hypoxemia (produced by the administration of a decreased maternal-inspired concentration of oxygen) resulted in greater blood flow to the brain, myocardium, and adrenal glands. In fetal lambs, a brief (4-minute) complete arrest of uterine and ovarian blood flow resulted in a decrease in blood flow to all organs except the myocardium and adrenal glands.[141]

FETAL AND NEONATAL ASSESSMENT

Fetal Neurobehavioral Assessment

With recent advances in the understanding of prenatal brain development and imaging technology, there is considerable interest in monitoring and codifying fetal neurologic development and behavior to predict postnatal neurodevelopment.[142] The driving principle is that fetal behavioral patterns reflect complex interactions between the maternal environment and primitive neuronal network generators in the developing brain. There is an overwhelming convergence of opinion that most neurodevelopmental disorders have an intrauterine origin and that there is extensive neurobehavioral continuity from the fetal to the neonatal period.[143]

Although the assessment of high-risk pregnancies has included an analysis of certain aspects of fetal behavior, until recently there have been no unified scales for assessment of fetal neurobehavior. Current fetal neurobehavioral scales assess a variety of behaviors that can be categorized into the four main domains described by DiPietro[142]: (1) heart rate, (2) motor activity, (3) existing behavioral state, and (4) responsiveness to external stimuli. The Fetal Neurobehavioral Coding System (FENS) incorporates most elements of fetal behavior and is a direct extension of the NICU Network Neurobehavioral Scale (NNNS) used for neonatal assessment.[144] Using ultrasonography, FENS analysis can identify specific behaviors in fetuses with growth restriction; compared with normally developing fetuses, fetuses with growth restriction demonstrate a delayed appearance of behavioral states, longer behavioral state transitions, and disorganized behavioral patterns. These tests have been validated in other paradigms, including pregnancies that were complicated by maternal diabetes, substance abuse, and cigarette smoking.

A recently developed, more comprehensive scale is the Kurjak Antenatal Neurodevelopmental Test (KANET), which includes an assessment of eight fetal parameters related to fetal behavior, general movements, and other physical signs (e.g., head circumference, presence or absence of overlapping cranial sutures, finger movements).[145] However, these fetal assessment studies are time-consuming and require specific training to codify behaviors. In addition, because the brain structures driving such behaviors have not been clearly identified, it is difficult to understand the significance of differences in behavior, if any.

Fetal Neuroimaging Assessment

In vivo MRI provides details of the architecture of the developing brain beginning in the 18th gestational week and can quantify brain growth and structural abnormalities.[146] The use of more sophisticated techniques such as MR tractography and functional fetal MRI is likely to enhance our understanding of normal brain development and thus facilitate identification of abnormal development. Until controlled trials demonstrate adequate sensitivity, specificity, and positive predictive power for these tests, their clinical potential is limited. These potential advantages will need to be balanced against the potential detrimental effects of ultrasonography and MRI on fetal neuronal development and migration.[147]

Neonatal Radiologic Diagnosis of Cerebral Injury

MRI is a useful tool in the diagnosis of neonatal brain injury.[148] MRI can assist in the diagnosis of hypoxic-ischemic encephalopathy in newborn infants, provide three-dimensional evaluations to determine the volume of gray matter and the extent of white matter myelination (thus providing valuable insights into normal and abnormal brain development), and estimate the timing of the brain injury in patients with cerebral palsy.[148] New imaging techniques, such as diffusion tensor imaging and magnetic resonance spectroscopy, may offer advantages over conventional MRI when performed early (i.e., hours) after a hypoxic-ischemic insult. Diffusion tensor imaging detects the microscopic movement of water particles in brain tissue. Magnetic resonance spectroscopy analyzes the signal of protons attached to molecules such as glutamate, glutamine, and lactate, among others.[149] These methods detect acute chemical changes in brain tissue and may accurately predict motor outcome in preterm infants.[150] Injury patterns detected with these methods are present for several days and resolve over the next week, at which point the chronic injury becomes visible with conventional MRI. Identification of injuries shortly after birth with these newer techniques can support the hypothesis that an injury occurred within days of delivery.[149] Thus, magnetic resonance spectroscopy and diffusion tensor imaging are powerful new tools for timing the occurrence and understanding the pathophysiology of perinatal brain injury. Cerebral ultrasonography remains a useful technique in the early neurologic neonatal assessment, especially for the critically ill infant who might not be a candidate for transfer to an MRI facility.[151]

ANESTHESIA AND BRAIN INJURY

Anesthetic agents have profound effects on brain metabolism and synaptic transmission. These effects may be direct or indirect and protective or harmful.

Labor Analgesia and the Fetal Brain

Labor analgesia usually entails administration of *lower concentrations* of analgesic/anesthetic agents for a *longer duration* than occurs during administration of anesthesia for surgical procedures. Despite widespread use of analgesic and sedative drugs during labor, little attention has been paid to the neurodevelopmental consequences of antepartum and intrapartum fetal exposure to these drugs. Because neurodevelopmental events at term are quite different from those that occur during the second trimester, there is a need to design experimental studies to investigate the effects of analgesic techniques and drugs administered during the third trimester of pregnancy.

Opioids

Among systemic opioids used for labor analgesia, meperidine remains the most widely studied. Although it is well

recognized that opioids cross the placenta and enter the fetal circulation,[152] the long-term effects of peripartum opioid exposure on the infant's neurodevelopmental trajectory are unclear. Only a few preclinical studies have addressed this question.[153,154] Endogenous opioid systems are active in the fetal brain, and the presence of their cognate receptors at critical sites during this period suggests that these systems are intricately linked to early neurodevelopment.[155–158] Preclinical evidence suggests that opioid mechanisms play an important role in both early and adult neurogenesis by modulating neuronal progenitor proliferation and differentiation.[159,160] Of concern, fetal rat exposure to morphine during the entire second trimester alters offspring hippocampal development.[161] However, animal studies of opioid abuse in pregnancy should not be extrapolated to peripartum opioid use in humans because of differences in the gestational age and differences in drug dose and duration of administration. Only focused studies will reveal the true consequences of intravenous opioid administration for labor analgesia at term gestation.

Neuraxial Techniques

Studies of neuraxial analgesia in labor usually focus on analgesic quality and obstetric and short-term neonatal outcomes. To date, no randomized trials have evaluated the long-term effects of neuraxial analgesia on brain development in offspring. Epidurally administered local anesthetics cross the placenta and enter the fetal circulation. Golub[162] randomized nonlaboring pregnant rhesus monkeys at term to receive epidural bupivacaine (total dose of 1.2 mg/kg) or saline. No differences in specific cognitive deficits were identified between groups; however, exposed offspring demonstrated a prolonged increase in motor disturbance behaviors at 10 to 12 months of age, suggesting that perinatal interventions can alter postnatal behavioral ontogeny. In the only human evidence to date, investigators examined the association between the use of neuraxial labor analgesia and the incidence of childhood learning disabilities in a population-based birth cohort of children from Olmsted County, Minnesota.[163] The incidence of childhood learning disabilities was not associated with the use of neuraxial labor analgesia (adjusted hazard ratio, 1.05).

Inhalational Agents

The use of inhalational anesthetic agents during labor and delivery became popular after the successful use of chloroform by John Snow during Queen Victoria's delivery of Prince Leopold in 1853. Other inhalational agents were subsequently introduced, including nitrous oxide, trichloroethylene, cyclopropane, and methoxyflurane. Although the use of halogenated agents has been supplanted by widespread adoption of neuraxial techniques for labor analgesia, nitrous oxide is still widely used. Typically, it is administered as 50% nitrous oxide in oxygen using a blender device (e.g., Nitronox in the United States) or premixed in a single cylinder (e.g., Entonox in the United Kingdom) (see Chapter 22).

Scientific studies of the fetal and neonatal effects of inhalational analgesics are generally of limited quality.[164] Available evidence suggests that inhalational anesthetic agents, including nitrous oxide, have minimal or no effect on Apgar and neurobehavioral adaptation scores immediately after delivery.[165,166] However, none of these studies has evaluated long-term neurodevelopmental outcomes. This knowledge gap is critical, because robust evidence suggests that early-life neural reprogramming, following pharmacologic and inflammatory insults, affects behavioral development later in life. Of concern is compelling animal evidence that anesthetic agents, when administered during a critical period of brain development, cause widespread neurodegeneration with subsequent learning, memory, and behavioral problems (see later discussion). Nitrous oxide, in particular, is now known to be a potent developmental neurotoxin in animal models, yet its effects (if any) on human neurodevelopment are unclear. Thus, although the pattern of nitrous oxide administration during labor is unlike its administration for surgical anesthesia, the administration of nitrous oxide for labor analgesia merits closer scientific scrutiny.[167]

Maternal Anesthesia and the Fetal Brain

Despite the widespread use of neuraxial techniques in obstetric anesthesia, many pregnant women continue to require general anesthesia for either pregnancy-related or nonobstetric surgical procedures. The commonly used anesthetic agents freely cross the placenta and reach the fetal brain, causing fetal sleep or sedation. Obstetric anesthesia research has focused primarily on the teratogenic effects of anesthetic agents administered during the first trimester (see Chapter 17) and the effects of anesthetic agents on neonatal behavior when administered during cesarean delivery. Historically, the second trimester has been assumed to be a safe period for surgery and anesthesia, primarily because of a lack of targeted studies. However, during the past decade, extensive animal research has shown that anesthetic agents, when administered during the phase of synaptogenesis, can induce a profound neurodegenerative response in the developing brain and cause functional impairment in offspring.[168,169] Human epidemiologic studies appear to support an association between early childhood exposure to anesthetic agents and subsequent functional impairment. However, it is unclear whether these adverse outcomes result from the underlying disease, surgery, or anesthesia, or a combination of these factors.[170–173] Because human synaptogenesis appears to begin during the third trimester, there is serious concern that intrauterine fetal exposure to these anesthetic agents may result in similar functional impairment. Because there is no precise way to monitor human fetal brain development *in utero,* the potential long-term effects of maternal anesthesia on the fetal brain must be investigated in animal models. However, given the considerable differences in neural maturation among species (Fig. 10.5; see also Fig. 10.3), and the duration of anesthesia exposure in relation to the lifespan of the organism, these results should be interpreted with caution.[174,175]

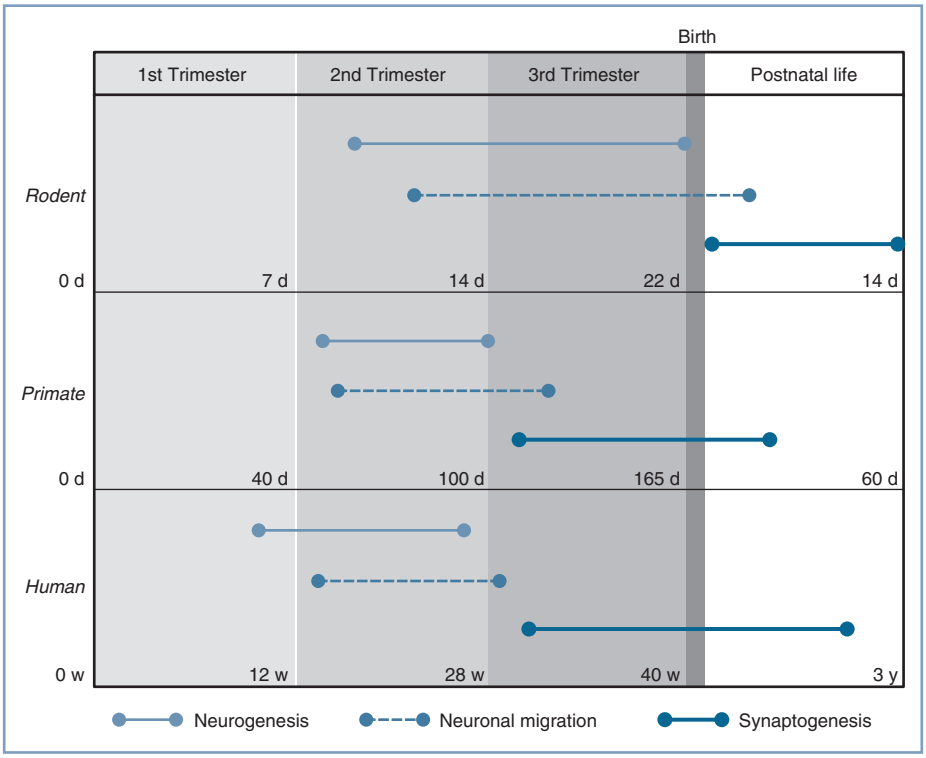

Fig. 10.5 Time lines of major neurodevelopmental events *in utero* in rodents, nonhuman primates, and humans. Events are as marked in the figure legend (*d,* days; *w,* weeks; *y,* years). Synaptogenesis is predominantly a postnatal event in rodents, unlike that in primates and humans. (From Palanisamy A. Maternal anesthesia and fetal neurodevelopment. *Int J Obstet Anesth.* 2012;21:152–162.)

The exact mechanisms by which anesthetic agents impair early brain development are still under active investigation.[176,177] Anesthetic agent interactions with GABA and the NMDA-subtype of glutamate receptors decrease activity-dependent synapse formation and cause apoptotic neurodegeneration in multiple areas of the developing brain. These histopathologic changes have been well investigated, especially in the hippocampal formation, which is an area that is crucial for memory. Early exposure to anesthetic agents affects long-term potentiation in the hippocampus and affects spatial working memory in animal models.[168] These changes do not appear to be caused by direct cytotoxicity[178] but rather by a combination of effects on both neuronal and non-neuronal cells in the developing brain (Box 10.5).

Of specific concern are the effects of anesthetic agents on neurogenesis and synapse formation in the fetal brain. Human neural ontogeny suggests that the second trimester is a period of active fetal brain development, with neuroblast proliferation peaking between the 5th and 25th postmenstrual weeks. Because GABA and glutamate play a crucial role in these processes, there is concern that prolonged and non-physiologic modulation of the fetal GABA and glutamatergic systems, as might occur during second-trimester maternal anesthesia, might affect neurogenesis, neuronal migration, and/or synapse formation.

In one of the first animal studies to simulate a clinically relevant scenario,[179] a single exposure to 1.4% isoflurane (1 MAC [minimum anesthetic concentration]) for 4 hours during the second trimester caused long-lasting impairment of spatial working memory in rodent offspring. Although the exact mechanisms behind these behavioral disturbances are unclear, other studies suggest that mid-gestational exposure to isoflurane upregulates the proapoptotic protein caspase-12, decreases overall synapse numbers in the fetal hippocampus, and downregulates the plasticity-associated protein GAP-43.[180,181] Similar results have been reported in pregnant guinea pigs and macaques, suggesting that the fetal brain remains highly susceptible to maternal mid-trimester anesthesia.[182,183] Furthermore, isoflurane suppresses neurogenesis in rodents both *in vitro* and *in vivo,*[184–186] causing a depletion of the neural stem cell pool. At least *in vitro,* this

BOX 10.5 Salient Features of Developmental Anesthetic Neurotoxicity

- Apoptotic neuronal death during synaptogenesis
- Suppression of neurogenesis
- Morphologically abnormal synapse formation
- Altered dendritic spinogenesis
- Impairment of hippocampal long-term potentiation
- Deformation of neuronal and astroglial cytoskeletal protein
- Aberrant cell cycle reentry during neuronal mitosis
- Neuronal mitochondrial dysfunction
- Abnormal intraneuronal calcium homeostasis

From Palanisamy A. Maternal anesthesia and fetal neurodevelopment. *Int J Obstet Anesth.* 2012;21:152–162.

phenomenon appears to be dose dependent.[186] At the present time, the impact of reduced neurogenesis on behavioral deficits and the effect of anesthetic agents on neuronal migration remain unknown.

When these studies are extended to the third trimester, the results are mixed. In one rodent study, maternal administration of 1.3% isoflurane for 6 hours during the third trimester had no effect on offspring neurodevelopment.[187] However, these investigators performed another dose-response study in term rodents and found that maternal administration of 3% isoflurane, but not 1.3% isoflurane, for 1 hour caused fetal brain hippocampal neurodegeneration.[188] No neurodegenerative changes were observed after third-trimester exposure in guinea pigs.[182] Thus, in rodent models it appears that the fetal brain is less vulnerable to the adverse effects of anesthetic agents during the third trimester. This phenomenon could be caused by the stage of neurodevelopment, or more likely, by an increase in the levels of neuroprotective hormones such as estrogen, progesterone, neurosteroids, and oxytocin during the third trimester. Elegant work from nonhuman primate models, however, shows that even a 5-hour exposure to either isoflurane (1% to 1.5%) or ketamine and propofol during the late second and early third trimester can cause a 2.5- to 5-fold increase in neuronal apoptosis in the fetal brain.[189–191]

Experiments evaluating the neurodevelopmental effects after shorter-duration anesthesia exposure are currently lacking. This is a critical knowledge gap because most surgical procedures requiring anesthesia in pregnant women are relatively short. The relative safety of short exposures is supported by a population-based birth cohort study (in Olmsted County, Minnesota) that sought to determine the incidence of learning disabilities in children after maternal administration of general or neuraxial anesthesia during cesarean or vaginal delivery.[192] Children exposed to general anesthesia during cesarean delivery were not more likely to develop learning disabilities compared with those born vaginally with no exposure to general anesthesia. Although the study was retrospective and used data from 1976 to 1982, it is reassuring that even the children whose mothers required emergency general anesthesia (presumably secondary to fetal compromise) did not have a higher incidence of learning disability.

Newer studies have explored the association between general anesthesia during the third trimester and autism spectrum disorders in offspring; the results are inconclusive. Using a propensity score-matched technique to adjust for underlying risk factors in a population-based data set derived from national registries in Taiwan, Chien et al.[193] reported that general anesthesia during cesarean delivery was associated with a 52% higher risk for developing autism than vaginal delivery. By contrast, a population-based sibling cohort study from Puerto Rico found no evidence for an association, although in this study, both exposures during pregnancy and the first 2 years of life were included.[194] Further epidemiologic work is required to ascertain the effects of maternal anesthesia during nonobstetric surgery in the second trimester.

The wealth of anesthetic neurotoxicity studies prompted the U.S. Food and Drug Administration (FDA) to issue an updated Drug Safety Communication in late 2016, warning that repeated or lengthy use of general anesthetic or sedative drugs during the third trimester of pregnancy or the first 3 years of life may have consequences for early brain development.[195] However, the results of recent prospective clinical trials suggest that short-duration exposure to anesthesia in children younger than three 3 years of age does not have a detrimental effect on cognitive development.[196,197] To date, no prospective study has addressed the effects of fetal anesthesia exposure during the third trimester on fetal/neonatal brain development.

Fetal Neuroprotection

Throughout gestation, the fetus remains concealed, protected, and nourished by a combination of maternal anatomic and physiologic factors. For example, the amniotic fluid cushions the fetus against trauma, and the placenta serves as a conduit to ensure a continuous supply of maternal nutrients to the developing fetus. Despite these inbuilt protective mechanisms, the fetus remains vulnerable to maternal insults such as infection and fever, drugs, and acute changes in placental physiology. Among all organ systems, the developing central nervous system appears to be most susceptible to such insults. Understanding the developmental aspects of neuroprotective mechanisms will therefore enable generation of targeted neuroprotective therapies.

Role of the Placenta

One of the fundamental neuroprotective mechanisms is the barrier function of the placenta. The placenta serves as a conduit for chemical communication between the mother and the developing fetus; endocrine signals, growth factors, and cytokines freely traverse the placenta, which dynamically adapts to chronic changes in the maternal-fetal environment to preserve fetal growth and viability.[198] However, this function also allows transplacental transfer of an array of pharmacologically active molecules either by passive diffusion or active transport.[199] By virtue of its enzymatic machinery, the placenta is capable of detoxification of some of these potentially harmful chemicals, making it the first line of defense against potentially harmful environmental agents.

Substances cross the placenta and enter the fetal circulation by several mechanisms, including passive and facilitated diffusion, active transport, and endocytosis (see Chapter 4). Molecules in the syncytiotrophoblast play important roles in active transport of molecules across the placenta, including phospho-glycoprotein (P-gp) and breast cancer resistance protein (BCRP).[199] The activity of these transporters varies with gestational age and certain pathophysiologic conditions (e.g., preeclampsia, intrauterine infection) and is influenced by the steroid hormones of pregnancy. Thus, it is possible that placental permeability to certain drugs depends on a complex interplay of several factors. In addition to this barrier function, the human placenta secretes estrogen and progesterone in very high concentrations; these hormones, and others, eventually enter the fetal circulation, where they serve as substrates for *de novo* neurosteroid synthesis in the

fetal brain.[200] In particular, allopregnanolone has been shown to exert neuroprotective effects in the fetal brain (see later discussion).

Humoral Mechanisms

Published studies have extensively investigated the intricate and symbiotic relationship between the fetus and maternal hormones throughout pregnancy. Much of our understanding comes from elaborate murine and primate research models in which changes in maternal levels of hormones closely parallel changes in the fetal plasma and/or brain. Throughout pregnancy, there is a gradual rise in the levels of many maternal hormones such as progesterone, estradiol, and oxytocin.[201–203] At term or during labor, the levels of these hormones are 40- to 100-fold higher than in the nonpregnant state.

Many of these hormones freely cross the placenta and are transported to the fetal brain, where they profoundly influence neurodevelopment. For example, estradiol and progesterone influence neural stem cell proliferation, modulate apoptosis and synaptogenesis in a region-specific manner, alter subcellular signaling mechanisms, and promote dendritic growth and spinogenesis through specific receptor mechanisms.[201,202] Estradiol, in particular, prevents cell death in both neuronal and non-neuronal cell lines.

Maternal plasma oxytocin levels gradually increase during pregnancy and reach a peak during the second stage of labor. Oxytocin is of particular importance because it has significant effects on GABAergic signaling in fetal neurons. In a series of elegant experiments, investigators showed that oxytocin transiently switched the action of GABA on immature rodent fetal neurons from *depolarizing* to *hyperpolarizing* at term gestation.[204] This finding raises the possibility that oxytocin protects the fetal brain during the stressful process of labor and delivery.[205]

NEUROPROTECTIVE THERAPIES

Magnesium Sulfate and Cerebral Palsy

Until recently there was considerable controversy regarding the role of magnesium sulfate in preventing or possibly exacerbating fetal brain injury. Some controversy remains, but the publication of several large randomized studies of the effect of antenatal maternal magnesium sulfate administration on offspring outcome has dramatically altered practice guidelines and clinical practice.[206–208] Although none of these studies demonstrated significant improvement in the primary outcome, all showed reduced cognitive morbidity, and none showed any increase in pediatric morbidity or mortality associated with magnesium sulfate use for neuroprotection.

In a placebo-controlled trial of women who were thought likely to deliver within 24 hours and before 30 weeks' gestation in New Zealand and Australia, Crowther et al.[206] reported a lower incidence of substantial gross motor dysfunction (3.4% vs. 6.6%; relative risk [RR], 0.51; 95% CI, 0.29 to 0.91) and combined death or substantial gross motor dysfunction (17% versus 22.7%; RR, 0.75; 95% CI, 0.59 to 0.96) in children whose mothers were randomized to receive antenatal magnesium sulfate treatment. In another large trial from France, which included women in preterm labor before 33 weeks' gestation, a significant reduction in death and/or gross motor dysfunction was again identified in the children whose mothers received magnesium sulfate (25.6% versus 30.8%; OR, 0.62; 95% CI, 0.41 to 0.99).[207] A reduction in death and/or motor or cognitive dysfunction (34.9% versus 40.5%; OR, 0.68; 95% CI, 0.47 to 0.99) was observed in the magnesium-exposed offspring at 2 years of age.[207] Finally, a randomized, controlled multicenter trial in the United States found that fetal exposure to magnesium sulfate within 24 hours of preterm delivery (between 24 and 32 completed weeks' gestational age) did not reduce the combined risk for moderate or severe cerebral palsy or death. However, fetal exposure to magnesium sulfate reduced the risk for moderate or severe cerebral palsy among survivors (1.9% versus 3.5%; RR, 0.55; 95% CI, 0.32 to 0.95) and was associated with a decreased overall rate of cerebral palsy (4.2% versus 7.3%; $P = .004$).[208]

Although the results are optimistic, it is difficult to compare these trials owing to differences in inclusion criteria, study interventions/dosages, and outcomes. Nonetheless, after the publications of these trials, it has been concluded from meta-analyses that fetal exposure to magnesium sulfate may reduce the risk for cerebral palsy without increasing the risk for neonatal death.[209,210]

In 2010, the ACOG and the SMFM released a joint committee opinion that supported antenatal maternal magnesium sulfate administration for fetal neuroprotection, stating that the available evidence suggests that magnesium sulfate administered before anticipated early preterm birth reduces the risk for cerebral palsy in surviving infants.[211] Physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimens, concurrent tocolysis, and monitoring. The ACOG and the SMFM have concluded that it is reasonable to use a protocol based on one of the large randomized trials[206–208]; magnesium sulfate should be offered to women at high risk for anticipated preterm delivery (< 28 to 32 weeks' gestational age) within 24 hours. A loading dose of magnesium sulfate 4 to 6 g should be administered, followed by a maintenance infusion of 1 to 2 g/h for 12 to 24 hours, at which point the risk for impending preterm delivery should be reassessed. If there is no longer a concern for impending delivery, the magnesium sulfate should be discontinued and restarted with active labor or when delivery is again thought to be imminent.

Hypothermia

Some investigators have described improved outcomes after the use of hypothermia in neonates at risk for hypoxic-ischemic encephalopathy. One group of investigators has described an experimental model of severe intrauterine hypoxia in preterm fetal sheep, in which asphyxia was produced by 25 minutes of complete umbilical cord occlusion.[212] Cerebral hypothermia (fetal extradural temperature reduced

from 39° to 29° C) decreased the loss of striatal neurons and oligodendroglia. This finding was associated with improved basal ganglia function after ischemia.

These and other experimental results prompted a randomized clinical trial of whole-body hypothermia for neonates with hypoxic-ischemic encephalopathy.[213] Eligible neonates were older than 36 weeks' gestational age, had moderate or severe encephalopathy, and were admitted to the neonatal intensive care unit within 6 hours of birth. Body temperature was lowered to 33.5° C for 72 hours in neonates randomized to hypothermia treatment. Death or moderate to severe disability at 18 to 22 months of age occurred in 44% of 102 infants in the hypothermia group, compared with 62% of 106 infants in the control group (risk ratio, 0.72; 95% CI, 0.54 to 0.95; $P = .01$). Although encouraging, these results are at odds with those from another large multicenter randomized trial.[214] In an editorial attempting to reconcile these opposing results, several possible explanations were suggested.[215] Importantly, in the study that demonstrated no benefit, cooling began later and more time was required to achieve complete cooling, because head (not total body) cooling was employed.[214] Moreover, the study that showed no benefit with hypothermia may have included infants who were so severely affected that no therapy would have been beneficial.[214] This possibility highlights the importance of patient selection in these clinical trials.

In 2012, the whole-body hypothermia investigators published the results of follow-up evaluations of the original study subjects at 6 to 7 years of age. There was no difference in the combined primary outcome of death or an IQ score less than 70 (47% versus 62%, $P = .06$) between the hypothermia group and the control group.[216] The hypothermia group had a lower incidence of death or severe disability (41% versus 60%, $P = .03$), but there was no difference in moderate or severe disability (35% versus 38%, $P = .87$). Attention-executive dysfunction occurred in 4% of the hypothermia group versus 13% of the usual care group ($P = .19$), and visuospatial dysfunction occurred in 4% of the hypothermia group versus 3% of the usual care group ($P = .80$).[216] Thus, although there was no significant difference in the primary outcome, whole-body hypothermia decreased the incidence of death and did not increase the rate of a low IQ score or severe disability among survivors.

A 2013 meta-analysis of 11 randomized controlled trials of hypothermia therapy, which included 1505 term and late preterm infants, concluded that the benefits of cooling on survival and neurodevelopment outweigh the short-term adverse effects.[217] The authors advised that hypothermia should be instituted in term and late preterm infants with moderate-to-severe hypoxic-ischemic encephalopathy if identified before 6 hours of age. Further trials are necessary to identify appropriate cooling techniques and to refine patient selection.

Experimental Neuroprotection

Perlman[218] reviewed various strategies for treating hypoxic-ischemic neonatal injuries, including administration of inflammatory mediator modulators, excitatory amino acid receptor agonists and antagonists, free radical scavengers, and platelet-activating factor antagonists. These emerging therapeutic strategies stem from basic neuroscience research on brain development and the pathophysiology of ischemic injury.

The role of white matter in the attenuation of hypoxic-ischemic brain damage (e.g., through uptake of excitatory amino acids or sequestration of potassium and hydrogen ions) is underappreciated,[219–221] and drugs that inhibit the release of excitatory amino acids or antagonize their receptors may be of benefit.[218] Multiple strategies may be necessary to inhibit the deleterious pathways initiated by brain ischemia and hypoxia.[222] A "brain cocktail," consisting of free radical scavengers, modifiers of nitric oxide activity, metabolic inhibitors, calcium and iron chelators, and drugs that affect the excitatory amino acid systems, may someday be administered to fetuses and neonates at risk for brain injury. Additional compounds that may inhibit CNS necrosis or apoptosis, either *in utero* or in the neonatal period, include agents that interrupt the inflammatory cascade, progesterone, and other steroids.

Among the pharmacologic candidates for neuroprotection, **erythropoietin** (EPO) appears promising[223]; EPO is known to have wide-ranging actions, including antiapoptotic, antioxidant, and anti-inflammatory effects.[224] Indirectly, EPO may support angiogenesis and neovascularization.[224] In the first human clinical study, EPO administration in full-term neonates was associated with an almost 50% reduction in death and disability at 18 months when the hypoxic-ischemic injury was moderate but not severe.[225] A 2017 systematic review summarized nine studies in which EPO was administered to neonates born at 35 weeks' gestation or greater with perinatal asphyxia.[224] In six trials, EPO was administered alone, and in three trials it was administered with therapeutic hypothermia. The authors concluded that long-term neurodevelopment outcomes are improved after EPO administration, and that the drug appears safe, without adverse effects.[224] However, the sample sizes were small in the included trials, and other study limitations precluded definitive conclusions. Several large trials are ongoing.

Another agent with potential for fetal neuroprotection is **melatonin,** a highly effective antioxidant with reliable transplacental transfer and a wide therapeutic index. Administration of melatonin to fetal sheep compromised by experimental umbilical cord occlusion prevents oxidative stress, reduces lipid peroxidation, modulates microglial activation, and decreases the extent of brain damage.[226] The translational potential of other agents such as *N*-acetylcysteine (NAC), allopurinol, neurosteroids such as allopregnanolone, anesthetic agents such as xenon, and creatine appears limited.

The ability to accurately predict which fetuses are at risk for neurologic injury, and when, is currently rudimentary. The most vulnerable periods of fetal development are still unknown, and large studies are required to validate the use of noninvasive (e.g., advanced neuroimaging) fetal surveillance

techniques.[227] Additional work has focused on identifying biomarkers of neurologic injury that could predict risk for cerebral palsy, thus identifying infants who would benefit from postdelivery interventions. The ability to identify these "at-risk" infants *in utero* or immediately after delivery is a necessary step in designing effective therapeutic regimens that interfere minimally with the normal trophic activities of the developing brain.

KEY POINTS

- Cerebral palsy is a nonprogressive disorder of the central nervous system that is present (but rarely obvious) at birth and involves some impairment of motor function or posture. Intellectual disability may or may not be present.
- The term *birth asphyxia* should be used sparingly, if at all, in medical records. More descriptive terms that describe the neonate's tone, color, respiratory effort, and metabolic status should be used when possible.
- The incidence of cerebral palsy is approximately 2 per 1000 live births and has not decreased despite the widespread use of intrapartum fetal heart rate monitoring and a higher cesarean delivery rate.
- The Apgar score is a poor predictor of cerebral palsy.
- Preterm delivery is a risk factor for cerebral palsy.
- Spastic quadriplegia and, less commonly, dyskinesia are the only types of cerebral palsy associated with acute intrapartum hypoxic events.
- Intrapartum hypoxia sufficient to cause cerebral palsy is always accompanied by neonatal encephalopathy and seizures.
- Fetal compensatory responses to hypoxemia *in utero* include (1) a redistribution of fetal cardiac output, with increased blood flow to the brain, myocardium, and adrenal glands; (2) decreased fetal energy consumption as a result of decreased fetal breathing and body movements; and (3) maintenance of essential cellular processes at the expense of fetal growth.
- Chorioamnionitis is associated with an increased risk for cerebral palsy. Epidural analgesia during labor is associated with an elevated maternal temperature (but not chorioamnionitis). Accurate diagnosis of chorioamnionitis may prevent unnecessary evaluations for sepsis in neonates of mothers with a small rise in temperature during labor.
- No published data suggest that a given anesthetic drug or technique is more likely to protect fetal neurologic function (provided that the anesthetic technique is administered according to the recommended guidelines for good anesthesia practice).
- In animal models, exposure of the developing brain to anesthetic agents that interact with GABA and NMDA-type glutamate receptors induce a neurodegenerative response associated with subsequent functional impairment in adulthood. It remains to be determined whether exposure of human fetuses (via maternal anesthesia) and infants to these agents in clinically relevant doses leads to functional central nervous system impairment.

Patient Safety and Team Training

David J. Birnbach, MD, MPH, Eduardo Salas, PhD

CHAPTER OUTLINE

In 2000, the publication of the Institute of Medicine (IOM) report *To Err is Human: Building a Safer Health Care System* was a seminal event for the health care system in the United States.[1] Before the publication of this report, many physicians and hospital administrators refused to acknowledge the frequent occurrence of preventable morbidity and the reality that our health care system was not adequately addressing the issue of patient safety. Subsequently, we have learned that tens of thousands of patients die each year because of medical errors. In the past 15 years, numerous changes have been advocated, including mandating minimum nurse-to-patient ratios,[2] reducing working hours of resident physicians,[3] use of bundles,[4] and advancing the science of simulation training and teamwork, particularly in the medical environment.[5,6] Data from high-reliability organizations suggest that health care errors do not usually occur because of ill-trained medical personnel but rather are because of systems that trap both the patient and the health care provider. As Pratt[7] eloquently stated, "Historically, medicine was simple, largely ineffective, and mostly safe (excluding perhaps trephination and bloodletting). Modern medicine is complex, highly effective, but dangerous." The field of patient safety attempts to reduce that danger, which is very real in the fields of obstetrics and obstetric anesthesiology.

Unfortunately, maternal mortality in the United States has risen over the last decade despite improvements in patient safety and health care. This is particularly troubling since it has occurred during a period when global death rates fell, thus making the United States an outlier for maternal mortality rates in the developed world.[8] In a review of maternal morbidity and mortality, Kilpatrick has suggested that communication and collaboration between all stakeholders involved in perinatal health are necessary to reverse this trend.[9]

In this chapter, methods of improved teamwork communication and collaboration, as well as issues related to medical errors, are reviewed, and solutions to enhance maternal safety are highlighted. Although anesthesia is now an exceedingly rare cause of maternal death, the anesthesiologist on the labor and delivery suite plays a key role in safety.[10] Several modalities that can be used by labor and delivery unit personnel to reduce both the incidence and sequelae of preventable errors are highlighted.

PATIENT SAFETY AND MEDICAL ERRORS

Traditional assessments of medical error often blamed individuals and failed to address the broader systems issues that allowed the error to occur. Newer approaches are based on an understanding that humans will make errors and, therefore, encourage creation of robust systems to prevent these errors from occurring or to minimize their impact on patients if they occur. This paradigm change has borrowed heavily from other high-risk arenas, such as the aviation and nuclear industries.

The Swiss Cheese Model

Patients are typically not injured by a single event resulting from a single act of a careless individual. More often an underlying systems problem made the error possible, and numerous individual actions "fall through the cracks" of a system that does not catch them, resulting in error and harm. James Reason described the "Swiss cheese" model of error

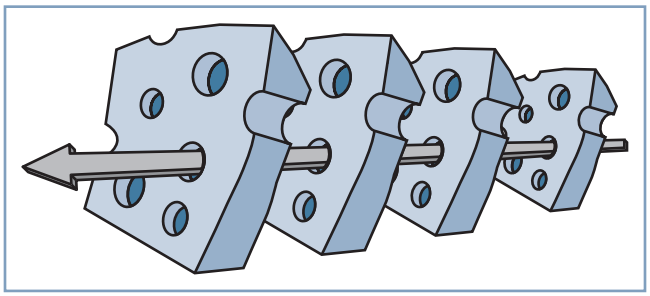

Fig. 11.1 Swiss cheese model of organizational accidents. (From Reason JT. *Human Error*. Cambridge, UK: Cambridge University Press; 1990.)

(Fig. 11.1), in which he explained how numerous contributing factors are responsible for the ultimate harm.[11] Reason developed this model to illustrate how analyses of major accidents and catastrophic systems failures tend to reveal multiple, smaller failures that led up to the actual adverse event. In the model, each slice of cheese represents a safety barrier or precaution relevant to a particular hazard. For example, if the hazard were wrong-site surgery, slices of the cheese might include processes for identifying the right or left side on radiology tests, a protocol for signing the correct site when the surgeon and patient first meet, and a second protocol for reviewing the medical record and checking the previously marked site in the operating room. Each barrier has "holes"; hence, the term *Swiss cheese.* For some serious events (e.g., operating on the wrong person) the holes will rarely align; however, even rare cases of harm are unacceptable. Reason's model highlights the need to think of safety as a system—a set of organizational and cultural layers that influence and shape one another. Reason has eloquently summarized the process, stating "rather than being the main instigators of an accident, operators tend to be the inheritors of system defects created by poor design, incorrect installation, faulty maintenance, and bad management decisions. Their part is usually that of adding the final garnish to a lethal brew whose ingredients have already been long in the cooking."[12]

Fig. 11.2 illustrates the use of the Swiss cheese model to evaluate a real near-miss case involving the misidentification of an obstetric patient who nearly underwent the wrong procedure (an unwanted tubal ligation). It describes how the combination of numerous system errors came very close to allowing the wrong procedure to be performed. The events unfolded as follows:

1. A nulliparous woman in active labor at term arrived on the labor and delivery unit in severe pain. She spoke a foreign language and was poorly understood by the labor and delivery staff. No translator was called because her husband was helping with the translation.
2. Because the patient was in such severe pain, she rushed to answer all the questions and answered several incorrectly. As per hospital policy (due to HIPAA [Health Insurance Portability and Accountability Act of 1996] regulations), the husband was asked to leave the room while the history was being taken and was therefore not present to assist in the translation.
3. There was another patient on the labor and delivery unit with the same last name and a similar sounding first name. The hospital protocol for this occurrence was not followed. Patient initials, not last names, were listed on the labor and delivery "board," so that other staff were unaware of the identical patient names.
4. The patient developed a nonreassuring fetal heart rate (FHR) tracing and was scheduled for urgent cesarean delivery. The obstetric resident physician informed the anesthesiologist of this decision and, mistaking the two patients with identical names, booked the case for a cesarean delivery *plus* bilateral tubal ligation. Unlike the other patient with the same name, the patient going to the operating room did not want or expect a tubal ligation.
5. The case was delayed because of a shift change, and the obstetricians urged the nurses to hurry. This caused friction between the nurses and obstetricians, and they did not work as a team. There was no "huddle," and communication between labor and delivery staff and operating room staff was suboptimal.
6. The patient arrived in the operating room and was very anxious and crying. The anesthesiologist administered fentanyl 50 μg to calm the patient, and she became very sedated.
7. A "time-out" was performed, but it was not taken seriously. The patient was asleep and did not participate. The attending obstetrician was not present. Conversations continued during the time-out.
8. Following the flawed time-out, it was agreed that this patient was to undergo a primary cesarean delivery and tubal ligation. Her husband was not present during the time-out but was brought to the room immediately after this activity. The surgical procedure began.
9. The attending obstetrician arrived after the start of the procedure and questioned the planned tubal ligation, not because he knew about the second patient but because he was informed that this patient was nulliparous. Immediate investigation revealed that the patient was not supposed to receive a tubal ligation. A major error was narrowly averted.

As in many such situations, a conglomeration of many missteps resulted in the potential for patient harm.

Medical Errors

Today there is widespread interest in changing the health care culture to build safer systems, including ensuring the appropriate physical work environment, developing redundancies in safety procedures and use of safety bundles,[4] allowing health care workers to report their mistakes (including near misses) without fear of punishment, and providing mechanisms to learn from the experiences. None of these steps will achieve the ultimate goal of complete patient safety without the support of physicians as well as hospital administrators and other key stakeholders. In addition, although vital to improving the current condition, these steps do not obviate

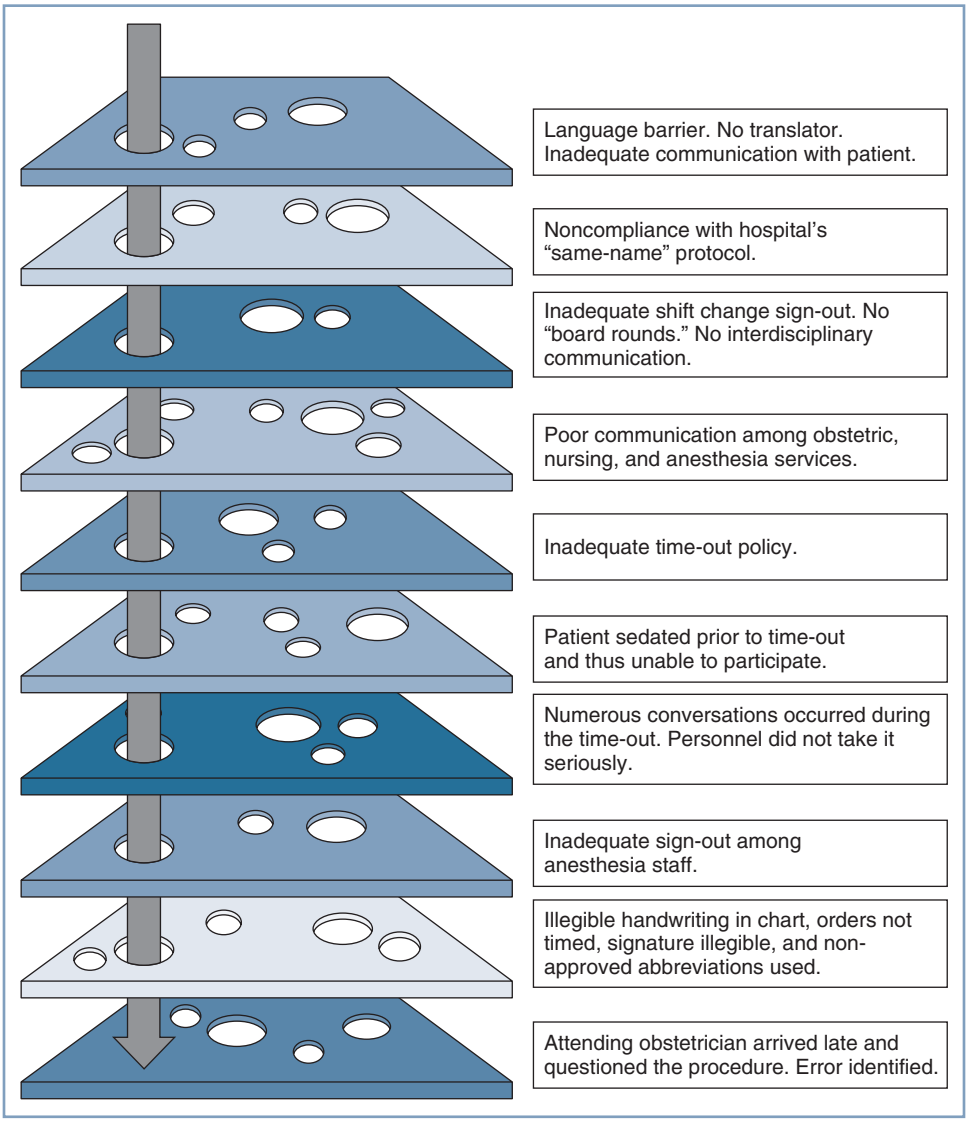

Fig. 11.2 "Swiss cheese" diagram of near-miss event illustrating how numerous layers/barriers to harm were breached and how these events almost resulted in permanent harm (permanent sterility) to the patient.

the need for well-trained and well-rested physicians and nurses. The American College of Obstetricians and Gynecologists (ACOG) Committee Opinion on Patient Safety in Obstetrics and Gynecology[13] highlights the following seven objectives for patient safety:

1. Develop a commitment to encourage a culture of patient safety.
2. Implement recommended safe medication practices.
3. Reduce the likelihood of surgical errors.
4. Improve communication with health care providers.
5. Improve communication with patients.
6. Establish a partnership with patients to improve safety.
7. Make safety a priority in every aspect of practice.

In a different committee opinion, the ACOG also states that there is increasing awareness within the patient safety movement that fatigue and even partial sleep deprivation impairs performance.[14] These goals and opinions relate to the anesthesia provider as well. Although the Accreditation Council on Graduate Medical Education (ACGME) has enacted restrictions on resident physician work hours to prevent sleep deprivation, there are no such limits on attending physician work hours. Rothschild et al.[15] found that the risk for surgical complications was increased if attending physicians had slept less than 6 hours the night before the procedure.

Medical error has been defined as a "failure of a planned action to be completed as intended, or the use of a wrong plan to achieve an aim."[16] Communication problems are consistently identified as a leading cause of medical errors in obstetrics, and perceptions are often misaligned.[17] The Joint Commission has found that although the majority of these events have multiple root causes, lack of effective communication along with leadership and human factors are often the primary causes of sentinel events.[18] Several of the 2017

BOX 11.1 Key Joint Commission National Patient Safety Goals (NPSG): 2017

- Identify patients correctly. Use at least two patient identifiers when providing care (NPSG.01.01.01).
- Improve staff communication. Get important test results to the right staff person on time (NPSG.02.03.01).
- Use medications safely. Label all medications, medication containers, and other solutions on and off the sterile field in perioperative and other procedural settings (NPSG.03.04.01).
- Use alarms safely. Make improvements to ensure that alarms on medical equipment are heard and responded to on time (NPSG.06.01.01).
- Prevent infection. Implement evidence-based practices for preventing surgical site infections. Use hand-cleaning guidelines from the Centers for Disease Control and Prevention or the World Health Organization. Set goals for improving hand cleaning. Monitor compliance with hand hygiene guidelines (NPSG 07.01.01).
- Identify patients at risk for suicide. Identify environmental features that may increase or decrease the risk for suicide (NPSG.15.01.01).
- Prevent mistakes in surgery. Make sure that the correct surgery is done on the correct patient and at the correct place on the patient's body (UP.01.01).
- Pause before the surgery to make sure that a mistake is not being made (UP.01.03.01).

Summarized from the Joint Commission 2017 National Patient Safety Goals. https://www.jointcommission.org/assets/1/6/2017_NPSG_HAP_ER.pdf. Accessed February 2018.

Joint Commission National Patient Safety Goals relate to error reduction on the labor and delivery unit (Box 11.1).[19] Departments of anesthesiology and obstetrics and gynecology should regularly review the national patient safety goals established by the Joint Commission. Hospitals are regularly surveyed to verify their compliance with these goals.

Although those working in health care have made great efforts to reduce preventable patient harm, the progress has not been as dramatic as necessary. Leape and Berwick, two "fathers" of the field of patient safety, suggested that the lack of progress following the release of the initial IOM report is a result of the "culture of medicine."[20] They, and others, believe that this culture is deeply rooted, both by custom and training, in autonomous individual performance. A recently published systematic review[21] found evidence that interventions to improve teamwork, communication, and safety culture demonstrated improvements in patient outcomes. It is probable that systematic and appropriate use of medical simulation for improved training, along with other important changes to our systems, will facilitate the necessary cultural changes and lead to improved patient safety.[22] Labor and delivery units are no different than other medical care environments, and most still have many opportunities to change culture and practice to optimize patient safety. Nabhan and Ahmed-Tawfik[23] have suggested that the concept of patient safety in obstetrics is "not as strong as desirable for the provision of reliable health care." In some units, a punitive culture still exists and results in suppression of error reporting, lack of proper communication, and failure of appropriate feedback. Obviously, this culture needs to change before we can significantly improve patient safety. Kacmar has opined that achieving the ideal of a culture of safety for all obstetric units requires multidisciplinary collaboration, frequent reassessment for areas of improvement, and a culture of openness to change when improvement opportunities arise.[24]

Pronovost and Freischlag[25] eloquently described the operating room environment when they stated that "operating rooms are among the most complex political, social, and cultural structures that exist, full of ritual, drama, hierarchy, and too often conflict." These authors concluded that poor teamwork contributes prominently to most adverse events, including those in the operating room.[25]

TEAMS AND TEAMWORK

Health care is a team activity; it can even be considered and evaluated as a team sport. Teams take care of patients in general and especially on the labor and delivery suite.[26] Furthermore, health care teams operate in an environment characterized by acute stress, heavy workload, and high stakes for decision and action errors.[27] Individuals have limited capabilities; when their limitations are combined with organizational and environmental complexity, human error is virtually inevitable.[28] The labor and delivery unit is a dynamic and complex care setting.[17] In fact, the labor and delivery unit requires intense, error-free vigilance with effective communication and teamwork among various clinical disciplines who, although working together, have probably never trained together. This group includes obstetricians, midwives, nurses, anesthesiologists and nurse anesthetists, and pediatricians. The addition of trainees at all levels and in all disciplines enhances the potential for communication error. Siassakos et al.[29] suggested that one of the most important components of effective training in obstetrics includes multiprofessional training and integration of teamwork training with clinical teaching. Multidisciplinary safety rounds enhance situational awareness among team members and encourage contingency plans for emergency management[10,30] Chau and colleagues at the Brigham and Women's Hospital recently reported that providers on labor and delivery suites perceived that structured interprofessional rounds are effective in promoting teamwork.[31]

A **team** consists of two or more individuals who have specific roles, perform independent tasks, are adaptable, and share common goals. Salas et al.[32] defined **teamwork** as a complex yet elegant phenomenon. It can be defined as a "set of interrelated behaviors, actions, cognitions, and attitudes that facilitate the required task work that must be completed." Lack of teamwork has been identified as a leading cause of adverse events in medicine. Team behavior and coordination, particularly communication or team information sharing, are critical for optimizing team performance. Baker et al.[33] stated that to work together effectively, team members must possess specific knowledge, skills, and attitudes (KSAs), including skill

TABLE 11.1 Characteristics of Effective Teams

Knowledge/Skills/Attitudes	Characteristics of the Team
Leadership	Roles are clear but not overly rigid. Team members believe leaders care about them.
Backup behavior	Members compensate for each other. Members provide feedback to each other.
Mutual performance monitoring	Members understand each other's roles.
Communication adaptability	Members communicate often and anticipate each other.
Mutual trust	Members trust each other's intentions.

Modified from Salas E, Sims DE, Klein C. Cooperation and teamwork at work. In Spielberger CD, ed. *Encyclopedia of Applied Physiology*. San Diego, CA: Academic Press; 2004:499–505.

in monitoring each other's performance, knowledge of their own and their teammates' task responsibilities, and a positive disposition toward working in a team. These authors have described characteristics of effective teams, which include team leadership, mutual performance monitoring, backup behavior, adaptability, shared mental models, communication, team/collective orientation, and mutual trust. Moreover, effective team performance in complex environments requires that team members hold a shared understanding of the task, their equipment, and their teammates (Table 11.1).[27]

Teamwork is essential for safe patient care on the labor and delivery suite. The Joint Commission has recommended a risk-reduction strategy for decreasing perinatal death or injury. This strategy includes the implementation of team training and mock emergency drills for shoulder dystocia, emergency cesarean delivery, and maternal hemorrhage.[34]

Team training promotes the acquisition of adaptive behaviors, shared cognitions, and relevant attitudes. It is an instructional strategy that ideally combines practice-based delivery methods with realistic events, guided by medical teamwork competencies (i.e., behaviors, cognitions, and/or attitudes). Murray and Enarson[35] stated that "when a crisis complicates patient care, teamwork among health care professionals is frequently strained, resulting in more frequent as well as more serious failures in managing critical events." This scenario occurs all too often on the labor and delivery unit. In a recent systematic review of communication in the operating room, Weldon et al. reported that communication was shown to affect operating room practices in all the reviewed studies and that anesthesiologists obtained low scores on communication.[36]

After many years of uncertainty, there is now encouraging evidence that team training may improve safety of clinical outcomes.[37] The obstetric literature has particularly highlighted successes related to major obstetric hemorrhage.[38]

Neily et al.[39] reported that surgical mortality decreased by 18% at 74 United States Veterans Health Administration hospitals that implemented a team training program, compared with a 7% mortality reduction in 34 control hospitals that did not implement such a program. Nielsen et al.[40] reported that team training effectively reduced the decision-to-delivery time for emergency cesarean delivery. Similarly, after mandatory interdisciplinary team training for all labor and delivery staff in a unit in the United Kingdom, the median decision-to-delivery interval for a prolapsed umbilical cord decreased from 25 to 14.5 minutes.[41] Other reports have demonstrated similar findings on team training and shortening of the decision-to-delivery interval.[42]

After initiation of team training in a community hospital, Shea-Lewis[43] reported a reduction in the adverse outcome index from 7% to 4%. A recent meta-analysis by Hughes et al.[44] further demonstrated that medical team training can reduce errors by 15% to 18% and save lives. Team training works, and now we have compelling data that it improves clinical outcomes.

Team Leadership

There is a clear difference between the *leadership of individuals* and *team leadership*. One who is leading independent individuals will diagnose a problem, generate possible solutions, and implement the most appropriate solution. In contrast, team leadership does not involve handing down solutions to team members but rather consists of defining team goals, setting expectations, coordinating activities, organizing team resources, and guiding the team toward its goals.[45]

Team leaders can improve team performance in many ways (e.g., by promoting coordination and cooperation). These individuals not only must be technically competent but also must be competent in leadership skills.[27] Anesthesia providers and other physicians do not routinely train to be competent team leaders. Many of the tasks necessary can and must be learned during team training.[45] Simulation may play a key role in this education. Team leadership training has been developed to successfully train specific team leader behaviors, and the implementation of these programs has been shown to improve team performance.[32] Hackman[46] described successful team performance as consisting of three primary elements:

1. Successful accomplishment of the team's goals
2. Satisfaction of team members with the team and commitment to the team's goals
3. The ability of the team to improve different facets of team effectiveness over time

High-Reliability Organizations and Teams

Despite the inevitability of human error, some organizations that operate in complex environments are able to maintain an exceptionally safe workplace. These organizations, including the aviation and nuclear power industries, have been termed *high-reliability organizations* (HROs). These organizations can also be hospitals and other health care organizations. HROs have been defined as institutions where individuals,

working together in high-acuity situations facing great potential for error and disastrous consequences, consistently deliver care with positive results and minimal errors.[47] Teams that exhibit behaviors that facilitate the characteristics and values held by the HRO may be defined as *high-reliability teams* (HRTs). It has recently been argued that zero patient harm is a fundamental imperative that can be promoted by high-reliability science.[48] Wilson et al.[28] defined five guidelines for HRTs. These teams must do the following:

1. Use closed-loop communication and other forms of information exchange to promote shared situational awareness regarding factors internal and external to the team.
2. Develop shared mental models that allow team members to monitor other members' performance and offer backup assistance when needed.
3. Demonstrate a collective organization that allows members to be assertive, to take advantage of functional expertise, and to seek and value input from other team members.
4. Seek to recognize complexities of their task environment and accordingly develop plans that are adequate and promote flexibility.
5. Use semistructured feedback mechanisms such as team self-correction to manage, and quickly learn from, errors.

Hunt et al.[49] defined characteristics associated with high-performing teams, including situational awareness, leadership, followership, closed-loop communication, critical language, standardized practice, assertive communication, adaptive behaviors, and workload management. Salas et al.[50] described an adaptive team performance framework that illustrates the relationship between variables, emergent states, and the multiple phases of the team adaptation cycle (Fig. 11.3).

Cultural factors may play a large role in team performance. According to Salas et al.,[51] these factors include attitudes (especially as they relate to previous experiences with teams) and motivation. Although it has been suggested that an individual team member's personality may be counterbalanced by others, Janis[52] suggested that openness and conscientiousness are essential for individuals to succeed in command positions.

Thomas et al.[53] conducted a qualitative assessment of teamwork and suggested that factors that influence the ability to work together could be divided into three categories: provider characteristics (personal attributes, reputation, expertise), workplace factors (staffing, work organization, work environment), and group influences (communication, relationships, and teamwork). These categories can be addressed, at least in part, by working together in teams in a simulated environment and evaluating teamwork and human performance. Lyndon suggested that the application of human performance–based theory has demonstrated that "communication patterns, team function, workload, and coping mechanisms affect both individual and group ability to identify evolving problems and make appropriate management decisions in complex decision-making situations."[54]

Team Training

Patient safety is "predicated on trust, open communication, and effective interdisciplinary teamwork."[55] It is often the *interactions* among health care workers that determine whether a specific plan of care is effective or ineffective.[56] However, in the current environment medical students, residents, attending physicians, nursing students, nurses, and midwives rarely learn or train to work as teams. It has recently been suggested that interprofessional education is a vital part of medical education, and students should not be permitted to exempt themselves from it.[57]

The Liaison Committee on Medical Education (LCME), which is jointly composed of members of the American Medical Association and the Association of American

BOX 11.2 Summary of Best Practices in Team Performance Measurement

- Ground measures in theory:
  - Use theory to determine what variables to measure.
  - Capture aspects of Input → Process → Output models of team performance.
- Design measures to meet specific learning outcomes.
- Clearly articulate the purpose of measurement.
- Design the measurement system to capture information necessary for making decisions about the learning outcomes.
- Capture competencies.
- Measure multiple levels of performance.
- Link measures to scenario events.
- Focus on observable behaviors.
- Incorporate multiple measures from different sources.
- Capture performance processes in addition to outcomes:
  - Obtain information not only about the end result but also about how the team reached that performance outcome.
- Train observers, and structure observation protocols.
- Facilitate posttraining debriefing and training remediation.

Modified from Rosen MA, Salas E, Wilson KA, et al. Measuring team performance in simulation-based training: adopting best practices for healthcare. *Sim Healthcare*. 2008;3:33–41.

Medical Colleges, has affirmed the importance of teaching communications skills and teamwork. For example, LCME standard ED19 states that "there must be specific instruction in communication skills as they relate to professional responsibilities, including communication with patients, families, colleagues, and other health professionals."[58] Teamwork needs to be not only taught but also monitored. Box 11.2 summarizes best practices in team performance measurement for simulation-based training.

Why is teamwork training important for labor and delivery unit personnel? As previously noted, communication problems are consistently identified as a leading cause of medical error, and these problems can be addressed during team training. The MBRRACE-UK report, a surveillance of maternal deaths in the United Kingdom from 2012 to 2014, reviewed lessons learned to inform maternity care from Confidential Enquiries into Maternal Deaths and Morbidity 2009 to 2014. The report emphasized that "the best multidisciplinary care occurs when different specialists consult together on the same day in the same room and talk with each other and the woman together."[59] The MBRRACE report evaluated 321 maternal deaths that occurred between 2009 and 2012 and found that there were relatively few deaths related directly to anesthesia, but that the role of the anesthesiologist is now shifted to indirect causes; the anesthesiologist is now a key member of the team. The term "anesthetic deaths" was replaced by "lessons for anesthesia." Of the deaths mentioned, two were related to neuraxial block and two were caused by hypoventilation following general anesthesia. These reports remind us not only of the need for appropriate training as well as supervision of trainees but also of the need to use simulation-based training for learning and practicing both crisis management and important techniques and procedures that are not frequently encountered in clinical practice. Emergency administration of general anesthesia for the parturient is such an event. In addition, the two cases of death related to neuraxial blockade[59] (subdural hematoma and cerebral venous sinus thrombosis) illustrate the need for multidisciplinary care of postneuraxial blockade complications.

Simulation-Based Training in Obstetrics

Traditional medical and nursing education has relied on the treatment of real patients in actual clinical settings. That is now rapidly changing with simulation-based education, which is a means for health care practitioners to learn and practice teamwork principles such as crisis resource management.[60] Many educators now believe that the current availability of medical simulations and the knowledge gained from the science of team training may improve practitioner competency as well as patient outcomes. Obstetricians have identified the importance of preparing for clinical emergencies and have reiterated that conducting emergency drills may reduce or prevent the severity of medical emergencies.[61] In addition, simulation may affect patient safety because it offers opportunities to discover latent conditions and performance gaps that could adversely affect patient care.[62] Simulation may also be useful in identifying and correcting specific institutional barriers, such as delays in transport to the operating room and initiation of emergency cesarean delivery.[63] During 46 *in situ* simulations of obstetric emergencies, Riley et al.[64] identified 965 breaches of defensive barriers (system elements that serve to prevent system errors from causing injury), of which 47.8% were classified as latent conditions (existing conditions that may interact with ongoing activities to precipitate error). The authors suggested that simulation helps providers recognize and remedy both active failures and latent conditions before they combine to cause bad outcomes.[64]

It has been suggested that drills are important on the labor and delivery unit, especially as related to inefficient verbal communication during obstetric emergencies.[65] Sorensen[66] stated that "mock emergency training is an opportunity for staff to learn to identify risk factors and prepare for interventions in the event of an obstetric emergency." Gardner and Raemer[67] suggested that simulation is a practical and safe approach to the acquisition and maintenance of task-oriented and behavioral skills across the spectrum of medical specialties. In the realm of obstetric anesthesia practice, investigators have demonstrated that simulation may be a useful tool for assessment of performance in a simulated emergency situation (e.g., failed intubation in an obstetric patient) when combined with practice and formal teaching.[68]

Training in perinatal emergencies with high-fidelity simulation improved the speed with which anesthesia providers responded to these emergencies and improved the quality of their care.[69] Lipman et al.[70] demonstrated, in a dramatic fashion, the use of simulation-based assessment to evaluate optimal performance of cardiopulmonary resuscitation during simulated maternal cardiac arrest. The authors

BOX 11.3 Advantages of Simulation for Research, Training, and Performance Assessment

- There is no risk to patients.
- Many scenarios can be presented, including uncommon but critical situations in which a rapid response is needed.
- Participants can see the results of their decisions and actions; errors can be allowed to occur and reach their conclusion (in real life, a more capable clinician would be obligated to intervene).
- Identical scenarios can be presented to different clinicians or teams.
- The underlying causes of the situation are known.
- With mannequin-based simulators, clinicians can use actual medical equipment, exposing limitations in the human-machine interface.
- With full re-creations of actual clinical environments, complete interpersonal interactions with other clinical staff can be explored, and teamwork, leadership, and communication training can be provided.
- Intensive and intrusive recording of the simulation session is feasible, including audiotaping, videotaping, and even physiologic monitoring of participants. There are no issues of patient confidentiality; the recordings can be preserved for research, performance assessment, or accreditation.

Modified from Gaba DM. Anesthesiology as a model for patient safety in health care. *BMJ*. 2000;320:785–788.

observed numerous deficiencies in the performance of key advanced cardiac life support (ACLS) tasks that are critical to resuscitation of a pregnant woman. These tasks included the ability to correctly deliver chest compressions (56% correct), ensure left uterine displacement (44% correct), switch chest compressors every 2 minutes (33% correct), and perform appropriate defibrillation (6% correct).[70] Box 11.3 outlines the advantages of simulation for research, training, and performance assessment.

When an adverse perinatal outcome associated with an error occurs, it is likely that more than one individual will be involved and blamed.[71] Similarly, when an unexpected injury occurs to a mother or infant, several providers are typically involved, and often there is a problem with the "system" that allowed the error to occur. Obstetricians, anesthesia providers, pediatricians, labor nurses, midwives, and operating room staff all work together as part of this system. Therefore, optimal simulation exercises involve all these key players and evaluate not only their behaviors and communication skills but also problems within the system in which they work. Simulation of reality-based scenarios in the labor and delivery unit or operating room allows anesthesia providers, obstetricians, midwives, nurses, and pediatricians to practice their roles and communication skills. Hunt et al.[49] suggested that medical teams require practiced interaction and communication to be effective and efficient.

Simulation of perinatal events range from high-fidelity human simulators (typically located off-site) to low-technology simulations and drills that can be performed on the labor and delivery unit.[37] Simulated scenarios (guided by desired learning outcomes) can be designed to train nurses, obstetric and anesthesia resident physicians, and midwives individually or as teams. However, simulation should not be reserved for individuals in training; attending physicians may also benefit from participation. Simulated events commonly include maternal hemorrhage (antepartum as well as postpartum), failed intubation, failed neuraxial blockade, seizures, cardiac arrest, anaphylaxis, umbilical cord prolapse, and shoulder dystocia. Thompson et al.[72] reported that drills to practice management of eclampsia were successful in the identification of deficiencies in team preparation. They concluded the following:

> *Repetition of drills in our unit has improved the care of simulated patients with eclampsia. In subsequent drills patient management has followed evidence-based practice, with an enhanced level of efficiency. Staff [are] summoned faster, the resuscitation process is better organized, and drugs are prepared and administered more quickly.*

Similarly, Crofts and colleagues reported significant improvement in participants' knowledge after multidisciplinary obstetric training.[73]

Maslovitz et al.[74] used simulation to identify five recurrent obstetric management mistakes:

1. Delay in transporting a bleeding patient to the operating room
2. Unfamiliarity with prostaglandin administration to treat uterine atony
3. Poor cardiopulmonary resuscitation techniques
4. Inadequate documentation of shoulder dystocia (important for the legal defense of these cases)
5. Delayed administration of blood products to reverse disseminated intravascular coagulation

The drills advocated for use by labor and delivery staff at the University of Miami Miller School of Medicine/Jackson Memorial Hospital Center for Patient Safety are outlined in Box 11.4.

BOX 11.4 Drills Advocated for Use by Labor and Delivery Staff Undergoing Team Training[a]

- Profound fetal bradycardia
- Magnesium sulfate overdose
- Shoulder dystocia
- Maternal hemorrhage
- Failed tracheal intubation
- Anaphylaxis
- Amniotic fluid embolism
- Eclampsia/HELLP syndrome

HELLP, hemolysis, elevated liver enzymes, low platelet count.
[a]Used at the University of Miami Miller School of Medicine/Jackson Memorial Hospital Center for Patient Safety.

Simulation-based training must be implemented appropriately if it is to be effective. Salas et al.[6] suggested the following guidelines for appropriate implementation:

1. Understand the training needs and requirements.
2. Embed instructional features (e.g., performance measurement and feedback) within the simulation.
3. Craft the scenarios based on expected/desired learning outcomes.
4. Create opportunities for assessing and diagnosing individual and/or team performance within the simulation.
5. Guide learning.
6. Focus on cognitive/psychological simulation fidelity.
7. Form a mutual partnership between subject matter experts and learning experts.
8. Ensure the effectiveness of the training program.

Simulation exercises may also affect outcome by teaching improved communication to individuals and teams during transfer of patients' care from one set of caregivers to another (i.e., so-called handovers or handoffs). A survey from the United Kingdom found that handovers were rarely documented in writing and that 4% of units reported critical incidents after inadequate handovers in the preceding 12-month period.[75] This interesting study describes the use of the SBAR technique (situation-background-assessment-recommendation) and the potential to practice signoffs and handovers during practice drills. Although this study is approximately 10 years old, there are few data to suggest that much has changed in the past decade as relates to handoffs.

Team Training in Obstetrics

As noted, teamwork is critical for the delivery of quality health care, especially in complex environments such as the labor and delivery unit. Awad et al.[76] reported that medical team training improved communication in the operating room as assessed by team members using a validated scoring system. Why initiate team training on the obstetric service? McQuaid-Hanson and Pian-Smith reported that effective communication is key for coordinated delivery of care and for "fostering a culture of community and safety in the workplace."[77] An Australian study evaluating the impact of introducing practical obstetric multiprofessional training (PROMPT) into maternity units found that there were significant improvements to 1-minute Apgar scores, cord lactate levels, and average baby's length of stay after the training.[78] The following case report by Sachs[79] illustrates the need for teamwork:

> *A healthy 38-year-old woman needed emergency cesarean delivery after a failed instrumental delivery. At surgery, the uterus was found to be ruptured and the infant was stillborn. After unsuccessful attempts to repair the uterus, the patient underwent a cesarean hysterectomy and required massive transfusion and a 3-week hospital stay.*

Was anyone at fault? According to the root cause analysis, lack of teamwork on many levels played a significant role in this patient's hospital course. In particular, Sachs[79] reported that communication was poor and there was a lack of mutual performance cross-monitoring, inadequate conflict resolution, suboptimal situational awareness, and work overload.

Crew Resource Management

Team drills have been successfully used in many areas of medicine, including anesthesia, intensive care, and emergency medicine, often using lessons learned from crew resource management (CRM) training. They are now becoming more popular on labor and delivery units and have been advocated by the ACOG.[61]

The human error aspects of many air crashes are thought to include failure of communication, decision making, and leadership.[80] In the airline industry, CRM began as a program to train pilots to reduce error by making better use of human resources in the cockpit.[81] CRM training has led to safety and performance improvements beyond those produced by improvements in equipment and technology.[6,80] Airlines use many tools to reduce human error; CRM training is just one. Other tools include use of checklists, standardized maintenance, ability to report errors without disciplinary repercussions, and simulator training. Not all of these, however, are easily adaptable to medicine. That said, Helmreich[82] identified several lessons learned from CRM that can be applied to the practice of medicine. He believes that errors in competence require technical training and that errors in decisions or communication require team training. Furthermore, Helmreich[82] suggested that adaptation of CRM to health care similarly requires the development of nonpunitive methods to collect information on errors so that this information can be used to evaluate team performance. It has been suggested that elements of CRM that are useful in medical settings include briefings, conflict resolution procedures, and performance reviews. There is evidence that operator attitudes about teamwork, hierarchy, errors, and stress affect performance among aviators working together in teams.[83] Evidence also suggests that these attitudes are relevant in the health care environment.[84]

Salas et al.[85] suggested that CRM training will not be effective or achieve its desired outcomes in health care without the following 12 prerequisites:

1. The physicians must be "on board."
2. The concept of teamwork becomes part of the "DNA" of the health care professional.
3. CRM is supplemented by other teamwork-focused training strategies.
4. The design, development, and delivery of CRM are scientifically rooted.
5. CRM training is designed systematically.
6. CRM is part of a learning organization's strategy to promote patient safety and quality care.
7. Teamwork is rewarded and reinforced by the health care provider.
8. CRM training is evaluated at multiple levels for specific outcomes.
9. CRM is supported by simulation or practice-based approaches.
10. The health care provider is "ready" to receive training.

11. The patient is part of the team.
12. The team training is recurrent.

Some health care providers will benefit more than others from CRM training and learning. For example, Alder et al. noted that physicians with poorer performance at the beginning of CRM training showed greater improvements after training.[86]

A discussion of optimal communication on the labor and delivery unit must also address improved communication between the anesthesia provider and patient. A recent article[87] co-written by a patient who had a traumatic experience resulting from a failed neuraxial block for cesarean delivery should be required reading for all anesthesia providers. A follow up editorial by Cyna and Simmons[88] suggests that the patient's story of her harrowing experience "represents one of the most important publications in an anaesthesia journal in recent years." The patient's painfully described perspective[87] reaffirms the importance of listening to our patients.

Disruptive Behavior

Whereas miscommunication is common on the labor and delivery unit, some events are not caused by difficulties with communication but rather result from disruptive behavior by a team member. It is estimated that 3% to 5% of physicians exhibit disruptive behavior.[89] The labor and delivery suite and obstetric operating room are complex and rapidly evolving environments where stress and anxiety abound. Studies have reported that as many as four "tense" communications occur between team members during each operating room procedure, with some of them evolving into outright conflict.[90] Disruptive and intimidating behavior is not only seen in the "main operating room"; it occurs frequently on labor and delivery units and is observed in personnel of diverse disciplines, including obstetricians, anesthesia providers, family practitioners, pediatricians, nurses, midwives, and administrators. In one survey, disruptive behavior was reported on more than 60% of labor and delivery units from personnel who responded to a questionnaire.[91]

Disruptive behavior includes angry outbursts, rudeness or verbal attacks, physical threats, intimidation, noncompliance with policies, and sexual harassment. Disruptive behavior contributes to the nursing shortage, near misses, and adverse occurrences. This behavior does not always involve physicians. Termed *horizontal hostility,* it occurs among nurses as well, and includes rudeness, verbal abuse, humiliating statements, unjustly critical statements, withholding information, and gossip.[92] Disruptive behavior is not always effectively managed by the organization[91] and should be considered when using simulation to improve team behaviors.

Options for Simulator Training in Obstetrics

Both high-technology and low-technology approaches to simulation have been used for training labor and delivery staff. Simulation centers often use high-fidelity simulation with interactive computerized mannequins in a realistic working environment (e.g., labor room or operating room) that includes a full complement of working equipment and staff.[93] The mannequin is quite realistic; it has a pulse, heart and breath sounds, ventilatory movements, and electrocardiographic and pulse oximetry tracings. All vital signs can be adjusted via computer control, as can the ability to intubate or ventilate.[93]

Not all simulation exercises and drills for obstetrics need to be performed in high-fidelity simulators. Pratt and colleagues[94] maintained that classroom training is a better option, particularly given the high cost[95] and resources necessary for high-fidelity simulation. The inability to arrange for staff of several disciplines to be absent from the labor and delivery unit simultaneously often precludes the use of high-technology simulation and may make on-site exercises more practical.

On the other hand, Gaba[96] countered that high-fidelity simulation need not be cost-prohibitive and that it provides the required "real-life" experience necessary for training in the management of complex real-life scenarios. Morgan et al.[97] reported an obstetric simulation model that included the participation of real surgeons (rather than actors playing the role of surgeons). This was the first published report of high-fidelity simulation of obstetric team performance with anesthesia providers, nurses, and obstetricians involved in the hands-on management of obstetric crises. To assess the success of simulation-based training, outcomes must be measured. Onwochei et al.[98] reported that the most reliable tools to assess team effectiveness in obstetric emergencies were the clinical teamwork scale, the global assessment of team performance, and the global rating scale of performance. As highlighted by Vasco Ramirez in his review of the future training of anesthesiologists in obstetric care,[99] we will need to move to a competency-based curriculum in which high-fidelity simulation should be considered in the acute care setting for the training of nontechnical skills such as teamwork.

Several options are available for teaching teamwork and crisis intervention in obstetrics. Multidisciplinary Obstetric Simulated Emergency Scenarios (MOSES) was developed by the St. Bartholomew Hospital Group in the United Kingdom[100] and involves participation of obstetricians, anesthesia providers, and midwives in team training using a high-fidelity simulator. MedTeams was developed by the U.S. Armed Forces and Dynamics Research Corporation. Originally employed in emergency departments,[80,101,102] it has now been used for labor and delivery teams.[40] The course consists of "train the trainer" sessions that focus on seven dimensions that are essential to teamwork. Behaviorally anchored rating scales (BARS) are used to assess various key behaviors. A recent paper by Weller et al.[103] described the implementation of their multidisciplinary operating room simulation (MORSim), which was shown to have lasting effects consistent with more effective teamwork and communication. Other evidence-based programs have emerged. TeamSTEPPS was developed by the U.S. Department of Defense and Agency for Healthcare Research and Quality (AHRQ) as a team training and implementation toolkit.[104] The program is adaptable, medically relevant, and based on findings from the science of team performance, and it is applicable to training on labor and delivery units.

An adapted TeamSTEPPS for obstetrics has been evaluated and was shown to be partially effective. Participants perceived the training as useful, and results of behavioral observation suggested that decision accuracy significantly improved.[105]

What is the evidence that team training and simulation reduce errors and improve outcomes? Morey et al.[80] reported that the MedTeams program reduced errors in the emergency department, and they observed a statistically significant improvement in team behaviors. The clinical error rate in providers who received MedTeams training decreased from 31% to 4%. Grunebaum et al.[106] implemented team training as well as other comprehensive patient safety changes to their obstetric practice and found that their interventions resulted in decreased compensation payments and sentinel events. Clark et al.[107] described implementation of a comprehensive redesign of patient safety processes that was associated with improved patient outcomes and a decline in litigation rates. They stressed that "every member of the obstetric team should be not only empowered but also required to intervene and halt any process that is deemed to be dangerous." This behavior can be achieved as part of a team training program. Phipps et al.[108] evaluated the implementation of a labor and delivery unit team training program that included CRM augmented with high-fidelity medical simulation at Women and Infants Hospital of Rhode Island. They demonstrated a correlation of clinically and statistically significant reductions in the obstetric adverse outcomes index (AOI) following implementation of their program.

Accumulating evidence suggests that medical simulation and team training, while not always perfect, improve teamwork and communication and allow recognition of potential areas of weakness in obstetric care. We, as well as others,[33,47,109] believe that these are viable strategies to mitigate medical errors. We also agree with Pearlman et al.,[110] who eloquently stated that "we have the moral imperative as a specialty to fully engage in the identification of our own best practices, to advance safety research in obstetrics and gynecology, and to implement broadly those practices which are best."

In addition to better communication, team training, and simulation-based education, several other changes to our cultures and systems need to occur to significantly improve patient safety on the labor and delivery unit. These changes include the following:

- Learning from our mistakes
- Changing the culture on the labor and delivery floor to one of a "just culture"[111]
- Having buy-in and support from hospital leadership to implement the necessary changes
- Improving the care of the high-risk parturient so that care is coordinated and every member of the team is more prepared and working as a team member[112]
- Improving and automating the collection of quality metrics, collecting appropriate data on outcomes, and sharing the data with practitioners on a regular basis[113]
- Developing and implementing systems to reduce drug administration errors[114,115]
- Tearing down the silos so that we learn from each other's mistakes and improvement processes, whether from department to department, hospital to hospital, or country to country[115]

The challenge for the next decade will be to implement these changes and test their effectiveness in improving patient safety.

KEY POINTS

- Medical errors harm tens of thousands of patients each year.
- To err is human; therefore, systems should be developed to prevent or "catch" errors before the patient is harmed.
- Poor communication among health care workers is the primary cause of sentinel events.
- Teamwork is essential to safe care of the pregnant patient, and team training may improve patient safety.
- Medical team training works; it saves lives.
- Simulation-based training is an educational tool that improves communication and may improve responses to obstetric emergencies.
- Adaptation of some elements of aviation crew resource management training may improve team performance in health care.
- Disruptive behavior interferes with safe patient care and is observed in physicians as well as other members of the health care team.

Spinal, Epidural, and Caudal Anesthesia: Anatomy, Physiology, and Technique

Naveen Nathan, MD, Cynthia A. Wong, MD

CHAPTER OUTLINE

The art and science of neuraxial anesthesia requires a thorough appreciation of neuroanatomy and the physiologic effects imposed by medications commonly administered via the spinal and/or epidural route. Successful administration and management of neuraxial anesthesia requires well-developed technical skills moderated by sound clinical judgment. The focus of this chapter is to characterize the anatomic and technical considerations for neuraxial anesthesia. The reader is referred to Chapter 23 for a corresponding discussion of the physiologic and untoward effects of neuraxial analgesia in laboring women and to Chapter 26 for a discussion of neuraxial anesthesia for cesarean delivery.

ANATOMY

Neuraxial Anatomy

The Spinal Cord, Spinal Canal, and Meninges

The cephalad aspect of the spinal cord is continuous with the brainstem through the foramen magnum. The spinal cord terminates as the conus medullaris, most often at the level of the lower border of the first lumbar vertebral body. The conus medullaris is attached to the coccyx by means of a neural-fibrous band called the filum terminale, which is surrounded by the nerves of the lower lumbar and sacral roots, known as the cauda equina. Within the bony vertebral column are three membranes: the pia mater, the arachnoid mater, and the dura mater. The pia mater is a highly vascular membrane that closely invests the spinal cord. The arachnoid mater is a delicate, nonvascular membrane closely adherent to the third and outermost layer, the dura. The subarachnoid space, located between the pia mater and arachnoid mater, contains (1) cerebrospinal fluid (CSF); (2) spinal nerves; (3) a trabecular network between the two membranes; (4) blood vessels that supply the spinal cord; and (5) lateral extensions of the pia mater—the dentate ligaments. The dura mater is a membrane, composed of collagen, that encapsulates the spinal cord, the deeper meningeal layers, and the subarachnoid space. This layer forms a connective tissue sheath along the

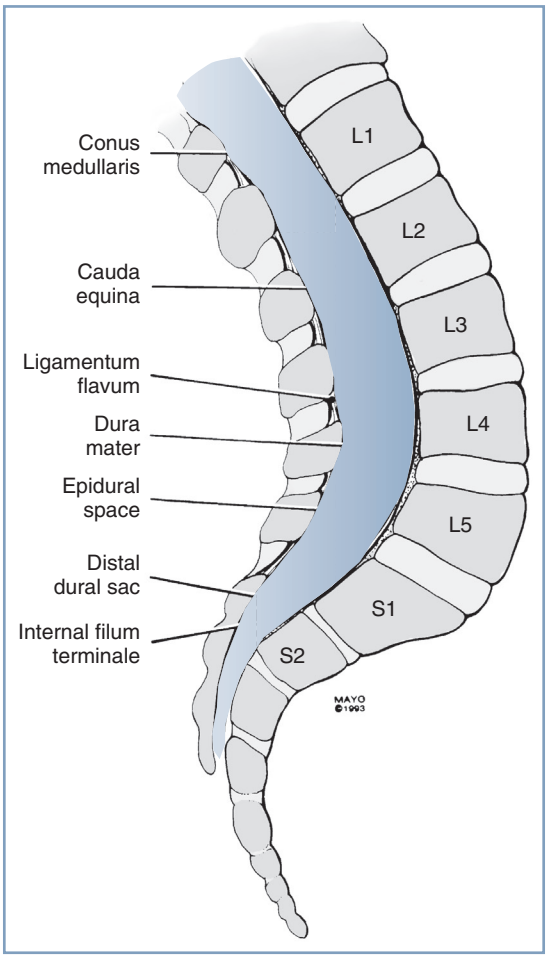

Fig. 12.1 Distal neuraxial anatomy. In pregnant women, the spinal cord usually ends at the lower border of the first lumbar vertebral body. The subarachnoid space continues to the second sacral vertebral level.

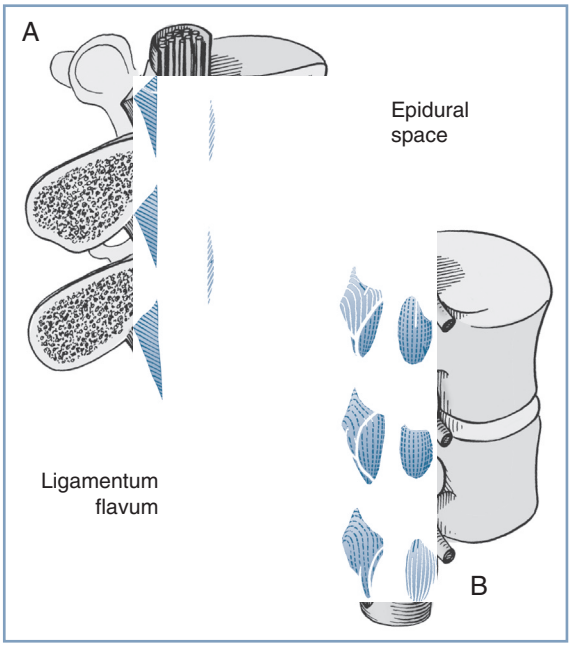

Fig. 12.2 (A) Sagittal section of the epidural space demonstrates that the contents of the epidural space depend on the level of the section. (B) Three-dimensional drawing of the epidural space shows the discontinuity of the epidural contents. However, this potential space can be dilated by the injection of fluid into the epidural space. (Redrawn from Stevens RA. Neuraxial blocks. In Brown DL, ed. *Regional Anesthesia and Analgesia.* Philadelphia: WB Saunders; 1976:323).

vertical axis of the central nervous system (CNS) that is contiguous with connective tissue covering the lateral extension of spinal nerve roots as they exit the intervertebral foramina. The interface between the dural and arachnoid layers has been described as a potential space capable of expansion subsequent to mechanical trauma. Unintentional injection of local anesthetic into this *subdural space* may explain some cases of failed spinal anesthesia. It may also explain the rare, slow-to-develop cases of high spinal anesthesia after the unintentional subdural injection of larger volumes of local anesthetic intended for epidural administration.[1] Although the spinal cord ends at the level of the bodies of L1 and L2 in most people, the subarachnoid space and cauda equina continue to the S2 level (Fig. 12.1).

The Epidural Space

The epidural space is located external to the sac of the dura mater and contains loose connective tissue, adipose tissue, lymphatics, spinal nerve roots, and the internal vertebral venous plexus (Batson's plexus) (Fig. 12.2). This space is bound by the posterior longitudinal ligament anteriorly, the ligamentum flavum and the periosteum of the lamina posteriorly, the pedicles of the vertebrae, and the intervertebral foramina with their contents laterally. The epidural space is closed at the foramen magnum, where the spinal dura attaches to the dura of the cranium and at the sacral hiatus by the sacrococcygeal ligament. Frequently, anatomic references will illustrate neuraxial anatomy by way of sagittal and/or transverse cross-section. This may result in the erroneous impression that the epidural space is a continuous columnar entity that envelops the dural sac at all points about its perimeter. Investigations using cryomicrotome sections and three-dimensional reconstruction of radiologic data verify that the epidural space is in fact discontinuous along the vertical and lateral axes of the spinal canal. It varies in anteroposterior thickness according to dermatomal distribution, being widest at the level of lumbar vertebrae and thinnest in the cervical region.[2,3] Epiduroscopy and epidurography suggest the presence of a dorsal median connective tissue band in some individuals.[4] Anatomic dissection and computed tomographic epidurography have also suggested the presence of epidural space septa. This band (or these septa) may provide an explanation for unilateral or incomplete epidural anesthesia.[5] However, some investigators have suggested that the dorsal median band is an artifact of epidural space distention or an anatomic manifestation of the previously unappreciated epidural space segmentation.[3]

The Vertebral Column and Ligaments

The ligamentum flavum lies posterior to the epidural space (Fig. 12.3). The lamina, the spinous processes of the vertebral

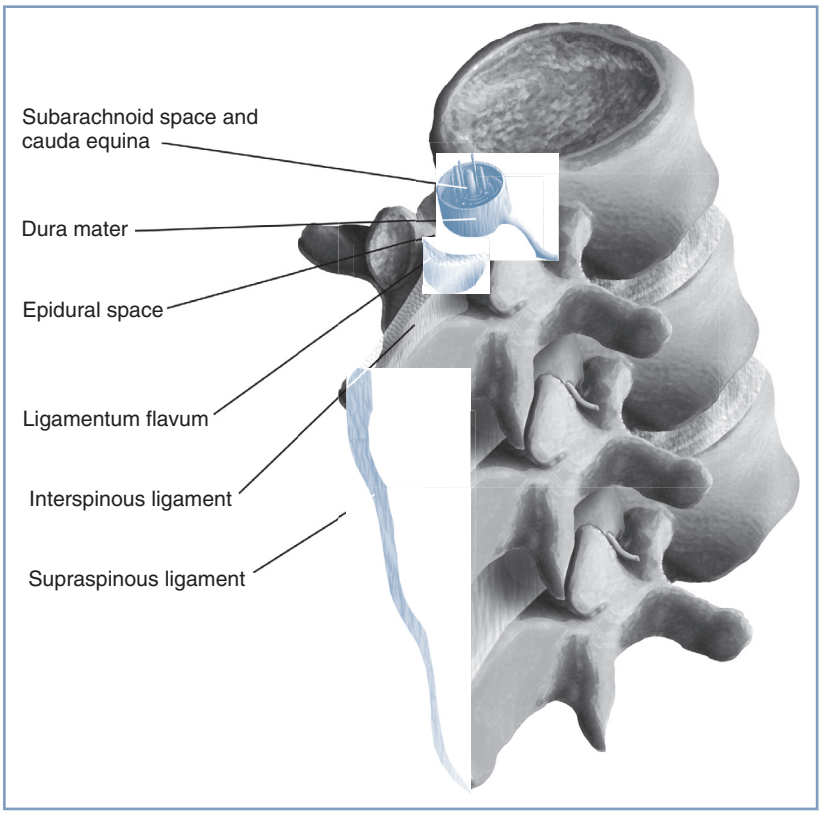

Fig. 12.3 Central neuraxial anatomy. Note the variable thickness of the ligamentum flavum, which is greatest in the midline and decreases as it fans out laterally. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

TABLE 12.1 Estimated Distance From the Skin to the Epidural Space

	ESTIMATED DISTANCE (CM)			
BMI (kg/m²)	**White (*n* = 708)**	**Asian/British Asian (*n* = 24)**	**Black/British Black (*n* = 127)**	**Chinese (*n* = 126)**
20	4.7	4.5	5.0	4.4
25	5.3	5.1	5.7	4.7
30	6.0	5.7	6.5	5.1
35	6.6	6.2	7.2	5.4
40	7.2	6.8	8.0	5.7

Estimated distance from skin to lumbar epidural space after adjusting for body mass index (BMI) and race.
From Sharma V, Swinson AK, Hughes C, et al. Effect of ethnicity and body mass index on the distance from skin to lumbar epidural space in parturients. *Anaesthesia*. 2011;66:907–912.

bodies, and the interspinous ligaments lie posterior to the ligamentum flavum. Posterior to these structures are the supraspinous ligament (which extends from the external occipital protuberance to the coccyx), subcutaneous tissue, and skin. Historically, some have described the ligamentum flavum as a single ligament. In actuality, however, it is composed of two curvilinear ligaments that join in the middle and form an acute angle with a ventral opening.[3,6] Much like the epidural space, the ligamentum flavum is not uniform from skull to sacrum; indeed, it is not uniform even within a single intervertebral space. The thickness of the ligamentum flavum varies with vertebral level, body mass index, race, and age, as does the distance between the skin and epidural space.[7,8] In a mixed-race adult population, the mean (SD) distance from the skin to the epidural space was 5.4 cm (1.1).[8] The distance was greater among black parturients and white parturients than among Asian parturients at any given body mass index (Table 12.1).

Anatomic Changes of Pregnancy

The normal anatomic changes of pregnancy affect neuraxial anesthesia techniques. Uterine enlargement and vena caval compression result in engorgement of the epidural veins. Unintentional intravascular epidural catheter cannulation and injection of local anesthetic are more common in pregnant patients than in nonpregnant patients. In addition, the vertebral foraminal veins, which are contiguous with the epidural veins, are enlarged and obstruct one of the pathways for

anesthetic egress from the epidural space during administration of epidural anesthesia. The enlarged epidural veins also may displace CSF from the thoracolumbar region of the subarachnoid space, as does the greater intra-abdominal pressure of pregnancy; this displacement partly explains the lowered dose requirement for spinal anesthesia in pregnant women.[9] Subarachnoid dose requirements are also affected by the lower specific gravity of CSF in pregnant patients than in nonpregnant patients.[10]

The hormonal changes of pregnancy affect the perivertebral ligamentous structures, including the ligamentum flavum. The ligamentum flavum may feel less dense and "softer" in pregnant women than in nonpregnant patients; thus, sensing the passage of the epidural needle through the ligamentum flavum may be more difficult. It may also be more difficult for a pregnant woman to achieve flexion of the lumbar spine. Progressive accentuation of lumbar lordosis alters the relationship of surface anatomy to the vertebral column. At least three changes may occur. First, a pregnant woman's pelvis rotates on the long axis of the spinal column; thus, the line joining the iliac crests (Tuffier's line) assumes a more cephalad relationship to the vertebral column (e.g., this imaginary line might cross the vertebral column at the L3 to L4 interspace rather than the L4 to L5 interspace). Second, there is less space between adjacent lumbar spinous processes during pregnancy. It may be more difficult to use the midline approach to identify the epidural or subarachnoid space in pregnant women. (Thus the often-heard comment, "She has a narrow interspace.") Third, magnetic resonance imaging has shown that the apex of the lumbar lordosis is shifted caudad during pregnancy, and the typical thoracic kyphosis in women is reduced during pregnancy.[11] These changes may influence the spread of subarachnoid anesthetic solutions in supine patients, leading to a higher sensory level in the pregnant patient (Fig. 12.4).[12] Finally, labor pain makes it more difficult for some women to assume and maintain an ideal position while the anesthesia provider performs neuraxial anesthesia.

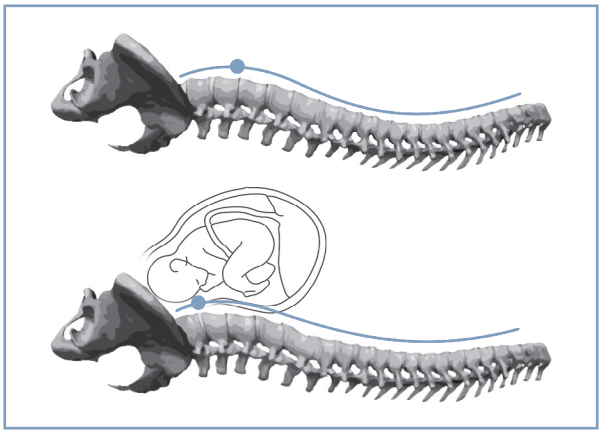

Fig. 12.4 The curvature of the spinal column in the nonpregnant *(top)* and pregnant patient *(bottom)*. The apex of the lumbar lordosis *(blue circle)* moves caudad in pregnancy. Additionally, the thoracic kyphosis is reduced and shifts cephalad. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

PHYSIOLOGY

Obstetric Pain Pathways

Pain during the first stage of labor results primarily from changes in the lower uterine segment and cervix. Pain is transmitted by visceral afferent nerve fibers that accompany the sympathetic nerves and enter the spinal cord at the T10 to L1 segments. During the late first stage and second stage of labor, pain results from distention of the pelvic floor, vagina, and perineum. Pelvic pain is transmitted by somatic nerve fibers, which enter the spinal cord at the S2 to S4 segments (Fig. 12.5).

During cesarean delivery, additional nociceptive pathways are involved in the transmission of pain, and a T6 to T4 sensory level of anesthesia is required to provide adequate anesthesia, depending on the modality used to test the sensory level (i.e., touch, pinprick, or temperature).[13] Most cesarean deliveries are performed with a horizontal (e.g., Pfannenstiel) skin incision, which involves the infraumbilical T11 to T12 dermatomes. During surgery, stretching of the skin may involve dermatomes two to four levels higher. Intraperitoneal manipulation and dissection involve poorly localized visceral

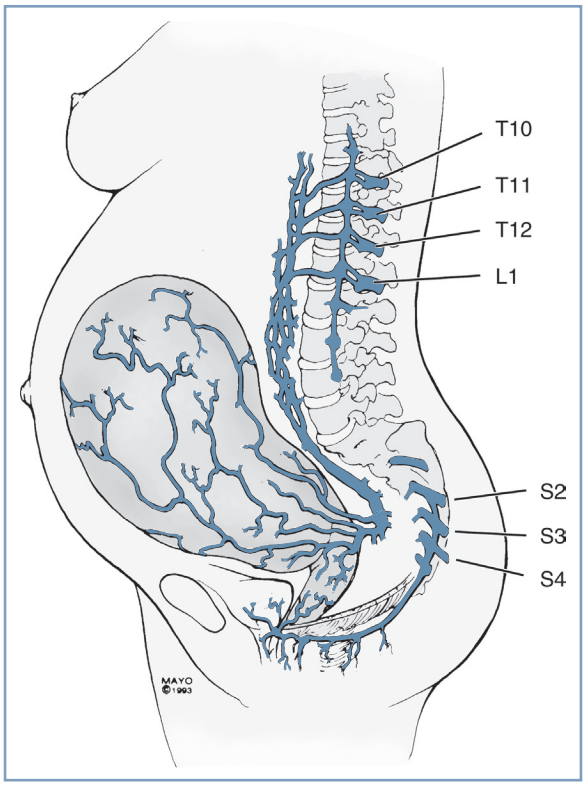

Fig. 12.5 Pain pathways during labor and delivery. The afferent pain pathways from the cervix and uterus involve nerves that accompany sympathetic fibers and enter the neuraxis at T10 to L1. The pain pathways for the pelvic floor and perineum include the pudendal nerve fibers, which enter the neuraxis at S2 to S4.

pain pathways. Visceral pain may be transmitted by pathways as high as the celiac plexus. Additional somatic pain impulses may occur because of diaphragmatic stimulation because the intercostal nerves innervate a portion of the peripheral diaphragm.

Physiology of Neural Blockade

Hormonal changes, anatomic changes, and decreases in CSF specific gravity likely are responsible for the lower local anesthetic dose requirements for spinal anesthesia in pregnant women. Local anesthetics produce conduction blockade primarily by blocking sodium channels in nerve membranes, thereby preventing the propagation of neural impulses. Differential blockade is manifested as differences in the extent of cephalad blockade of temperature discrimination and vasomotor tone, sensory loss to pinprick, sensory loss to touch, and motor function. Temperature discrimination and vasomotor tone are blocked to the greatest extent (i.e., most cephalad level) and motor function to the least extent. During spinal anesthesia, local anesthetics act directly on neural tissue in the subarachnoid space. Regression of anesthesia can be explained by the vascular uptake of local anesthetic from the subarachnoid space and spinal cord. Epidural anesthesia has a much smaller zone of differential motor–sensory–sympathetic blockade; this difference suggests that the mechanism of epidural anesthesia must involve more than simple diffusion across the dura. Nerve fiber size (i.e., smaller fibers are blocked more readily than larger fibers), myelination, and the length of nerve fiber exposed to local anesthetic are determinants of susceptibility to local anesthetic blockade and affect the extent of the differential zone of motor and sensory blockade.[14] With spinal anesthesia, the local anesthetic concentration required to block sufficient sodium channels to affect motor, sensory, and sympathetic function is less than that needed for the better-protected nerves found in the epidural space; thus, a wider band of differential blockade occurs during spinal anesthesia than during epidural anesthesia.

The understanding of the mechanisms of spinal and epidural anesthesia likely remains oversimplified. Nonetheless, it seems clear that spinal anesthesia results primarily from the effects of local anesthetic on the spinal cord, whereas epidural anesthesia results from the effects of local anesthetic on nerve tissue within both the epidural and subarachnoid spaces.

TECHNIQUE

Preprocedural Considerations

Monitoring

The American Society of Anesthesiologists (ASA) has published guidelines for administration of neuraxial anesthesia in obstetric patients (see Appendix A). Among other things, these recommendations address (1) the required presence of qualified anesthesia and obstetric care providers; (2) immediate availability of resuscitation medication and equipment (Box 12.1); (3) mandatory preprocedural intravenous access; and (4) employment and documentation of maternal vital signs and fetal heart rate (FHR) monitoring.

BOX 12.1 Suggested Resuscitation Equipment and Drugs That Should Be Available During Administration of Neuraxial Analgesia/Anesthesia

Drugs

- Hypnotic-amnestic agents (propofol, ketamine, midazolam)
- Succinylcholine
- Ephedrine
- Epinephrine
- Phenylephrine
- Atropine
- Calcium chloride
- Sodium bicarbonate
- Naloxone

Equipment

- Oxygen source
- Suction source with tubing and catheters
- Self-inflating bag and mask for positive-pressure ventilation
- Face masks
- Oral airways
- Laryngoscope and assorted blades
- Endotracheal tubes with stylet
- Eschmann stylet (bougie)
- Qualitative carbon dioxide detector

During the initiation of neuraxial analgesia for labor, all patients are monitored with an automatic blood pressure cuff and a pulse oximeter to facilitate continuous assessment of the maternal heart rate and oxygenation. Maternal blood pressure is measured every 1 to 2 minutes after the administration of the test and therapeutic doses of local anesthetic for approximately 15 to 20 minutes, or until the mother is hemodynamically stable. Subsequently (during maintenance of neuraxial analgesia), maternal blood pressure is measured every 15 to 30 minutes or more frequently if hypotension ensues. Continuous pulse oximetry during maintenance analgesia is used in selected patients (e.g., patients with obstructive sleep apnea or cardiovascular disease). Rarely, invasive hemodynamic monitoring is necessary. The sensory level of analgesia and the intensity of motor block are assessed after the administration of the test and therapeutic doses of local anesthetic and at regular intervals thereafter.

The ASA Task Force on Obstetric Anesthesia[15] has made the following recommendation regarding FHR monitoring during performance of neuraxial anesthesia procedures:

> *Fetal heart rate patterns should be monitored by a qualified individual before and after administration of neuraxial analgesia for labor. Continuous electronic recording of the fetal heart rate patterns may not be necessary in every clinical setting and may not be possible during placement of a neuraxial catheter.*

The anesthesia provider cannot predict when hypotension will occur during the administration of neuraxial anesthesia. In addition, there is concern that intrathecal administration

of an opioid is associated with a higher incidence of nonreassuring FHR patterns than other neuraxial techniques (see Chapter 23).[16] Thus, we believe that continuous electronic FHR monitoring should be performed both during (if possible) and after the administration of neuraxial analgesia in all laboring women. In some cases, the mother's position or maternal obesity precludes the use of an external Doppler device to monitor the FHR. In such cases (especially when there is concern regarding fetal well-being), it is helpful for the obstetric provider to place a fetal scalp electrode to monitor the FHR.

Informed Consent, Patient-Procedure Verification, and Partner's Presence

Before initiation of neuraxial anesthesia, a preprocedural verification process (i.e., "time-out") is performed in compliance with national patient safety recommendations. The participation of the patient, the anesthesia care provider, and a third party such as a member of the nursing staff may lead to the discovery of concerns that should be addressed before the initiation of neuraxial anesthesia. The risk associated with neuraxial procedures relates to (1) the physical instrumentation of the spinal axis and (2) physiologic changes associated with medication administration via this anatomic route. Contraindications to needle or catheter placement include patient refusal or inability to cooperate, ongoing bleeding diathesis, infection either at the site of intended intervention or untreated systemic blood-borne illness, and increased intracranial pressure predisposing to cerebral herniation. Contraindications to injecting local anesthetics via the epidural or spinal route include severe hypovolemia and allergy to local anesthetics. It is axiomatic that patient refusal represents an absolute contraindication to an elective procedure. A thorough preoperative assessment of current fetal well-being, maternal volume status, intrapartum systemic opioid use, antibiotic administration for ongoing chorioamnionitis or other infectious process, and a brief reiteration of known maternal disease states, including allergies, will readily identify most of the major concerns that would render neuraxial anesthesia potentially hazardous. The anesthesia provider should weigh the risks and benefits of neuraxial anesthesia for each patient.

Informed consent should include a frank discussion about anesthetic procedures and risks (see Chapter 32). Surveys of postpartum women have demonstrated that most parturients want to know the possible complications of epidural analgesia, even those that are rare.[17,18] It is best to relay this information before the onset of labor (e.g., during antenatal classes), or early in the intrapartum period, although doing so is not always feasible.[19] Some anesthesia providers fear that distressed, desperate, or sedated parturients may not understand the discussion of anesthetic procedures. A 2017 survey study of 206 postpartum women found no difference in recall of risks (discussed early after admission for labor) between women with and without pain at the time of the consent discussion.[20] The preanesthetic evaluation allows the physician to communicate a sense of concern and to demonstrate a commitment to the patient's care. Most laboring women understand the need for informed consent, and they appreciate the opportunity to participate in decisions about their care. Adequacy of consent can be demonstrated not only by documentation of information provided to the patient but also by the lack of patient objection to a procedure and the cooperation provided by the patient during the procedure.

Management of the pregnant patient occurs in a unique clinical care environment in which the presence of the patient's spouse or family members must be addressed. Most often, the dictates of local institutions will establish whether a partner's presence during neuraxial labor analgesia is acceptable. Intuition may suggest that a partner who remains present during the conduct of neuraxial analgesia may help alleviate the patient's ongoing anxiety regarding the procedure. Conversely, the partner may be so apprehensive or disruptive that the partner's presence becomes counterproductive to the care of the patient. Orbach-Zinger et al.[21] randomized 84 nulliparous women to either presence or absence of their partner during labor epidural catheter placement. Interestingly, patient and partner anxiety, as measured by a validated anxiety questionnaire, were less when partners were absent during the procedure.

Patient Positioning

Pregnant women have an exaggerated lumbar lordosis, and it is more difficult for them to flex the lumbar spine. However, most pregnant women are young, and youth usually allows sufficient flexibility to facilitate the insertion of a needle into the epidural or subarachnoid space. Whether the block is initiated in the lateral or sitting position is a matter of provider and patient preference. Notable advantages of the lateral position include (1) orthostatic hypotension is less likely and (2) the position often facilitates continuous FHR monitoring during placement of the epidural catheter. Vincent and Chestnut[22] performed a study in which they observed that neither the sitting nor the lateral position was consistently superior with regard to patient comfort. The sitting position is likely associated with a higher incidence of orthostatic hypotension and syncope. However, the sitting position is preferred—and may be required—in obese parturients, in whom identification of the midline is usually significantly easier in the sitting position. Further, morbidly obese women may experience hypoxemia when placed in the lateral decubitus position.

One study demonstrated a greater reduction in maternal cardiac output with maximal lumbar flexion in the lateral decubitus position than in the sitting position during identification of the epidural space in laboring women.[23] The researchers speculated that maximal lumbar flexion in the lateral decubitus position results in concealed aortocaval compression. They recommended that "the tight fetal curl position be avoided," especially when the patient assumes the lateral decubitus position.

Aortocaval compression must be avoided to the extent possible (see Chapter 2). If maternal hydration is inadequate and if aortocaval compression is not avoided, the onset of

anesthesia-induced sympathetic blockade may result in decreased venous return, cardiac output, and uteroplacental perfusion.

Maternal position during placement of the epidural catheter does not seem to affect the incidence of unintentional dural puncture. However, adoption of the lateral recumbent head-down position for epidural catheter placement may reduce the incidence of unintentional epidural venous puncture.[24]

When spinal or epidural anesthesia is performed with the patient in a lateral position, the patient's back should lie at, and parallel to, the edge of the bed, for at least two reasons. First, the edge is the firmest section of the mattress. If the patient lies away from the edge of the bed, the patient's weight will depress the mattress, and the anesthesia provider must work in a "downhill" direction. Second, this position allows anesthesia providers to keep their elbows flexed, facilitating control of fine hand and wrist muscle movements. The plane of the entire back should be perpendicular to the mattress. When asked to flex the lower back, patients typically roll the top shoulder forward, an action that rotates the spine (which is undesirable) but does not flex the lower back.

Similarly, patients positioned sitting should have their feet supported by a stool with the backs of their knees against the edge of the bed, a maneuver that helps position the patient's back closer to the anesthesia provider. The shoulders should be relaxed symmetrically over the hips and buttocks. Beds in obstetric units often break at the foot, and the split in the mattress encourages the patient's seat to slope downhill if she is straddling the mattress split; this position will cause spine rotation and may make the procedure more difficult.

When spinal anesthesia is performed, the patient's posture relative to the baricity of the anesthetic solution should be considered, because it influences the extent and latency of blockade, and the incidence of hypotension. The incidence, timing, and extent of hypotension in the period immediately after initiation of the block depend on the type of block (e.g., spinal, epidural, or combined spinal-epidural [CSE]), drug characteristics (e.g., baricity, concentration, dose), patient position during the procedure, and patient position in the period following the procedure. For example, when spinal anesthesia is initiated with a hyperbaric solution for instrumental vaginal delivery, it often makes sense for the patient to be sitting to ensure the rapid onset of sacral anesthesia. Conversely, spinal anesthesia for cervical cerclage can be initiated with the patient in the steep lateral Trendelenburg position with a hypobaric anesthetic solution.

Posture has less influence on the spread of epidural anesthesia.[25–27] During epidural anesthesia, a unilateral block more likely results from the malposition of the catheter (or perhaps an anatomic barrier within the epidural space) than from patient position, particularly after a bolus injection. Norris and Dewan[25] observed that gravity did not augment the spread of anesthesia in patients receiving epidural anesthesia for cesarean delivery, and they concluded that posture does not need to be manipulated to ensure adequate bilateral epidural anesthesia. In at least two studies, it was noted that the use of the sitting position is not necessary for the development of good sacral anesthesia when large volumes of epidural local anesthetic are given for cesarean delivery.[25,27] However, Reid and Thorburn[27] observed that use of the sitting position appeared to delay the spread of anesthesia to the midthoracic dermatomes. In comparison with the bolus administration of epidural local anesthetic, the extent of blockade may be more gravity dependent when the anesthetic is administered as a continuous infusion over a prolonged period.

Some anesthesiologists contend that maternal position after epidural catheter placement affects the efficacy of epidural analgesia, although this is a matter of some dispute. Beilin et al.[28] observed that the placement of the laboring woman in the supine position with a 30-degree leftward tilt was associated with better epidural analgesia than maintenance of the left lateral decubitus position. In contrast, Preston et al.[29] observed no difference in analgesia and a significantly higher incidence of fetal bradycardia with the supine wedged position than with the full lateral position.

Caudal anesthesia is used infrequently in modern obstetric anesthesia practice. However, there remain some circumstances in which a caudal technique is useful and/or advantageous. It is a good choice for the second stage of labor in selected patients in whom the lumbar epidural approach is hazardous or contraindicated (e.g., fusion or instrumentation of the lumbar spine). In most cases, caudal anesthesia can be successfully performed with the patient in a lateral decubitus position.

Aseptic Technique

In the past decade, there has been growing appreciation for the importance of sterile technique and the gravity of infectious complications related to neuraxial anesthesia.[30–33] The incidence of epidural abscess and spinal meningitis is generally so low that many of the available recommendations are based on evidence from other domains of infection control (e.g., surgical wound site and central venous catheter–related infection).[34-36] Nonetheless, death and devastating neurologic compromise resulting from neuraxial infection can occur.

Infection of the epidural space tends to result in the formation of an abscess, most commonly formed by *Staphylococcus aureus* found in the epidermis of either the patient or the anesthesia provider. In contrast, meningitis associated with neuraxial procedures is most commonly caused by *Streptococcus viridans*. Viridans species of streptococcus may reside in the oronasopharyngeal tract of providers or patients or in the patient's vagina. Potential routes of infection include the (1) epidural catheter track, (2) bloodstream, (3) equipment, and (4) injectate contamination. A more in-depth discussion of neuraxial infection is found in Chapter 31.

Guidelines describing aseptic technique for regional and neuraxial anesthetic procedures have been published by professional anesthesiology organizations and the U.S. Centers for Disease Control and Prevention (CDC).[34,35,37] The following recommendations deserve emphasis:

1. Given that the oropharyngeal and skin flora of the anesthesia provider are implicated in many cases of neuraxial

infection, the provider should don a surgical face mask and hat before initiation of spinal/epidural anesthesia. Microbial sampling in laminar-flow operating theaters has shown a 22-fold increase in bacterial counts when a face mask and hat are not worn.[38]

2. Washing hands with an alcohol-based antiseptic solution is recommended because this has been shown to be superior to antimicrobial soap. Jewelry (e.g., rings, watches) should be removed before and sterile gloves worn after hand cleansing.
3. The patient's skin should be decontaminated, preferably with a chlorhexidine-in-alcohol solution.[36] Evidence suggests that chlorhexidine has superior bacteriocidal and bacteriostatic efficacy compared with povidone-iodine.[39] If chlorhexidine is not available, then povidone-iodine with alcohol, rather than povidone-iodine alone, is preferred.[36] Of importance, the anesthesia provider is encouraged to exercise patience in allowing the antiseptic to dry, because a major mechanism of antisepsis is the desiccating action of alcohol.

Equipment and Placement of Needle/Catheter

Spinal Anesthesia

The first equipment decision involves determining whether to perform a single-shot or continuous technique. Traditionally, a large-bore epidural needle and catheter are used for continuous spinal anesthesia, because the U.S. Food and Drug Administration rescinded approval for the use of small-bore microcatheters in 1992. Therefore, the risk for post–dural puncture headache is significant. Continuous spinal analgesia or anesthesia using an "epidural" catheter sited in the subarachnoid space is useful after *unintentional* dural puncture with an epidural needle. In the morbidly obese patient, it may be easier to manipulate and advance a rigid epidural needle than a more flexible spinal needle; thus, the technique is useful for establishing continuous analgesia or anesthesia in this patient population, particularly when the need for anesthesia is urgent. A 23-gauge, FDA-approved, spinal catheter is now available in the United States. The catheter is inserted using a "catheter-over-needle" technique. Initial observational study found that this catheter may have clinical utility[40]; however, further study is required to characterize ease of use and complications. Several commercial spinal catheters are available in Europe, but at the current time, a single-shot technique is preferred for spinal anesthesia for most obstetric patients.

The primary equipment choice for spinal anesthesia concerns the type and size of the spinal needle. Cutting-bevel needles (e.g., Quincke) are rarely used in contemporary obstetric anesthesia practice because of the unacceptably high incidence of post–dural puncture headache associated with their use. Instead, noncutting ("pencil-point") needles (e.g., Whitacre, Sprotte, Gertie Marx) are used almost exclusively (Fig. 12.6). Pencil-point needles cause more trauma to the dura than occurs with cutting-bevel needles. This likely results in a more intense inflammatory response. Presumably, the inflammation results in more rapid closure of the dural defect.[41]

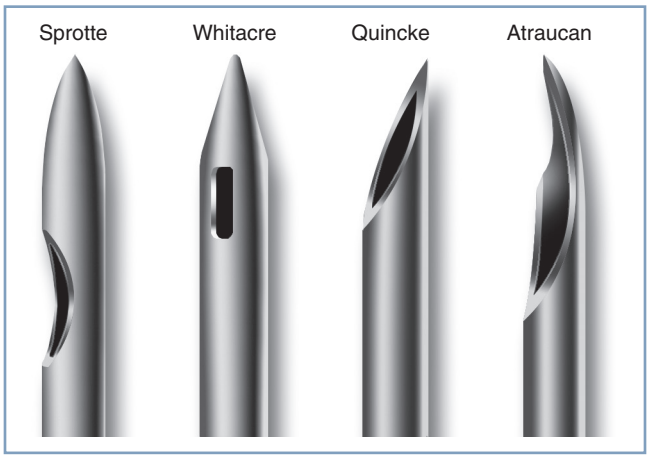

Fig. 12.6 Spinal needle assortment often used in parturients. The Sprotte and Whitacre needles have cone-shaped bevels, whereas the Quincke and Atraucan needles have a cutting bevel. (Other sizes are available in some of these needle designs.)

Needle size must also be determined. Larger needles offer a greater fidelity of tactile feedback as the anesthesia provider traverses tissue planes of variable impedance when performing spinal anesthesia. Furthermore, larger needles are more likely to withstand the high resistance encountered when contacting bone without bending or shearing. In general, the "ease-of-use" advantages associated with larger needles must be balanced against a lower incidence of post–dural puncture headache with smaller needles. Most anesthesia providers use 25- or 27-gauge noncutting needles for routine spinal anesthesia in obstetric patients. However, anesthesia providers should make individual decisions based on their own skills, the practice setting, and the patient. The urgency of the procedure may also influence the choice of needle size. For example, a 27-gauge needle might be chosen for spinal anesthesia for an elective procedure, and a larger (e.g., 22-gauge) needle might be chosen when the subarachnoid space must be entered quickly because of severe fetal compromise.

With a small-gauge needle (i.e., 24-gauge or smaller), use of an introducer needle is preferable. The introducer needle engages the interspinous ligament and more accurately guides the trajectory of the smaller spinal needle than is possible with use of a small-gauge spinal needle alone. The introducer needle also aids with skin puncture; it is often difficult to puncture the skin with noncutting needles.

Either the midline or the paramedian approach can be used to enter the subarachnoid space. The midline approach requires the patient to reduce her lumbar lordosis to allow access to the subarachnoid space between adjacent spinous processes (usually L3 to L4, sometimes L4 to L5 or L2 to L3). The interspinous space may be identified with one (usually the thumb or index finger) or two fingers (usually the index and middle fingers) of the anesthesia provider's nondominant hand. The single finger "slides" along the skin in the midline from cephalad to caudad until it "settles" into an interspinous space. The two fingers identify the interspinous space by palpating the caudad border of the more cephalad spine. The

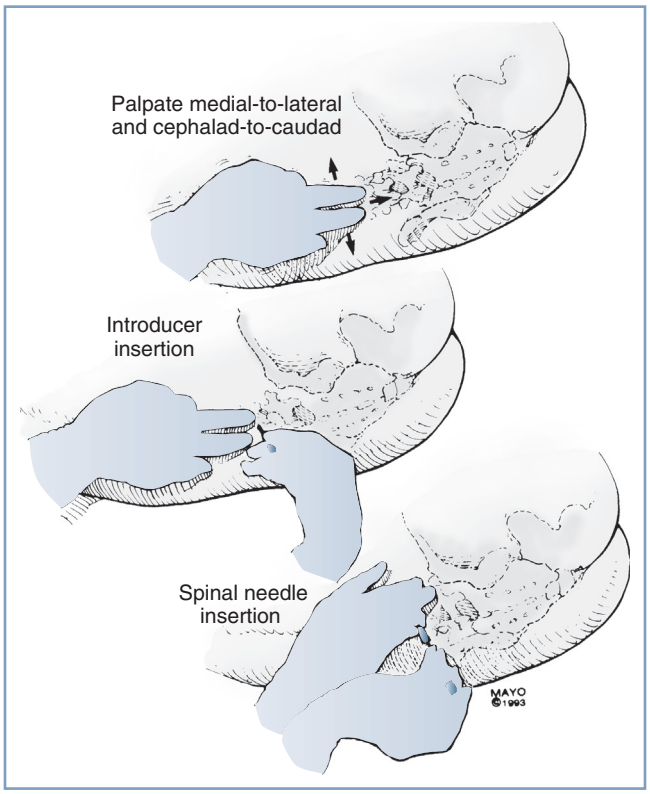

Fig. 12.7 The midline approach for spinal needle insertion requires accurate identification of a lumbar interspinous space. The palpating fingers are rolled in a medial-to-lateral and cephalad-to-caudad direction; an introducer is then inserted through the interspinous space almost perpendicular to the lumbar spinous process. Once the introducer is seated in the interspinous ligament, the spinal needle is inserted; the needle is stabilized in a tripod fashion during insertion (much like a dart being thrown).

fingers identify the midline by rolling in a medial-to-lateral direction (Fig. 12.7).

Next, the anesthesia provider injects local anesthetic intradermally and subcutaneously. The introducer needle is inserted into the substance of the interspinous ligament. It is helpful if the introducer needle is embedded in the interspinous ligament; therefore, obese patients may require a longer introducer needle. The introducer needle should lie in the sagittal midline plane. It is then grasped and steadied with the fingers of the nondominant hand while the dominant hand holds the spinal needle like a dart. The fifth finger may be used as a tripod against the patient's back to prevent patient movement from causing unintentional needle insertion to a level deeper than intended, and to "brake" the needle. As the needle passes through the ligamentum flavum and the dura, characteristic changes in resistance are noted. A "pop" is often perceived as the needle tip traverses the ligamentum flavum. A subsequent and more pronounced pop is perceived as the needle tip exits the dura-arachnoid. The stylet is removed, and CSF should appear in the needle hub. If CSF does not appear, the stylet is replaced, and the needle is advanced a few millimeters and again checked for CSF flow. This process continues until either bone is encountered or CSF returns through the needle. If neither occurs, the needle and introducer are withdrawn and the process is repeated.

Although with time and practice the tactile feedback produced by advancing a needle through tissues of variable resistance will become utterly familiar to the anesthesia provider, the novice may be unsure of the anatomic position of the needle tip, especially if unexpected resistance (i.e., contact with bone) or an unexpected and premature "pop sensation" is encountered during needle advancement. A stepwise problem-solving approach is reasonable. First, the anesthesia provider should reconfirm that (1) the patient has normal anatomy (i.e., not scoliotic); (2) she is acceptably positioned without rotation of the spine (often recognized by asymmetric shoulder position); and (3) the chosen point of needle insertion is the true midline plane. If these assertions are true, and the needle tip encounters bone, it is highly likely that the osseous structure is either the inferior or superior spinous process. One of two maneuvers may overcome this barrier. After slight withdrawal of the needle, simple angulation in a cephalad or caudad direction may redirect the needle trajectory sufficiently to achieve access to the central neuraxial canal. One must appreciate the "toughness" of the interspinous ligament. Even a 17-gauge epidural needle can be bent if the angle is changed without some prior retraction of the needle. Furthermore, if a spinal needle/introducer complex is used, care must be exercised that angulation of the spinal needle does not occur without first withdrawing it into the lumen of the introducer. Thereafter, the entire spinal needle/introducer complex is angulated before the spinal needle is re-advanced. Angulation of the spinal needle without first withdrawing it into the introducer creates a fulcrum at the junction of the introducer tip where the spinal needle emerges and can potentially damage or even shear the delicate spinal needle (Fig. 12.8).

Alternatively, the needle may be withdrawn fully into subcutaneous tissue and either raised or lowered (cephalad or caudad) while still maintaining an angulation that is parallel to the original trajectory. Which approach is more effective may depend on the reason for the initial bone contact. If the patient has very narrow interspaces, then careful raising or lowering of the needle while maintaining a trajectory parallel to the floor may be appropriate. However, if the patient is overly flexed forward, it is possible that her lumbar spinous processes are projecting in a slightly upward angulation (relative to the perpendicular transverse plane). This may require that the needle be re-angulated accordingly. If bone is still encountered despite all these considerations, it is likely that the needle tip is in fact *not* in the midline plane and is contacting the vertebral lamina. This may occur if the initial skin puncture is not in the midline, the needle tip deviates from the midline as it is advanced, or the patient's spine is rotated (either from poor positioning or scoliosis). Clues that the needle tip is not midline include (1) the patient complaining of lateralizing pain, (2) lack of CSF flow despite appropriate needle depth, and (3) the perception of "soft" or "mushy" tissue (paraspinous tissue) during needle advancement rather than the more "rigid" ligamentous tissue, or even a false "pop" as the needle tip exits the interspinous ligament laterally into

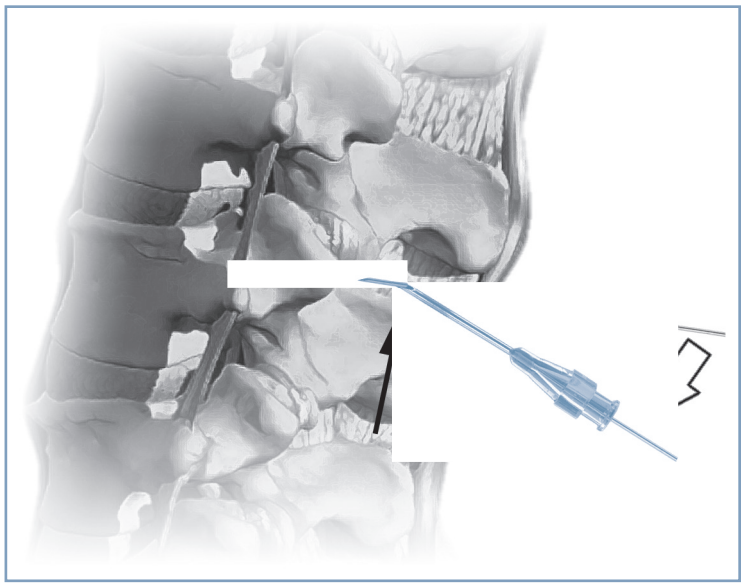

Fig. 12.8 Change of needle trajectory during spinal anesthesia. Note that if both the spinal needle and its introducer needle are manipulated without prior retraction of the spinal needle into the lumen of the introducer *(open arrow),* a fulcrum is created *(dark arrow)* where the risk for bending or shearing the delicate spinal needle may occur. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

paraspinous tissue. Much like the progressive modifications described earlier for correct alignment in the superoinferior plane, so too can these approaches be employed for redirecting in the lateral plane (Fig. 12.9). The novice is advised to make systematic changes in a stepwise fashion, rather than indiscriminately changing needle direction without first considering the anatomic problem.

Once CSF is freely dripping from the needle hub, the dorsum of the provider's nondominant hand steadies the spinal needle against the patient's back while the syringe with local anesthetic is attached to the needle. After aspirating to ensure the free flow of CSF, the anesthesia provider injects the local anesthetic at a rate of approximately 0.2 mL per second. After completion of the injection, some anesthesia providers again aspirate approximately 0.2 mL of CSF and reinject it into the subarachnoid space. This last step reconfirms the needle location and clears the needle of the remaining local anesthetic. The patient is then repositioned as appropriate.

For most patients, the midline approach is faster and less painful than the paramedian approach. The midline approach is also easier to teach than the paramedian approach, because it requires mental projection of the anatomy in only two planes, whereas the paramedian approach requires appreciation of a third plane and estimation of the depth of the subarachnoid space from the skin (Fig. 12.10).

Nevertheless, the paramedian approach is a useful technique that allows for the successful identification of the subarachnoid or epidural space in difficult cases. The paramedian approach does not require that the patient fully reduce her lumbar lordosis. This approach exploits the larger target that is available when the needle is inserted slightly off the midline.

A common error that is made with the paramedian approach is the insertion of the needle too far off the midline; the vertebral lamina then becomes a barrier to needle insertion. With the paramedian approach, the palpating fingers should again identify the caudad edge of the more cephalad spinous process. A skin wheal is raised 1 cm lateral and 1 cm caudad to this point; a longer needle is then used to infiltrate the deeper tissues in a cephalomedial plane. This step contrasts to the midline approach, in which the local anesthetic is not injected beyond the subcutaneous tissue. The spinal introducer is then inserted 10 to 15 degrees off the sagittal plane in a cephalomedial direction, and the spinal needle is advanced through the introducer needle toward the subarachnoid space. Another common error is to use an excessive cephalad angle with initial needle insertion. When the needle is inserted correctly and contacts bone, it is redirected slightly cephalad. If bone is again encountered, but at a deeper level, the slight stepwise increase in cephalad angulation is continued, and the needle is "walked" up and off the lamina. As with the midline approach, the characteristic feel of the ligamentum flavum and dura can be appreciated. The aim of the paramedian approach is to puncture the dura in the midline, even though the needle is inserted off the midline. Use of the paramedian approach requires insertion of a greater length of needle. Once CSF is obtained, the block is performed as it is with the midline approach.

During the performance of any nerve block technique, needle advancement should stop if the patient complains of pain. If pain is the result of inadequate soft tissue anesthesia, additional local anesthetic should be injected. Pain or paresthesias may also result from needle contact with central nerves or the spinal cord. Patient perception of paresthesias during the initiation of spinal anesthesia may indicate that the needle tip is in the subarachnoid space. The anesthesia provider should remove the stylet and check for CSF. If the paresthesia has resolved, the local anesthetic may be injected. If the paresthesia persists, however, the needle should be withdrawn and repositioned. In any case, the anesthesia provider should never inject the local anesthetic if the patient is complaining of paresthesias or lancinating pain, either of which may signal injection into a nerve or the spinal cord.

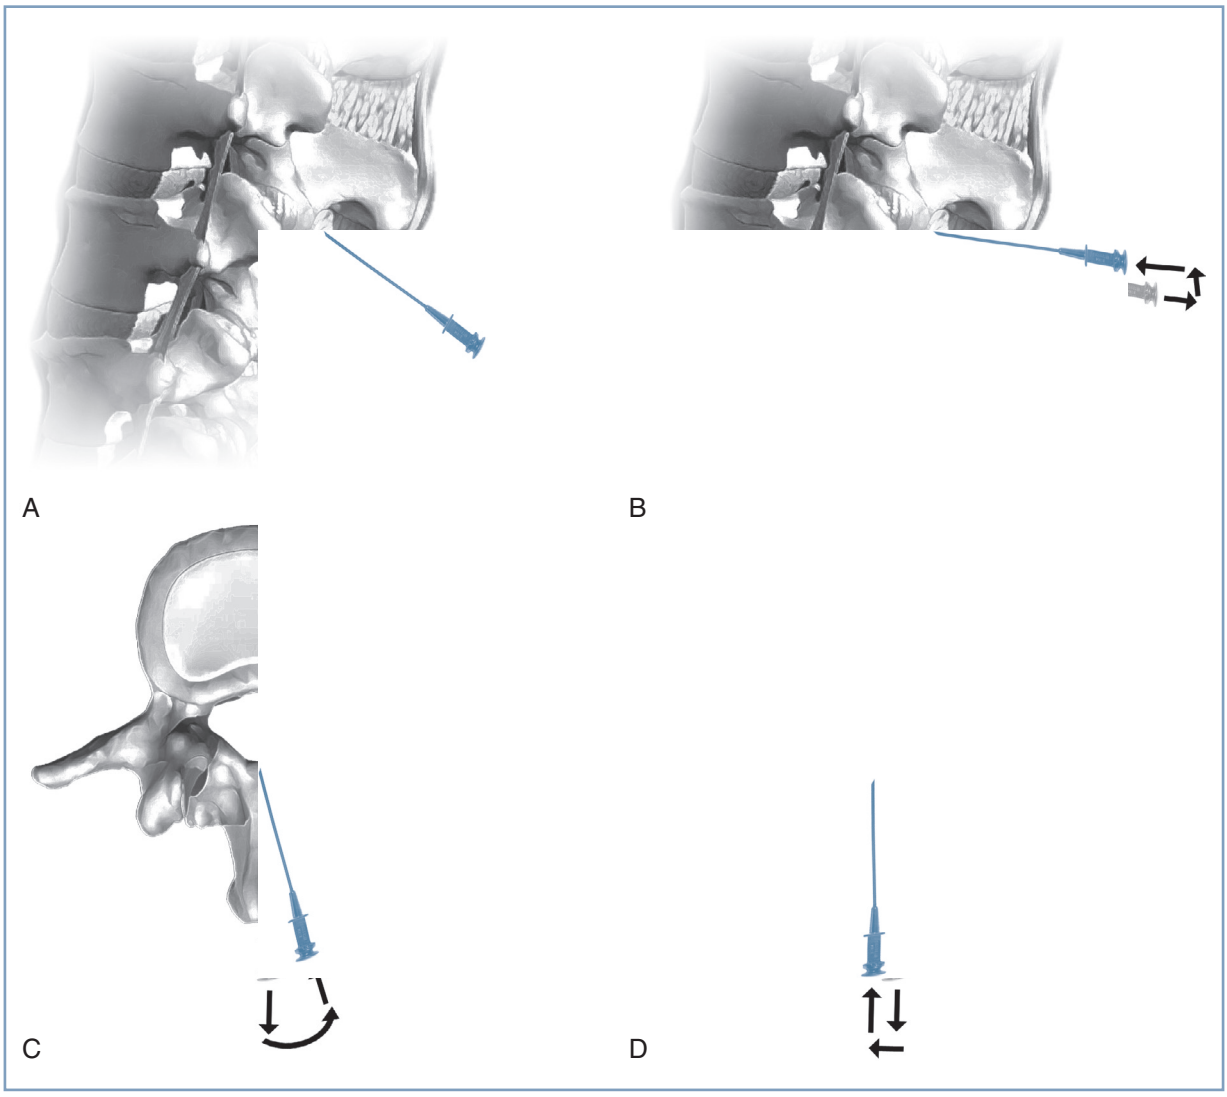

Fig. 12.9 Troubleshooting contact with bony structures during needle placement. The gray needle represents the initial needle trajectory; the blue needle represents the adjusted needle trajectory. (A) Assuming correct midline needle placement, the needle can be retracted slightly and angulated to overcome a spinous process. (B) Alternatively, the needle may be "lifted" after slight retraction while keeping the original trajectory constant. (C) Assuming the needle is deviating from the midline plane and contacting lamina, an action similar to that in *A* may be executed. (D) Alternatively, a stepwise lateral shift similar in concept to that shown in *B* may correctly achieve midline alignment. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

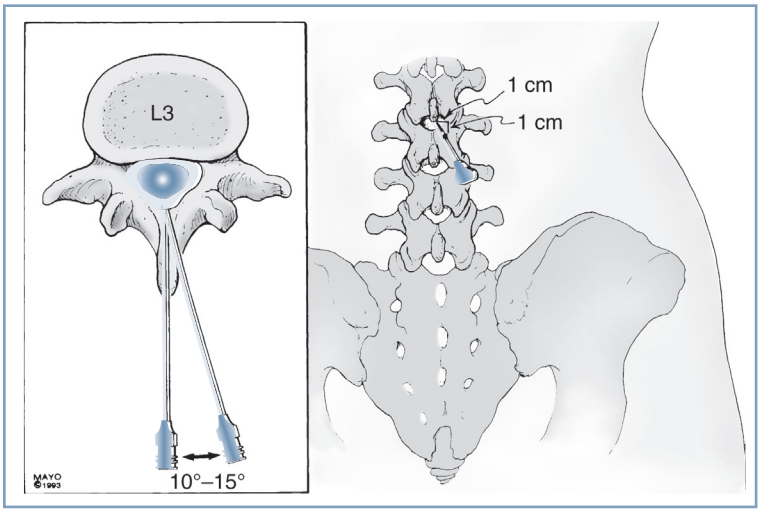

Fig. 12.10 Vertebral anatomy of midline and paramedian approaches for spinal and epidural anesthesia. The midline approach requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach also requires consideration of the oblique plane. However, the paramedian approach requires less patient cooperation in reducing lumbar lordosis to allow for successful needle insertion. The paramedian needle insertion site is made 1 cm lateral and 1 cm caudad to the caudad edge of the more cephalad spinous process. The paramedian needle is inserted 10 to 15 degrees off the sagittal plane *(inset)*.

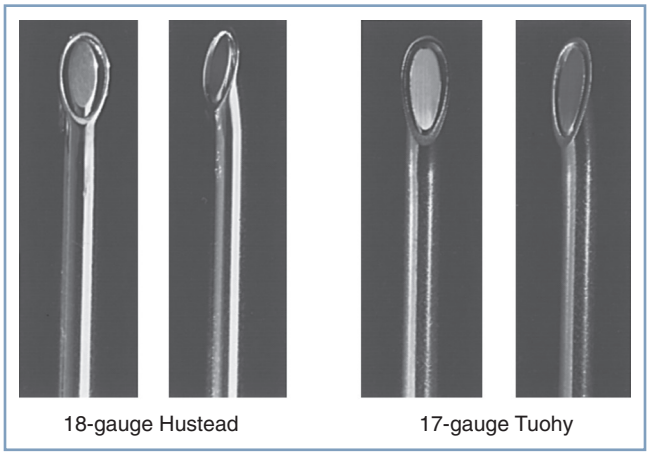

Fig. 12.11 Epidural needles often used in parturients. Each needle is shown in an open-bevel view and an oblique orientation. The 18-gauge Hustead and 17-gauge Tuohy needles have lateral-facing openings, which direct epidural catheters to enter the epidural space more easily than if a single-shot Crawford needle design is used. (Other sizes and needle designs are available for obstetric epidural anesthesia.)

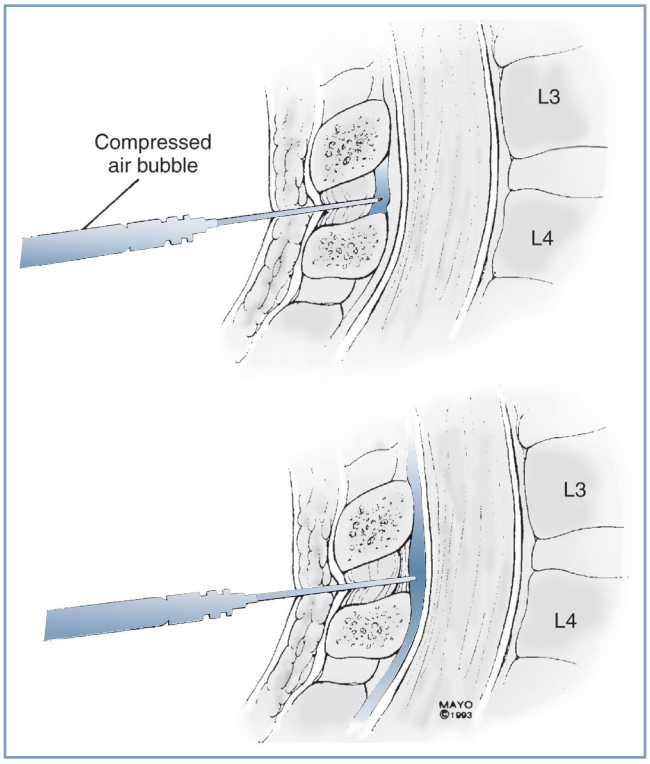

Fig. 12.12 Loss-of-resistance technique for identifying the epidural space. The needle is first inserted into the interspinous ligament or ligamentum flavum, and a syringe containing an air bubble in saline is attached to the hub. After compression of the air bubble by pressure on the syringe-plunger, the needle is carefully advanced until a loss of resistance to syringe-plunger pressure is noted as the needle enters the epidural space.

Epidural Anesthesia

Special equipment for epidural analgesia or anesthesia includes an epidural needle, an epidural catheter (for a continuous technique), and a loss-of-resistance syringe (for the loss-of-resistance technique to identify the epidural space). Single-shot epidural anesthesia is rarely used in obstetric practice, because the major advantage of epidural over spinal anesthesia is the ability to provide continuous anesthesia or analgesia without puncturing the dura with a large needle. An epidural needle with a lateral opening (e.g., Hustead, Tuohy) is most commonly used because it allows a catheter to be threaded through its orifice (Fig. 12.11).

Two methods are used to identify the epidural space during needle advancement: (1) hanging drop method and (2) loss-of-resistance method. Most anesthesia providers use the loss-of-resistance method (Fig. 12.12).

The traditional loss-of-resistance syringe is a finely ground glass syringe with a Luer-lock connector. Plastic syringes are also available, and the choice is generally a matter of the anesthesia provider's preference. The syringe is filled with 2 to 4 mL of saline, air, or saline with a small (0.25 to 0.5 mL) air bubble. There is some controversy regarding the use of air versus saline for detecting the point of loss of resistance.[42] Saline causes some syringe plungers to stick and may be confused with CSF during initiation of CSE anesthesia. Conversely, injection of air into the epidural space may contribute to patchy anesthesia,[43] and unintentional pneumocephalus may increase the risk for headache.[44]

Results of investigations comparing air to saline for loss of resistance are conflicting. A 2014 meta-analysis that included 852 patients (most were obstetric patients) found no differences in inability to locate the epidural space, unintentional intravascular or intrathecal catheter placement, block failure, unblocked segments, or pain between the two mediums.[45] However, the confidence intervals of the relative risks were wide, and the authors concluded that the evidence was of low quality. In a retrospective, single-institution study of loss of resistance to air versus saline by Segal and Arendt,[46] no significant differences in block success were found in 929 patients. The authors intentionally chose a retrospective approach to the question; they stated that because "it is impossible to mask the anesthesiologist to the medium used for loss-of-resistance, [they] hypothesized that randomized controlled trials might *overestimate* the difference between air and saline by forcing the operator to use a less-preferred technique in half of the subjects." Thus, we recommend that anesthesia providers use the technique with which they are most comfortable. We use saline with a small bubble of air.

Regardless of the technique used, success depends on correct placement of the needle tip. The needle should be advanced sufficiently into the interspinous ligament before the syringe is attached or before the hanging drop of solution is placed into the needle hub. This approach has at least three advantages. First, it encourages the anesthesia provider to use proprioception while directing and advancing the needle. Second, it shortens the time required for successful identification of the epidural space. Third, it lowers the likelihood of a false-positive loss of resistance. Undoubtedly, this false-positive identification of the epidural space is responsible for

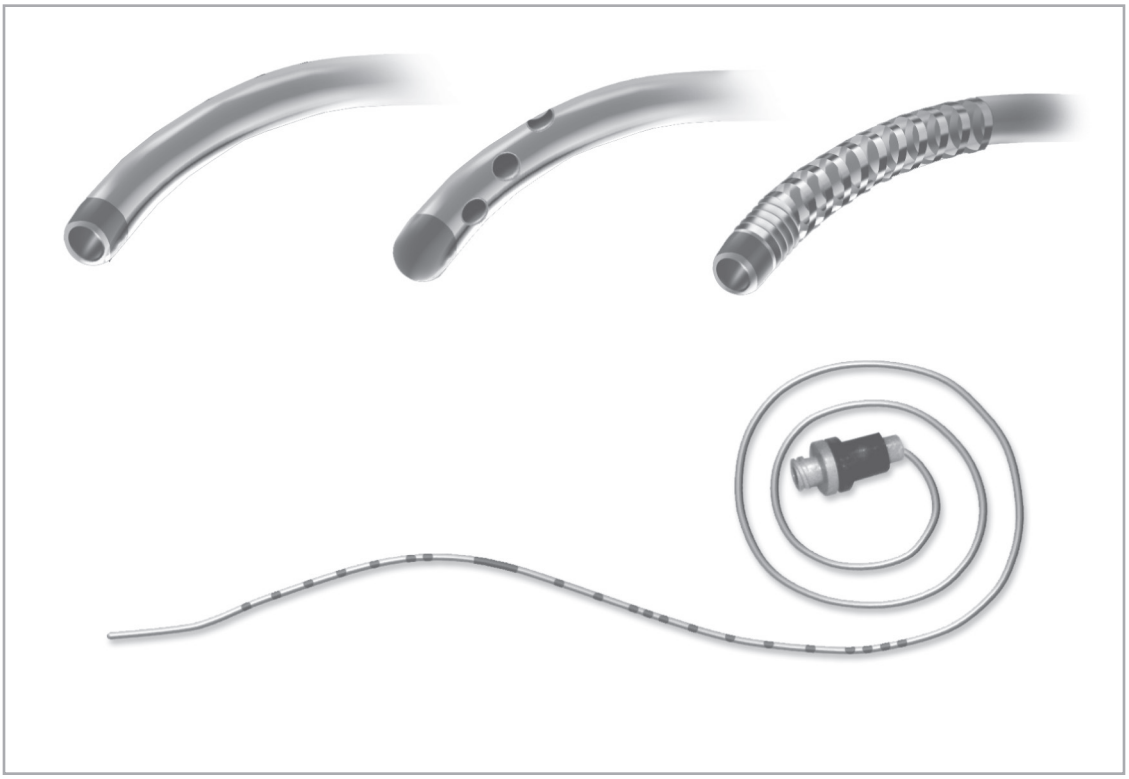

Fig. 12.13 Epidural catheters. (A) Single-orifice catheter; (B) multi-orifice catheter with bullet tip; (C) coiled wire reinforced catheter. *Bottom,* Epidural catheter with centimeter markings along distal end and Luer-lock connector at proximal end. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

many cases of unsuccessful epidural anesthesia; it is even possible to insert a catheter between the interspinous ligament and the ligamentum flavum.

During advancement of the needle-syringe assembly, the needle should be moved toward the epidural space by the provider's nondominant hand while the thumb of the dominant hand applies constant pressure on the syringe plunger, thereby compressing the small air bubble. Alternatively, the intermittent, oscillating technique is employed when using the loss-of-resistance to air technique. When the needle enters the epidural space, the pressure applied to the syringe plunger causes the saline solution or air to flow easily into the epidural space (see Fig. 12.12).

In most obstetric cases, the anesthesia provider inserts a catheter and uses an intermittent bolus or continuous infusion technique to maintain analgesia. Most practitioners insert the catheter before injecting local anesthetic to allow for the slow, incremental injection of local anesthetic/opioid solution and the more controlled development of epidural anesthesia. If the principal reason for using an epidural technique is the provision of continuous analgesia, it seems most practical to insert the catheter before injecting the therapeutic dose of local anesthetic so that correct catheter placement can be verified promptly.

Several types of single-use, disposable epidural catheters are available.[47] Catheters are made from plastic materials and differ as to the degree of "stiffness." Wire-embedded catheters are more flexible and are associated with a lower incidence of paresthesias and intravascular placement during catheter insertion.[24,48,49] The single-orifice catheter has one opening at its tip, whereas the multi-orifice catheter has a closed "bullet" tip with three lateral orifices between 0.5 and 1.8 cm from the tip (Fig. 12.13).

The proposed advantage of single-orifice, open-end catheters is that the injection of drugs is restricted to a single anatomic site. In theory, this arrangement should facilitate the detection of intravenous or subarachnoid placement of the catheter. Likewise, a theoretical disadvantage of multi-orifice, closed-end catheters is that local anesthetic may be injected into more than one anatomic site (e.g., both the epidural and subarachnoid spaces). A catheter initially placed in the epidural space can migrate into a vein or the subdural or subarachnoid space. Fortunately, this does not seem to be a common clinical problem. Regardless of the choice of catheter, aspiration should be performed before each dose of local anesthetic is injected.

An advantage of the multi-orifice catheter over the single-orifice catheter is the consistent ability to aspirate fluid (either blood or CSF) when the catheter is in a vessel or the subarachnoid space.[50] Early studies suggested that multi-orifice catheters may lead to more even distribution of local anesthetic and a lower incidence of "patchy" or unilateral anesthesia when the anesthetic is injected as a bolus.[51] However, during an infusion into the epidural space, the solution exits

only the most proximal hole,[52] and multi-orifice catheters thus behave like single-orifice catheters. A randomized trial comparing single- and multi-orifice wire-reinforced catheters found no differences in block success or complications.[53]

If the catheter is placed before the test and therapeutic doses of local anesthetic, it may be helpful to inject 5 to 10 mL of saline before threading the catheter, because this may reduce the incidence of epidural vein cannulation,[24] particularly when using stiffer epidural catheters. Rolbin et al.[54] noted that there was no advantage to the injection of 3 mL of fluid into the epidural space before insertion of the epidural catheter.

Six to eight centimeters of catheter are threaded into the epidural space before the epidural needle is removed. The catheter may then be pulled back until it is at the desired distance at the skin. Occasionally, the anesthesia provider will have difficulty advancing the catheter past the tip of the epidural needle. This difficulty may indicate that the epidural needle tip is not in the epidural space. However, if the provider is convinced that the needle is correctly placed, several maneuvers may facilitate catheter advancement. Often, having the patient take a deep breath allows catheter advancement. Saline may be injected through the epidural needle if this has not been done. Although some providers rotate the epidural needle in an attempt to successfully advance the catheter, we do not recommend this maneuver, because it may increase the risk for dural puncture. Instead, the epidural needle should be withdrawn 0.5 to 1 cm and again advanced into the epidural space.

Many techniques are available for securing the epidural catheter at the skin entry site. A transparent, sterile adhesive dressing applied over the catheter after application of skin adhesive generally works well, and the periphery of the dressing can be reinforced with tape. The position of the epidural catheter may change significantly with patient movement from the sitting-flexed to the sitting-upright or lateral decubitus position.[55] D'Angelo et al.[56] found that the risk for catheter dislodgement was higher when catheters were inserted 2 cm into the epidural space, but the risk for unilateral blockade was greater when catheters were inserted 6 to 8 cm. Therefore, if the catheter is to be used for a short period (e.g., during cesarean delivery), it should be left 2 to 4 cm into the epidural space. In contrast, if the catheter will be used for many hours (e.g., during labor), it should be left 4 to 6 cm into the space.[56,57] To minimize catheter movement at the skin, the patient should be positioned sitting upright or in the lateral position before the catheter is secured, especially if the patient is obese.[55]

The potential for the contamination of local anesthetic solutions has prompted the use of micropore filters during the administration of continuous epidural analgesia for labor. There is no evidence that filters decrease the rate of infection or of injection of undesirable foreign substances.[58] Additionally, filters may reduce the reliability of aspiration[59] and absorb local anesthetic solution, unless they are primed.[60] We believe that micropore filters have little use in clinical obstetric anesthesia practice.

BOX 12.2 Advantages of Combined Spinal-Epidural Anesthetic Technique

Compared With Epidural Anesthesia

- Lower maternal, fetal, and neonatal plasma concentrations of anesthetic agents
- More rapid onset of analgesia and anesthesia
- Denser sensory blockade
- Complete early labor analgesia with opioid alone (no local anesthetic necessary)
- Lower failure rate

Compared With Spinal Anesthesia

- Technically easier in obese individuals: The epidural needle acts as an introducer for the spinal needle (it is easier to advance a rigid epidural needle)
- Ability to titrate anesthetic dose: Start with low subarachnoid dose, and titrate to effect using epidural injection
- Results in less hypotension
- Ability to extend the extent of neuroblockade: Spinal anesthesia for forceps delivery may be extended to epidural anesthesia for cesarean delivery after failed forceps delivery
- Continuous technique: ability to extend duration of anesthesia

Combined Spinal-Epidural Anesthesia

CSE anesthesia combines the advantages and mitigates the disadvantages of single-shot spinal anesthesia and continuous epidural anesthesia (Box 12.2). Anesthesia is initiated with a subarachnoid injection of opioid and local anesthetic and maintained via an epidural catheter. It is useful for both cesarean delivery anesthesia and labor analgesia. For cesarean delivery, the injection of the smaller dose of local anesthetic required for spinal (compared with epidural) anesthesia is inherently safer with regard to the possibility of unintentional intravascular injection. Additionally, the anesthesia provider can inject a local anesthetic dose that is lower than the ED_{95} (effective dose in 95% of cases) without fear of inadequate anesthesia. These lower doses result in less maternal hypotension.[61] If surgical anesthesia is inadequate, the block can be "rescued" with epidural administration of local anesthetic. For example, a randomized trial comparing 7, 8, and 9 mg of intrathecal bupivacaine administered as part of a CSE technique for cesarean delivery produced equivalent latencies to T4 sensory block with lower rates of maternal hypotension in the lowest-dose group.[62] The shorter duration of action seen in the low-dose (7 mg) group was easily addressed through the administration of local anesthetic via the indwelling epidural catheter. Compared with conventional epidural anesthesia for cesarean delivery, CSE anesthesia is associated with a more rapid onset of surgical anesthesia, less intraoperative pain and discomfort (because of a more dense block), better muscle relaxation, and less shivering and vomiting.[63]

The CSE technique is associated with a faster onset of labor analgesia, achieved with the subarachnoid injection of an opioid alone or an opioid combined with a small dose of local anesthetic. Studies differ as to whether CSE analgesia

is associated with greater maternal satisfaction and fewer requests for supplemental analgesia. Goodman et al.[64] randomized 100 parous women in early labor to receive either CSE or conventional epidural analgesia. There were no differences in requests for supplemental analgesia, although pain scores were lower in the CSE group within the first 30 minutes. A single-institution randomized trial in 800 women found better first-stage analgesia and fewer requirements for treatment of breakthrough pain in women randomized to receive CSE compared with epidural analgesia.[65] A 2012 systematic review comparing CSE and epidural labor analgesia concluded that onset was faster with the CSE technique, but that there was no evidence for differences in maternal satisfaction, mode of delivery, ability to ambulate, or incidence of hypotension between the two techniques.[66] Several studies have found a lower incidence of failed epidural analgesia after the initiation of analgesia with a CSE technique.[67–69] Presumably, verification of the correct placement of the spinal needle by visualization of CSF increases the likelihood that the tip of the epidural needle is correctly placed in the epidural space.

A purported disadvantage of the CSE technique is that correct placement of the epidural catheter in the epidural space cannot be verified until spinal analgesia or anesthesia wanes. Therefore, it has been suggested that if a functioning epidural catheter is important to the safe care of the mother and fetus (e.g., in the setting of a suspected difficult airway or nonreassuring fetal status), an epidural rather than CSE technique is indicated. However, in a retrospective study that included 2395 neuraxial labor analgesia procedures, the CSE technique did not result in delayed recognition of epidural catheter failure, and the overall catheter failure rate was lower when the catheter was cited as part of CSE analgesia.[69] Therefore, fear of unrecognized catheter malposition should not be a consideration when choosing a neuraxial technique.

There are several techniques for initiation of CSE anesthesia/analgesia.[70] The most popular is the needle-through-needle technique, in which the epidural needle is sited in the epidural space and serves as an introducer for the spinal needle. The spinal needle passes through the epidural needle to puncture the dura. After injection of the subarachnoid dose, the spinal needle is removed, and the epidural catheter is threaded through the epidural needle. An alternative technique uses two skin punctures and two different interspaces: the spinal needle and epidural needle and catheter are introduced sequentially in two different interspaces.

The needle-through-needle technique requires a long spinal needle. Typically, a small (25- or 27-gauge) noncutting needle is used to minimize the risk for post–dural puncture headache. The tip of the spinal needle must protrude 12 to 17 mm beyond the tip of the epidural needle when the two needles are fully engaged (Fig. 12.14). Failure to puncture the dura and visualize CSF occurred in 25% of patients when the spinal needle protruded 9 mm, compared with no patients when the needle protruded 17 mm.[71] A 127-mm spinal needle is commonly used with a standard 9-cm epidural needle. However, because of differences in hub configurations among needles, the two hubs may not "mesh," and spinal needle protrusion may vary with specific needle combinations. Alternatively, manufacturers sell CSE needle "kits," in which the spinal needle is designed for a specific epidural needle. An additional small syringe (1 to 3 mL) is required for the spinal dose.

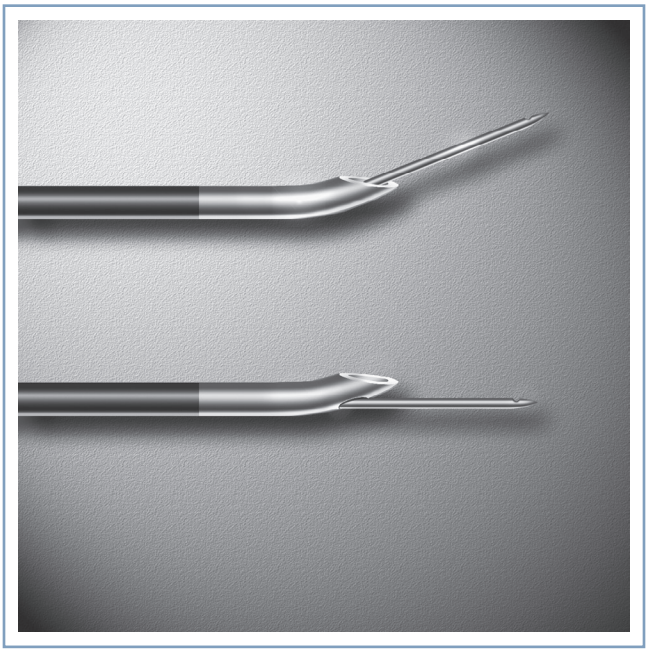

Fig. 12.14 Combined spinal-epidural needle configuration. *Top,* Spinal needle exits the epidural needle through the normal epidural needle bevel. Because the epidural needle bevel opening faces sideways, the spinal needle exits the epidural needle at a slight angle to the long axis of the epidural needle. *Bottom,* Spinal needle exits the epidural needle through a special orifice. The axes of the spinal and epidural needles are aligned. The spinal needle must protrude 12 to 17 mm from the tip of the epidural needle when the hubs are engaged, or the ability to puncture the dura with the spinal needle is compromised. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

CSE anesthesia is initiated much like epidural anesthesia. The epidural needle is sited in the epidural space (Fig. 12.15). Before inserting the epidural catheter, the spinal needle is introduced through the epidural needle with the anesthesia provider's dominant hand, while the nondominant hand is anchored against the patient's back to serve as a brake for further advancement of the spinal needle. The provider usually perceives the tip of the spinal needle passing the tip of the epidural needle as a slight increase in resistance. Spinal needle advancement should stop immediately after the anesthesia provider perceives the dural puncture "pop." Dural puncture is verified by visualization of CSF after removal of the spinal needle stylet. The provider's nondominant hand is anchored on the patient's back, and the spinal and epidural needle hubs are grasped together between the thumb and index finger of this hand. The dominant hand attaches the spinal syringe. If aspiration of CSF is attempted, care must be taken not to dislodge the spinal needle. After injection of the spinal dose and removal of the spinal syringe and needle as a unit, the epidural catheter is threaded in the usual fashion.

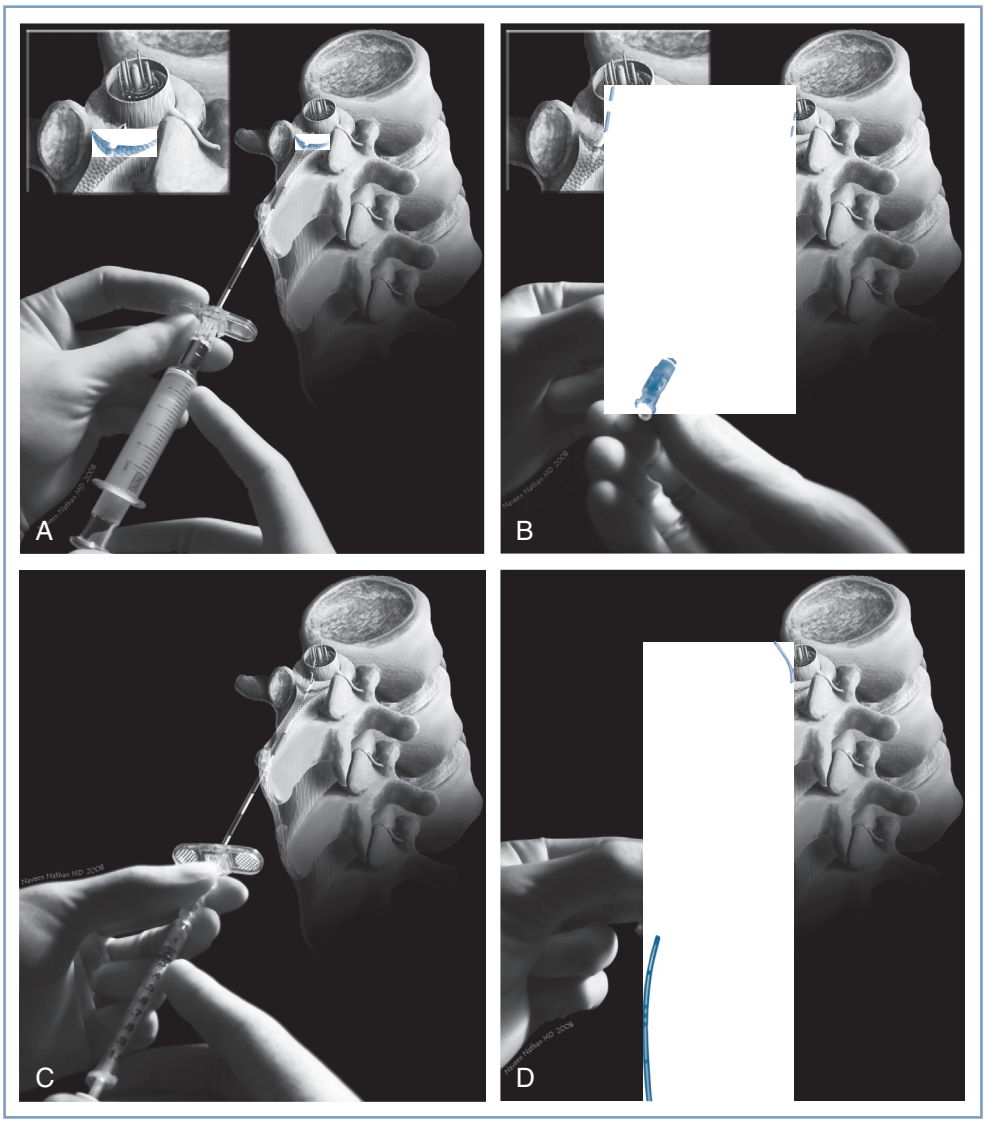

Fig. 12.15 Needle-through-needle combined spinal-epidural technique. (A) The epidural needle is sited in the epidural space. (B) The long spinal needle is passed through the epidural needle and punctures the dura mater. The operator's nondominant hand stabilizes the spinal and epidural needles, and the spinal needle stylet is withdrawn. Cerebrospinal fluid is seen spontaneously dripping from the spinal needle. (C) The syringe is attached to the spinal needle, and the intrathecal dose is injected. (D) The spinal needle is withdrawn, and the epidural catheter is threaded through the epidural needle into the epidural space. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

Failure to puncture the dura with the spinal needle may occur in several circumstances (Fig. 12.16). The epidural needle tip may not be in the epidural space, or the needle tip may be correctly placed, but the spinal needle may fail to puncture the dura or may not reach the dura because of the depth of the posterior epidural space. Alternatively, the epidural needle may be angled away from the midline or in a sagittal plane off the midline, and the spinal needle may traverse the lateral epidural space without puncturing the dura. In this latter circumstance, the anesthesia provider may elect to abandon the CSE technique and continue with epidural anesthesia (if convinced that the epidural needle tip is in the epidural space) or to reposition the epidural needle and reattempt the CSE technique.

Dural-Puncture Epidural Anesthesia

Dural puncture epidural (DPE) analgesia is another neuraxial technique that aims to exploit the advantages of CSE anesthesia while minimizing its shortcomings. It is procedurally identical to CSE anesthesia except for the omission of drug injection into the subarachnoid space. Presumably, excluding direct subarachnoid administration of opioid and local anesthetic at the time of dural puncture avoids the precipitous development of adverse effects such as hypotension and fetal bradycardia. However, the presence of the dural puncture allows for augmented transdural migration of epidurally injected drugs into the subarachnoid space. Hypothetically, this facilitates more reliable block of sacral dermatomes, which may be inadequately anesthetized with conventional

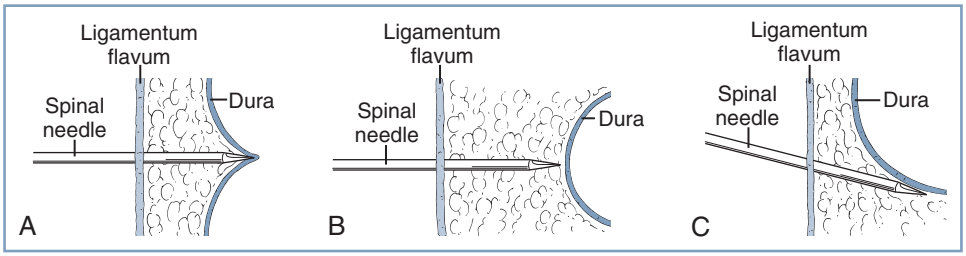

Fig. 12.16 Reasons for failure of the combined spinal-epidural technique. (A) The spinal needle tents the dura but does not puncture it. (B) The spinal needle does not reach the dura. (C) The spinal needle passes to the side of the dural sac. (Redrawn with permission from Riley ET, Hamilton CL, Ratner EF, Cohen SE. A comparison of the 24-gauge Sprotte and Gertie Marx spinal needles for combined spinal-epidural analgesia during labor. *Anesthesiology*. 2002;97:574.)

epidural anesthesia. The subarachnoid translocation of drugs may also act to compensate for an epidural catheter that would otherwise provide asymmetric block, leading to breakthrough pain and the requirement for manual top-up bolus injections of local anesthetic.

Results of two early trials comparing traditional epidural to DPE analgesia were inconsistent.[72,73] Thomas et al.,[72] using a 27-gauge spinal needle, found no differences in analgesia outcomes, including catheter manipulation and replacement rate, inadequate analgesia, unilateral block, sacral sparing, and the incidence of breakthrough pain. In contrast, Cappiello et al.,[73] using a 25-gauge spinal needle, found improved sacral analgesia, lower pain scores at 20 minutes, and a lower incidence of unilateral block in women randomized to receive DPE compared with epidural analgesia. A third trial compared epidural, CSE, and DPE analgesia.[74] Onset of analgesia (the primary outcome) was faster in the CSE group than in the epidural and DPE groups, but there was no difference between the epidural and DPE techniques. Compared with the traditional epidural technique, women randomized to receive DPE analgesia had a greater incidence of bilateral sacral block at 10 minutes and a lower incidence of asymmetric block at 30 minutes. Compared with CSE analgesia, women in the DPE group had a lower incidence of pruritus and hypotension. The combined incidence of uterine tachysystole and hypertonus was greater in the CSE compared with the epidural and DPE groups. Finally, a fourth trial comparing epidural to DPE analgesia found no difference in adequate analgesia at 10 minutes (defined by a visual analog scale score less than 10 mm), but those in the DPE group had a shorter time to adequate analgesia (median time 8 minutes versus 10 minutes).[75] There were no differences in complication rates, including maternal hypotension, nausea, and pruritus. Further investigations will likely define the role of the DPE technique in the routine management of labor pain.

Caudal Anesthesia

Equipment for caudal anesthesia is similar to that used for lumbar epidural techniques, except that a needle with a lateral-faced opening is not needed. A blunt-tipped needle is satisfactory even when a catheter is used, because the angle of needle insertion allows insertion of the catheter. Successful administration of caudal anesthesia requires the accurate identification of the sacral hiatus. The sacrococcygeal ligament (an extension of the ligamentum flavum) overlies the sacral hiatus between the sacral cornua. Identification of the posterior superior iliac spines facilitates the identification of the sacral cornua; the location of the sacral hiatus is approximated by using the line between them as one side of an equilateral triangle (Fig. 12.17). Alternatively, ultrasonography can assist in the identification of the sacral hiatus.[76] Once the sacral hiatus is identified, the palpating fingers are placed on the cornua, the skin is anesthetized, and the caudal needle is inserted with the hub at an angle approximately 45 degrees from the skin. A decrease in resistance is noted when the needle enters the caudal canal. The needle is advanced until it contacts bone (the dorsal aspect of the ventral plate of the sacrum). Next, the needle is withdrawn slightly and redirected so that the angle of insertion relative to the skin surface is decreased. In pregnant women, the final angle is approximately 15 degrees from a plane parallel to the sacrum.

Accurate placement of the caudal needle is verified primarily from the "feel" of the needle passing through the sacrococcygeal ligament. An additional maneuver may help providers with less experience to verify correct needle placement: Once the needle is believed to be within the caudal canal, 5 mL of saline is rapidly injected through the needle while the anesthesia provider's other hand is placed over the dorsum of the sacrum. If the needle is placed correctly, no mass or pressure wave is detected over the midline of the sacrum. Conversely, if the needle is malpositioned (often posterior to the caudal canal), a fluid mass or pressure wave is felt by the palpating hand.

The needle should be advanced only 1 to 2 cm into the caudal canal. Dural puncture or unintentional intravascular cannulation is more likely to occur with deeper insertion. A test dose similar to that used during administration of lumbar epidural anesthesia should be administered.

Ultrasonographic Guidance

The past two decades have witnessed an enormous increase in the use of ultrasound-guided regional anesthesia. Unlike the use of ultrasonography for vascular access and peripheral nerve block techniques, ultrasonography for neuraxial techniques is not used in real time. Most often, ultrasonography is a preprocedural tool used to aid the operator in the assessment of

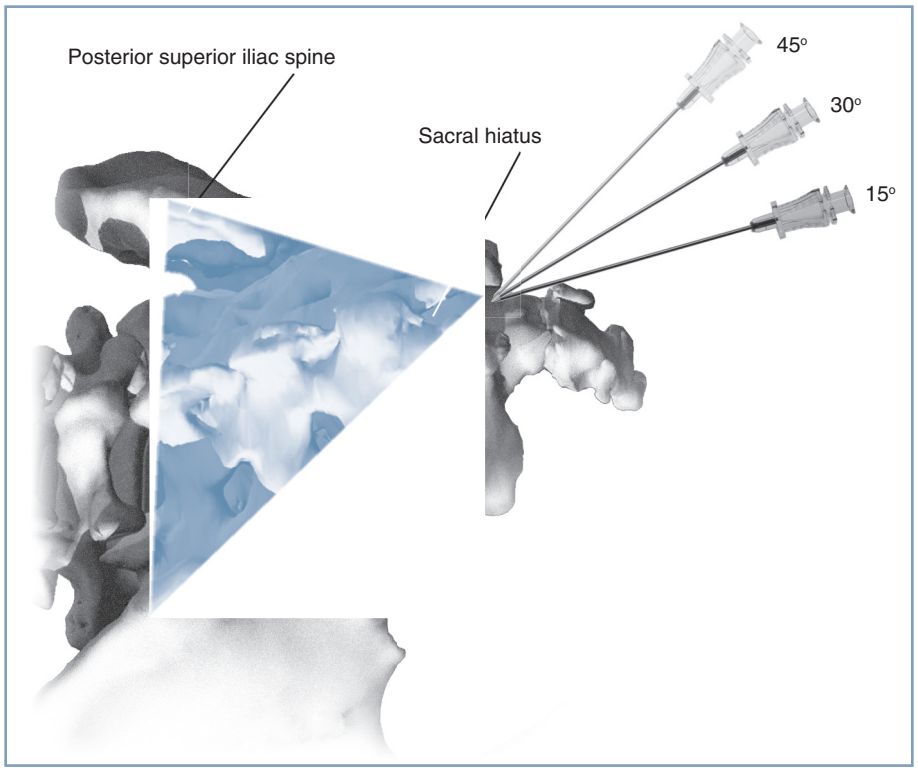

Fig. 12.17 The location of the sacral hiatus for caudal anesthesia is facilitated by the identification of the posterior superior iliac spines. The posterior superior spines are marked, and a line drawn between them forms one edge of an equilateral triangle. If the triangle is completed as illustrated, the sacral hiatus should underlie the caudad tip of the equilateral triangle. Once the sacral hiatus is identified, the needle is inserted by insertion and withdrawal in a stepwise fashion from an initial 45-degree angle off the coronal plane. In pregnant women, the needle eventually enters the caudal canal at an angle approximately 15 degrees off the coronal plane. If the needle is placed properly, no subcutaneous "lump" develops after injection of the local anesthetic solution. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

needle insertion site, needle angle, and estimated depth of the epidural space. A 2016 meta-analysis of randomized controlled trials and cohort studies comparing the traditional landmark technique to preprocedural ultrasonography as an adjunct to neuraxial procedures concluded that use of ultrasonography (1) results in more accurate identification of a given lumbar interspace, (2) allows accurate prediction of the depth of needle insertion to the epidural or intrathecal space, and (3) reduces technical difficulty (fewer attempts and needle redirections necessary for a successful procedure).[77] Evidence has not yet accumulated that preprocedural ultrasonography results in improved success of anesthesia and procedural safety (e.g., lower rate of complications such as unintentional dural puncture), although this would logically be assumed.

In the obstetric population, a host of randomized controlled trials have explored outcomes related to block placement and success comparing the traditional landmark-based technique versus the ultrasound-guided technique.[77] In many of these studies, an experienced ultrasonographer imaged the spine and marked the midline and interspaces on the skin, and a trainee performed the actual neuraxial procedure. In contrast, Arzola et al.[78] provided comprehensive neuraxial ultrasonography training to anesthesiology residents and fellows. Following training, low-risk women with easily palpable spinous processes requesting neuraxial labor analgesia were randomized to the use of preprocedural ultrasonography versus a traditional landmark technique; the trainee used the allocated technique to perform the procedure. There were no differences in epidural procedure time and number of attempted interspaces and needle passes between the two techniques. Total procedure time was longer in the ultrasonography group. An explanation for these findings is that expert ultrasonography skills are necessary to realize the advantages of the technique as an adjunct to neuraxial procedures. Another explanation is that ultrasonography offers no advantages in low-risk patients. Indeed, in a randomized controlled trial of CSE procedures for cesarean delivery performed by a single experienced anesthesiologist and ultrasonographer in women with palpable spinous processes, there were no differences in the first needle-pass success rate, number of needle passes, or patient satisfaction when women were randomized to an ultrasound-guided technique versus a traditional technique.[79] Thus, at the present time, an experienced anesthesiologist managing an uncomplicated pregnant patient is unlikely to benefit from the use of preprocedural ultrasonographic imaging.

There exist, however, unique clinical circumstances in which preprocedural imaging of neuraxial anatomy may be highly beneficial. Such may be the case in patients with morbid obesity; derangements of spinal anatomy resulting from scoliosis, spinal stenosis, or a history of spinal instrumentation; and in patients in whom identification of specific vertebral levels might be warranted (e.g., known preexisting disc herniation or nerve root compression at a specific interspace).[80] For example, Creaney et al.[81] assessed the utility of preprocedural ultrasonography in pregnant patients with impalpable spinous processes presenting for spinal anesthesia for cesarean delivery. The mean body mass index was approximately 40 kg/m^2. Although there was no difference in the total procedure time between groups, women in the ultrasonography group required fewer needle passes to locate the intrathecal space.

Preprocedural ultrasonography is useful for estimating the distance from the skin to the epidural or intrathecal space. In general, although studies have shown high correlation between the ultrasonographic and actual measurement, ultrasonographic measurements underestimate the true distance from the skin to epidural space.[82,83] The factors that influence the small disparity between the predicted and actual distance include (1) differences between the angulation of the imaging beam versus the angulation of the needle; (2) differences between the degree of exerted pressure and skin compression of the ultrasonographic probe versus the needle; (3) current lack of fidelity in the ability of ultrasonography to discriminate between ligamentum flavum, epidural space, and dura mater; and (4) dependency of onscreen measurement tools (e.g., digital calipers) on operator skill and consistency. In a general obstetric population, the mean difference between the needle depth and ultrasonographic depth to the epidural space was 0.01 cm (95% confidence interval, –0.67 to 0.69 cm),[83] whereas in a second study by the same investigator group in which subjects were limited to obese parturients, the mean difference was 0.3 cm (95% confidence interval, –0.7 cm to 1.3 cm).[82]

A low-frequency (2- to 5-Hz) curvilinear probe allows visualization of neuraxial structures beneath the skin. Low-frequency waves are preferable owing to the requisite depth of penetration. The curvilinear array allows the capture of lateral structures such as the transverse processes. The ultrasound beam can be used to identify the spinous processes if these are not palpable, the interspinous spaces, and the ligamentous structures. The ligamentum flavum–epidural space–dura mater will appear as a hyperechoic (white) complex, like bone, whereas the less dense subarachnoid space will appear hypoechoic (black).

Imaging is commonly performed in two planes, the longitudinal (sagittal) paramedian plane and the transverse plane. In the longitudinal paramedian plane, the probe is placed vertically over the sacral area, 2 to 3 cm lateral of the midline, and angled medially to focus on the neuraxial canal (Fig. 12.18). The sacrum is visualized as a hyperechoic line. As the probe is moved cephalad, a sawtooth pattern is visualized, corresponding to the laminae of the vertebrae. The gaps between the teeth of the saw are the intervertebral spaces. The ultrasonographer can mark the chosen interspace on the skin as the probe is moved cephalad. Imaging in the transverse plane is used to identify the midline and assess the distance to the epidural space. The probe is positioned horizontally at the appropriate level and moved slightly cephalad and caudad to visualize the cephalad and caudad spinous processes. The midline is marked by centering the shadow cast by the spinous processes in the middle of the ultrasonographic image. The probe is then centered in the interspinous space and manipulated to achieve a clear view of the neuraxial canal structures. The midline of the ultrasonographic probe on both the left and right is marked on the skin, and these points are joined with a horizontal line after

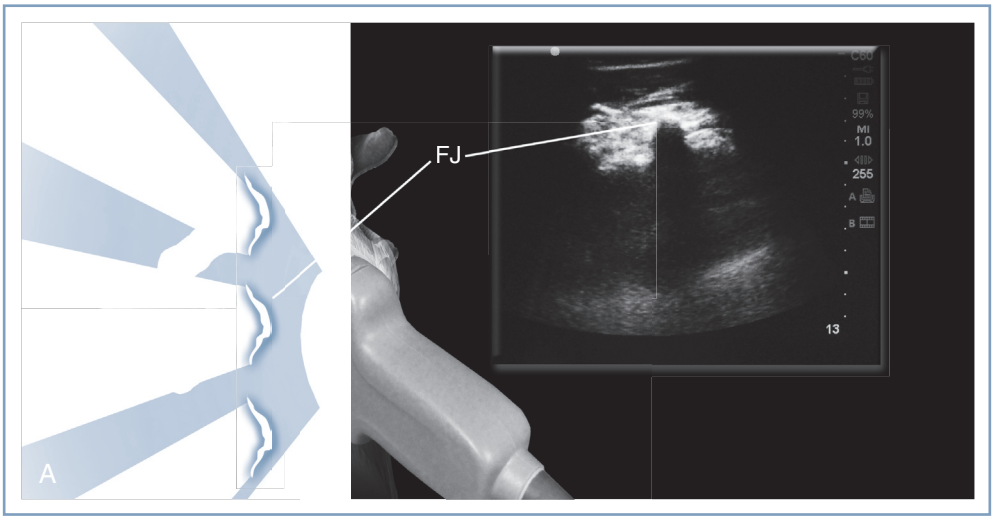

Fig. 12.18 Use of ultrasonography. (A) Paramedian view: A so-called sawtooth pattern may be seen as the lamina and facet joints *(FJ)* are captured by this view, typically achieved 1 cm lateral to the midline sagittal plane.

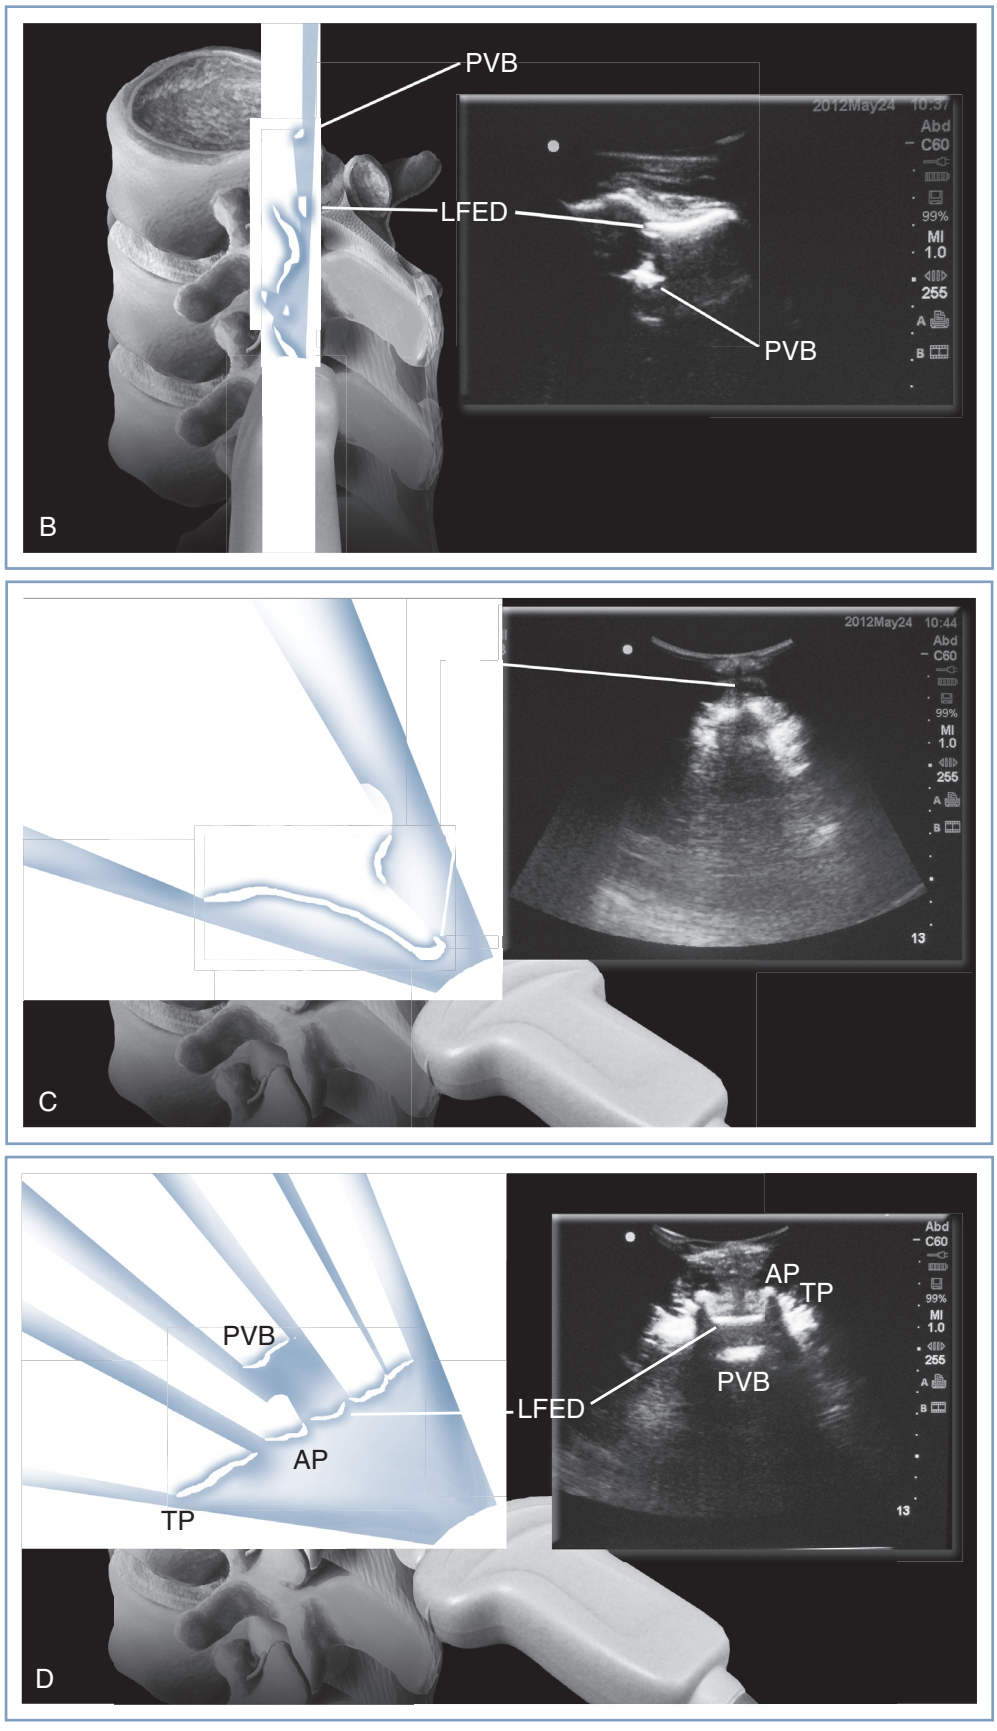

Fig. 12.18, cont'd (B) Paramedian view: By angulating the ultrasonographic probe, the ultrasound waves may escape through the interlaminar and transforaminal "windows" and capture the ligamentum flavum–epidural space–dura mater complex *(LFED)* as well as the posterior surface of the vertebral body *(PVB)*. (C) Transverse spinous process view: A long, dark shadow is cast with little to no discernible anatomy beyond the osseous tip of the spinous process *(SP)*. (D) Transverse interlaminar view: ultrasound waves propagate through the interspinous ligament leading to signals partially reflected by the ligamentum flavum–epidural space–dura mater complex *(LFED)*. The rays that continue to transmit through this complex encounter the posterior wall of the vertebral body *(PVB)*. Articular processes *(AP)* and transverse processes *(TP)* can be seen as well. removal of the probe. The intersection of this line with the midline mark is the point of needle entry. The distance from the skin to the anterior aspect of the ligamentum flavum–dura mater complex is measured on the frozen image with ultrasonographic machine calipers.

EPIDURAL TEST DOSE

Epidural catheter placement may be complicated by blood vessel or dural puncture with the needle or catheter. To prevent possible local anesthetic toxicity and high or total spinal anesthesia, the anesthesia provider must recognize the unintentional intravenous or subarachnoid placement of the needle or catheter. The purpose of the test dose is to allow early recognition of a malpositioned catheter. The ideal test dose must be readily available, safe, and effective. Its use should have a high sensitivity (i.e., low false-negative rate) and a high specificity (i.e., low false-positive rate). The intravascular and intrathecal test doses may be combined (a single injection to test for both intravascular and subarachnoid placement) or administered separately. A negative response to an epidural test dose does not guarantee the correct placement of the epidural catheter in the epidural space, nor does it guarantee that the catheter is not malpositioned in a blood vessel or the subarachnoid space. Rather, it decreases the likelihood that the catheter tip is in a blood vessel or the subarachnoid space.

Intravascular Test Dose

Intravascular placement of the epidural catheter may occur in as many as 7% to 8.5% of obstetric patients, although the rate may be lower with wire-embedded catheters.[24,84] Failure to recognize intravenous placement of the epidural catheter and subsequent intravenous injection of a large dose of local anesthetic may lead to local anesthetic systemic toxicity, with CNS symptoms, seizures, cardiovascular collapse, and death.[85]

The most common intravascular test dose contains epinephrine 15 µg. In normal volunteers, intravenous injection of epinephrine 15 µg (3 mL of a 1:200,000 solution) reliably causes tachycardia.[86,87] An increase in heart rate of 20 beats per minute (bpm) within 45 seconds was 100% sensitive and specific for intravascular injection in unpremedicated patients.[86] An increase in systolic blood pressure of between 15 and 25 mm Hg was also observed.

Some anesthesiologists have expressed concerns about the use of an epinephrine-containing test dose in laboring women. Intravenous epinephrine may cause a decline in uterine blood flow as a result of alpha-adrenergic receptor–mediated constriction of the uterine arteries (Fig. 12.19).[88] However, this decrease in uterine blood flow is transient and comparable to the decrease that occurs during a uterine contraction. In healthy parturients, any transient effect of epinephrine on uterine blood flow likely represents a less severe insult than local anesthetic systemic toxicity. An epinephrine-containing test dose, however, may not be appropriate in parturients with severe hypertension or uteroplacental insufficiency.

Concern has been expressed that the epinephrine-containing test dose lacks *specificity* in laboring women. The maternal tachycardic response to intravenous injection of epinephrine cannot always be distinguished from other causes of tachycardia (e.g., pain during a uterine contraction) (Fig. 12.20).[89,90] Cartwright et al.[89] noted that 12% of laboring women had an increase in heart rate of at least 30 bpm after epidural injection of 3 mL of 0.5% bupivacaine without epinephrine. A study in laboring women compared the intravenous injection of epinephrine (10 to 15 µg) with that of saline; the sensitivity was 100%, the area under the receiver operator characteristic curve was 0.91 to 0.93, and the negative predictive value was 100%.[91] However, the positive predictive value was 55% to 73%. The results suggested that if a positive heart rate response to an epinephrine-containing test dose occurs in 20% of patients, 5% to 9% of epidural catheters would be identified incorrectly as intravascular and removed unnecessarily. Colonna-Romano and Nagaraj[92] concluded that the intravenous injection of an epinephrine-containing test dose results in "a sudden and fast acceleration in maternal heart rate within one minute." Thus, careful assessment of the rate of increase in maternal heart rate may help distinguish a contraction-induced increase in heart rate from the effect of intravenously injected epinephrine, thereby improving the *specificity* of the epinephrine test. It is unclear whether such an assessment is clinically practical or will actually reduce the incidence of false-positive results.

Some anesthesiologists argue that the epinephrine-containing test dose lacks *sensitivity*. An increase in maternal heart rate of 25 bpm occurring within 2 minutes of drug injection and lasting at least 15 seconds was observed in only 5 of 10 laboring women who received intravenous epinephrine 15 µg.[93] Detection of intravenous epinephrine injection was improved when the authors retrospectively defined a positive maternal tachycardic response as a 10-bpm increase above the maximum maternal heart rate observed in the

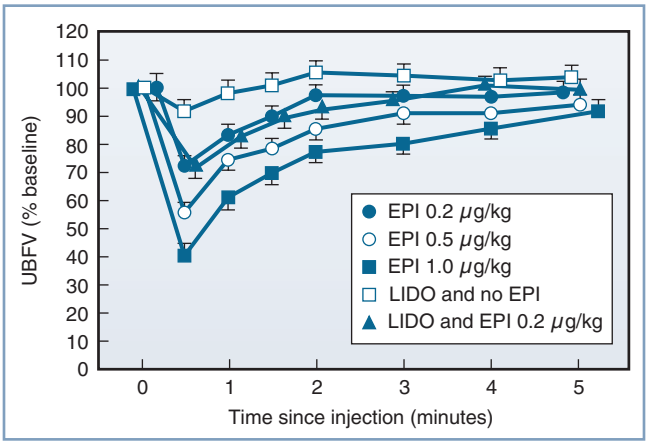

Fig. 12.19 The effect of intravenous epinephrine *(EPI),* lidocaine *(LIDO),* and lidocaine with epinephrine on uterine artery blood flow velocity *(UBFV)* in the pregnant guinea pig. The dose of lidocaine was 0.4 mg/kg. Values are presented as mean ± standard error of mean (SEM) percentage of baseline. (From Chestnut DH, Weiner CP, Martin JG, et al. Effect of intravenous epinephrine on uterine artery blood flow velocity in the pregnant guinea pig. *Anesthesiology*. 1986; 65:633–636.)

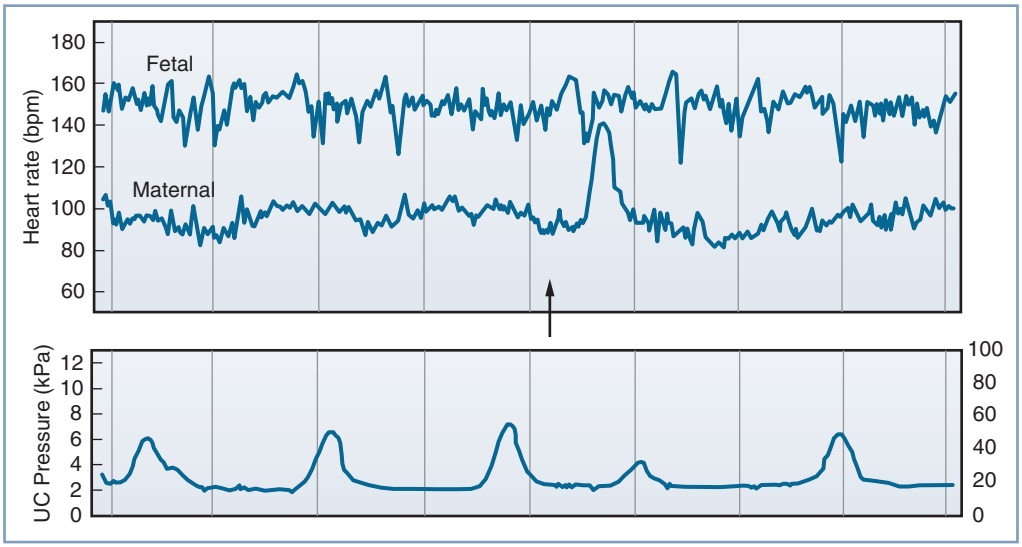

Fig. 12.20 Heart rate of a laboring patient (maternal heart rate [MHR]), fetal heart rate, and uterine contractions *(UC)* are shown. This tracing was obtained with the use of an fetal heart rate monitor with dual heart rate capacity. Note the variability of the MHR with uterine contractions. An intravenous injection of bupivacaine 12.5 mg and epinephrine 12.5 µg was given *(arrow)*. Note the marked increase in MHR in response to intravenous injection of the test dose. The maternal tachycardia had a duration of approximately 40 seconds. (From Van Zundert AA, Vaes LE, De Wolf AM. ECG monitoring of mother and fetus during epidural anesthesia. *Anesthesiology*. 1987;66:584–585.)

2-minute period preceding the epinephrine injection. Others have confirmed that these revised criteria improve the sensitivity of the epinephrine-containing test dose in laboring women.[91] These findings stress the importance of tracking the chronotropic variability that occurs in laboring patients during neuraxial anesthesia procedures to reduce the risk for misinterpretation of the test dose.

The usefulness of an epinephrine-containing test dose also improves if additional information is obtained. For example, investigators administered intravenous bupivacaine 12.5 mg with epinephrine 12.5 µg or saline to laboring women.[94] They correctly identified the test solution in 39 of 40 women when they assessed maternal heart rate, blood pressure, uterine contractions, the timing of the injection, the presence of analgesia, and subjective signs and symptoms of intravascular injection (e.g., palpitations, lightheadedness, dizziness). The tachycardic response to intravenous epinephrine is not a reliable indicator of intravascular injection in patients who have received a beta-adrenergic receptor antagonist.[95]

Other means of identifying intravascular placement of an epidural catheter have been proposed and may be clinically useful in specific patients (Table 12.2). Intravenous injection of 1 or 2 mL of air through a single-orifice catheter consistently produces changes in heart sounds as detected by the use of precordial Doppler ultrasonography.[96] (The external FHR monitor can be used for this purpose.) False-negative results may occur when small volumes of air are injected through a multi-orifice epidural catheter; thus, the air test is not a reliable test for intravascular injection when multi-orifice epidural catheters are used.[97]

Local anesthetic–induced symptoms of subclinical CNS toxicity have also been evaluated as a means of recognizing unintentional intravenous injection. Colonna-Romano et al.[98] administered intravenous saline, lidocaine 100 mg, or 2-chloroprocaine 100 mg to laboring women. Observers blinded as to which substance was administered recorded the presence of CNS symptoms (i.e., dizziness, tinnitus, funny taste) after injection. Lidocaine 100 mg was a reliable marker of intravenous injection when the symptoms of tinnitus and funny taste were considered (sensitivity 100%; specificity 81%). 2-Chloroprocaine was less reliable (sensitivity 81% to 94%; specificity 69% to 81%). In a volunteer study, a dose of 1.5 mg/kg of 2-chloroprocaine was necessary to produce a probability of 90% that the subject would report symptoms of intravenous injection.[99]

Administration of fentanyl 100 µg has been described as a test for intravenous injection.[100,101] Dizziness was the most reliable symptom of intravenous fentanyl injection, with a sensitivity of 92% and a specificity of 92%.

Some situations reduce the reliability of subjective symptoms as a signal of intravenous injection of a drug. Tests that rely on the self-reporting of subjective symptoms require clear communication with the patient and thus are less useful when the anesthesia provider and patient speak different languages. Patient exhaustion and/or prior opioid administration also may affect the reliability of the test.

Lastly, the epidural catheter design and speed of injection may affect the reliability of the epidural test dose. An epinephrine-containing test dose should be injected rapidly; otherwise rapid redistribution and metabolism of the drug decrease the actual dose administered to chronoreceptors. Multi-orifice epidural catheters have three potential sites of exit for injected fluid or air, and the orifices may lie within two different body compartments. If injected too slowly, air

TABLE 12.2 Epidural Test Dose Regimens[a]

Test Dose Components	Positive Intravascular Test Dose	Positive Intrathecal Test Dose
Combined Intrathecal and Intravenous Test Dose:		
Lidocaine 1.5% with epinephrine 5 µg/mL (1:200,000): 3 mL Bupivacaine 0.25% with epinephrine 5 µg/mL (1:200,000): 3 mL	Increase in heart rate of 20 bpm within 1 minute	Motor blockade at 3–5 minutes[b]
Intravenous Test Dose:		
Lidocaine 100 mg Bupivacaine 25 mg 2-Chloroprocaine 100 mg	Tinnitus, circumoral numbness, "dizziness"	
Fentanyl 100 µg	Dizziness, drowsiness	
Air 1 mL	Change in Doppler heart sounds over right side of heart	
Intrathecal Test Dose:		
Lidocaine 40–60 mg Bupivacaine 7.5 mg		Motor blockade at 3–5 minutes[b]

[a]Test doses may be less sensitive in premedicated patients, patients treated with a beta-adrenergic receptor antagonist, pregnant patients, and anesthetized patients.
[b]Weakness in hip flexion.
Modified from Yilmaz M, Wong CA. Technique of neuraxial anesthesia. In Wong CA, ed. *Spinal and Epidural Anesthesia.* New York, NY: McGraw-Hill; 2007:27–73.

or fluid preferentially exits the proximal orifice. The rate of injection used in clinical practice typically exceeds that required to ensure that fluid will exit all three orifices. In contrast, air must be injected at a much greater rate to ensure that it exits all three orifices; this rate is not practical for clinical use. The distal orifice is both the most difficult to test and the one most likely to be positioned outside the epidural space.[102]

Intrathecal Test Dose

The intrathecal test dose should allow easy identification of subarachnoid (intrathecal) placement of the catheter without causing high or total spinal anesthesia and hemodynamic compromise. Bupivacaine (7.5 mg) and lidocaine (45 to 60 mg) are the local anesthetics most often used for an intrathecal test dose (see Table 12.2; Fig. 12.21).[103,104]

In a study of older, nonpregnant patients receiving continuous spinal anesthesia for surgery, Colonna-Romano et al.[104] used plain lidocaine 45 mg plus epinephrine 15 µg and assessed patient perception of lower-extremity warmth and heaviness, sensory loss to pinprick, and ability to perform a straight-leg raise. Patients usually perceived warmth in their legs within 1 minute of the intrathecal injection; however, impaired straight-leg raise 4 minutes after an intrathecal test dose injection was the only test that had a sensitivity of 100% for intrathecal injection. The application of these data to pregnant patients is unclear.

Richardson et al.[105] described the rapid onset (1 to 3 minutes) of high levels of spinal anesthesia with motor block and hypotension in five parturients who had received a test dose of plain lidocaine 45 mg plus epinephrine 15 µg. This solution is slightly hypobaric; thus, the upright posture of

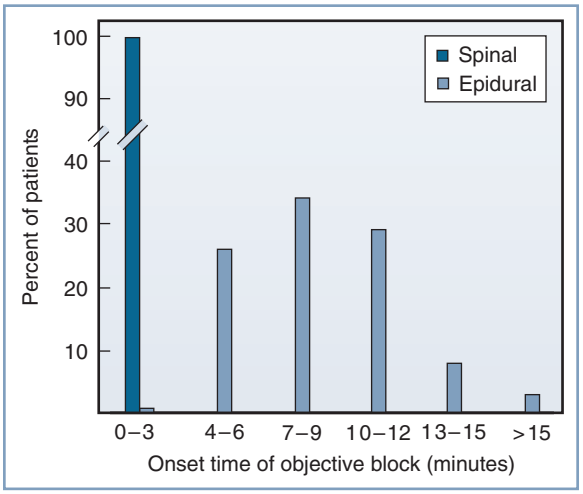

Fig. 12.21 Percentage of pregnant patients who demonstrated objective evidence of anesthesia (defined as the loss of sensation to pinprick) after epidural injection of 2 to 3 mL of hyperbaric 1.5% lidocaine with 1:200,000 epinephrine *(light teal bars)* (n = 250) or after intrathecal injection of 2 mL of hyperbaric 1.5% lidocaine with 1:200,000 epinephrine *(dark teal bar)* (n = 15). (From Abraham RA, Harris AP, Maxwell LG, et al. The efficacy of 1.5% lidocaine with 7.5% dextrose and epinephrine as an epidural test dose for obstetrics. *Anesthesiology.* 1986;64:116–119.)

these parturients during the injection may have contributed to the high sensory levels of anesthesia. The anesthesia provider must recognize the possible range of responses to the dose of local anesthetic used to assess the position of an epidural catheter and should perform a careful assessment of sensory, motor, and sympathetic function 3 to 5 minutes after administration of the test dose before concluding that the

intrathecal test dose result is negative. Ropivacaine 15 mg is *not* a useful intrathecal test dose because the slow onset of motor blockade precludes timely diagnosis of intrathecal injection.[106] 2-Chloroprocaine is the only local anesthetic that can be used as a single, combined intravascular and intrathecal test dose in the nonpregnant patient; in most patients, 90 mg results in dense, but not total, spinal anesthesia after intrathecal injection and produces systemic signs of subclinical toxicity (tinnitus, funny taste) after intravascular injection.[107] The application to the pregnant woman is unclear.

The epidural injection of local anesthetic-containing test dose augments *epidural* analgesia and should be considered in the calculation of the initial therapeutic dose of local anesthetic. Several groups of investigators demonstrated that the test dose enhanced the density of epidural blockade and adversely affected the ability to ambulate.[108,109]

Techniques to Minimize Local Anesthetic Systemic Toxicity

No perfect test dose exists. Some anesthesia providers elect not to administer a test dose because it contributes to motor blockade.[108,109] In addition, aspiration of a *multi-orifice* epidural catheter for blood has 98% sensitivity for detection of an intravascular location.[50] Unintentional intravascular injection of a small volume of solution containing a low concentration of local anesthetic is unlikely to result in serious morbidity. However, laboring women may need large doses of local anesthetic administered quickly (without incremental injection) for emergency operative delivery. The anesthesia provider must determine as soon as possible that the epidural catheter is correctly positioned within the epidural space. Even if no morbidity results, it is inconvenient for both the patient and the anesthesia provider to have to repeat the procedure and replace the catheter once the drape has been removed and the patient has been repositioned. The epinephrine-containing test dose provides an objective marker of intravascular injection that has stood the test of time. Thus, we typically give a test dose that contains either bupivacaine 7.5 mg or lidocaine 45 to 60 mg with 15 μg of epinephrine. No matter whether a test dose is injected, drugs should be injected incrementally into the epidural space, because no test is 100% sensitive and catheters may migrate during use. Each incremental dose should be treated as a "test dose" (i.e., the dose should be small enough that it will not cause systemic toxicity if unintentionally injected intravascularly or total spinal anesthesia if injected intrathecally). Pregnant women are difficult to resuscitate from local anesthetic cardiovascular toxicity.[85]

Steps to minimize the possibility of local anesthetic toxicity are summarized in Box 12.3. They include observation for passive return of CSF or blood (by lowering the proximal end of the epidural catheter below the insertion site), administration of the test dose between contractions, aspiration before each dose, incremental dose administration, maintaining verbal contact with the patient, and regular assessments throughout labor for an appropriate level and density of sensory and motor blockade (which indicates correct placement of the catheter in the epidural space).

BOX 12.3 Steps to Decrease Risk for Unintentional Intravenous or Subarachnoid Injection of Local Anesthetic

- Lower the proximal end of the catheter below the site of insertion. Observe for the passive return of blood or cerebrospinal fluid.
- Aspirate before injecting each dose of local anesthetic.
- Give the test dose between uterine contractions.
- Use dilute solutions of local anesthetic during labor.
- Do not inject more than 5 mL of local anesthetic as a single bolus.
- Maintain verbal contact with the patient.
- If little or no block is produced after the injection of an appropriate dose of local anesthetic, assume that the local anesthetic was injected intravenously and remove the catheter.

CHOICE OF DRUG[a]

The dose requirement of both epidural and spinal local anesthetics is decreased approximately 25% in pregnancy owing to anatomic and physiologic changes (see Chapter 2). These alterations begin to revert to the prepregnancy state within hours of delivery.

Spinal Anesthesia

Anesthesia providers may give spinal anesthesia for cerclage, nonobstetric surgery during pregnancy, instrumental vaginal delivery, cesarean delivery, removal of a retained placenta, or postpartum tubal ligation. Spinal analgesia may be used for labor analgesia. Cesarean delivery represents the most common indication for spinal anesthesia in pregnant women. Most anesthesia providers administer a hyperbaric solution of local anesthetic for spinal anesthesia in obstetric patients. Use of a hyperbaric solution as compared with a plain solution without dextrose results in a faster onset of block and a higher maximum sensory level with a shorter duration of blockade.[110] The urgency and anticipated duration of surgery dictate the choice of local anesthetic agent. The most common choice in the United States is bupivacaine. Lidocaine is used less commonly. Ropivacaine, 2-chloroprocaine, and levobupivacaine may be used but are not approved for spinal administration in the United States, and levobupivacaine is not available in the United States. 2-Chloroprocaine provides a short duration of action, and lidocaine provides a short to intermediate duration of action. Bupivacaine, levobupivacaine, and ropivacaine provide intermediate to long durations of action.

Anesthesia providers often add an opioid to the local anesthetic to improve the quality of anesthesia, particularly with regard to visceral stimulation, and to provide postoperative analgesia.[111] The addition of an opioid to the local anesthetic decreases the incidence of intraoperative nausea and vomiting.

[a]Chapter 13 contains a detailed discussion of anesthetic agents used for neuraxial anesthetic techniques.

The short-acting, lipid-soluble opioids (i.e., fentanyl, sufentanil) contribute to intraoperative anesthesia, and morphine is often administered for postoperative analgesia. Epinephrine may be added to prolong block duration and perhaps improve block density. Adverse effects of other adjuncts (e.g., clonidine, neostigmine) have limited their wide use in obstetric anesthesia practice (see Chapters 23, 26, and 27).

Epidural Anesthesia

Local anesthetic agents available for epidural administration in obstetric patients include 2-chloroprocaine, lidocaine, mepivacaine, bupivacaine, and ropivacaine. Mepivacaine is used infrequently in obstetric anesthesia practice.

Bupivacaine remains a popular local anesthetic for analgesia during labor and vaginal delivery because of its differential sensory blockade, long duration of action, low frequency of tachyphylaxis, and low cost. Anesthesia providers infrequently administer bupivacaine for cesarean delivery because of the risk for cardiac toxicity and maternal mortality after unintentional intravascular injection of the drug.

Ropivacaine has gained popularity as an agent for epidural analgesia and anesthesia because it may result in less cardiac toxicity and greater differential sensory-motor blockade than bupivacaine.[112]

Levobupivacaine also has a more favorable safety profile than bupivacaine. Clinical trials have shown that ropivacaine and levobupivacaine have potency[113] and analgesic qualities similar to those of bupivacaine,[114,115] with the probable exception of less motor nerve block.[116]

Bupivacaine, ropivacaine, and levobupivacaine all have longer durations of action than lidocaine, and are preferred over shorter-acting agents when a longer duration of anesthesia or analgesia is desirable. They are more commonly used for maintenance of epidural labor analgesia, whereas the shorter-acting agents are used for epidural surgical anesthesia. Despite some variation among reports, published clinical studies suggest no more than slight differences in onset, and no differences in quality or duration of neural blockade, among the three drugs. However, bupivacaine is more cardiotoxic than the other agents *in vitro* and probably after unintentional intravascular administration.[117] It would seem prudent to use ropivacaine or levobupivacaine rather than bupivacaine when a bolus dose of a concentrated solution is being given. When administered as a low-concentration infusion, improved safety has not been demonstrated with ropivacaine and levobupivacaine compared with bupivacaine.

The most popular choice of local anesthetic for epidural anesthesia for cesarean delivery is **2% lidocaine with epinephrine.** The addition of epinephrine (5 μg/mL) causes a modest prolongation of the block. The major advantage of epinephrine is that it improves the quality of epidural lidocaine anesthesia. Lam et al.[118] have shown that epidural labor analgesia can be extended to surgical anesthesia for cesarean delivery in 5.2 ± 1.5 minutes (mean ± SD) with the addition of bicarbonate and fentanyl to 2% lidocaine with epinephrine.

Many anesthesia providers reserve **2-chloroprocaine** for cases in which rapid extension of epidural anesthesia for vaginal delivery or urgent cesarean delivery is necessary. The onset of surgical anesthesia was several minutes faster with 2-chloroprocaine compared with lidocaine with freshly mixed epinephrine and sodium bicarbonate in the setting of urgent cesarean delivery after epidural labor analgesia.[119] Therefore, when time is of the essence, 2-chloroprocaine is the drug of choice. Typically, in an emergency, a large volume of concentrated local anesthetic solution is injected quickly. An additional advantage of 2-chloroprocaine in this situation is that it is rapidly metabolized by plasma esterases. Therefore, the unintentional intravascular injection of a large volume of 2-chloroprocaine may be less likely to have serious adverse consequences. A potential disadvantage of 2-chloroprocaine is that it may interfere with the subsequent actions of opioids[120] and bupivacaine,[121] although this possibility is controversial.[122,123]

As in spinal anesthesia, epidural opioids work synergistically with local anesthetics. Fentanyl 50 to 100 μg or sufentanil 5 to 10 μg is frequently added to an amide local anesthetic for both labor analgesia (allowing a lower dose of local anesthetic and less motor block) and cesarean delivery (resulting in a denser block with better blockade of visceral stimulation). **Sodium bicarbonate** may be added to lidocaine[124] and 2-chloroprocaine[125] (1 mEq/10 mL local anesthetic) to decrease latency.

Caudal Anesthesia

The drugs used for caudal epidural anesthesia are identical to those used for lumbar epidural block. However, a much larger volume (e.g., 25 to 35 mL) of local anesthetic solution must be administered to extend a caudal block for cesarean delivery or labor analgesia. Such large volumes entail a greater risk for local anesthetic systemic toxicity. Additionally, the caudal epidural space is highly vascular, which further predisposes to intravasation of drugs administered via this route.

COMPLICATIONS OF NEURAXIAL TECHNIQUES

Unintentional Dural Puncture

Unintentional dural puncture with an epidural needle occurs at a rate of approximately 1.5% in the obstetric population.[126] Approximately 52% of women will experience a post–dural puncture headache after puncture with an epidural needle (see Chapter 30). Techniques to minimize the incidence of unintentional dural puncture include (1) identification of the ligamentum flavum during epidural needle advancement; (2) understanding the likely depth of the epidural space in an individual patient; (3) advancement of the needle between contractions, when unexpected patient movement is less likely; (4) adequate control of the needle-syringe assembly during advancement of the needle; and (5) clearing the needle of clotted blood or bone plugs. Studies are conflicting as to whether the incidence of post–dural puncture headache after unintentional dural puncture is less likely if the epidural needle bevel faced lateral rather than cephalad.[127,128] An *in vitro* study using cadaver dura found that the fluid leakage

rate through dural tears was not dependent on the orientation of the dura relative to the needle bevel.[129] We prefer to insert the epidural needle with the bevel oriented in a cephalad direction so that there is no need to rotate the needle bevel within the epidural space. Cephalad bevel orientation also increases the likelihood of successful epidural anesthesia.[130]

The anesthesia provider has two options after unintentional dural puncture: site the epidural catheter within the subarachnoid space and use a continuous spinal anesthetic technique, or site the epidural catheter in a different interspace (i.e., starting afresh). Management may depend on the clinical setting. If advancement of an epidural needle results in dural trespass and the free flow of CSF is perceived in the barrel of the epidural syringe, the anesthesia provider should halt advancement of the epidural needle and either remove the epidural needle (if the plan is to resite the epidural catheter) or replace the stylet back into the lumen of the epidural needle to prevent further egress of CSF (if the plan is to administer intrathecal medication or perform a continuous spinal technique). Reinjection of CSF contained in the syringe should not be entertained because there is a high likelihood that air will concomitantly be introduced into the subarachnoid space and cause pneumocephalus. The risks and benefits of administering an intrathecal dose of anesthetic should be considered. Although intrathecal administration of local anesthetic through the epidural needle will result in rapid analgesia for an uncomfortable patient, the rapid efflux of CSF may render the injectate ineffective. Additionally, spinal analgesia may mask paresthesias during subsequent attempts at neuraxial anesthesia. Furthermore, spinal anesthesia may cause profound hypotension. If the patient is sitting, and likely to remain so for the next few minutes, the anesthesia provider may struggle to manage two problems instead of one (i.e., a challenging neuraxial procedure and maternal hypotension). However, rapid provision of analgesia may enable the patient to better assume an optimal position without moving. One option is to administer intrathecal opioid, thus providing analgesia without the risk for hypotension.

Evidence is conflicting as to whether the insertion of an epidural catheter through the dural puncture site decreases the incidence of post–dural puncture headache.[131–136] Most studies are retrospective; a prospective study in which institutions were randomized to manage unintentional dural puncture with an intrathecal catheter or siting the epidural catheter in another interspace found no difference in the rate of post–dural puncture headache or need for an epidural blood patch.[137] Continuous spinal anesthesia is an attractive option if identification of the epidural space has been difficult or if the anticipated duration of anesthesia or analgesia is relatively short (e.g., cesarean delivery, or vaginal delivery in parous women). The major disadvantage of an intrathecal catheter is the risk that it may be mistaken for an epidural catheter. Given that the local anesthetic dose required for epidural anesthesia is many times greater than that required for spinal anesthesia, unintentional administration of an epidural dose into the subarachnoid space will lead to total spinal anesthesia. Therefore, on a busy labor and delivery unit where multiple providers are giving anesthesia care, it may be safer to use an epidural catheter rather than an intrathecal catheter in women in whom prolonged analgesia is anticipated.

Thus, the anesthesia provider may elect to initiate epidural anesthesia in another lumbar epidural interspace. However, even if the attempt results in a correctly placed catheter, the provider must be wary of an unexpectedly high level of anesthesia after the epidural administration of usual doses of local anesthetic.[138,139] Leach and Smith[139] reported a patient who had an extensive block after unintentional dural puncture and subsequent epidural injection of bupivacaine. They presented radiologic evidence of the spread of local anesthetic from the epidural space to the subarachnoid space. The extent to which a dural tear affects the movement of substances from the epidural space to the subarachnoid space depends on the size of the hole, the lipophilicity of the drug (highly lipophilic drugs cross quickly regardless of the presence of a hole, whereas water-soluble drugs cross more quickly in the presence of a hole),[140] and whether the drug is administered into the epidural space as a bolus or an infusion. Rapid bolus administration of medications through an epidural catheter in a patient with a known dural puncture with a large-bore needle significantly increases the likelihood of high spinal anesthesia.

Unfortunately, there is no reliable method to decrease the risk for post–dural puncture headache once dural puncture occurs. Studies regarding the utility of a prophylactic epidural blood patch (injection of autologous blood before removal of the epidural catheter and before onset of a headache) for the prevention of post–dural puncture headache are conflicting,[141,142] but the only randomized and blinded trial found no difference in the incidence of headache in women who received a prophylactic blood patch compared with a sham patch.[142]

Occasionally, unintentional dural puncture is not recognized until the epidural catheter is threaded and CSF spontaneously appears at the proximal end of the catheter, or the catheter aspiration or intrathecal test dose is positive. Rarely, an epidural catheter that has been correctly sited in the epidural space may migrate into the subarachnoid space. The most significant clinical threat in this scenario is the continued use of a large-volume infusion of local anesthetic drug intended for epidural administration. An unrecognized spinal catheter was the cause of 24% of high neuraxial anesthetics reported to the Serious Complication Repository Project of the Society for Obstetric Anesthesia and Perinatology.[143] Thus, during prolonged epidural labor analgesia, the patient should be regularly monitored for evidence of high or dense neuraxial anesthesia.

Unintentional Intravascular or Subarachnoid Injection

The unintentional injection of large doses of local anesthetics into the subarachnoid space can lead to catastrophe. The rapid onset of high or total spinal anesthesia results in profound hypotension, loss of consciousness, and apnea secondary to hypoperfusion of the brain stem. Prompt treatment

necessitates assisted ventilation, volume resuscitation, and pharmacologic support of blood pressure. Administration of chronotropic agents such as epinephrine may also be necessary if blockade of cardiac sympathetic drive results in bradycardia. The patient is at high risk for awareness in this setting, and the judicious use of an amnestic agent such as midazolam should be considered once cardiorespiratory stability has been restored.

Pregnant women are at higher risk for unintentional intravenous cannulation because of the engorgement of epidural veins. Intravascular injection of a local anesthetic may initially result in altered sensorium, tinnitus, and perioral numbness. Higher blood concentrations may result in seizures, and even higher concentrations may cause dysrhythmias and cardiovascular collapse (see Chapter 13). Management of local anesthetic systemic toxicity includes prompt institution of advanced cardiac life support (ACLS), gamma-aminobutyric acid (GABA)–potentiating agents such as benzodiazepines to mitigate seizure activity, and the use of lipid emulsion to detoxify the patient. Several modifications have been made to the conventional ACLS protocol for the specific treatment of local anesthetic–induced cardiac arrest.[144] These include (1) use of small, judicious doses of intravenous epinephrine for circulatory support (10- to 100-μg boluses in adults); (2) avoidance of vasopressin, calcium-entry blocking agents, and beta-adrenergic blocking agents; and (3) avoidance of local anesthetics for treatment of ventricular arrhythmias.

Inadequate Anesthesia

Pain during anesthesia represents a higher proportion of obstetric malpractice claims than of nonobstetric claims.[145,146] During labor, inadequate epidural analgesia may result from the inadequate extent of sensory blockade, nonuniform blockade, or inadequate density of blockade. When called to evaluate breakthrough pain, the anesthesia provider should first evaluate the extent of bilateral sensory blockade in *both the cephalad and caudad directions* (see Chapter 23). Particularly if labor is progressing quickly, the extent of sacral blockade may not be adequate. In this case, epidural injection of a large volume of local anesthetic may improve sacral blockade. In contrast, if the extent of sensory blockade is adequate but the patient is still experiencing pain, the density of blockade may be insufficient. In this case, the provider should reestablish and maintain analgesia using a more concentrated solution of local anesthetic.

Why do some obstetric epidural anesthetics fail over time? Collier[147] administered epidural radiocontrast dye in 25 parturients reporting unsatisfactory analgesia. The two major causes of inadequate block in this small study were transforaminal migration of the catheter tip and an obstructive barrier in the epidural space. Total block failure usually results from failure to identify the epidural space correctly or from malposition of the catheter tip outside the epidural space (e.g., in a neuroforamen). A unilateral block may occur despite the use of good technique. Unilateral blocks can often be prevented by limiting the length of catheter within the epidural space to 3 cm or less, but this may increase the risk for outward migration of the catheter over time. (Patients undergoing surgery remain still; by contrast, laboring women change position frequently.) Obese women seem to be at higher risk for outward migration of the catheter tip.[55]

Whether catheter withdrawal in the setting of breakthrough pain is beneficial is not clear. Beilin et al.[148] compared catheter withdrawal followed by injection of local anesthetic with injection of local anesthetic without catheter withdrawal for the treatment of breakthrough pain. The ability to rescue analgesia was not different between the groups. Gielen et al.[149] performed a radiologic study in which they observed no consistent relationship between catheter position and the asymmetric onset of sympathetic blockade. Unilateral or patchy sensory blockade likely results from the nonuniform distribution of local anesthetic solution in the epidural space.[150] Injection of a large volume of dilute local anesthetic solution into the epidural space usually corrects this problem, regardless of the location of the tip of the epidural catheter (provided it is actually in the epidural space). If analgesia cannot be rescued with a second injection, the catheter should be removed and replaced at another interspace.

The management of inadequate anesthesia is more problematic during cesarean delivery. Failure of spinal anesthesia may result from the maldistribution of local anesthetic within the subarachnoid space.[151] If inadequate spinal anesthesia is noted before incision, the anesthesia provider may augment the block with additional local anesthetic by either performing a second spinal anesthetic procedure or placing an epidural catheter, or both. However, care must be taken if performing a second spinal anesthetic procedure. In the ASA Closed-Claims Project database, Drasner and Rigler[152] identified three cases of cauda equina syndrome complicating spinal anesthesia. In two cases, "failed spinal" anesthesia had occurred, followed by a repeat injection of local anesthetic. The researchers recommended that anesthesia providers determine the presence of anesthesia in the sacral dermatomes before administering additional local anesthetic into the subarachnoid space. Additionally, they stated that if CSF was aspirated during the original procedure, it should be assumed that local anesthetic was delivered into the subarachnoid space, and the total dose of local anesthetic be limited to the maximum dose a clinician would consider reasonable to administer in a single injection.[152] If partial blockade is present (even if it is limited to the sacral dermatomes), the second dose should be reduced accordingly. It may also be advisable to perform the second procedure at a different interspace or make other changes to the original procedure (e.g., alter the patient's position, use a local anesthetic with different baricity, or straighten the lumbosacral curvature).

If the patient complains of pain after incision, the anesthesia provider must decide between the administration of inhalation or intravenous analgesia, and the administration of general anesthesia. Supplemental analgesia may be provided by giving 60% nitrous oxide in oxygen, small incremental boluses of ketamine (0.1 to 0.25 mg/kg), or small boluses of intravenous opioid. Supplemental infiltration of the

wound with local anesthetic is sometimes helpful, especially when spinal anesthesia regresses near the end of an unexpectedly long operation. The anesthesia provider must ensure that the patient remains sufficiently alert to protect her airway. In most cases, severe pain unrelieved by modest doses of analgesic drug requires rapid-sequence induction of general anesthesia followed by endotracheal intubation and general anesthesia.

Risk factors for failed conversion of epidural labor analgesia to epidural anesthesia for intrapartum cesarean delivery include an increasing number of clinician-administered boluses during labor (requirement for top-up doses), greater urgency of cesarean delivery, and provision of anesthesia care by a nonobstetric anesthesiologist.[153] In some cases, inadequate epidural anesthesia results from failure to give a sufficient dose of local anesthetic or failure to wait a sufficient time after its administration. For example, after the epidural administration of 2% lidocaine with epinephrine, approximately 10 to 20 minutes must pass to achieve an adequate level of anesthesia, and additional local anesthetic may be needed to achieve an adequate density of blockade. In urgent cases or in cases with a "missed" segment, local infiltration with a local anesthetic often results in satisfactory anesthesia. Sometimes it is difficult to separate the beneficial effect of the local infiltration from the beneficial effect of waiting for the obstetrician to obtain, prepare, and inject the local anesthetic solution. Finally, the anesthesia provider should exercise caution when initiating spinal anesthesia after failure of epidural anesthesia because of a greater incidence of high spinal anesthesia in this setting.[154] Presumably, the large volume of local anesthetic within, or near, the epidural space results in decreased lumbar CSF volume, which predisposes to high spinal anesthesia. It may be advisable to reduce the dose of intrathecal local anesthetic, particularly in the presence of partial epidural blockade.

Equipment Problems

The frequency of major equipment malfunction is very low during the administration of neuraxial anesthesia. Most anesthesia providers in the United States use disposable needles. If a needle should break, the portion of the needle that remains in the patient should be removed, because it may migrate and cause injury.

An epidural or spinal catheter may shear and break off if the catheter is withdrawn through a needle; thus an epidural or spinal catheter should never be withdrawn in this manner. Rather, if the catheter must be withdrawn, the needle and catheter should be withdrawn as a unit. It is also possible to break a catheter during attempts at removing it, although this is rare. If resistance to catheter removal is encountered, the patient should assume a position that reduces lumbar lordosis, thereby lessening the kinking of the catheter between perivertebral structures. If position change is not successful, the catheter should be taped under tension to the patient's back and left undisturbed for several hours. The catheter usually works its way out and is then easy to remove. Once the catheter has been removed successfully, it should be examined to ensure that it has been removed completely. Complete removal of the catheter should be documented in the medical record.

Rarely, catheters do break on removal. We favor aggressive attempts to remove broken catheters located in the subarachnoid space. However, it may be unnecessary to remove broken catheters located in the epidural space; rather, in these circumstances, the patient can be informed of the complication and observed over time. The incidence of catheter migration or other delayed sequelae appears to be low. Imaging (radiography, computed tomography, magnetic resonance) may help identify the precise location of a broken catheter.

During use, an epidural catheter occasionally becomes disconnected from the catheter connector. Options include replacing the epidural catheter or reconnecting the connector to the catheter. Langevin et al.[155] used an *in vitro* model to investigate whether microbial contamination precludes reconnection. They found that an area of the interior of the catheter distal to the disconnection may remain sterile for up to 8 hours if the fluid column within the catheter remains static (i.e., if "fluid does not move within the catheter when it is raised above the level of the patient").[155] Therefore, they concluded that it *may* be safe to decontaminate the exterior of the catheter, cut the catheter with a sterile instrument, and reconnect it to a new sterile connector. However, given the potential catastrophic consequences of neuraxial infection, we recommend replacing the catheter. Also, wire-embedded catheters cannot be cut.

TEACHING NEURAXIAL ANESTHESIA PROCEDURES

Teaching mastery of neuraxial anesthesia is an important skill of academic anesthesiologists. A logical approach to learning neuraxial procedures might begin with self-study aimed at mastering the spatial geometry of the central neuraxis, via written or online material, spine models, sonoanatomy, or combinations of these. This may be followed by procedural practice on a simulator, followed by procedures performed on patients with close supervision of an experienced teacher. Beyond technical skills, the safe practice of neuraxial anesthesia requires knowledge of the pharmacologic and physiologic aspects of neuraxial procedures.

The importance of applying a consistent and thoughtful methodology when teaching procedural skills cannot be understated. Unlike video laryngoscopy, which allows the observer real-time assessment of a trainee's mechanical technique, no such analogous technology facilitates guidance during neuraxial anesthesia procedures. Spinal and epidural anesthesia remain essentially "blind" procedures. The past decade has seen the development of a number of high-fidelity simulators for teaching neuraxial techniques.[156–158] Use of low-technology simulators, such a vegetables and fruits, have also been described and may be equally effective.[159–161]

Offering meaningful feedback is highly conducive to shaping procedural habits. An effective debriefing session results from a systematic approach to observation and

analysis of clinical skill. One example is described by Chuan et al.[162] Their comprehensive checklist identifies 25 executable actions for regional anesthetic block that are amenable to observation and assessment.

Mastery of technical skills requires practice. Kopacz et al.[163] determined that a 90% success rate is not attained and maintained until first-year anesthesiology residents perform approximately 45 spinal and 60 epidural procedures.

KEY POINTS

- Physiologic changes of pregnancy alter neuraxial anatomy; alterations include accentuation of lumbar lordosis, a "softer" ligamentum flavum, and decreased space in the spinal canal caused by vascular engorgement of epidural veins.
- Physiologic changes of pregnancy cause a more pronounced response to neuraxial anesthesia–induced sympathetic blockade than is seen in nonpregnant patients. These include higher baseline sympathetic tone and aortocaval compression.
- Pregnant women, particularly those with neuraxial blockade, should not be cared for in the supine position but rather in lateral tilt or in the full lateral position.
- Correct patient positioning, equipment, and technique are important to the success and safety of neuraxial techniques.
- The midline approach is faster and less painful than the paramedian approach to the epidural or subarachnoid space. However, the paramedian approach may allow for the successful identification of the subarachnoid or epidural space in difficult cases.
- Use of a noncutting ("pencil-point") needle for spinal anesthesia reduces the incidence of post–dural puncture headache.
- Combined spinal-epidural anesthesia has the advantages of both spinal anesthesia and epidural anesthesia.
- Approximately 20% to 30% less local anesthetic is required for epidural and spinal anesthesia in pregnant patients than in nonpregnant patients.
- Multiple techniques (e.g., test dose, aspiration, incremental dose injection) should be used to reduce the incidence and risk for unintentional subarachnoid or intravascular injection, because no one technique will completely exclude all cases of malpositioned needles or catheters.

Local Anesthetics and Opioids

Brenda A. Bucklin, MD, Alan C. Santos, MD, MPH

CHAPTER OUTLINE

Local anesthetics and opioids are often used for pain relief in obstetric practice. Local anesthetics may be used for infiltration anesthesia, peripheral (pudendal) nerve block, or neuraxial block, whereas opioids are administered both systemically and neuraxially. The physiologic changes that occur during pregnancy may affect the pharmacology of both local anesthetics and opioids. In turn, these analgesic drugs may have effects on the mother and the fetus.

LOCAL ANESTHETICS

Molecular Structure

All local anesthetic molecules except cocaine contain a desaturated carbon ring (aromatic portion) and a tertiary amine connected by an alkyl chain (Fig. 13.1). The intermediate alkyl chain, by virtue of its ester or amide linkage, is the basis for the classification of local anesthetics as **amino-esters** (which are hydrolyzed by pseudocholinesterase) and **amino-amides** (which undergo hepatic microsomal metabolism) (Table 13.1). The aromatic ring of the esters, which renders the molecule lipid soluble, is a derivative of benzoic acid. The amide aromatic ring is a homologue of aniline. The tertiary-amine portion acts as a proton acceptor; thus, local anesthetics behave as weak bases. In its quaternary (i.e., "protonated") form, the terminal amine is the water-soluble portion. The Henderson-Hasselbalch equation predicts the relative proportions of local anesthetic that exist in the ionized and un-ionized form. The higher the pK_a (acid dissociation constant) relative to physiologic pH, the smaller the proportion of drug that exists in the un-ionized form. All clinically used amide local anesthetics (with the exception of lidocaine) exist as stereoisomers because of an asymmetric carbon on the terminal amine.

Clinical formulations of local anesthetics are prepared as hydrochloride salts to increase their solubility in water. These formulations are usually acidic (i.e., pH of 4 to 6) to enhance formation of the water-soluble quaternary amine and to prevent oxidation of the epinephrine present in epinephrine-containing solutions.

Chirality

With the exception of lidocaine, amide local anesthetics are **chiral compounds** because they have a single asymmetric carbon adjacent to the amino group and thus exist in isomeric forms that are mirror images of each other. The direction in which the isomers rotate polarized light distinguishes them as either dextrorotary (D) or levorotary (L) isomers. This distinction is important, because individual isomers of the same

TABLE 13.1 Physicochemical Characteristics and Fetal-to-Maternal (F/M) Blood Concentration Ratios at Delivery for Commonly Used Local Anesthetic Agents

	Molecular Weight (Base) (Da)	pK_a	Lipid Solubility[a]	% Protein Bound	F/M Ratio

Modified from Santos AC, Pedersen H. Local anesthetics in obstetrics. In Petrie RH, ed. *Perinatal Pharmacology*. Cambridge, MA: Blackwell Scientific; 1989:375.

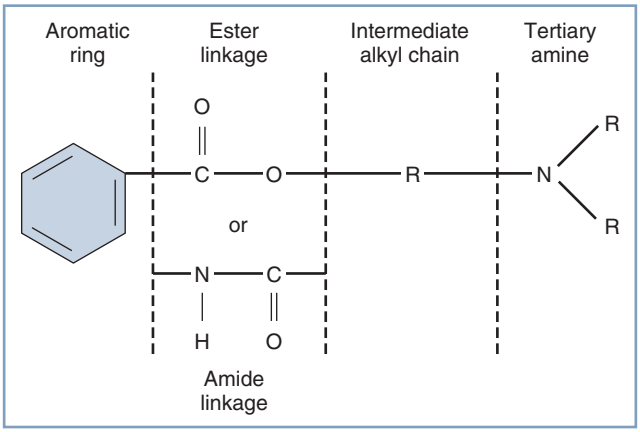

Fig. 13.1 Structure of the molecule of a local anesthetic. *R,* alkyl group. (Modified from Santos AC, Pedersen H. Local anesthetics in obstetrics. In Petrie RH, ed. *Perinatal Pharmacology*. Cambridge, MA: Blackwell Scientific; 1989:373.)

drug may have different biologic effects. As a rule, the levorotary isomer of a drug has greater vasoconstrictor activity and a longer duration of action but less potential for systemic toxicity than the dextrorotary form.[1]

In the past, single-isomer formulations were costly to produce; and for that reason, local anesthetics used clinically (e.g., **bupivacaine**) have contained a racemic mixture of both the dextrorotary and levorotary forms of the drug. However, with improved techniques of selective extraction, two commercially available single-isomer formulations of local anesthetic are now available, ropivacaine and levobupivacaine. **Levobupivacaine** is the levorotary isomer of bupivacaine; it is currently not marketed in the United States. **Ropivacaine** is a homologue of mepivacaine and bupivacaine but is formulated as a single levorotary isomer rather than as a racemic mixture. A propyl group on the pipechol ring distinguishes ropivacaine from bupivacaine (which has a butyl group) and mepivacaine (which has a methyl group).[2] Thus, it is not surprising that the physicochemical characteristics of ropivacaine are intermediate between those of mepivacaine and bupivacaine.

The reduction in systemic toxicity observed with administration of the levorotary isomers may be both drug and concentration dependent. For example, one study in isolated guinea pig hearts noted that bupivacaine isomers lengthened atrioventricular conduction time more than ropivacaine isomers did. In contrast to other measured variables, "atrioventricular conduction time showed evident stereoselectivity" for bupivacaine at the lowest concentration studied (0.5 μM) but only at much higher concentrations for ropivacaine (> 30 μM).[3]

Mechanism of Action

At rest, the interior of a nerve cell is negatively charged in relation to its exterior. This resting potential of 60 to 90 mV exists because the concentration of sodium in the extracellular space greatly exceeds that in the intracellular space. The converse is true for potassium. Excitation results in the opening of membrane channels, which allows sodium ions to flow freely down their concentration gradient into the cell interior. Thus, the electrical potential within the nerve cell becomes less negative until, at the critical threshold, rapid depolarization occurs. This depolarization is needed to initiate the same sequence of events in adjacent membrane segments and for propagation of the action potential. Thereafter, sodium channels close and the membrane once again becomes impermeable to the influx of sodium. The negative resting membrane potential is reestablished as sodium is removed from the cell by active transport. At the same time, potassium passively accumulates within the resting cell.

Interference with sodium-ion conductance appears to be the mechanism by which local anesthetics reversibly inhibit the propagation of the action potential. Four major theories attempt to explain this effect. The most prominent hypothesis is that the local anesthetic interacts with receptors in the nerve cell membrane involved in sodium conductance.[4] There may be more than one site at which local anesthetics bind to sodium-channel receptors (Fig. 13.2).

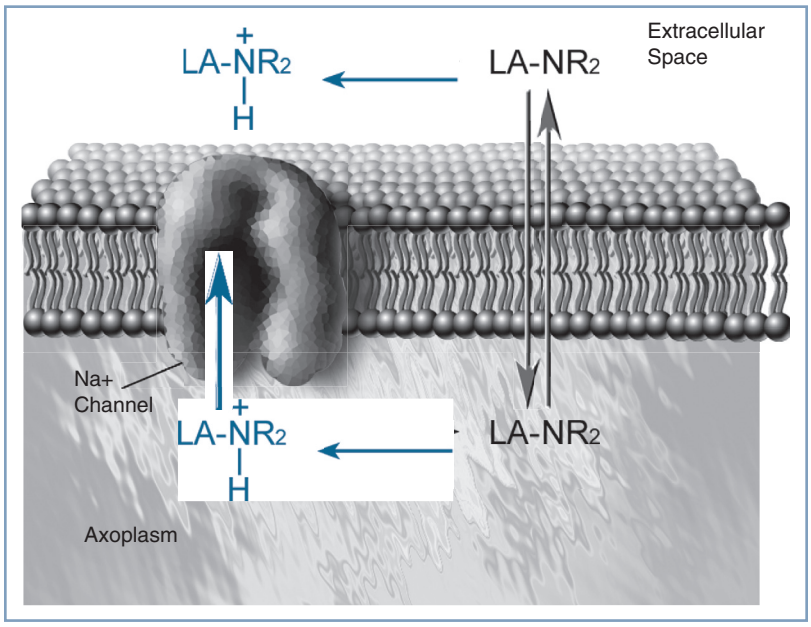

Fig. 13.2 Local anesthetic access to the sodium channel. The uncharged molecule ($LA\text{-}NR_2$) diffuses most easily across the lipid membrane and interacts with the sodium channel at an intramembranous site. The charged molecule ($LA\text{-}NR_2H^+$) gains access to a specific receptor on the sodium channel in the intracellular space. (Illustration by Naveen Nathan, MD, Northwestern University Feinberg School of Medicine, Chicago, IL.)

The Meyer-Overton theory offers a second explanation; it suggests that the lipid-soluble portion of the local anesthetic molecule expands the cell membrane, thus interfering with rapid sodium conductance. A third possibility is that local anesthetics may alter the membrane surface charge, a change that would inhibit propagation of the action potential. Fourth, local anesthetics may displace calcium from sites that control sodium conductance.

Both the un-ionized and ionized forms of a local anesthetic are involved in pharmacologic activity. The un-ionized base, which is lipid soluble, diffuses through the cell membrane, whereas the charged form is active in blocking the sodium channel.

Pharmacodynamics

Pregnant women typically require smaller doses of local anesthetic compared with nonpregnant women for neuraxial blockade. This effect may be evident as early as the second trimester[5,6] and has been attributed to enhanced spread of local anesthetic caused by epidural venous engorgement. However, mechanical effects alone do not account for the observation that the spread of spinal and epidural analgesia in early pregnancy is similar to that in pregnant women at term.[5–7] In fact, pregnancy may also enhance neuronal sensitivity to local anesthetics. For example, pregnancy increases median nerve susceptibility to lidocaine.[8] *In vitro* studies demonstrated that the onset of neural blockade was faster, and lower concentrations of bupivacaine were required to block vagal fibers, in pregnant than in nonpregnant rabbits.[9]

Hormonal and biochemical changes may be responsible for the greater susceptibility to neural blockade during pregnancy. It has been speculated that the hormonal effects may be caused by progesterone or a metabolite since an enhanced effect of bupivacaine in isolated vagus fibers from nonpregnant, ovariectomized rabbits only occurred after long-term (4 days) but not short-term exposure to progesterone.[10] A higher pH and lower bicarbonate and total carbon dioxide content have been demonstrated in cerebrospinal fluid (CSF) from women undergoing cesarean delivery than from age-matched nonpregnant controls; this may increase the proportion of local anesthetic that exists as the base form and facilitates diffusion of the drug across nerve membranes.[7]

Pharmacokinetics

Pregnancy is associated with progressive physiologic adaptations that may influence drug disposition (see Chapter 2). However, it is difficult to predict with certainty the effects of pregnancy on the pharmacokinetics of an individual drug.

2-Chloroprocaine

2-Chloroprocaine is hydrolyzed rapidly by plasma pseudocholinesterase to chloroaminobenzoic acid and H_2O. Although pregnancy is associated with a 30% to 40% decrease in pseudocholinesterase activity, the half-life of 2-chloroprocaine in maternal plasma *in vitro* is 11 to 21 seconds. After epidural injection, the half-life of 2-chloroprocaine in the mother ranges from 1.5 to 6.4 minutes.[11] The longer half-life after epidural administration results from continued absorption of the drug from the injection site. Administration of 2-chloroprocaine to patients with low pseudocholinesterase activity may result in prolonged local anesthetic effect and a greater potential for systemic toxicity.[12]

Lidocaine

The volume of the central compartment and the volume of distribution of lidocaine are greater in pregnant than in nonpregnant ewes.[13,14] Bloedow et al.[14] observed that the total

body clearance of lidocaine was similar in the two groups of animals but the elimination half-life of lidocaine, which depends on the balance between volume of distribution and clearance, was longer in pregnant ewes.[14] In contrast, Santos et al.[13] concluded that the elimination half-life of lidocaine was similar in the two groups of sheep because the total body clearance of the drug was greater in pregnant than in nonpregnant animals. This discrepancy could result from differences in the complexity of the surgical preparation and the allowed recovery period. In pregnant women, the elimination half-life of lidocaine after epidural injection is approximately 114 minutes.[15]

Lidocaine is metabolized into two active compounds, monoethylglycinexylidide (MEGX) and glycinexylidide (GX). Monoethylglycinexylidide can be detected in maternal plasma within 10 to 20 minutes after neuraxial injection of lidocaine, whereas glycinexylidide can be detected within 1 hour of epidural injection but rarely after subarachnoid injection.[16,17] Urinary excretion of unchanged lidocaine is negligible in sheep (i.e., < 2% of the administered dose) and is not affected by pregnancy.[13]

The physiologic changes that occur during pregnancy are progressive. However, little information is available about the pharmacokinetics of local anesthetics before term. In one study, total clearance of lidocaine was similar at 119 and 138 days' gestation in gravid ewes (term is 148 days).[18]

Lidocaine is predominantly bound to alpha$_1$-acid glycoprotein (AAG) in plasma.[19] Pregnancy leads to a decreased concentration of AAG; thus, the free plasma fraction of lidocaine is higher in term pregnant women than in nonpregnant controls.[19] The increase in the free fraction of lidocaine occurs early in gestation and is progressive.[20]

Bupivacaine

At least two studies compared the pharmacokinetics of bupivacaine after epidural administration in pregnant and nonpregnant women.[21,22] The absorption rate, the area under the concentration-time curve, and the elimination half-life (12 to 13 hours) were similar in the two groups. The elimination half-life of bupivacaine after epidural administration is much longer than that after intravenous injection, largely because the drug is continuously absorbed over time from the epidural space.

In contrast to lidocaine,[13,14] the volume of distribution of bupivacaine is lower in pregnant than in nonpregnant sheep after intravenous injection.[23] The differences in gestational effects on the volume of distribution of the two local anesthetics may result from the greater binding of bupivacaine to plasma proteins during gestation (whereas the converse occurs with lidocaine).[23] In one study, urinary excretion of unchanged bupivacaine was not affected by pregnancy and was less than 1% of the administered dose.[21] Nonetheless, low concentrations of bupivacaine may be detected in the urine of pregnant women for as long as 3 days after delivery.[24]

Bupivacaine undergoes dealkylation in the liver to 2,6-pipecolyxylidide (PPX). After epidural injection of bupivacaine for cesarean delivery, PPX was detected in maternal plasma within 5 minutes and remained detectable for as long as 24 hours.[24] With the lower doses required for labor analgesia, PPX was found only if the block was maintained with multiple reinjections during a period that exceeded 4 hours.[25] Pregnancy may affect metabolism of bupivacaine.[21] For example, pregnant women have higher serum PPX concentrations, but the unconjugated 4-hydroxy metabolite is not produced in significant amounts. The reason for this finding is unclear but may be related to effects of hormonal changes on hepatic enzyme systems. Both progesterone and estradiol are competitive inhibitors of microsomal oxidases, whereas reductive enzymes are induced by progesterone.[23] Bupivacaine is bound extensively to AAG and albumin.[26] This protein binding is reduced during late pregnancy in humans.[27]

Long-acting pipechol amide local anesthetics, such as bupivacaine, are beneficial for neuraxial labor analgesia because they produce a relative motor-sparing block compared with other local anesthetics. The effective dose in 50% of cases (ED_{50}) for motor block after intrathecally administered bupivacaine was lower in pregnant than in nonpregnant women (3.96 mg and 4.14 mg, respectively).[28]

Ropivacaine

Pregnant sheep have a smaller volume of distribution and a slower clearance of ropivacaine than nonpregnant animals.[23] However, the relationship between volume of distribution and clearance is such that the elimination half-life is similar in pregnant and nonpregnant animals.

After intravenous injection in laboratory animals or nonpregnant volunteers, the elimination half-life of ropivacaine is shorter than that of bupivacaine.[23,29] The shorter elimination half-life of ropivacaine has been attributed to a faster clearance and a shorter mean residence time than for bupivacaine.[23]

Peak plasma concentration (C_{max}) of 0.5% ropivacaine and 0.5% bupivacaine after epidural administration for cesarean delivery are similar (1.3 μg/mL and 1.1 μg/mL, respectively).[30] The elimination half-life of ropivacaine is 5.2 ± 0.6 hours, which is shorter than that for bupivacaine, at 10.9 ± 1.1 hours. No difference in clearance between the two drugs has been noted.

Like bupivacaine, ropivacaine is metabolized by hepatic microsomal cytochrome P450. The major metabolite is PPX, and minor metabolites are 3′- and 4′-hydroxy-ropivacaine.[31]

Ropivacaine is highly bound (approximately 92%) to plasma proteins but less so than bupivacaine (96%).[32] Indeed, at plasma concentrations occurring during epidural anesthesia for cesarean delivery, the free fraction of ropivacaine is almost twice that of bupivacaine.[30] In pregnant women undergoing epidural analgesia, the free fraction of ropivacaine decreases as the concentration of AAG increases, up to the point at which the receptors are saturated.[33] However, there is little correlation between the free fraction and umbilical cord blood levels of ropivacaine at delivery.[33]

Effect of Histamine (H_2)-Receptor Antagonists

Histamine (H_2)-receptor antagonists are administered to increase gastric pH and reduce the risk for aspiration pneumonitis. Drug disposition may be affected by binding to hepatic cytochrome

P450, reducing hepatic blood flow and renal clearance, especially with cimetidine. However, short-term administration of H_2-receptor antagonists does not alter the pharmacokinetics of amide local anesthetics in pregnant women.[34,35]

Effects of Preeclampsia

Pathophysiologic changes associated with preeclampsia (e.g., reduced hepatic blood flow, abnormal liver function, decreased intravascular volume) may also affect maternal blood concentrations of local anesthetics (see Chapter 35). For example, Ramanathan et al.[36] found that total body clearance of lidocaine after epidural injection was significantly lower in preeclamptic than in normotensive women; however, the elimination half-life of lidocaine was similar in the two groups. Nonetheless, decreased clearance may result in greater drug accumulation with repeated injections of lidocaine in women with preeclampsia. In contrast, long-acting amides have a relatively low hepatic extraction, and changes in liver blood flow with preeclampsia may have less effect on the metabolic clearance.

Effect of Gestational Diabetes Mellitus

Gestational diabetes mellitus may have profound transient effects on the microcirculation. The placental transfer of lidocaine was unchanged for women at term with diabetes who received epidural lidocaine 200 mg, but the transfer of its metabolite, MEGX, was increased.[37] A weakness of the methodology was that umbilical artery/vein ratios were used to estimate placental transfer (see later in the chapter).

Effect of Diurnal Variation

Pain may exhibit temporal variation in intensity because of diurnal neuroendocrine or external factors. In one study, the duration of action of epidural bupivacaine was approximately 25% longer when it was administered between 7:00 AM and 7:00 PM than between 7:00 PM and 7:00 AM.[38] In contrast, another study found no diurnal variation with intrathecal bupivacaine administered for labor analgesia.[39] The authors of this study suggested the diurnal variation may also be explained by external influences such as shift changes for nurses and anesthesiologists.[39]

Effect of Injectate Temperature

Latency of local anesthetic affect may be affected by temperature. For instance, onset of labor analgesia is faster when a solution of epidural bupivacaine 0.125% with fentanyl 2 µg/mL is injected at 37° C compared with 20° C.[40]

Toxicity

Systemic absorption or intravascular injection of a local anesthetic may result in **local anesthetic systemic toxicity (LAST)**. Toxicity most often involves the central nervous system (CNS), but cardiovascular toxicity also may occur. Less common are tissue toxicity and hypersensitivity reactions.

Central Nervous System Toxicity

The severity of CNS effects is proportional to the blood concentration of local anesthetic. This relationship is well described for lidocaine (Fig. 13.3). Initially, the patient may complain of numbness of the tongue, tinnitus, or lightheadedness. At high plasma concentrations, convulsions occur because of a selective blockade of central inhibitory neurons that leads to increased CNS excitation.[41] At still higher concentrations, generalized CNS depression or coma may result from reversible blockade of both inhibitory and excitatory neuronal pathways. Finally, depression of the brainstem and cardiorespiratory centers may occur.

The relative toxicity of a local anesthetic correlates with its potency. For lidocaine, etidocaine, and bupivacaine, the ratio of the mean cumulative doses that cause convulsions in dogs and human volunteers is approximately 4:2:1, which is similar to their relative anesthetic potencies.[42] Local anesthetics may be ranked in order of decreasing CNS toxicity as follows: bupivacaine, ropivacaine, levobupivacaine, lidocaine, and 2-chloroprocaine.[43] Tetracaine, etidocaine, and mepivacaine are used rarely in obstetric anesthesia practice.

Other factors (e.g., the speed of injection) may affect CNS toxicity. In humans, the mean dose of etidocaine that elicited signs of CNS toxicity was lower during a 20-mg/min infusion than during a 10-mg/min infusion.[44] Metabolic factors may also affect the seizure threshold. For example, in cats, an increase in $Paco_2$ or a decrease in pH results in a reduction in the seizure-dose threshold for local anesthetics. Respiratory acidosis may result in delivery of more drug to the brain; alternatively, respiratory acidosis may result in "ion trapping" of the local anesthetic and/or an increase in the unbound fraction of drug available for pharmacologic effect.[45,46]

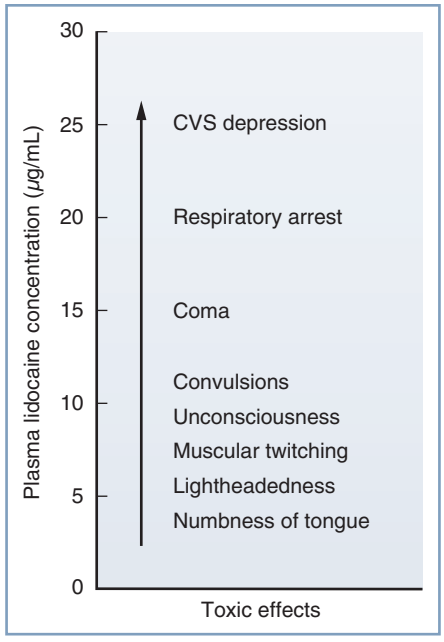

Fig. 13.3 Signs and symptoms of systemic toxicity with increasing lidocaine concentrations. *CVS,* cardiovascular system. (Modified from Carpenter RL, Mackey DC. Local anesthetics. In Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* Philadelphia, PA: Lippincott; 1992:527.)

Cardiovascular Toxicity

The cardiovascular system is typically much more resistant than the CNS to the toxic effects of local anesthetics. Severe, direct cardiovascular depression is rare, especially in association with the use of lidocaine. Prompt administration of oxygen and, if necessary, initiation of ventilatory and circulatory support usually prevent cardiac arrest after unintentional intravenous injection of lidocaine.[47] Progressive depression of myocardial function and profound vasodilation occur only at extremely high plasma concentrations.[47] In contrast, the more potent amide local anesthetics (i.e., bupivacaine) have a more narrow margin of safety, expressed as the ratio between the dose (or plasma concentration) required to produce cardiovascular collapse and the dose (or plasma concentration) required to produce convulsions.[47] A partial explanation is the fact that supraconvulsant doses of bupivacaine (but not of lidocaine) precipitate lethal ventricular arrhythmias.[48,49] These arrhythmias may be caused by exaggerated electrophysiologic effects (e.g., depression of ventricular conduction) out of proportion to bupivacaine's anesthetic potency.[50]

Two theories have been proposed to explain why malignant ventricular arrhythmias occur with bupivacaine but not with lidocaine. Both bupivacaine and lidocaine rapidly block cardiac sodium channels during systole, but bupivacaine dissociates from these channels during diastole at a much slower rate than lidocaine.[50] Thus, at physiologic heart rates, the diastolic period is of sufficient duration for lidocaine to dissociate from sodium channels, whereas a bupivacaine block becomes intensified. This difference makes bupivacaine much more potent than lidocaine in depressing conduction and inducing reentrant-type ventricular arrhythmias. Alternatively, other investigators have suggested that high concentrations of local anesthetic in the brainstem may lead to systemic hypotension, bradycardia, and ventricular arrhythmias.[51] These effects occur more commonly with bupivacaine because of its high lipid solubility, which facilitates transfer across the blood-brain barrier. An echocardiographic study in anesthetized dogs suggested that bolus injection of bupivacaine results in systolic dysfunction, especially involving the right ventricle, which precedes the occurrence of arrhythmias.[52]

Metoclopramide is used in obstetric anesthesia as an antiemetic and to enhance gastric emptying. In rat myocytes, metoclopramide inhibits cardiac sodium channels similar to local anesthetics.[53] The potential interaction with bupivacaine is unknown and requires further study.

Systemic Toxicity of Ropivacaine and Levobupivacaine

In vitro, ropivacaine is intermediate between bupivacaine and lidocaine in its depressant effect on cardiac excitation and conduction as well as in its potential to induce reentrant-type ventricular arrhythmias.[32,54] In dogs, the margin of safety between convulsive or lethal doses and plasma concentrations of drug is greater for ropivacaine than for bupivacaine but less than that for lidocaine.[54] The arrhythmogenicity of ropivacaine in pigs also is intermediate between that of lidocaine and bupivacaine.[55] In sheep, the ratio of fatal doses of bupivacaine, ropivacaine, and lidocaine is 1:2:9.[56] Ropivacaine was found to cause fewer CNS symptoms and was 25% less toxic than bupivacaine (as defined by the doses and plasma concentrations that were tolerated) when administered to healthy male volunteers.[57]

However, studies comparing the systemic toxicity of ropivacaine and bupivacaine have used equal doses of each, and, therefore, cannot resolve the controversy as to whether ropivacaine truly is less cardiotoxic or merely less potent than bupivacaine. This issue would be of concern only if larger doses of ropivacaine than bupivacaine were required to produce comparable regional blocks. Indeed, several studies in laboring women suggest that ropivacaine is 25% to 40% less potent than bupivacaine.[58–60] Thus, the need for a larger dose of ropivacaine may negate the expected benefits of its wider margin of safety. Results from one laboratory study showed that ropivacaine produces less cardiotoxicity than bupivacaine, even when given at equipotent doses.[61]

Long-acting amide local anesthetics—even the newer drugs—are very potent and may cause cardiac arrest with a misplaced injection or relative overdose. Indeed, several cardiac arrests have been reported with the use of ropivacaine,[62,63] including one in a woman undergoing a cesarean delivery with epidural anesthesia.[64] In contrast to bupivacaine,[65] resuscitation from a cardiac arrest induced by ropivacaine may be successful more often than not.[62–64]

Evidence suggests that levobupivacaine, which is not available for use in the United States, causes fewer arrhythmias than the racemic drug. Levobupivacaine caused less inhibition of inactivated sodium channels than either the dextrorotary or racemic drug.[66] In comparison with dextrorotary and racemic bupivacaine, levobupivacaine resulted in less QRS widening and a lower frequency of malignant ventricular arrhythmias in isolated, perfused rabbit hearts.[67] Similarly, levobupivacaine produced less second-degree heart block and atrioventricular conduction delay than the other two forms of the drug in isolated perfused guinea pig hearts.[3]

In laboratory animals, the systemic toxicity of levobupivacaine is intermediate between that of bupivacaine and ropivacaine.[68] Potency ratio data for epidural bupivacaine, ropivacaine, and levobupivacaine in laboring women are inconsistent, but studies suggest that levobupivacaine is equipotent or slightly less potent than bupivacaine (see Chapter 23).[69,70] Altogether, published data and clinical experience suggest that the benefit of a lower risk for systemic toxicity with levobupivacaine is not obtained at the expense of efficacy. Like ropivacaine, levobupivacaine may cause cardiac arrest but is associated with a better response to resuscitation than racemic bupivacaine.[71]

Effects of Pregnancy on Systemic Toxicity

Central nervous system toxicity. Pregnancy-related hormones, such as estradiol and progesterone, have a neuroprotective effect in laboratory animals.[72] However, it is unclear whether pregnancy lowers the seizure threshold for amide local anesthetic agents. In one study, seizures occurred at lower doses of bupivacaine, levobupivacaine, and ropivacaine in pregnant than in nonpregnant ewes.[68] However, the difference was small

(10% to 15%) and probably of negligible clinical significance. In studies in sheep and rats, pregnancy did not reduce the doses required to cause convulsions after intravenous administration of mepivacaine, bupivacaine, or lidocaine.[49] Magnesium sulfate, which is frequently used in obstetric practice, does not affect the seizure-dose threshold of lidocaine.[73]

Cardiovascular toxicity. In 1979, Albright[65] alerted anesthesiologists to several cases of sudden and immediate cardiovascular collapse after unintentional intravascular injection of bupivacaine and etidocaine in pregnant women. Most of these cases were fatal, and subsequent controversy centered on whether resuscitation was instituted promptly and effectively or whether the cardiovascular collapse and inability to resuscitate were unique to bupivacaine. Nonetheless, the U.S. Food and Drug Administration (FDA) restricted the use of the highest concentration (0.75%) of bupivacaine in pregnant women.

Several physiologic changes that occur during pregnancy place the parturient at higher risk for refractory cardiac arrest than the nonpregnant patient. First, reduced functional residual capacity and a higher metabolic rate hasten the onset of hypoxemia during periods of hypoventilation or apnea. Second, aortocaval compression decreases the efficacy of closed-chest cardiac massage in the supine position.[74] Third, a large bolus of drug injected into an epidural vein might reach the heart rapidly through a dilated azygous system. However, none of these factors adequately explains why cardiac arrest and difficult resuscitation are rare in parturients intoxicated with lidocaine or mepivacaine.[65,75]

Results of laboratory studies of the effects of pregnancy on bupivacaine cardiotoxicity have been contradictory. Pregnancy-related hormones enhance the cardiotoxicity and arrhythmogenicity of bupivacaine *in vitro*.[76,77] For example, the magnitude and severity of bupivacaine-induced electrophysiologic changes are greater in myocardium obtained from nonpregnant rabbits treated with progesterone or beta-estradiol than in myocardium from untreated controls.[76,77] The electrophysiologic effects of lidocaine are less pronounced than those of bupivacaine, even in hormonally treated animals. Studies conducted *in vivo* have been less conclusive. In earlier investigations, significantly lower doses and plasma concentrations of bupivacaine, but not of mepivacaine or lidocaine, were required to produce circulatory collapse in pregnant than in nonpregnant sheep.[48,49] However, a study involving a larger number of sheep and more rigorous methods (e.g., randomization, blinding) failed to confirm that pregnancy enhances the cardiotoxicity of bupivacaine.[68]

Progesterone does not increase myocardial sensitivity to ropivacaine.[78] Likewise, pregnancy does not enhance the systemic toxicity of ropivacaine or levobupivacaine in sheep.[68]

Extrapolation of results of animal studies to obstetric anesthesia practice is difficult, for several reasons. First, in the aforementioned sheep studies, the drug was administered by constant-rate intravenous infusion. In contrast, in pregnant women intoxicated with bupivacaine, cardiac arrest occurred after unintended intravascular injection of a large bolus of drug. Second, a potential for bias existed in the animal studies because randomization and blinding were not used in all studies and some relied on historical controls.[48,49] Third, it is unclear whether resuscitation in the reported clinical cases was accompanied by prompt and effective relief of aortocaval compression.[74]

Nonetheless, bupivacaine remains a popular local anesthetic for obstetric anesthesia. In current practice, heightened vigilance, use of an appropriate test dose, and fractionation of the therapeutic dose have made epidural anesthesia a safe technique for use in obstetric patients (see Chapter 12). In a study of anesthesia-related maternal mortality, Hawkins et al.[79] noted that the number of maternal deaths resulting from local anesthetic toxicity decreased after 1984, the year that the FDA withdrew approval for the epidural administration of 0.75% bupivacaine in obstetric patients. However, LAST has been recognized for decades as an important potential cause of maternal mortality.[80] In our judgment, adherence to the aforementioned clinical precautions—rather than the proscription against the epidural administration of 0.75% bupivacaine—has been responsible for the lower number of maternal deaths caused by LAST. Anesthesia providers should be aware that intravenous injection of 0.25% and 0.5% bupivacaine can also cause LAST.

The availability of single levorotary isomers of a local anesthetic may be advantageous because these drugs have a greater margin of safety than bupivacaine, with similar blocking properties, although at a higher cost. From the standpoint of systemic toxicity, the use of these isoforms may be more beneficial in parturients undergoing cesarean delivery, who require higher doses than administered for analgesia during labor. Nonetheless, a greater margin of safety with these new drugs should not be a substitute for proper technique.

Treatment of Systemic Toxicity

Meticulous attention to good technique and adherence to guidelines for maximum recommended dose are mandatory. (The use of a test dose to identify misplaced injections is discussed in Chapter 12.) Incremental injection of the therapeutic dose, careful observation of the patient, and monitoring of vital signs usually provide early warning of an impending reaction. In mild cases, discontinuation of the administration of drug, administration of supplemental oxygen, and maintenance of normal ventilation often limit the severity of the reaction. In 2018, the American Society of Regional Anesthesia and Pain Medicine (ASRA) updated their checklist for managing LAST (Box 13.1).[81] In patients who show signs of CNS excitation, a small dose of an intravenous sedative-hypnotic drug with strong anticonvulsant properties such as a benzodiazepine (diazepam up to 5 mg or midazolam 1 to 2 mg) may prevent progression to convulsions. Prophylactic administration of a benzodiazepine or dexmedetomidine to laboratory animals reduced the incidence of both convulsions and possibly mortality after intoxication with amide local anesthetics.[82] Propofol should be avoided in patients with cardiovascular instability because of its cardiovascular depressant properties.[81]

If convulsions should occur, oxygenation and ventilation must be maintained to prevent hypoxemia, hypercarbia, and acidosis.[44,81,83] Patency of the airway must be maintained. It may be necessary to suction the airway first in some patients. Management should consist of administration of 100% oxygen and tracheal intubation, if required. Convulsions may be terminated quickly with a small dose of an anticonvulsant; a benzodiazepine is preferred.[81] Large doses of propofol should be avoided in the setting of hemodynamic instability. Maternal circulation should be supported by maintenance of left uterine displacement and administration of a vasopressor as needed. Because a high plasma concentration of local anesthetic may cause myocardial depression and vasodilation, a mixed alpha- and beta-adrenergic agonist (e.g., ephedrine or even epinephrine) may be preferable to a pure alpha-adrenergic agonist. Vasopressin, calcium entry-blocking agents, beta-adrenergic blocking agents, and local anesthetics should be avoided.[81] Fortunately, convulsions induced by local anesthetics, with the exception of the long-acting amide local anesthetics, are usually self-limited because of rapid redistribution of the drug.

Persistent hypotension and bradycardia may require administration of epinephrine. However, individual epinephrine doses should not exceed 1 μg/kg.[81] Although the mainstay of treatment, epinephrine itself may cause ventricular tachyarrythmias and binds the very same cardiac sodium channels that bupivacaine binds, in theory, potentially worsening cardiac toxicity.[84] Bupivacaine-induced ventricular arrhythmias should not be treated with lidocaine, because local anesthetic toxicity is additive.

Cardiac arrest should be treated according to the American Heart Association's Advanced Cardiac Life Support (ACLS) guidelines, modified for pregnancy (see Chapter 54).[85] The uterus should be displaced leftward, generally best achieved with manual displacement, to prevent or relieve aortocaval compression, which renders cardiac massage ineffective. Prompt cesarean delivery of the infant may be necessary to relieve aortocaval compression (venous return) and restore maternal circulation. Prolonged resuscitation may be needed until myocardial washout of bupivacaine has occurred.[50]

Lipid emulsion therapy has been incorporated into guidelines for the treatment of LAST and should be readily available.[81,85] The mechanism of lipid emulsion therapy includes a direct scavenging effect that removes the local anesthetic from tissue and a direct cardiac effect that serves to improve cardiac output once the drug is removed from cardiac tissue; the mechanisms of these effects are incompletely understood.[86] Lipid emulsion is now an accepted therapy, and the updated 2018 American Society of Regional Anesthesia and Pain Medicine (ASRA) checklist for the treatment of LAST states that lipid emulsion therapy should be considered at the first sign of a serious LAST event (see Box 13.1).[81] Propofol should *not* be used to treat LAST; its lipid content is inadequate, and the cardiodepressant effects of the drug are detrimental during resuscitation from LAST. In a suspected case of bupivacaine intoxication in a parturient, manifested by facial and limb twitching and unconsciousness, prophylactic administration of 100 mL of lipid emulsion prevented progression to full cardiovascular collapse.[87] A protocol for treatment of LAST in pregnancy, including the administration of lipid emulsion, is presented in Box 13.1.

After maternal recovery, fetal condition should be assessed promptly. In theory, a delay in delivery may allow back-diffusion of local anesthetic from the fetus to the mother, which may be of benefit to the neonate by decreasing neonatal plasma bupivacaine levels. Laboratory studies have demonstrated this phenomenon after the administration of bupivacaine[88] but not lidocaine.[89]

Tissue Toxicity

Neurologic complications of neuraxial anesthesia are rare and result mostly from direct neural trauma, infection, injection of toxic doses of local anesthetic, or the injection of the wrong drug.

BOX 13.1 Management of Local Anesthetic Systemic Toxicity

- Stop injecting local anesthetic.
- Call for help.
- Position patient with left uterine displacement.
- Prepare for emergency delivery. Consider delivery of the infant if the mother is not resuscitated within several minutes, because this may facilitate successful resuscitation of the mother.
- Consider 20% intravenous lipid emulsion administration at the first sign of LAST.
  - Bolus dose: 1.5 mL/kg over 2–3 min (approximately 100 mL)
  - Infusion: 200–250 mL over 15–20 min
  - Repeat bolus dose once or twice for persistent cardiovascular collapse.
  - Recommended maximum dose: 12 mL/kg
- Administer 100% oxygen to maintain maternal oxygenation.
- Use positive-pressure ventilation if necessary. Tracheal intubation will facilitate support of ventilation and help protect the airway, but do not delay administration of oxygen to intubate the trachea.
- Control seizure (benzodiazepine preferred, avoid high doses of propofol in hemodynamically unstable patients). Be aware that hypoxemia and acidosis develop rapidly during a seizure.
- Alert the nearest facility capable of cardiopulmonary bypass.
- Monitor maternal vital signs and fetal heart rate.
- Support maternal blood pressure with fluids and vasopressors.
- Initiate advanced cardiac life support if necessary, including modifications for pregnancy (see Chapter 54).
  - **Avoid** vasopressin, calcium entry–blocking agents, beta-adrenergic receptor antagonists, and local anesthetics.
  - **Reduce** individual epinephrine doses to less than 1 μg/kg.

LAST, local anesthetic systemic toxicity.
Modified from the American Society of Regional Anesthesia and Pain Medicine. Checklist for treatment of local anesthetic systemic toxicity (LAST). https://www.asra.com/content/documents/asra_last_checklist_2018.pdf. Accessed April 1, 2018.

Several cases of prolonged or permanent sensory and motor deficits after subarachnoid injection of a large dose of 2-chloroprocaine intended for epidural block have been described.[90] Studies comparing the neurotoxicity of 2-chloroprocaine with that of other local anesthetics have yielded conflicting results, most likely related to the use of different methodologies and different species.[91,92] It has been suggested that neurotoxicity was caused by sodium metabisulfite, an antioxidant present in the commercial formulation used in the reported cases and a low pH (2.7 to 4.0) of the formulation.[91] In CSF rendered more acidic by 2-chloroprocaine, metabisulfite generates sulfur dioxide, which is lipid soluble and can diffuse into the nerve cells.[93] Intracellular hydration of sulfur dioxide generates sulfurous acid, which may cause profound intracellular acidosis and irreversible damage. In contrast, others have suggested that 2-chloroprocaine itself, and not metabisulfite, was the cause of neurologic deficits.[93]

Subsequently, the manufacturer released another preparation of 2-chloroprocaine, which was free of bisulfite but contained ethylenediaminetetraacetic acid (EDTA). This was followed by several reports of severe, incapacitating paralumbar pain and spasm associated with epidural injection of large volumes of drug,[94] likely resulting from chelation of calcium by disodium EDTA and tetany of the affected muscles caused by local hypocalcemia. The current preparation of 2-chloroprocaine that is marketed for *epidural* administration does not contain EDTA or other preservatives. It is packaged in colored vials to reduce the oxidation.

Lidocaine has been used for spinal anesthesia for more than 50 years, in thousands upon thousands of patients, with apparent safety. However, **cauda equina syndrome,** sacral nerve root deficits, or transient neurologic toxicity can occur after subarachnoid injection of lidocaine.[95,96] Neurotoxicity of local anesthetics is concentration dependent[97] and is not unique to lidocaine.[98,99] Some investigators have speculated that slow injection of local anesthetic through a spinal microcatheter results in maldistribution and pooling of high concentrations of hyperbaric lidocaine in the cauda equina area, resulting in increased risk for neurotoxicity and cauda equina syndrome.[95,96]

Milder manifestations of neurotoxicity also may occur. As early as 1954, mild, transient neurologic symptoms were reported after spinal anesthesia with lidocaine.[100] **Transient neurologic symptoms** (TNS) (dysesthesia or low back pain radiating to the buttocks, thighs, and calves) have been observed in surgical patients even after conventional (i.e., single-shot) spinal anesthesia with hyperbaric 5% lidocaine (see Chapter 31).[96] In response to concerns that intrathecal injection of hyperbaric 5% lidocaine might be associated with TNS, in 1994 the FDA Advisory Committee on Anesthetic Drugs recommended that the injected drug concentration be reduced by dilution with an equal volume of either preservative-free saline or CSF. However, Pollock et al.[101] reported that there was no difference in the incidence of TNS when spinal lidocaine 50 mg was diluted to 2%, 1%, or 0.5% solutions before administration and that the overall incidence of TNS did not differ from that of historic controls given 5% lidocaine.

Interestingly, the exposure of frog sciatic nerve to lidocaine results in a progressive, irreversible loss of impulse activity beginning at a concentration of 1%.[97] The investigators of this study noted that "the range of lidocaine that produces such changes in mammalian nerve awaits determination."[97] Meanwhile, it seems prudent to take the following precautions[95,102]:

1. Dilute the commercial 5% lidocaine for intrathecal injection as recommended by the FDA.
2. Administer the lowest possible dose.
3. Avoid the use of hyperbaric lidocaine in clinical conditions (e.g., obesity) or situations (e.g., the lithotomy position) that may be associated with a higher incidence of TNS.

Generally, if pencil-point, side-hole spinal needles are used, it is recommended that the injection port should be directed cephalad. However, an epidemiologic survey did not implicate dose and needle-bevel direction as factors that affect the risk for TNS.[102] A meta-analysis of randomized controlled trials comparing spinal lidocaine with other local anesthetics (bupivacaine, prilocaine, procaine, and mepivacaine) found that the relative risk (RR) for development of TNS was higher with lidocaine than with the other local anesthetic agents (RR, 4.35; 95% confidence interval [CI], 1.98 to 9.54).[103] It has not been conclusively proven that TNS are manifestations of neurotoxicity.

Pregnancy may be associated with a reduced risk for TNS. Studies suggest that the incidence of TNS after spinal anesthesia with lidocaine or bupivacaine is equally low (< 3%) in women having cesarean delivery and those undergoing postpartum tubal ligation.[104,105]

Allergic Reactions

True allergy to a local anesthetic is rare.[106] Further, anaphylactic and anaphylactoid reactions may be the result of additives such as methylparaben and metabisulfite.[106,107] Experts judged that only 15% of patients referred to an allergy clinic for suspected local anesthetic allergy actually had a clinical reaction (urticaria, bronchospasm, facial edema, and/or cardiovascular instability) consistent with a real allergic response.[108] Adverse reactions (e.g., CNS and cardiovascular symptoms) may mimic hypersensitivity but not actually be a result of hypersensitivity. The potential range of allergic manifestations are listed in Box 13.2.

Obstetricians should refer women with alleged allergy to an anesthesiologist for appropriate evaluation well before the expected date of delivery. In many cases, a carefully obtained history excludes true hypersensitivity. If IgE-mediated hypersensitivity is suspected, patients should be referred to an allergist for further evaluation. Skin prick or intradermal testing using appropriate positive (diluted histamine) and negative (normal saline) controls is recommended.[107] Intradermal testing is more sensitive but is associated with a false-positive rate of 8% to 15%.[106] If the skin testing is negative, subcutaneous provocative dose testing is a useful method to confirm that the drug is safe to use clinically.[107] Alternatively, if skin testing is positive, the testing sequence (skin testing followed by provocative subcutaneous testing) should be repeated with an alternative agent.

BOX 13.2 Non–IgE-Mediated Reactions to Local Anesthetics

- Psychomotor responses
  - Vasovagal episode
  - Hyperventilation or panic attack
- Endogenous sympathetic stimulation
- Responses to procedural trauma
- Delayed hypersensitivity reaction
- Non–IgE-mediated reaction to another agent
  - Epinephrine
  - Metabisulfite and other additives
- IgE-mediated reaction to another agent
  - Additives and preservatives
  - Latex
  - Antibiotic

TABLE 13.2 A Protocol for Provocative Dose Testing With Local Anesthetics

Step	Route	Volume (mL)	Dilution[a]
1	Skin prick		Undiluted
2	Subcutaneous	0.1	Undiluted
3	Subcutaneous	0.5	Undiluted
4	Subcutaneous	1.0	Undiluted
5	Subcutaneous	2.0	Undiluted

[a]See text for initial dilution suggestions for patients with a history of severe allergy.

From Chandler MJ, Grammer LC, Patterson R. Provocative challenge with local anesthetics in patients with a prior history of reaction. *J Allergy Clin Immunol.* 1987;79:885.

The subcutaneous provocative test can be performed by any physician qualified to manage hypersensitivity reactions. Appropriate emergency equipment and drugs (e.g., epinephrine, H_1- and H_2-receptor antagonists) should be immediately available. Establishing intravenous access before testing is prudent. The back and the ventral aspects of the forearm are the preferred sites for testing. Areas with abnormal skin coloration or dermographia should be avoided. A history of recent treatment with antihistamines, salicylates, or corticosteroids may alter the test results.[109]

The following protocol has been proposed by Chandler et al.[110] (Table 13.2).[111] After a negative needle-prick test, increasing volumes of undiluted local anesthetic (typically 1% concentration) are injected subcutaneously at 15-minute intervals. In patients with an especially strong history of a prior severe reaction, the series may be preceded by injection of diluted solutions (e.g., a 1:100 solution, followed by a 1:10 solution). A fresh syringe should be used for each subsequent injection. A negative control and a positive control injection may also be used. A local anesthetic that is not in the same class as the drug in question should be tested; if an ester is suspected as the offending agent, testing should be performed with an amide agent, and vice versa. If possible, the drug tested should be suitable for local infiltration and for epidural and subarachnoid block.

The test is considered positive if there is a change in the patient's clinical status or if a skin wheal more than 10 mm in diameter, with or without a flare, arises within 10 minutes of injection and persists for at least 30 minutes.[109] If provocative dose testing is completed without a reaction, the local anesthetic used and the final dose given should be recorded; the patient (and the referring physician) should be informed that her risk for an adverse reaction to subsequent administration of that drug and dose is no greater than that for the general population.[110,111]

Management of an allergic reaction. Pharmacologic therapy of a severe allergic reaction involves (1) inhibition of mediator synthesis and release, (2) reversal of the effects of these mediators on target organs, and (3) prevention of the recruitment of other inflammatory processes. In general, catecholamines, especially epinephrine, but also phosphodiesterase inhibitors, antihistamines, and corticosteroids, have been used for this purpose (Box 13.3).[112] Higher doses of catecholamines may be required in a patient who has a sympathetic blockade. In addition, pregnancy itself decreases responsiveness to catecholamines.[113] Once the patient is stable, a serum tryptase level should be obtained; an elevated level is suggestive of anaphylaxis.

Effects on the Uterus and Placenta

Uterine Blood Flow

The association of paracervical block with fetal bradycardia has been attributed to the high concentration of local anesthetic deposited in the vicinity of the uterine arteries (see Chapter 24). Human uterine artery segments obtained at the time of cesarean hysterectomy constrict when exposed to high concentrations of lidocaine,[114] mepivacaine,[114] or bupivacaine.[115]

These findings also have been confirmed in laboratory animals. Fishburne et al.[116] observed a dose-related decrease in uterine blood flow during uterine arterial infusion of 2-chloroprocaine, lidocaine, or bupivacaine in gravid ewes. A 25% reduction in uterine blood flow occurred at the following calculated plasma concentrations of local anesthetic: bupivacaine, 7 μg/mL; 2-chloroprocaine, 11.5 μg/mL; and lidocaine, 19.5 μg/mL. However, when plasma local anesthetic concentrations mimic those that occur in ordinary clinical practice, local anesthetics have no adverse effect on uterine blood flow.[117-119] For example, in pregnant ewes, uterine blood flow remained unchanged during an intravenous infusion of lidocaine or bupivacaine that resulted in plasma concentrations of 0.81 to 4.60 and 1.5 to 2.0 μg/mL, respectively.[117,119] Similarly, intravenous injection of 2-chloroprocaine, 0.67 and 1.34 mg/kg, did not reduce uterine blood flow velocity in pregnant guinea pigs.[118]

Pregnancy itself may enhance uterine vascular reactivity to local anesthetic agents. Isolated human uterine artery segments obtained from term parturients constrict at a lower lidocaine concentration than uterine artery segments from nonpregnant patients.[114,120] Uterine artery sensitivity to local

BOX 13.3 Management of Anaphylaxis

Immediate Management

- If cardiac arrest, follow ACLS guidelines.[85]
- Discontinue or remove all triggers (e.g., chlorhexidine, synthetic colloids, latex).
  - Stop procedure; use minimal volatile anesthetic agents.
- Call for help.
- Maintain airway: FiO_2 1.0, consider need for tracheal intubation.
- Rapid large-volume fluid administration
  - Crystalloid bolus: 2 L, repeat as needed
  - Large-bore IV access
  - Elevate legs
- IV epinephrine bolus, repeat every 1–2 min as needed
  - Mild hypotension: 5–10 μg
  - Moderate hypotension: 20 μg
  - Life-threatening hypotension: 100–200 μg
  - Epinephrine infusion: 3–40 μg/min (0.05–0.5 μg/kg/min)

Refractory Management

- Consider requesting more help.
- Consider cesarean delivery if still pregnant (initiate within 4 min of cardiovascular collapse).
- Make sure triggers have been removed.
- Monitoring: consider arterial line, transthoracic or transesophageal echocardiography.
- Resistant hypotension
  - Norepinephrine infusion: 3–40 μg/min (0.05–0.5 μg/kg/min)
  - Vasopressin bolus 1–2 U, then infusion 2 U/h
  - Glucagon: 1–2 mg IV every 5 min until a response
- Resistant bronchospasm
  - Continue epinephrine infusion.
  - Salbutamol metered dose inhaler 12 puffs (1200 μg)
  - Magnesium 2 g over 20 min
  - Consider volatile anesthetic agent or ketamine.
- Consider other diagnoses.

Post-Crisis Management

- Consider steroids: dexamethasone 0.1–0.4 mg/kg or hydrocortisone 2–4 mg/kg.
- Consider oral antihistamines.
- Consider canceling surgical procedure, ICU monitoring.
- Investigations: draw blood for tryptase level.
- Documentation in medical record, letter for patient, referral for allergy assessment

ACLS, Advanced cardiac life support; *IV,* intravenous.
Modified from Kolawole H, Marshall SD, Crilly H, et al. Australian and New Zealand Anaesthetic Allergy Group/Australian and New Zealand College of Anaesthetists perioperative anaphylaxis management guidelines. *Anaesth Intensive Care*. 2017;45:151–158.

anesthetics increases as early as the second trimester of pregnancy and may be related to an increase in estrogen.[114,116] However, these studies were performed before the recognition of the importance of intact vascular endothelium in the *in vitro* assessment of vascular tone.

The exact mechanism by which high concentrations of local anesthetics cause uterine artery vasoconstriction (while causing dilation in other vascular beds) is unclear. This vasoconstriction may result from modulation of calcium-channel regulation because verapamil and nifedipine ablate the response.[120] Alternatively, local anesthetics may affect cyclic nucleotides and alter the ionic content and contractility of uterine vascular smooth muscle.[121] Clinical experience with the use of local anesthetics supports the view that clinical concentrations of these drugs do not adversely affect the uterine vasculature (see Chapter 3).[122,123]

All local anesthetics can reduce uterine blood flow at plasma concentrations that greatly exceed those occurring during the routine practice of obstetric anesthesia.[116] There has been an added concern that the levorotary isomers of local anesthetics, which produce vasoconstriction at clinical doses,[124] may reduce uteroplacental perfusion and adversely affect fetal well-being. It is reassuring to note that ropivacaine, even at plasma concentrations that are almost two times greater than would be expected to occur during clinical use, does not reduce uterine blood flow or affect fetal heart rate (FHR), blood pressure, or acid-base measurements in pregnant sheep.[117] In humans, Doppler velocimetry studies have shown that ropivacaine has little effect on the uteroplacental or fetal circulation when it is administered to provide epidural anesthesia for cesarean delivery.[122] Similarly, clinically relevant plasma concentrations of levobupivacaine had no adverse effect on uterine blood flow.[117]

Umbilical Blood Flow

Fetal well-being also depends on the adequacy of fetal perfusion of the placenta. The regulatory mechanisms that control flow through the umbilical vessels are poorly understood. Lidocaine does not affect spiral strips obtained from human umbilical artery segments at concentrations up to 5 μg/mL, but it produces relaxation in concentrations from 30 to 900 μg/mL.[125] Bupivacaine also does not constrict umbilical artery segments at clinically relevant concentrations of 0.3 and 1 μg/mL.[125] At higher concentrations, the effect of bupivacaine appears to be biphasic. Constriction occurs at concentrations of 5 to 25 μg/mL, and relaxation occurs at concentrations greater than 125 μg/mL.[125,126] Hypercarbia but not hypoxemia lessens the contractile response of umbilical vessels to bupivacaine *in vitro*.[127]

Decreases in umbilical blood flow of as much as 43% accompany intravenous administration of lidocaine 4 mg/kg in pregnant sheep.[128] However, plasma concentrations of the drug were higher than would be expected with clinical use, and all ewes exhibited signs of CNS toxicity, which may reduce umbilical blood flow itself.

Advances in noninvasive Doppler imaging have facilitated clinical assessment of umbilical cord blood flow velocity. The ratio of the systolic (S) peak to the diastolic (D) trough of the umbilical artery waveform is used as a measure of vascular resistance. The S/D ratio in the umbilical artery decreases during normal pregnancy, and high ratios usually are associated with fetal compromise (see Chapter 6). Local anesthetics administered for epidural anesthesia do not adversely affect the umbilical artery S/D ratio.[129,130] In fact, labor epidural

analgesia with 1.5% lidocaine or 2% 2-chloroprocaine resulted in a decrease in the S/D ratio.[129,130] This favorable change may have resulted from pain relief. Other investigators have noted no appreciable change or a slight decrease in the S/D ratio after the epidural administration of amide local anesthetics for elective cesarean delivery.[122,123,131]

Uterine Tone and Contractility

Changes in uterine tone and contractility may affect uteroplacental perfusion. Local anesthetics exert direct effects on uterine smooth muscle. One study reported that exposure to high concentrations of local anesthetic *in vitro* led to contraction of human myometrial segments obtained at the time of cesarean delivery.[132] These findings have been corroborated in laboratory animals.[133] Further, Belitzky et al.[134] observed that direct intramyometrial injection of 1% procaine resulted in uterine hyperstimulation and fetal compromise in pregnant women. In all of these reports, the myometrium was exposed to higher than normal concentrations of the drug. In other studies, however, intravenous infusion of lidocaine or bupivacaine that resulted in clinically relevant plasma concentrations did not affect uterine tone or uterine activity in pregnant ewes.[117,119] In a study using electrohysterogram monitoring, levobupivacaine caused less uterine muscle relaxation after intramyometrial injection in rats than did bupivacaine.[135]

Drug Interactions with 2-Chloroprocaine and Lidocaine

Epidural 2-chloroprocaine may affect the efficacy of other drugs administered in the neuraxis. Previous administration of 2-chloroprocaine (even a test dose) has been observed to reduce the quality and duration of analgesia produced by subsequent epidural injection of morphine or fentanyl.[136,137] Several hypotheses have been proposed for this antagonism. The low pH of the 2-chloroprocaine solution may result in acidification of the epidural space and thus may favor formation of the poorly diffusible, charged form of the opioid. Second, it has been suggested that 2-chloroprocaine (or its metabolite, chloroaminobenzoic acid) may act as a specific μ-opioid receptor antagonist because a κ-opioid receptor agonist (e.g., butorphanol) is not antagonized by 2-chloroprocaine.[136] However, using an *in vitro* hippocampal slice model, Coda et al.[138] concluded that 2-chloroprocaine opioid antagonism did not appear to act through a μ-opioid receptor. Third, and most likely, a "window" may be caused by the rapid regression of 2-chloroprocaine before the onset of analgesia with epidural morphine.

2-Chloroprocaine also reduces the subsequent efficacy of bupivacaine.[139] Corke et al.[140] suggested that chloroaminobenzoic acid is responsible for this effect. Administration of buffered 2-chloroprocaine does not prevent the antagonism of epidural bupivacaine.[141]

The use of neuraxial opioids alone or in combination with local anesthetics has become ubiquitous in obstetric anesthesia for enhancing analgesia during labor or for providing effective pain relief after cesarean delivery. Lidocaine is a frequently used drug for epidural anesthesia during cesarean delivery. In one study,[142] epidural administration of 20 to 35 mL of 2% lidocaine with fentanyl 1 hour before administration of extended-release epidural morphine (EREM) increased the peak plasma concentration (C_{max}) of morphine compared with the peak concentration in women who received a combined spinal-epidural (CSE) technique (intrathecal bupivacaine and fentanyl) with no prior epidural medication (see Chapter 27).

Potency of Bupivacaine, Ropivacaine, and Levobupivacaine

The levorotary compounds ropivacaine and levobupivacaine were developed because of the concerns about the safety of high doses of bupivacaine. Many studies have addressed the question of relative potency among the three drugs. Ropivacaine is approximately 10 times less lipid soluble (*N*-heptane/buffer) than bupivacaine, a difference that is important for two reasons.[2] First, ropivacaine may penetrate more slowly into the large, heavily myelinated motor neurons, resulting in less motor block than occurs with bupivacaine. Second, the issue raises questions as to whether ropivacaine is equipotent to bupivacaine. Indeed, a higher dose of ropivacaine is required to produce a sensory and motor block comparable with that produced by bupivacaine after spinal injection.[143,144] Similarly, the EC_{50} (the local anesthetic concentration at which 50% of women have pain relief, also known as the minimum local anesthetic concentration [MLAC]) of epidural ropivacaine is almost twice as great as that of epidural bupivacaine in laboring women.[58] Critics of the use of EC_{50} data to compare potency argue that it provides no information on the shape and slope of the dose-effect relationship, which can vary with drug concentration, and further, that it provides no information on the effective clinical dose (ED_{95} [effective dose in 95% of cases]).[145]

Studies of the EC_{50} of epidural levobupivacaine are conflicting; one study found that levobupivacaine was essentially equipotent to bupivacaine,[69] whereas others suggest that ropivacaine and levobupivacaine have similar potency.[146,147] Levobupivacaine may have a greater motor-sparing effect than bupivacaine when given for the initial intrathecal injection.[148]

In obstetric anesthesia practice, the clinical effects of epidural levobupivacaine and ropivacaine are indistinguishable from those of epidural bupivacaine for labor analgesia.[149] The choice of bupivacaine, levobupivacaine, or ropivacaine does not affect the method of delivery or neonatal condition.[149] For cesarean delivery, epidural levobupivacaine 0.5% is virtually identical to epidural bupivacaine 0.5%.[150] The levorotary isomers (ropivacaine and levobupivacaine) may provide a greater margin of safety when large volumes of a concentrated solution of local anesthetic are required (e.g., epidural anesthesia for cesarean delivery). However, there may be little advantage to using levobupivacaine or ropivacaine when dilute solutions are used for epidural labor analgesia or when a small dose is used for spinal anesthesia.

Placental Transfer

Most drugs, including local anesthetics, cross the placenta. The factors that influence the placental transfer of a

drug include (1) the physicochemical characteristics of the drug, (2) the concentration of free drug in the maternal blood, (3) the permeability of the placenta, and (4) the hemodynamic events occurring within the fetal-maternal unit (see Chapter 4).

Local anesthetics cross placental membranes by a process of simple (i.e., passive) diffusion. The rate of transfer of a particular drug is described by the Fick equation, as follows:

$$\frac{Q}{t} = \frac{K \times A(C_m - C_f)}{D}$$

where Q/t is the rate of diffusion; K is the diffusion constant for the drug; A is the surface area available for transfer; C_m is the free drug concentration in the maternal blood; C_f is the free drug concentration in the fetal blood; and D is the thickness of the trophoblastic epithelium. In general, K is affected by molecular size, lipid solubility, and degree of ionization.

Molecular Size

Compounds with a molecular weight of less than 500 Da cross the placenta easily, whereas drugs like digoxin, which have a molecular weight higher than 500 Da, have a slower rate of diffusion. Molecular weights of local anesthetics range from 234 to 288 Da (see Table 13.1). These small differences in molecular weight should not affect the rate of placental transfer because the diffusion constant (K) is inversely proportional to the square root of the molecular weight.[151]

Ionization and Lipid Solubility

Local anesthetics are weak bases; they have a relatively low degree of ionization and considerable lipid solubility at physiologic pH. The basic un-ionized local anesthetic molecule is more lipid soluble than the ionized moiety and determines placental transfer in a protein-free perfusate.[152]

The relationship between pH and pK_a may affect drug accumulation in the fetus. For the amide local anesthetics, pK_a values are close enough to physiologic pH that changes in fetal pH may alter the balance between ionized and un-ionized drug. In the acidotic fetus, a greater proportion of drug in the ionized form results in a larger total amount of local anesthetic in fetal plasma, because of "ion trapping" (Fig. 13.4).[153–155] Elimination of lidocaine from fetal blood is slower in the asphyxiated fetus than in the nonasphyxiated fetus.[128] Accumulation of lidocaine may be greater in fetal tissues, where the pH is even lower than that in fetal blood.[155]

Protein Binding

Perhaps most confusing and least understood are the effects of protein binding on placental transfer. Amide local anesthetics are bound to AAG and to a lesser extent to albumin.[19] The extent of protein binding varies among the local anesthetic agents (see Table 13.1). For a given local anesthetic, the proportion of free drug increases as blood concentration increases because of the saturation of binding sites. Binding of local anesthetics in the fetal plasma is approximately half that in the mother.[88,89]

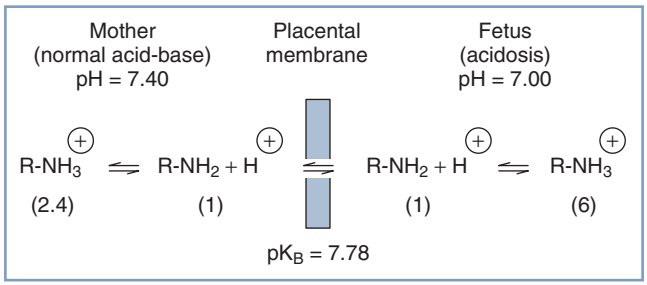

Fig. 13.4 "Ion trapping" of a local anesthetic. The numbers in parentheses represent relative numbers of molecules. (From the American College of Obstetricians and Gynecologists. *Obstet Gynecol.* 1976; 48:29.)

The fetal-to-maternal (F/M) blood concentration ratios of amide local anesthetic agents are listed in Table 13.1. The lower F/M blood concentration ratios of highly protein-bound drugs (e.g., bupivacaine) have been attributed to their more restricted placental transfer compared with less protein-bound drugs (e.g., lidocaine). Indeed, the rate of bupivacaine transfer across rabbit placenta perfused *in situ* is lower than that of lidocaine transfer.[156,157] Some investigators have suggested that protein binding in the maternal plasma should not affect the diffusion of drugs across the placenta because the dissociation from plasma proteins is essentially instantaneous.[151,158] In subsequent studies, the relatively low umbilical vein–to–maternal vein blood concentration ratio for bupivacaine has been attributed to differences in protein binding between maternal plasma and fetal plasma (Fig. 13.5).[88,89,159,160] Let us assume that the total concentration of lidocaine or bupivacaine in the maternal plasma is 2 mg/L. Lidocaine and bupivacaine are approximately 50% and 90% bound to maternal plasma proteins, respectively. Thus, the free concentrations of drug available for placental transfer are 1.0 and 0.2 mg/L, respectively. At equilibrium, the concentration of free drug is equal on the two sides of the placenta. In the fetus, however, lidocaine and bupivacaine are approximately 25% and 50% bound to fetal plasma proteins, respectively. Thus, the total lidocaine concentration in fetal plasma is 1.33 mg/L, resulting in an F/M ratio of 0.67; for bupivacaine, the corresponding values are 0.4 mg/L and 0.2.

In fact, accumulation of bupivacaine occurs in human fetuses whose mothers received the drug for epidural anesthesia.[24] After delivery, measurable plasma and urine concentrations persisted for as long as 3 days.[24] *In vitro* studies using a perfused human placental model have found that the placental transfer of ropivacaine is similar to that of bupivacaine.[161] Intravenous infusion of ropivacaine or bupivacaine to pregnant sheep results in steady-state maternal plasma concentrations of 1.5 to 1.6 μg/mL and fetal concentrations of approximately 0.28 μg/mL.[117] Tissue concentrations of ropivacaine in fetal heart, brain, liver, lung, kidneys, and adrenal glands were similar to those of bupivacaine.[117] Datta et al.[30] noted that the free fraction of ropivacaine at delivery was approximately twice that of bupivacaine in neonates whose mothers received the drug for epidural anesthesia during labor or cesarean delivery.

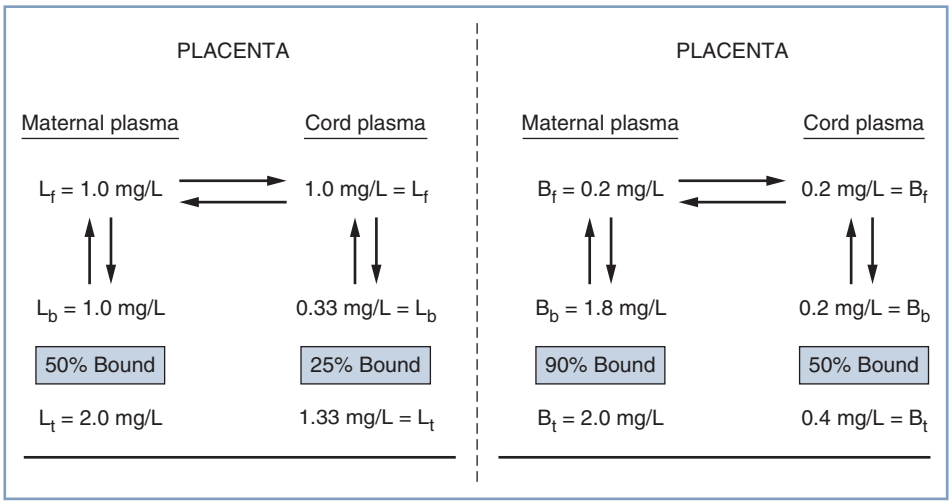

Fig. 13.5 Demonstration of how distribution of local anesthetics across the placenta may be predicted from differences in drug protein binding in maternal and fetal plasma. *Left,* lidocaine *(L); f, b, t,* free, bound, and total drug concentrations, respectively. *Right,* bupivacaine *(B).* Lidocaine umbilical cord–to–maternal plasma ratio (F/M) = 0.67; bupivacaine F/M = 0.20. (From Mather LE, Tucker GT. Properties, absorption, and disposition of local anesthetic agents. In Cousins MJ, Carr DB, Horlocker TT, Bridenbaugh PO [eds.]: *Neural Blockade in Clinical Anesthesia and Management of Pain.* 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:85.)

Maternal Blood Concentration of Drug

The maternal blood concentration of local anesthetic is determined by (1) the dose, (2) the site of administration, (3) metabolism and excretion, and (4) the effects of adjuvants such as epinephrine (see later discussion). For a given local anesthetic, the maternal blood concentration determines fetal drug exposure and is the only variable of the Fick equation that may be influenced by the clinician.

Dose. In general, higher doses result in higher maternal and fetal blood concentrations. For example, Kuhnert et al.[17] found that doubling the mean (± SD) dose of epidural lidocaine from 300 ± 195 mg to 595 ± 127 mg almost doubled the concentration in umbilical cord blood. The elimination half-life of amide local anesthetics is relatively long; thus, repeated epidural injection or continuous infusion of the drug may lead to accumulation in the maternal plasma. This does not apply to 2-chloroprocaine, however, which is rapidly hydrolyzed by pseudocholinesterase.[11]

Site of administration. The rates of absorption and peak plasma concentrations depend on the vascularity at the site of administration. The peak plasma concentration of lidocaine is achieved within 9 to 10 minutes after paracervical block.[162] In contrast, absorption from the lumbar epidural space, which is less vascular, occurs at a slower rate; the peak plasma concentration is not achieved until 25 to 40 minutes after administration.[17] Injection of local anesthetic into the caudal rather than the lumbar epidural space may result in higher blood levels because of the need for a higher drug volume to provide comparable anesthesia to that provided by lumbar epidural injection.[163]

The transversus abdominis plane (TAP) block is sometimes used for postcesarean delivery analgesia. In a study of TAP block with bupivacaine 100 mg (50 mg on each side), plasma levels of drug reached the low toxic range in 3 of 17 parturients.[164] No women exhibited signs or symptoms of LAST.[164]

In the past, it was thought that subarachnoid administration of a local anesthetic resulted in less systemic absorption than epidural administration. However, peak blood concentrations of lidocaine have been reported to be similar after subarachnoid and epidural administration.[165] In another study, subarachnoid administration of lidocaine 75 mg for cesarean delivery resulted in low but measurable fetal plasma concentrations of the drug.[16]

Placenta. Maturation of the placenta may affect the rate of drug transfer. In pregnant mice, diazepam and its metabolites cross the placenta more rapidly in late pregnancy.[166] Uptake and metabolism of drugs by the placenta would be expected to reduce transfer to the fetus. However, placental drug uptake of local anesthetics is limited, and it is unlikely that this organ metabolizes the amide local anesthetic agents.[167] The same may not be true for the ester local anesthetics. For example, cocaine is biotransformed when it is incubated with human placental microsomal fraction, presumably because of cholinesterase activity within the placenta.[168] Placental metabolism of para-aminobenzoic acid also has been demonstrated.[169]

Teratogenicity

The teratogenicity of local anesthetics is not an issue during parturition, but local anesthetics often are used for procedures during the first trimester of pregnancy (see Chapter 17). *In vitro* studies have suggested that local anesthetics may have some adverse developmental effects. Even at low concentrations, these agents have caused reversible reduction of cell division in tissue culture.[170–175] However, structural anomalies

have not been observed in intact animals.[176–178] Mid-pregnancy administration of lidocaine or mepivacaine in rats has been associated with behavioral changes in the offspring.[179,180]

Extrapolation of laboratory findings to humans is tenuous for several reasons. First, a drug may be teratogenic in one species but not in others. Second, a 1-hour drug exposure in a pregnant rat (with a gestation of 21 days) is excessive and not analogous to several hours of clinical anesthesia during human pregnancy. Third, the doses of local anesthetics used in animal studies greatly exceed those administered for clinical anesthesia. Indeed, a large, multicenter study demonstrated that the risk for congenital anomalies in humans was not increased by the administration of benzocaine, procaine, tetracaine, or lidocaine during early pregnancy.[181] However, a twofold increase in the incidence of congenital anomalies was noted in infants whose mothers had received mepivacaine. The small number of patients who received mepivacaine in this study ($n = 82$) and the fact that no adverse effects occurred with the use of other amide agents have raised doubts about the validity of this observation.[182]

Fetal and Neonatal Effects

Pharmacokinetics

Local anesthetics, once transferred across the placenta, are distributed in the fetus. Factors that influence tissue uptake of the drug include (1) fetal plasma protein binding, (2) lipid solubility, (3) the degree of ionization of the drug, and (4) hemodynamic changes that affect the distribution of fetal cardiac output. Fetal plasma protein-binding capacity of local anesthetics is approximately 50% that of maternal plasma.[88,89,183] Thus, there is greater availability of free drug in the fetus than in the mother.[88,89,183–185] Studies have examined the distribution of lidocaine in fetal tissues after an intravenous injection of the drug to animals.[18,186] The higher concentration of lidocaine in the liver, myocardium, and brain (compared with other fetal tissues) reflects rapid distribution of the drug to highly perfused tissues. Only the liver had lidocaine concentrations that exceeded those in the mother. This finding is not surprising, given the high lipid content of the fetal liver and the fact that it receives most of the blood returning from the placenta by means of the umbilical vein.[186] Fetal asphyxia results in adaptations that increase blood flow to vital organs (e.g., brain, heart, adrenal glands).[187] The concentration of lidocaine in these organs is higher in asphyxiated fetuses than in healthy fetuses.[155,187]

Any drug that reaches the fetus undergoes metabolism and excretion. The term newborn has the hepatic enzymes necessary to metabolize local anesthetics.[16,17,188–190] Nonetheless, the elimination half-life of these drugs is longer in the neonate than in the adult.[189,190] The use of mepivacaine in obstetric epidural analgesia fell into disfavor after a report indicating that the elimination half-life of the drug in the neonate was approximately 9 hours, or three times as long as the neonatal half-life for lidocaine.[191] It is ironic that the neonatal elimination half-life for bupivacaine may be as long as 14 hours.[192] In contrast, a study suggested that lidocaine had greater placental transfer in term pregnant women having epidural analgesia for labor than the bupivacaine enantiomers.[193] The study is difficult to interpret because single time-point concentrations of drugs were compared in the maternal vein and the umbilical artery and vein; the F/M ratio may reflect the difference in plasma protein binding between the mother and the fetus and not placental drug transfer.[89,90,160,161]

Morishima et al.[190] compared the pharmacokinetics of lidocaine among adult ewes and fetal and neonatal lambs. The metabolic (hepatic) clearance in the lambs was similar to that in adults, but renal clearance was greater in adults. Nonetheless, the elimination half-life was prolonged in the lambs. This latter finding has been attributed to a greater volume of distribution in the neonatal lamb. Thus, at any given time, a smaller fraction of lidocaine accumulated in the body is available for clearance by hepatic metabolism. The greater renal clearance noted in neonates is a result of decreased protein binding, which increases the proportion of drug available for excretion.

The elimination half-life of local anesthetics in the fetus is similar to that in the adult because, unlike the newborn, the fetus can excrete drug across the placenta back to the mother.[88,190] With bupivacaine, this transfer may occur even though the total plasma drug concentration in the mother may exceed that in the fetus.[88]

Systemic Toxicity

In general, the neonate is more sensitive than the adult to the depressant effects of drugs. However, the seizure threshold for local anesthetics in the neonate appears to be similar to that in the adult. Morishima et al.[194] compared the relative CNS toxicity and cardiovascular toxicity of lidocaine in adult ewes and fetal and neonatal lambs. Greater doses (when calculated on a milligram-per-kilogram basis) were required to elicit toxic manifestations in the fetus and neonatal lamb than in the adult. However, the plasma concentrations of the drug associated with toxic manifestations were similar in the three groups of animals. The greater dose tolerated by fetuses than by neonates and adults was attributed to placental clearance of drug back to the mother and better maintenance of blood gas tensions during convulsions. In the neonate, a large volume of distribution is most likely responsible for the high doses of local anesthetic required for fetal toxicity.

Studies of bupivacaine cardiotoxicity are inconsistent. *In vitro,* the sinoatrial node of neonatal guinea pigs was found to be more sensitive than that of adults to the cardiodepressant effect of bupivacaine.[195] In contrast, 2-day-old piglets demonstrated greater resistance than older animals to the arrhythmogenic and CNS effects of bupivacaine.[196]

Fetal Heart Rate

Changes in FHR after administration of local anesthetics are most often related to indirect effects such as maternal hypotension and uterine tachysystole (see Chapter 23). Local anesthetics probably have little direct effect on FHR, except perhaps after paracervical block. Rather, labor itself may be the single most important factor that alters FHR patterns.[197] Transient changes in FHR variability and an increase in the

incidence of periodic decelerations have been observed during neuraxial analgesia in laboring women.[198,199] In contrast, in the absence of labor, FHR patterns are not affected even by the larger doses of local anesthetics required during epidural anesthesia for cesarean delivery.[197] The FHR changes noted in laboring women were transient and did not affect the condition of the newborns.[198,199] Further, Becker et al.[200] found no significant difference in the number or type of fetal electrocardiographic ST-segment changes (ST-waveform analysis [STAN] events) in women with a high-risk singleton gestation who received epidural analgesia for labor compared with a control group of women who did not receive epidural analgesia.

Neurobehavioral Tests

Many neurobehavioral tests have been developed to detect subtle changes in organized behavior in the newborn. However, these tests are not reliable because they are subjective and lack specificity.[201] Other perinatal factors appear to have a more important effect on neonatal test performance than the choice of local anesthetic.[202]

Preterm Fetus and Newborn

It has become axiomatic that the preterm infant is more vulnerable than the term infant to the effects of analgesic and anesthetic drugs. Causes of enhanced drug sensitivity in the preterm newborn that have been postulated are as follows: (1) less protein is available for drug binding, (2) higher levels of bilirubin are present and may compete with the drug for protein binding, (3) greater access of the drug to the CNS occurs because of a poorly developed blood-brain barrier, (4) the preterm infant has greater total body water and less fat content, and (5) the preterm infant has a diminished ability to metabolize and excrete drugs. Unfortunately, few systematic studies have determined the maternal and fetal pharmacokinetics and pharmacodynamics of drugs throughout gestation; nevertheless, these deficiencies of the preterm infant may not be as serious as we have been led to believe. Although the plasma albumin and AAG concentrations are lower in the preterm fetus, these factors primarily affect drugs that are highly bound to these proteins. Most local anesthetics, however, exhibit only low to moderate degrees of binding in fetal plasma.[88,89]

The placenta efficiently eliminates fetal bilirubin. Thus, the hyperbilirubinemia of prematurity normally occurs in the postpartum period. Bupivacaine has been implicated as a possible cause of neonatal jaundice.[203,204] High affinity of the drug for fetal erythrocyte membranes may lead to a decrease in filterability and deformability, which may render red blood cells more prone to hemolysis.[204] However, increased bilirubin production has not been demonstrated in newborns whose mothers received bupivacaine for epidural anesthesia during labor and cesarean delivery.[205,206]

Greater total body water in the preterm fetus results in a larger volume of distribution for drugs. Thus, to achieve equal blood concentrations, the immature fetus must receive a greater amount of drug transplacentally than the mature fetus.

The diminished ability to metabolize or excrete drugs associated with prematurity is certainly not a universal phenomenon. One study of the pharmacokinetics of lidocaine in preterm newborns noted that plasma clearance was similar to that in adults.[189]

During anesthesia for preterm labor, concerns about drug effects on the newborn are far less important than the prevention of asphyxia and trauma to the fetus. Indeed, healthy preterm fetal lambs tolerated clinically relevant plasma concentrations of lidocaine (e.g., approximately 1.5 μg/mL) as well as mature ones.[18,207]

Asphyxia

Circulatory adaptations important for fetal survival during asphyxia result in increased blood flow and oxygen delivery to vital organs (e.g., heart, brain, adrenal glands).[187] Little information exists about the effects of local anesthetics on these fetal responses. Adaptation to asphyxia was unaffected in mature fetal lambs exposed to lidocaine.[187] In contrast, lidocaine adversely affected asphyxiated preterm fetal lambs, which experienced a further deterioration of acid-base status and a reduction in cardiac output and blood flow to the brain and heart (Fig. 13.6).[208] Also in asphyxiated preterm fetal lambs, exposure to bupivacaine reduced blood flow to vital organs; however, FHR, blood pressure, and acid-base measurements did not change.[209]

After performing an *in vitro* study using perfused human placentas, Johnson et al.[210] suggested that bupivacaine might be preferable to lidocaine in the presence of fetal acidosis because the greater maternal protein binding of bupivacaine may limit its placental transfer. However, this methodology does not consider the potential for greater fetal tissue uptake of bupivacaine (than of lidocaine) because it is more lipid soluble and more protein bound than lidocaine.

In 1997, Santos et al.[209] reported that the effects of bupivacaine appeared less severe than those of lidocaine in asphyxiated preterm fetal lambs. However, the lidocaine data were generated in a separate experiment reported in 1989.[208] There are inherent limitations in a historical comparison of two studies performed 8 years apart. Further, it is unclear whether these findings are applicable to humans because both lidocaine and bupivacaine have enjoyed a long history of safe use in obstetric anesthesia practice; prospective clinical studies are required before one drug can be recommended over the other in the setting of fetal asphyxia.

OPIOIDS

Neuraxial opioid administration is unique in that it produces analgesia without loss of sensation or proprioception. Opioids are often co-administered with local anesthetic agents during intrapartum administration of neuraxial analgesia and anesthesia.

The term *opioid* refers to a series of compounds that are related to opium. These compounds may be classified as follows: (1) naturally occurring (e.g., morphine), (2) semisynthetic compounds (e.g., dihydromorphone), and (3)

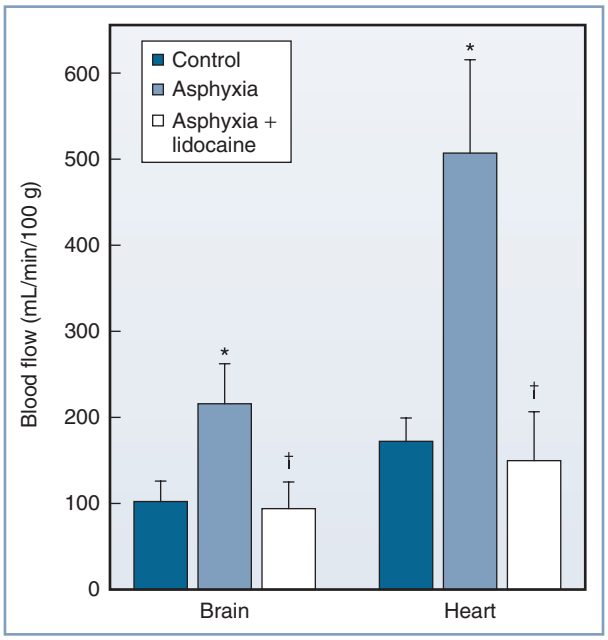

Fig. 13.6 Blood flow to the brain and heart in the preterm fetal lamb before and during asphyxia and during exposure to lidocaine while asphyxiated (mean ± SEM). *Significantly different from control. †Significantly different from asphyxia. synthetic compounds (e.g., fentanyl) (Box 13.4). The only three naturally occurring opioids of clinical significance are morphine, codeine, and papaverine. These substances can be obtained from the poppy plant known botanically as *Papaver somniferum*. Development of synthetic drugs with morphine-like properties has led to development of the broad term *opioid*. These substances bind to several subpopulations of opioid receptors with resulting morphine-like effects. More than 30 years ago, identification of a dense concentration of opioid receptors in the dorsal horn of the spinal cord led to the use of neuraxial opioids as important adjuncts in obstetric anesthesia.

Opioid Receptors

Three broad opioid receptor systems have been identified: μ (mu: MOR), δ (delta: DOR), and κ (kappa: KOR) receptors.[211] Although there is a fourth receptor system,[212] the opiate receptor–like protein (ORL_1 or NOP), its role in pain modulation is not well characterized.[211] Each opioid receptor is encoded by a different gene and mediates different physiologic effects (Table 13.3). Although all these receptors may be involved with pain processing, the μ or κ receptors have the most important clinical pharmacologic effects.

Common pharmacologic effects (e.g., analgesia, respiratory depression) of morphine are mediated by μ-opioid receptors. Widely distributed throughout the brain and spinal cord, the μ, δ, and κ receptors are also present in a wide variety of peripheral tissues, including vascular, cardiac, airway/lung, and the gut. Opioids also act at several receptor sites with different affinities. Morphine has the greatest affinity for μ receptors and has less affinity for δ and κ receptors. However, morphine also has effects at δ and κ receptors when higher doses are administered. Responsible for analgesic, sedative, dysphoric, and diuretic effects,[211] δ and κ receptors are located both within the CNS and peripherally.[213] Peripheral κ agonists have been shown to modulate visceral pain, particularly in conditions that involve inflammation.[213]

The δ receptor is responsible for mediating some of the analgesic effects of the endogenous opioids (e.g., enkephalins, prodynorphan, pro-opiomelanocortin, pro-orphanin, endomorphins) in the spinal cord.[214] Few of the opioids have effects at the δ receptor in clinically relevant doses, but if a δ receptor agonist drug is administered in high doses (e.g., for treatment of pain in an opioid-tolerant patient), the drug may be less μ-receptor selective and produce δ-receptor effects.

Since their discovery, opioid receptors and their signaling continues to be an area of great research interest with potential development of better opioid analgesics with less risk for tolerance and addiction.

Molecular Structure

Naturally occurring opioids of significance can be divided into two distinct chemical classes, phenanthrenes (e.g., morphine) and benzylisoquinolines (e.g., papaverine, codeine) (Fig. 13.7). The phenanthrenes are five-ring structures, and the benzylisoquinolines are three-ring structures. The semisynthetic opioids are morphine derivatives that have undergone relatively simple modifications of the morphine molecule. However, these modifications can produce profound alterations in the pharmacologic activity of the opioid. For example, substitution of an ester for the hydroxyl group on carbon 6 of morphine results in hydromorphone (Fig. 13.8). Synthetic opioids can be classified into the following four groups: (1) morphinan derivatives (e.g., levorphanol),

BOX 13.4 Classification of Opioid Compounds

Naturally Occurring Compounds
- Morphine
- Codeine
- Papaverine
- Thebaine

Semisynthetic Compounds
- Heroin (diamorphine)
- Dihydromorphone
- Thebaine derivatives (e.g., etorphine, buprenorphine)

Synthetic Compounds
- Morphinan series (e.g., levorphanol, butorphanol)
- Diphenylpropylamine series (e.g., methadone)
- Benzomorphan series (e.g., pentazocine)
- Phenylpiperidine series (e.g., meperidine, fentanyl, sufentanil, alfentanil, remifentanil)

TABLE 13.3 Subtypes of Opioid Receptors

Receptor Type	Physiologic Response	Receptor Agonist
Mu (μ)	Analgesia Miosis Bradycardia Sedation Respiratory depression Decreased gastrointestinal transit	Morphine Fentanyl Sufentanil Meperidine
Kappa (κ)	Analgesia Sedation Respiratory depression Diuresis Psychotomimesis	Buprenorphine Pentazocine
Delta (δ)	Analgesia	Prodynorphin Endomorphins Enkephalins

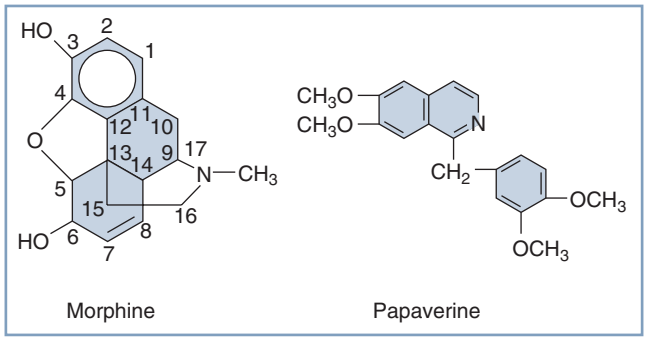

Fig. 13.7 Naturally occurring opioids: phenanthrenes (e.g., morphine) and benzylisoquinolines (e.g., papaverine).

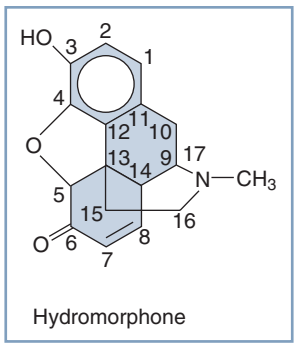

Fig. 13.8 Semisynthetic opioids are morphine derivatives. For example, substitution of an ester for the hydroxyl group on carbon 6 of morphine results in hydromorphone.

(2) diphenyl or methadone derivatives (e.g., methadone, D-propoxyphene), (3) benzomorphan derivatives (phenazocine, pentazocine), and (4) phenylpiperidines (e.g., meperidine, fentanyl, alfentanil, sufentanil, remifentanil).

Morphine is the prototypical opioid with a five-ring structure that conforms to a *T* shape.[215] Three of the rings lie in one plane, and the other two rings are perpendicular to the plane (Fig. 13.9). Although the analgesic activity of the opioid depends on its stereochemical structure,[216] the levorotary isomer is usually the only isomer capable of producing

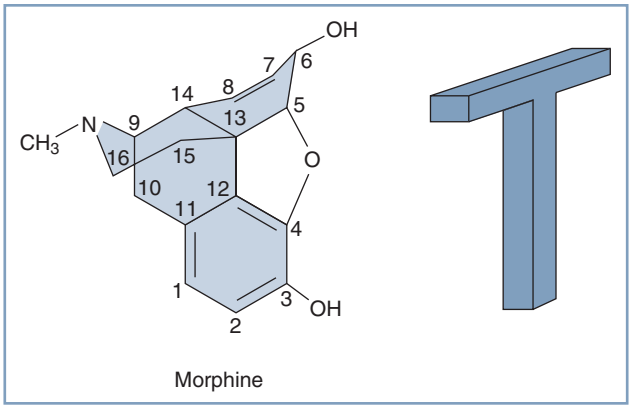

Fig. 13.9 The *T*-shaped molecule of morphine.

analgesia. Morphine demonstrates several other characteristics that are common to other opioids: (1) a tertiary, positively charged basic nitrogen; (2) a quaternary carbon that is separated from the basic nitrogen by an ethane chain and attached to a phenyl group; (3) a phenolic hydroxyl group (morphine derivatives) or a ketone group (meperidine); and (4) the presence of an aromatic ring.[215]

A phenylpiperidine structure (i.e., an aromatic ring attached to a six-member ring containing five carbons and one nitrogen) is also part of the morphine molecule and is present in some other opioids (e.g., fentanyl) (Fig. 13.10).[215] Phenylalanine and tyrosine moieties are structural elements that are important to all opioids, including endogenous neurotransmitters and modulators.[217,218]

Mechanism of Action

Since first described in 1979,[219] neuraxial opioid administration has become a mainstay in obstetric anesthesia practice. Clinical and laboratory research has focused on the mechanisms of synaptic transmission as well as the study of opioids and neurotransmitters that modulate this transmission.

Pain perception involves a complex series of nociceptive transmissions that begin with stimulation of sensory nerves in the periphery, resulting in generation of action potentials within the spinal cord and synaptic transmission to other supraspinal sites. Intraspinal administration of an opioid exploits the pharmacology of pain-modulating and pain-relieving systems that exist within the spinal cord (see Fig. 20.9). In early studies, Yaksh[220] demonstrated that morphine could produce selective suppression of nociceptive processing without affecting motor function, sympathetic tone, or proprioception when it was administered to the superficial layers of the dorsal horn of the spinal cord. However, when small amounts of opioid were administered to the cortex, the effects on nociceptive processing were negligible. Collectively, this work demonstrated that small doses of opioid can be selectively administered to a receptor site (i.e., spinal cord) and produce profound analgesia. In contrast, systemic administration of a much larger dose of opioid results in activation of multiple central and peripheral receptors to produce analgesia, but with unwanted side effects.

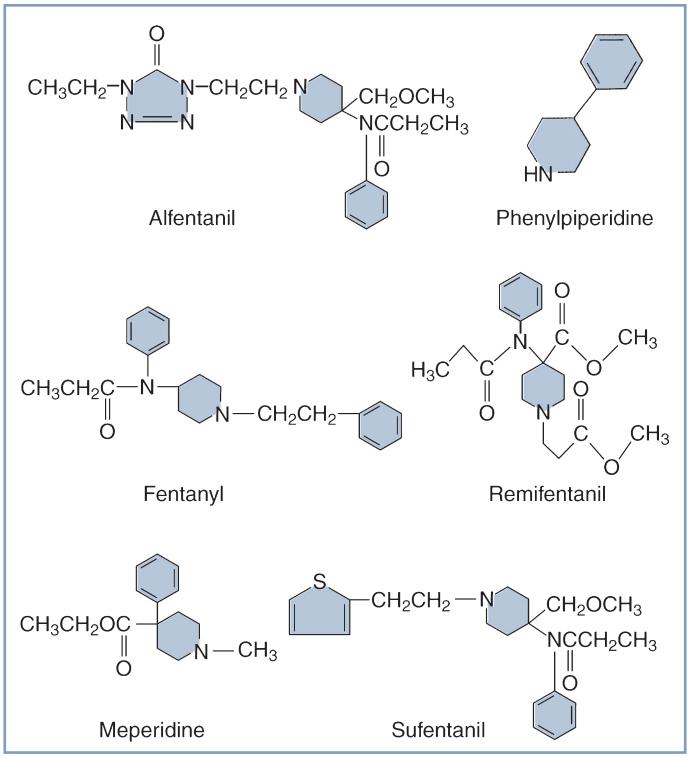

Fig. 13.10 Chemical structures of phenylpiperidine, meperidine, and the 4-anilinopiperidine derivatives fentanyl, sufentanil, alfentanil, and remifentanil.

All opioids produce analgesia by binding to G protein–coupled opioid receptors. Activation of opioid receptors subsequently inhibits both adenylate cyclase and voltage-gated calcium channels. Inhibition of these calcium channels inhibits the release of excitatory afferent neurotransmitters, including glutamate, substance P, and other tachykinins.[211,221] The result is inhibition of ascending nociceptive stimuli from the dorsal horn of the spinal cord.

Opioid receptors are nonuniformly distributed throughout the CNS. Although parenterally administered opioids most likely have both direct spinal and supraspinal effects, neuraxially administered opioids block the transmission of pain-related information by binding at presynaptic and postsynaptic receptor sites in the dorsal horn of the spinal cord (i.e., Rexed laminae I, II, V) (Fig. 13.11). However, the rate and extent of neuraxial analgesia depends largely on the specific drug's physicochemical properties and ability to reach the opioid receptors in the spinal cord.

Pharmacokinetics and Pharmacodynamics

Many of the pharmacologic differences observed among neuraxially administered opioids depend on an opioid's ability to reach opioid receptors. An opioid's physicochemical properties, especially lipophilicity or hydrophilicity, largely determine the bioavailability of neuraxially administered opioids as well as the drug's ability to produce spinally mediated analgesia.

Before G protein–receptor activation can occur, the opioid must undergo a series of complex processes. Although several mechanisms have been proposed to explain the movement of opioids from the epidural space to the spinal cord, studies demonstrate that the only relevant mechanism is diffusion through the spinal meninges.[222,223] The opioid must traverse the dura and arachnoid membranes, diffuse through the CSF, and cross the pia membrane to reach the spinal cord (Fig. 13.12). Once the drug reaches the surface of the spinal cord, it must diffuse through the white matter and then the gray matter to reach the site of action, the dorsal horn.[224] The rate and extent of opioid transfer to receptors largely depend on a drug's physicochemical properties, particularly lipid solubility, because competing processes (e.g., uptake into the epidural fat or systemic circulation) limit the agent's diffusion to opioid receptors. Greater lipid solubility of a drug results in more rapid onset of analgesia. For example, fentanyl is a highly lipid-soluble opioid (i.e., 600 times more lipid soluble

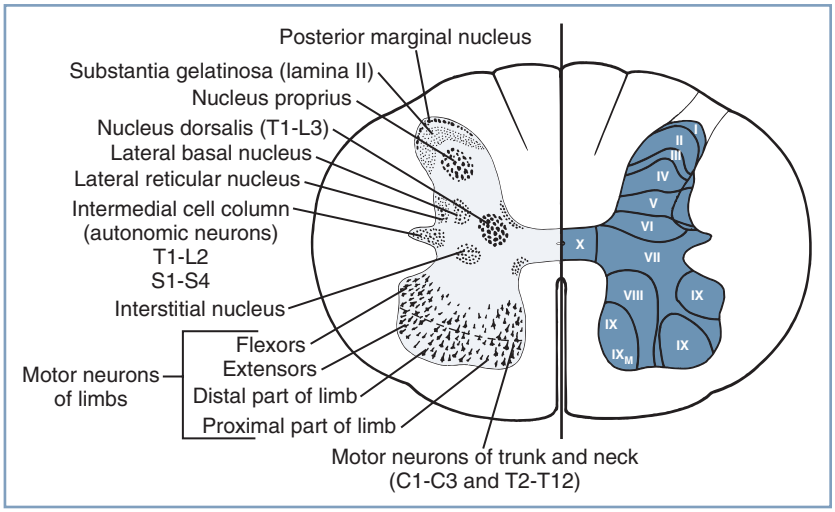

Fig. 13.11 Architecture of the spinal cord, showing the gray matter nuclei *(left)* and Rexed laminae *(right)*. (From Ross BK, Hughes SC. Epidural and spinal narcotic analgesia. *Clin Obstet Gynecol.* 1987;30:552–565.)

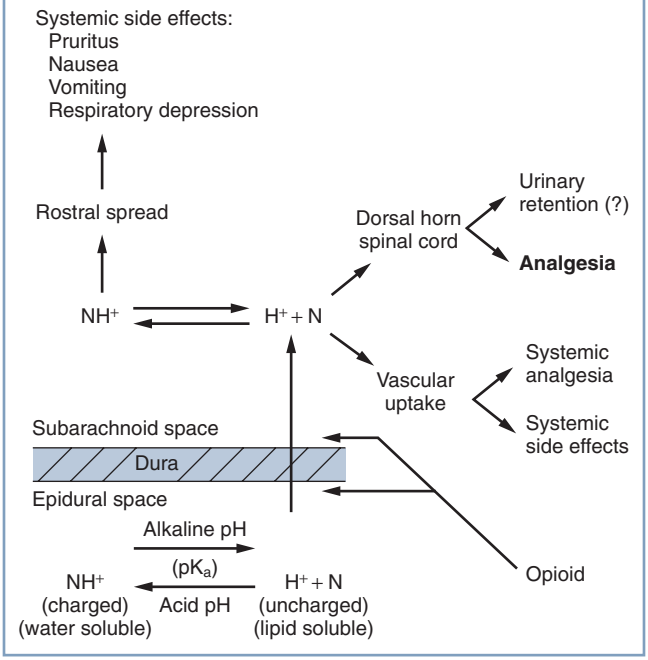

Fig. 13.12 Epidural opioids traverse the dura and arachnoid membranes, diffuse through cerebrospinal fluid, and cross the pia membrane before reaching the spinal cord. Several factors, including physicochemical properties (e.g., pK_a), affect the distribution of opioids within the neuraxis. (From Ross BK, Hughes SC. Epidural and spinal narcotic analgesia. *Clin Obstet Gynecol.* 1987;30:552–565.)

TABLE 13.4 Physicochemical Properties of Opioids Used for Neuraxial Analgesia

Opioid	Lipid Solubility[a]	pK_a	Protein Binding (%)
Morphine	0.70	7.9	35
Hydromorphone	1.28	8.1	19
Meperidine	39	8.5	70
Diamorphine	280	7.8	40
Fentanyl	717	8.4	84
Sufentanil	2842	8.0	93

Is the clinical efficacy of epidural diamorphine concentration-dependent when used as analgesia for labour? *Br J Anaesth*. 2005;94:229–233.

than morphine); therefore, it has a more rapid onset of action than morphine (Table 13.4).

Latency, potency, and duration are also affected by other physicochemical properties, including molecular weight, pK_a, and protein binding. For example, the lower the pK_a, the greater the percentage of opioid existing in uncharged form (i.e., the anionic base) at a pH of 7.4. In the uncharged form, opioids penetrate the dura mater and dorsal horn more easily, resulting in a more rapid onset of analgesia.

The boundaries of the epidural space are the vertebral bodies, ligaments, and spinal meninges. Fat and the epidural venous plexus account for a large volume of the epidural space. The spinal meninges consist of the dura, arachnoid, and pia mater. Of these membranes, the arachnoid is the primary barrier for drug transfer from the epidural space to the spinal cord.[225] The arachnoid mater has multiple layers of overlapping cells that represent both a hydrophilic domain (consisting of extracellular and intracellular fluid) and a hydrophobic domain (the cell membranes).[223] For an opioid to navigate the arachnoid, it must diffuse through both domains before entering the CSF. Therefore, drugs of intermediate hydrophobicity move most readily across the arachnoid. Other physical characteristics of drugs (e.g., molecular weight) do not appear to play an important role in determining redistribution from the epidural space to the subarachnoid space.[223]

The efficacy of a drug also depends on its physicochemical properties, particularly lipid solubility. For example, the amount of drug that is sequestered in the epidural fat is entirely dependent on the drug's octanol-to-buffer distribution coefficient.[226] Consequently, lipophilic drugs (e.g., fentanyl) with a high octanol-to-buffer coefficient may never reach the arachnoid membrane and may partition in epidural fat. This lack of drug transfer across the meninges results in poor CSF bioavailability. Bernards et al.[226] used a porcine model to evaluate the movement of opioids from the epidural to the subarachnoid space. Alfentanil, fentanyl, and sufentanil were administered by bolus injection into the epidural space, and opioid concentrations were continuously sampled and measured over time in the epidural and subarachnoid spaces, and in the systemic venous and epidural plasma, using microdialysis techniques. They found a strong linear relationship between lipid solubility and mean residence time, indicating that more lipid-soluble opioids spend a longer time in the epidural space. Consequently, these drugs partition themselves into the epidural fat with ongoing slow release back into the epidural space. Because of their long residence time in the epidural space, more lipid-soluble drugs are found in lower concentrations in the CSF (i.e., decreased bioavailability to opioid receptors in the dorsal horn).

Several human studies have evaluated whether epidurally administered fentanyl produces analgesia by a selective spinal mechanism or by systemic absorption and redistribution. Results of studies of lipophilic opioids (administered by epidural infusion) have suggested that low concentrations of lipophilic opioids are subject to rapid vascular uptake from the epidural space or sequestration in epidural fat, thereby limiting access to the spinal cord.[227,228] However, the results of other studies have suggested a spinal effect when lipophilic opioids are administered by epidural bolus injection[229] or by epidural infusion of short duration.[230] Ginosar et al.[231] compared the analgesic effects of epidural bolus injection and epidural infusion of fentanyl in human volunteers. Study results suggested that epidural fentanyl infusion produced analgesia by uptake into the systemic circulation with redistribution to brain and

peripheral opioid receptors. However, epidural bolus administration of fentanyl produced analgesia by selective spinal mechanisms.[231] These results were consistent with previous reports that an epidural fentanyl bolus results in a larger amount of fentanyl in the epidural space than occurs at any time during an epidural infusion of clinically relevant doses, leading to the greater availability of drug to activate opioid receptors in the dorsal horn of the spinal cord.

Although hydrophilic drugs (e.g., morphine) are subject to less systemic and epidural fat uptake than lipophilic drugs, the transfer of the former into the CSF is an inefficient process because they have difficulty in crossing the lipid bilayer of the arachnoid. However, despite these inefficiencies, morphine content in the spinal cord is significantly greater than lipophilic drug (e.g., fentanyl) content,[232] and morphine has much greater bioavailability in the spinal cord than do fentanyl and sufentanil.[226,232] Thus, although morphine clearly produces analgesia via a spinal mechanism, the extent of spinal analgesia produced by the neuraxial administration of fentanyl and sufentanil is less clear.

After a drug reaches the subarachnoid space, either by diffusion across the meninges or by direct injection into the CSF, its effects depend on its lipid solubility. All opioids produce at least some analgesia by spinal-specific mechanisms. Movement of these drugs within the CSF depends on their physicochemical properties. Drugs can diffuse within the CSF in either a cephalad or a caudad direction. Both morphine and fentanyl have been shown to move rapidly within the CSF.[233] Lipophilic drugs can also return to the epidural space by traversing previously mentioned structures.

Ummenhofer et al.[232] used a porcine model to investigate intrathecal administration of opioids. These investigators found that lipophilic opioids have a very large volume of distribution compared with hydrophilic drugs; the volume of distribution of sufentanil was 40 times greater than that of morphine. This is caused by sufentanil's extreme lipid solubility, with the drug rapidly leaving the CSF and entering the epidural fat, from where it is absorbed systemically.[234]

The goal of neuraxial opioid administration is for the drug to penetrate the dorsal horn of the spinal cord and activate μ-opioid receptors. A drug's ability to move from the CSF to the dorsal horn depends on its physicochemical properties. Of the clinically relevant opioids, morphine has the most favorable physicochemical properties to allow penetration of the dorsal horn of the spinal cord (i.e., gray matter). Because of its extreme lipid solubility, sufentanil redistributes itself or partitions itself on the superficial layer (i.e., white matter) of the spinal cord.[232] Data suggest that the spinal bioavailability of the hydrophilic drugs (e.g., morphine, hydromorphone) is greater than that of hydrophobic opioids (e.g., fentanyl, sufentanil).

Morphine is a commonly used neuraxial opioid for postcesarean analgesia (Chapter 27). Limited availability of preservative-free morphine has led to investigation of hydromorphone as an alternative agent. The estimated effective intrathecal morphine : hydromorphone dose ratio is 2:1.[235] Because morphine is more hydrophilic than hydromorphone, a shorter duration of analgesia can be expected with hydromorphone. Indeed, a retrospective study in 1020 women undergoing cesarean delivery found that both intrathecal and epidural hydromorphone had a shorter duration of action (defined as time interval from administration to first request for analgesia) than intrathecal and epidural morphine, respectively.[236] The adverse effect profiles of the two drugs were similar.

Extended-release epidural morphine (EREM) was developed to prolong the duration of a single epidural injection of morphine or obviate the need for a continuous catheter. Multivesicular liposomal preparations gradually release morphine so that a larger epidural dose can be administered, providing analgesia for up to 48 hours (see Chapter 27). Studies that compared EREM 10 to 15 mg with conventional epidural morphine for provision of analgesia after cesarean delivery determined that EREM provided superior and prolonged analgesia without increasing the incidence of adverse effects (e.g., nausea, pruritus, sedation, respiratory depression).[237,238] This morphine formulation is no longer available in the United States.

In summary, the onset and duration of analgesia as well as adverse effects produced by neuraxial opioid administration depend on the specific type of opioid receptor that is activated as well as the dose, lipid solubility, and rate of movement and clearance of the opioid in the CSF.

Pharmacogenetics

Pain associated with labor and delivery is influenced by a multitude of physiologic, psychosocial, and environmental factors (see Chapter 20). Among these factors, genetic variability may also contribute to patients' sensation, experience, and perception of pain. In obstetric patients, the μ-opioid receptor gene *(OPRM1)* has been most widely studied, particularly polymorphism at position 118. At this position, a single nucleotide polymorphism (SNP) occurs in some individuals when guanine is substituted for adenosine. The allelic frequency of this variant is population dependent; it is more common in Asians and less frequent in whites and blacks. Although the literature on the genetic influences of pain and opioid responses is extensive, results are inconsistent.[239]

In an early investigation of the role of the A118G variant in neuraxial opioid analgesia, Landau et al.[240] used both up-down sequential allocation and random allocation methods to estimate the ED_{50} of intrathecal fentanyl in nulliparous A118 homozygotes and G118 hetero/homozygotes as part of a CSE technique for labor analgesia. The ED_{50} of intrathecal fentanyl was 1.5- to 2-fold higher in women with the wild-type allele (A118) compared with the minor allele (A118G).[240] However, when Wong et al.[241] evaluated the duration of intrathecal fentanyl analgesia (25 μg) in women who were classified into the same genetic groups, there were no differences between the groups in the duration of analgesia or treatment of breakthrough pain. A possible explanation was the high dose of intrathecal fentanyl.[241] Camorcia et al.[242] examined the effect of the A118G variant on the ED_{50} of epidural sufentanil in nulliparous women. Similar to the findings of Landau et al.,[240] the estimated ED_{50} was significantly lower

in women with the variant allele compared with women without the variant. Landau et al.[243] also evaluated the possible effects of common *OPRM1* and *COMT* (gene encoding catechol-O-methyltransferase) SNPs on the analgesic efficacy of intravenous fentanyl labor analgesia. No differences were detected. The authors concluded that the study was likely underpowered to detect a difference between groups and, if differences exist, the impact on response to opioid labor analgesia is likely to be modest.

The potential role of the A118 genetic variant in influencing opioid analgesic requirements after cesarean delivery has been investigated in several studies. Wong et al.,[241] in a mixed race/ethnicity population, found no difference in duration of intrathecal morphine analgesia or need for supplemental analgesia in women carrying the variant allele. In contrast, Sia et al.[244] reported that Asian women with the variant allele had an *increased* incidence of breakthrough pain (as assessed by patient-controlled intravenous morphine requirements) after intrathecal administration of morphine compared with women without the variant allele. In a second study, the variant allele was found to independently predict increased postoperative morphine use in women undergoing cesarean delivery.[245]

The results of these studies are difficult to reconcile.[239,246] Although genetic components may influence patients' responses to nociceptive stimuli, current evidence suggests that genetic polymorphism in *OPRM1* plays a minor role, if any, in opioid pain management.[246,247] A meta-analysis examining the A118 genetic variant of *OPRM1* failed to identify a strong association between this variant allele and the response to opioids in different clinical settings.[247] Finally, other factors besides genetics may influence pain and opioid response including: (1) type of pain (visceral versus somatic), (2) type of opioid (hydrophilic versus hydrophobic), (3) route of administration, and (4) differences in metabolic pathways.

Toxicity

Any agent that is injected into the epidural or subarachnoid space should be administered with caution owing to the potential for neurotoxicity and permanent neurologic damage. Although there is concern about injecting any type of medication into the neuraxis, the epidural space is more forgiving than the subarachnoid space (see Chapter 31). In many cases, clinicians have injected medications that were not well tested in animal models. Yaksh and Collins[248] have urged careful administration of neuraxial drugs, stating that "studies in animals should precede human use of spinally administered drugs."

The most commonly administered neuraxial opioids in obstetric patients are preservative-free formulations of morphine, fentanyl, and sufentanil. Preservative-free morphine is commercially available for both epidural and intrathecal administration. In the animal model, clinically relevant doses of preservative-free intrathecal morphine (< 5 mg) were administered for 28 days via an indwelling subarachnoid catheter. Spinal cord blood flow and histopathology were unaffected.[249,250] To further evaluate preservative-free morphine for potential neurotoxicity, Yaksh et al.[251] studied the effects of continuous infusions of high-dose intrathecal morphine (1.5 to 12 mg/day for 28 days) in dogs. At higher doses (9 to 12 mg), the animals demonstrated allodynia soon after beginning the infusion, and at 12 mg, an inflammatory process developed and caused local tissue compression. In humans, long-term neuraxial opioid administration (up to 480 mg of epidural morphine over 124 days or 60 mg intrathecal morphine over 47 days) in patients with cancer pain resulted in no evidence of physiologic or neurologic adverse effects.[252]

Fentanyl is also available in a preservative-free formulation. Despite its widespread clinical use, few studies have assessed the histologic, physiologic, or clinical evidence of neurotoxicity with spinally administered fentanyl. One *in vitro* study evaluated the effects of fentanyl administration on nerve conduction.[253] Histopathologic studies of isolated rabbit vagus nerve axons did not show localized nerve damage after nerves were bathed in an isotonic solution of fentanyl. When axons were bathed in a hypotonic solution of fentanyl, permanent conduction deficits were noted. However, in clinical practice, large doses of fentanyl would be required to create a hypotonic intrathecal environment.

Although no formal neurotoxicology studies have evaluated sufentanil administration in humans, there are no clinical reports of neurotoxicity despite its widespread use. In one study, sufentanil was administered to cats through an indwelling intrathecal catheter over 5 days.[249] Sabbe et al.[254] administered clinically relevant doses of intrathecal sufentanil to dogs over several weeks and reported no histopathologic changes. In a sheep model, Rawal et al.[255] demonstrated dose-dependent spinal cord histopathologic changes after intrathecal administration of sufentanil (50 to 100 μg) every 6 hours for 72 hours. These doses are much larger than those used in clinical practice. It is possible that these findings reflect an artifact of experimental design (e.g., the frequent administration of a large-volume, hypotonic preparation).

Despite the paucity of data about possible neurotoxicity, both fentanyl and sufentanil are widely used in clinical practice. Although these drugs are not approved by the FDA for neuraxial use,[256] there are no published reports of neurologic deficits after epidural or intrathecal administration of either agent in humans. In general, anesthesia providers should exercise extreme caution before injecting any untested agent into the spinal or epidural space, to prevent irritation or damage to neural structures.

Side Effects

Neuraxial opioid administration is associated with beneficial effects as well as potential complications and side effects. Intrathecal administration of clinically relevant doses of morphine is associated with a high incidence of side effects, including somnolence, nausea and vomiting, pruritus, urinary retention, and respiratory depression (Table 13.5). However, epidural and intrathecal injection of more lipid-soluble opioids have fewer side effects.

TABLE 13.5 Incidence of Adverse Side Effects After Intrathecal Injection of 0.5 or 1.0 mg of Morphine

	INCIDENCE (%)		
Side Effect	Morphine 0.5 mg ($n = 12$)	Morphine 1 mg ($n = 18$)	Overall ($n = 30$)
Pruritus	58	94	80
Nausea/vomiting	50	56	53
Urinary retention	42	44	43
Drowsiness	33	50	43
Respiratory depression	0	6	3

Modified from Abboud TK, Shnider SM, Dailey PA, et al. Intrathecal administration of hyperbaric morphine for the relief of pain in labour. *Br J Anaesth*. 1984;56:1351–1360.

Sensory Changes

An early study evaluating intrathecal sufentanil in laboring women reported sensory changes and hypotension, although no local anesthetics were administered.[257] Other investigators have reported high cervical sensory blockade associated with mental status changes, dysphagia, dyspnea, and automatisms after intrathecal sufentanil or fentanyl injection.[258,259] These symptoms are likely to be related to a dose-dependent opioid effect rather than neuraxial blockade–induced sympathectomy.[260] Further, these changes do not predict the quality or duration of analgesia or degree of hemodynamic change.[260] These sensory changes can be clinically significant, especially when they extend to the cervical dermatomes. Patients may feel that they cannot breathe or swallow, an effect that can be distressing. Fortunately, neither intrathecal sufentanil nor fentanyl affects the efferent limb of the nervous system, and motor function is not impaired. Patients should be reassured that their respiratory efforts are not impaired and that these symptoms will subside in 30 to 60 minutes. One report described the use of naloxone to treat the sensory changes associated with intrathecal sufentanil.[258]

Nausea and Vomiting

Nausea and vomiting are common during labor and delivery. Intrapartum nausea and vomiting can occur from a variety of causes, including pregnancy, physiology of labor itself, pain associated with labor, and parenteral administration of an opioid that may have preceded the neuraxial opioid administration. Therefore, it is difficult to determine the incidence of nausea and vomiting as direct side effects of neuraxial analgesia. Although the mechanism of neuraxial opioid–mediated nausea is unclear, there are suggestions that it may be caused by modulation of afferent input to the area postrema (i.e., the chemoreceptor trigger zone) or at the nucleus of the tractus solitarius, a key relay station in the visceral sensory network.[261] Because opioid receptors and others (i.e., dopaminergic, muscarinic) are abundant in these areas, neuraxial opioids are an important cause of nausea and vomiting in the obstetric population.

In two dose-response studies in women undergoing cesarean delivery with spinal and epidural anesthesia, the incidence of neuraxial morphine–induced nausea and vomiting was not dose-related.[262,263]

Studies suggest that the incidence of nausea and vomiting is lower with lipophilic opioids compared with morphine. Moreover, adding lipophilic opioid to local anesthetic for neuraxial cesarean delivery anesthesia may actually prevent intraoperative nausea and vomiting because of the improved quality of analgesia. Manullang et al.[264] randomized 30 healthy parturients to receive either intrathecal fentanyl or intravenous ondansetron for prevention of intraoperative nausea and vomiting during cesarean delivery performed with spinal anesthesia. The incidence of intraoperative nausea was decreased in the fentanyl group compared with the ondansetron group.

A number of prophylactic options are available for reducing the incidence of neuraxial opioid-induced nausea and vomiting (see Chapters 26 and 27). In a systematic review, the efficacy of prophylactic **dexamethasone** in reducing opioid-related side effects in patients receiving neuraxial morphine was examined.[265] Dexamethasone reduced the incidence of postoperative nausea (relative risk [RR] 0.57, 95% confidence interval [CI], 0.45 to 0.72), vomiting (RR 0.56, 95% CI, 0.43 to 0.72), and the use of rescue antiemetic therapy (RR 0.47, 95% CI 0.36 to 0.61) compared with placebo. In a randomized, double-blind placebo-controlled study, Cardoso et al.[266] evaluated 72 patients undergoing cesarean delivery with spinal anesthesia including intrathecal morphine. Pain scores and the incidence of nausea were decreased in the group receiving prophylactic dexamethasone.

George et al.[267] performed a systematic review of randomized, controlled trials comparing prophylaxis or treatment of nausea and vomiting using one of the 5-hydroxytryptamine-3 (5-HT_3) receptor antagonists (i.e., **ondansetron, granisetron**, or placebo) in women receiving spinal anesthesia with intrathecal morphine for cesarean delivery. The authors determined that 5-HT_3 receptor antagonists reduced the incidence of postoperative nausea and vomiting as well as the need for postoperative rescue antiemetic therapy compared with placebo.

A meta-analysis suggested that **metoclopramide** administration (10 mg) before initiation of spinal anesthesia or after delivery resulted in a significant reduction in intraoperative nausea and vomiting as well as early postoperative nausea and vomiting.[268] In a study comparing transdermal scopolamine 1.5 mg, intravenous ondansetron 4 mg, and placebo, **scopolamine** was an effective prophylactic medication against nausea in parturients who received intrathecal morphine for analgesia after cesarean delivery.[269] However, the use of scopolamine may be limited by bothersome side effects, including dry mouth, drowsiness, and blurred vision.

Droperidol is effective for the treatment of nausea; however, the FDA has issued a "black box" warning against its use because of concern for QT-interval prolongation in association with droperidol administration. Acupressure and acupuncture have been used for antiemetic prophylaxis with inconsistent results.[270]

Pruritus

Pruritus is the most common side effect of neuraxial opioid administration, with reports suggesting that more than 60% of parturients experience pruritus after neuraxial opioid administration.[271,272] Presentation is highly variable, but the incidence is dependent upon opioid, dose, and route of administration. Pruritus is more common after intrathecal than epidural opioid administration. A systematic review concluded that pruritus was more common in women who received CSE labor analgesia compared with epidural analgesia.[273] Some observers have noted segmental pruritus, especially with lipophilic opioids. For example, patients often complain of perineal and truncal pruritus after intrathecal sufentanil injection.[257] The onset of pruritus occurs shortly after analgesia develops, though many patients do not complain and thus appear asymptomatic. However, when questioned, they acknowledge the symptom. The incidence and severity of pruritus is dose-dependent.[274] Administration of a minimum effective dose of intrathecal lipophilic opioid in combination with local anesthetic appears to reduce the incidence and severity of pruritus.[275]

Although the cause of opioid-induced pruritus is unknown, it appears to be unrelated to histamine release.[276] Some investigators have suggested that pruritus results from a perturbation of sensory input resulting from rostral spread of the opioid within the CSF to the trigeminal nucleus or subnucleus caudalis.[276] Itch-specific neuronal pathways may interact with pain pathways so that continuing activity of the pain-processing system suppresses activity in the spinal itch-processing neurons. Consequently, if pain is inhibited, pruritus can be unmasked.

The serotoninergic system may contribute to modulation of pain by providing a balance between nociception and antinociception in the network of pain-processing neurons.[277,278] The dorsal horn of the spinal cord and the spinal tract of the trigeminal nerve are abundant in 5-HT_3 receptors. Because morphine is known to activate 5-HT_3 receptors by a mechanism independent of opioid receptors,[279] it is postulated that morphine may directly stimulate 5-HT_3 receptors and may cause intrathecal morphine–induced pruritus. Consequently, occupation of 5-HT_3 receptors by a 5-HT_3–receptor antagonist potentially prevents the pruritus.

Several pharmacologic treatments have been proposed to decrease the incidence of neuraxial opioid–related pruritus. A systematic review evaluated the efficacy of 5-HT_3 receptor antagonists for the prophylaxis and treatment of neuraxial opioid–induced pruritus. The investigators determined that prophylactic 5-HT_3 receptor antagonists did not alter the incidence of pruritus compared with placebo but did reduce the incidence of *severe* pruritus and the need for therapy.[267] Additionally, 5-HT_3 receptor antagonists were efficacious for the treatment of established pruritus.

Opioid antagonists have also been used to treat opioid-induced pruritus. Naloxone (40 to 80 µg intravenously) is very effective in treating the pruritus but may reverse the analgesia as well. Administration of **nalbuphine** (2.5 to 5 mg intravenously[280,281] or 10 mg subcutaneously[280,282]) may be helpful in reducing symptoms. The advantage of nalbuphine compared with naloxone is that it is less likely to reverse neuraxial opioid analgesia.[281] Paech et al.[283] randomized women who underwent elective cesarean delivery under spinal anesthesia with intrathecal morphine 100 µg to receive either subcutaneous methylnaltrexone bromide 12 mg (an opioid antagonist) or placebo after delivery. They did not find a difference in the overall severity of pruritus in the treatment group. Opioid antagonists have also been administered by the neuraxial route. Nalbuphine 0.2, 0.8, or 1.6 mg was co-administered with intrathecal morphine in a randomized, double-blind multicenter trial of women undergoing cesarean delivery.[284] All doses of nalbuphine reduced the incidence of pruritus; however, the duration of analgesia was also reduced. Jeon et al.[285] co-administered naloxone or placebo with morphine for continuous epidural postoperative analgesia in a randomized double-blind trial in women who had undergone cesarean delivery. The incidence and severity of pruritus were reduced in the group receiving epidural naloxone (82% versus 47%) without significant differences in pain scores or in the incidence of nausea, vomiting, or urinary retention between groups. The opioid antagonists have not been approved by regulatory bodies for neuraxial administration.

Diphenhydramine (25 mg) has also been administered to treat opioid-induced pruritus.[286] Despite the probability that the pruritus is unrelated to histamine release, there may be some benefit from the modest sedation that follows diphenhydramine administration. Propofol 10 to 20 mg was effective for the treatment of pruritus in several studies in nonobstetric patients, but its efficacy was no better than placebo in an obstetric study.[287] Regardless of the chosen treatment, pruritus can contribute significantly to patient dissatisfaction and should be treated promptly upon request.

Hypotension

Decreased blood pressure was reported in early studies that evaluated intrathecal opioid administration.[257,260] Although hypotension occurs in 5% to 10% of parturients who receive intrathecal opioids,[257,260] the incidence is higher when a local anesthetic or clonidine is added to the opioid. Early reports suggested that hypotension was caused by a sympathectomy, but later work suggests that hypotension results from pain relief[260] and decreased maternal levels of catecholamines, especially epinephrine.[288] Wang et al.[289] demonstrated that intrathecal opioids block the afferent information from A-delta and C-fibers to the spinal cord but that efferent nerve impulses (e.g., sympathetic efferents) are not directly blocked.

Respiratory Depression

All opioids can cause respiratory depression regardless of their route of administration. The incidence of respiratory depression after neuraxial morphine is low and varies from 0% to 0.9%.[290,291] When opioids are administered either epidurally or intrathecally, the following factors affect the risk for respiratory depression: (1) choice of drug and its pharmacokinetics, (2) drug dose, and (3) concomitantly administered

CNS depressants. Morphine is the prototype opioid against to which all other opioids are measured. The dose of opioid has been shown to be an important factor in the occurrence of respiratory depression. In a dose-response study, Palmer et al.[262] concluded that there was little justification for giving more than 0.1 mg of intrathecal morphine for analgesia after cesarean delivery. Similarly, a dose-response study of epidural morphine administration after cesarean delivery determined that the quality of analgesia increases as the dose of epidural morphine increases to 3.75 mg but that increasing the dose to 5 mg does not improve analgesia.[263]

The most important factor affecting the onset time of neuraxial opioid–induced respiratory depression is lipid solubility.[261] Respiratory depression may occur within minutes of the administration of a lipophilic opioid (e.g., fentanyl, sufentanil) because of rapid absorption of the opioid from the CSF to lipophilic tissues.[224] Its subsequent clearance and elimination are similar to those of the drug injected intravenously; thus the "time frame" for respiratory depression is short. In contrast, hydrophilic drugs (e.g., morphine, hydromorphone) are associated with a delayed onset of respiratory depression. This potentially serious side effect occurs because hydrophilic opioids remain in the CSF for several hours. Although this characteristic improves the bioavailability of these opioids, there is a biphasic pattern of respiratory depression with early (less than 2 h after administration) or late (6 to 12 h after administration) respiratory depression caused by rostral migration in CSF and absorption of the drug into the respiratory centers in the brainstem (Fig. 13.13).

Although most cases of respiratory depression associated with sufentanil administration occur with larger doses, respiratory depression has also been reported with as little as 10 µg of intrathecal sufentanil administered for labor analgesia.[292,293] Larger doses (e.g., 15 µg) have not been found to produce better or more prolonged analgesia but do result in increased plasma opioid concentrations and a higher risk for respiratory depression. In a female volunteer study, Lu et al.[234] reported that doses of intrathecal sufentanil larger than 12.5 µg did not produce a proportionate increase in intensity or duration of analgesia. Similarly, there is little benefit to increasing the dose of intrathecal fentanyl beyond 25 µg when it is used as the sole agent for labor analgesia. Higher doses (i.e., more than 10 µg of sufentanil or more than 25 µg of fentanyl) should not be used in routine clinical practice. Respiratory depression from epidural fentanyl is rare, and most studies have used up to 100 µg without evidence of respiratory depression.[294] Doses greater than 100 µg have not been studied.

Several case reports have implicated previous parenteral administration of opioid as a contributing factor in respiratory arrest associated with intrathecal sufentanil administration in laboring women.[295,296] For example, Jaffee et al.[297] reported a case of apnea and unresponsiveness in a parturient who had received several doses of intravenous fentanyl in the 4 hours before intrathecal sufentanil administration. Although the pregnancy-induced increase in respiratory drive continues throughout labor and into the postpartum period and may provide some protection against respiratory depression, respiratory depression is the most serious side effect of neuraxial opioid administration.

Practice guidelines from the American Society of Anesthesiologists recommend that all patients who receive neuraxial opioids should be monitored for adequacy of **ventilation** (e.g., respiratory rate, depth of respiration), **oxygenation** (e.g., pulse oximetry when appropriate), and **level of consciousness.**[298] In patients who receive a single neuraxial injection of a lipophilic opioid (e.g., fentanyl), monitoring should be continual for the first 20 minutes after administration, followed by monitoring at least hourly until 2 hours have passed. In patients who receive a single neuraxial injection of a hydrophilic opioid (e.g., morphine), monitoring should be performed at least hourly for the first 12 hours and then at

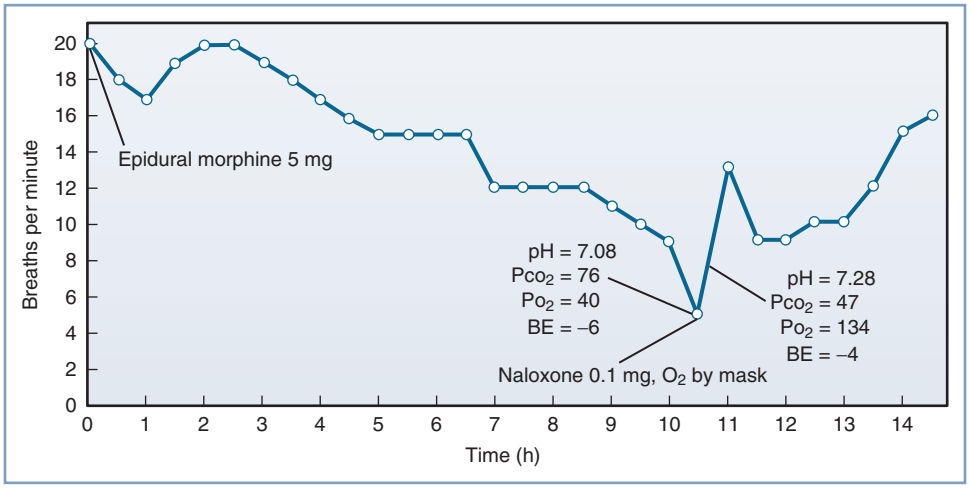

Fig. 13.13 Respiratory rate of an obstetric patient who received 5 mg of morphine after cesarean delivery and who experienced delayed respiratory depression. (From Leicht CH, Hughes SC, Dailey PA, et al. Epidural morphine sulfate for analgesia after cesarean section: a prospective report of 1000 patients [abstract]. *Anesthesiology.* 1986;65:A366.)

least every 2 hours for the next 12 hours after opioid administration. For patients who receive a continuous infusion of a neuraxial opioid, monitoring should be performed hourly during the first 12 hours, every 2 hours for the next 12 hours, and then every 4 hours for the duration of the opioid infusion.

Recommendations for women who received EREM are similar to those who received a hydrophilic opioid (e.g., morphine) except that monitoring should continue at least once every 4 hours between 24 and 48 hours after administration. Extra precautions should be taken if unintended spinal administration of EREM occurs.[299]

In addition, the guidelines state that greater duration and intensity of monitoring and/or additional methods of monitoring may be indicated in patients who received neuraxial opioids if the patient is at increased risk for respiratory depression (e.g., obesity, obstructive sleep apnea, concomitant administration of opioid analgesics by other routes).

Urinary Retention

Urinary retention is a bothersome side effect of intraspinal opioid administration. The reported rates following neuraxial opioids vary widely and range from 9% to 80% depending on the procedure performed, type of local anesthetic and/or opioid administered, and definition of urinary retention.[300] Urinary retention is more common with neuraxial opioid administration than with intramuscular or intravenous administration of equivalent doses. It is unrelated to systemic absorption and is dose independent. The onset of urinary retention appears to parallel the onset of analgesia. Evidence suggests that the rapid onset of this side effect is produced by relaxation of the detrusor muscle (Fig. 13.14),[301] which most likely results from the sacral spinal action of opioids. Urinary retention can be treated with naloxone; however, because many parturients require catheterization for other reasons, urinary retention is often treated with bladder catheterization.

Delayed Gastric Emptying

Labor may delay gastric emptying, and opioids may further exacerbate this delay (see Chapter 28). Parenterally administered opioids are known to delay gastric emptying in laboring women.[302] However, clinically useful doses of epidural fentanyl have minimal effects on gastric emptying. Intrathecal administration of fentanyl produces greater delays in gastric emptying than epidural administration.[303] Delays in gastric emptying may increase the risk for nausea and vomiting and also increase the risk for aspiration if general anesthesia is necessary for emergency cesarean delivery.

Recrudescence of Herpes Simplex Virus Infections

Genital herpes infection (herpes simplex virus [HSV]) is the most common type of herpes virus infection during pregnancy[304]; however, oral HSV infections (common cold sore or fever blister) resulting from reactivation of latent HSV infection also occur during pregnancy. Reports have suggested a relationship between neuraxial opioid administration and reactivation of oral herpes infection. Crone et al.[305] reported a 10% incidence of reactivation after cesarean delivery in patients who had received epidural morphine, compared with a 1% incidence in similar patients who did not receive

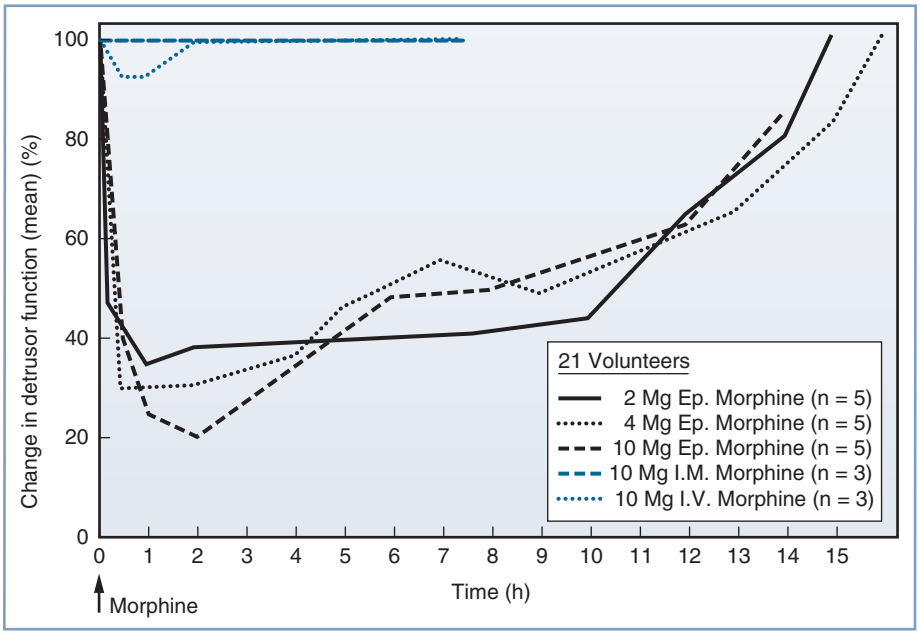

Fig. 13.14 Urodynamic effects of epidural (Ep.), intramuscular (I.M.), and intravenous (I.V.) morphine administration in male volunteers. Depression of detrusor muscle function persisted for many hours after epidural morphine administration. This did not occur with parenteral opioids and may represent a local spinal cause (i.e., opioid receptors). (From Rawal N, Mollefors K, Axelsson K, et al. An experimental study of urodynamic effects of epidural morphine and of naloxone reversal. *Anesth Analg.* 1983;62:641-647.)

epidural morphine. These observations have been confirmed in two prospective studies.[306,307] Davies et al.[308] reported an increased incidence of postpartum herpes infection in patients with a history of HSV-1 who had received intrathecal morphine.

The mechanism of herpes reaction is unknown.[309] Viral reactivation is known to occur with exposure to ultraviolet light, immunosuppression, trauma, and fever. Proposed causes include (1) a skin trigger mechanism, whereby pruritus and scratching trigger reactivation; (2) an altered immunologic response[310]; and (3) a ganglion trigger mechanism, whereby the intraspinal opioid spreads rostrally and binds to the trigeminal nerve.[311] The ganglion trigger mechanism involves an alteration of sensory modulation that results in reactivation. We are unaware of any serious maternal or neonatal complications that have resulted from neuraxial administration of an opioid and reactivation of oral herpes infection.

Placental Transfer and Fetal and Neonatal Effects

Neuraxial opioid administration may have a direct effect on the infant (i.e., respiratory depression at delivery) that results from systemic absorption of the opioid followed by transplacental transfer. The fetus may also be affected indirectly by opioid-related maternal side effects (i.e., hypoxemia, respiratory depression).

Neonatal Depression

Systemic opioid absorption can result in neonatal respiratory depression, which is sometimes observed after systemic opioid administration during labor.[312,313] Neuraxial opioid analgesia techniques may result in better Apgar scores and umbilical cord blood gas and pH measurements at delivery than systemic opioid analgesia. Despite the rapid systemic uptake of intrathecally administered opioids, the neuraxial analgesia requires the administration of smaller doses of opioid.

Several studies have evaluated neonatal outcome after continuous maternal epidural infusion of opioids and local anesthetics.[314,315] Collectively, these studies have demonstrated that maternal epidural opioid administration by continuous infusion rarely results in drug accumulation and subsequent neonatal depression. Reynolds et al.[316] performed a systematic review of randomized and nonrandomized studies comparing epidural with systemic opioid analgesia. They reviewed 12 trials with a total study population of 2102 parturients. Epidural analgesia was associated with better umbilical cord blood acid-base measurements than systemic opioid analgesia, suggesting that placental perfusion and gas exchange was well preserved despite maternal sympathetic blockade and effective analgesia. Although not all of the studies used neuraxial opioid infusions, the researchers suggested that replacement of systemic opioids with modest doses of neuraxial opioids not only produces superior analgesia but also may have a favorable effect on neonatal outcome.[316]

The effect of epidural fentanyl on breast-feeding has been investigated. Historically, most studies have been observational and poorly controlled. In a randomized controlled trial that included parous women who had previously successfully breast-fed, Beilin et al.[317] found that women who received greater than 150 μg of epidural fentanyl during labor were less likely to be breast-feeding at 6 weeks postpartum compared with women who did not receive any fentanyl or those who received less fentanyl. In contrast, Lee et al.[318] performed a similar study and found that increasing doses of epidural fentanyl does not affect breast-feeding at 6 weeks and 3 months postpartum. However, only 19% of women in the study received a cumulative fentanyl dose greater than 150 μg.[318] Further study is needed to address this important concern.

Fetal Heart Rate Abnormalities

An association between neuraxial labor analgesia and FHR abnormalities has been observed (see Chapter 23). Several reports have described the abrupt onset of fetal bradycardia after intrathecal administration of fentanyl or sufentanil.[319–321] Clarke et al.[320] suggested that the bradycardia is an indirect effect of decreased circulating maternal epinephrine associated with the rapid onset of analgesia. Epinephrine has a tocolytic effect and causes uterine relaxation by stimulating β_2-adrenergic receptors. Consequently, reduced epinephrine levels may lead to increased uterine tone. Because uteroplacental perfusion occurs during periods of uterine diastole (i.e., uterine relaxation), uterine tachysystole may result in diminished uteroplacental perfusion and fetal hypoxia. Norepinephrine is known to have a uterine-stimulating effect[322]; thus, the decrease in epinephrine concentration alongside an unchanged norepinephrine concentration may produce uterine hyperactivity and fetal compromise.

An earlier published report suggests that uterine tachysystole and fetal bradycardia may follow administration of either intrathecal opioids or epidural local anesthetics for labor analgesia.[323] In the study, FHR abnormalities and obstetric outcome were evaluated after administration of either intrathecal sufentanil or epidural bupivacaine in a prospective blinded comparison. There were no observed differences in the incidence of FHR abnormalities (i.e., recurrent late decelerations and/or bradycardia) between groups (22% in the intrathecal sufentanil group versus 23% in the epidural bupivacaine group).[323]

Subsequently, Van de Velde et al.[324] investigated whether intrathecal sufentanil 7.5 μg produced more FHR abnormalities than either conventional epidural analgesia or intrathecal bupivacaine 2.5 mg combined with sufentanil 1.5 μg and epinephrine 2.5 μg. The high-dose sufentanil group had more FHR abnormalities (i.e., late decelerations, fetal bradycardia) but less hypotension than the low-dose sufentanil/bupivacaine group. The incidence of FHR abnormalities was similar in the low-dose sufentanil/bupivacaine/epinephrine and conventional epidural analgesia groups. The rates of cesarean delivery for FHR abnormalities were similar in the three groups.

To further evaluate these findings, Abrao et al.,[325] in a randomized trial, evaluated the effects of CSE versus traditional epidural analgesia on basal uterine tone and the occurrence of FHR abnormalities. Use of the CSE technique was the only

independent predictor of an increase in basal intrauterine pressure of 10 mm Hg or more (OR, 3.53; 95% CI, 1.21 to 10.36; $P = .022$). The authors also demonstrated that the only predictor of FHR abnormalities was an increase in intrauterine pressure after initiation of analgesia (OR, 18.62; 95% CI, 4.46 to 77.72). A decrease in visual analog scale pain scores immediately after administration of analgesia also correlated with an increased probability of increased intrauterine pressure and FHR abnormalities. No emergency cesarean deliveries resulted from either neuraxial technique, but the authors concluded that more studies are needed to better understand the effects of the CSE technique on labor progress and fetal physiology.[325] Of note, in a letter to the editor, Landau et al.[326] suggested that the analgesic techniques were not equipotent. Additionally, monitoring for FHR abnormalities was only performed for 15 minutes. Given that the onset of analgesia is slower with epidural compared with CSE techniques, FHR abnormalities may occur earlier after intrathecal analgesia. Patel et al.[327] evaluated fetal/neonatal outcome in patients who were randomized to either a CSE or an epidural technique containing both bupivacaine and fentanyl. There were no significant differences in FHR patterns, Apgar scores, or umbilical artery acid-base measurements between groups. However, there was a significant increase in the incidence of abnormal FHR patterns following administration of neuraxial analgesia in both groups. Given the inconsistencies in the data, further study is necessary to determine the mechanisms and risk factors for fetal bradycardia following the initiation of neuraxial labor analgesia.

Other mechanisms may also be relevant to explain the fetal bradycardia sometimes observed after CSE analgesia. Van de Velde et al.[324] questioned the catecholamine imbalance theory, because intrathecal bupivacaine combined with low-dose sufentanil (1.5 μg) produced analgesia similar to that provided by intrathecal sufentanil (7.5 μg), but the incidence of fetal bradycardia was greater with sufentanil 7.5 μg. Russell et al.[328] demonstrated that intravenous opioids have central effects, altering the release of oxytocin and vasopressin and inducing uterine hyperactivity. Lipid-soluble opioids undergo rapid systemic redistribution after neuraxial injection; therefore, even neuraxial opioids may have central effects.

Given the potential risk for fetal bradycardia after neuraxial analgesia in laboring women,[320,329] the FHR should be monitored before and after the initiation of epidural and intrathecal analgesia. FHR changes are usually transient and may be managed successfully with conservative *in utero* fetal resuscitation measures, including the administration of a tocolytic agent for persistent uterine tachysystole.

Historically, intravenous or subcutaneous **terbutaline** was used to treat persistent uterine tachysystole, but **nitroglycerin,** also a potent tocolytic agent, may have several advantages. First, nitroglycerin has a short duration of action and labor resumes shortly after the period of tachysystole. In addition, nitroglycerin rarely produces significant hypotension, and if hypotension occurs, it is easily treated. Several studies have evaluated nitroglycerin for the treatment of uterine tachysystole. Mercier et al.[330] described consistent success in treating FHR abnormalities resulting from uterine tachysystole after the administration of one or two doses of nitroglycerin (60 to 90 μg), and Bell[331] described the successful use of sublingual nitroglycerin (400 μg) in the treatment of uterine tachysystole. In a randomized trial comparing intravenous terbutaline 250 μg to nitroglycerin 400 μg for the treatment of intrapartum tachysystole and nonreassuring FHR tracings, acute intrauterine resuscitation success rates were similar between the two groups (72% versus 64% for terbutaline and nitroglycerin, respectively; $P = .38$), but the incidence of tachysystole 10 minutes after drug administration was lower in the terbutaline group.[332] Therefore, if there is no response within 2 to 3 minutes of nitroglycerin administration, terbutaline 0.25 mg (250 μg) should be administered, and preparations should be made for emergency cesarean delivery if the fetal bradycardia does not resolve.

ADJUVANTS

Epinephrine

Epinephrine is added to local anesthetic solutions to increase the duration of anesthesia, reduce peak plasma drug concentrations, improve block reliability, and intensify analgesia/anesthesia.[333–335] Uptake of epinephrine varies with the choice and concentration of local anesthetic, concentration of epinephrine, and site of injection. The effect of epinephrine is greater when it is combined with lidocaine than when it is combined with bupivacaine.[151,191] Even concentrations of epinephrine as low as 3.3 μg/mL (1:300,000) have been shown to be effective in reducing the plasma concentrations of lidocaine.[335]

The efficacy of epinephrine depends on the specific local anesthetic as well as the site of injection. Epinephrine prolongs the duration of epidural lidocaine anesthesia by reducing uptake of local anesthetic into the systemic circulation through constriction of the epidural venous plexus and maintaining the concentration of local anesthetic at the site of injection. An epinephrine concentration of 5 μg/mL (1:200,000) nearly doubles the duration of epidural lidocaine anesthesia.[336] In contrast to lidocaine, the addition of epinephrine 3.3 μg/mL to epidural bupivacaine 0.5% had no effect on maternal venous plasma concentrations of drug in laboring women.[337] Similarly, Reynolds et al.[338] observed no effect when epinephrine 5 μg/mL was added to bupivacaine during administration of epidural anesthesia for cesarean delivery. Although epinephrine did not prolong the epidural anesthesia produced by ropivacaine,[339] one group reported that the addition of epinephrine to bupivacaine resulted in a 50% decrease in maternal plasma concentrations of bupivacaine after *paracervical* block,[340] and Katz et al.[341] found that epinephrine 200 μg added to intrathecal hyperbaric bupivacaine for cesarean delivery prolongs the time until T-10 regression by 40 minutes.

Greater reliability and intensity of the block can be observed when epinephrine is added to epidurally administered local anesthetics because of stimulation of α_2-adrenergic receptors. These presynaptic adrenergic receptors are found

at the terminals of primary afferent neurons as well as centrally on neurons in superficial laminae of the spinal cord and in several brainstem nuclei.

In addition to the intrinsic analgesic effects of epinephrine, the inherent lipid solubility of each local anesthetic affects the degree of sensory blockade. Each local anesthetic has a lipid-to-water partition coefficient that determines the drug uptake between the aqueous and lipid phases within the spinal canal. If a local anesthetic is more lipid soluble, the advantage of adding epinephrine to the local anesthetic is less significant. For example, the lipid-to-water partition coefficient of lidocaine is 2.7. When epinephrine is added to lidocaine, there is marked improvement in the intensity of the block. However, bupivacaine, which has a lipid-to-water partition coefficient 10 times greater than that of lidocaine, is affected by epinephrine to a lesser degree. Ropivacaine has a lipid-to-water partition coefficient similar to that of lidocaine, and epinephrine will intensify a ropivacaine block similar to that of lidocaine. However, the duration of the block remains unchanged.

Despite the advantages of epinephrine, concern remains about the effects of epinephrine on uterine blood flow and the maternal cardiovascular system. In healthy fetuses, epidural administration of epinephrine does not affect umbilical cord blood flow. However, in fetuses with increased vascular resistance, epidural epinephrine administration may increase the umbilical artery S/D ratio.[342] Studies of the effects of epinephrine on the placental transfer of local anesthetics have yielded contradictory results. In rabbits, epinephrine did not affect the F/M ratio of bupivacaine.[343] As a result of the addition of epinephrine, the F/M ratio for bupivacaine has been found to be increased[344] or unchanged.[340] For lidocaine, the F/M ratio has variously been reported to be increased,[191,345] decreased,[335] or unchanged.[346]

Bicarbonate

The addition of sodium bicarbonate to a local anesthetic solution increases the pH closer to the pK_a of the local anesthetic. This change increases the proportion of drug in unionized form that is available to penetrate the nerve sheath and membrane, thereby accelerating the onset of the block and decreasing the minimum concentration required for conduction blockade.[347] Most studies have demonstrated that the addition of sodium bicarbonate to lidocaine, bupivacaine, or 2-chloroprocaine hastens the onset of epidural blockade by as much as 10 minutes.[141,348,349] The speed of onset of a ropivacaine block does not seem to be affected by alkalinization, but as with the other local anesthetics, evidence suggests that alkalinization intensifies epidural ropivacaine anesthesia and improves spread to sacral dermatomes.[350] The effects of alkalinization are most pronounced in epinephrine-containing solutions, particularly commercially prepared epinephrine-containing formulations. These solutions are prepared at a lower pH, ranging from 3.2 to 4.2.[351] Although the lower pH of these solutions stabilizes the solution and provides bacteriostasis, it increases the latency of onset.

Sodium bicarbonate 1 mEq/mL (8.4%) may be freshly added to local anesthetic solutions shortly before use (Table 13.6). Alkalinization of bupivacaine must be performed carefully because the margin between satisfactory alkalinization and complete precipitation is very narrow. All local anesthetics have a tendency to precipitate, so solutions containing bicarbonate should be inspected for precipitation before being administered.

Hypotension occurs more frequently with epidural administration of an alkalinized local anesthetic than with administration of an unbuffered solution.[352] This likely results from an accelerated onset of sympathetic blockade. Carbonated salts of local anesthetics can also be administered for a rapid onset of epidural blockade. However, these drugs have limited availability. Like alkalinized local anesthetics, these preparations are more likely to produce hypotension.

Clonidine

α_2-Adrenergic agonists (e.g., **clonidine**) have been investigated as adjuvants to local anesthetics and opioids to improve analgesic efficacy without increasing side effects. The advantage of clonidine is its ability to provide analgesia without affecting sensation or producing motor blockade.[353] However, epidural and intrathecal administration of α_2-adrenergic agonists are known to produce hypotension, probably by acting on α_2-adrenergic receptors on preganglionic cholinergic neurons.[354] In addition, α_2-adrenergic agonists produce dose-dependent sedation, which results from α_2-adrenergic stimulation in the locus ceruleus.[355]

Neuraxial clonidine exerts its effects by binding to α_2-adrenergic receptors located on primary afferent terminals of the spinal cord, substantia gelatinosa, and brainstem nuclei[356] as well as via a cholinergic mechanism.[357] Conduction blockade is produced by increases in potassium conductance and in acetylcholine and norepinephrine in the CSF, leading to decreased release of substance P and subsequent analgesia.[358]

Approximately 70% of alpha-adrenergic receptors on human myometrium are α_2-adrenergic receptors[359]; therefore, the potential effects of clonidine on labor and delivery have been evaluated. In an *in vitro* study, clonidine directly enhanced the frequency and amplitude of human myometrial contraction.[360] α_2-Adrenergic receptor stimulation in the uterus could theoretically enhance uterine contractions and decrease uterine blood flow.[354] Indeed, in animal studies, large doses of clonidine produced a decrease in FHR.[361] This effect probably resulted from direct fetal transfer of drug and from direct and indirect effects on baroreflexes. However, this effect is unlikely to occur with clinical doses of neuraxial clonidine.

TABLE 13.6 Alkalinization of Local Anesthetic Solutions

Local Anesthetic	Sodium Bicarbonate (mL)[a]
Lidocaine	1.0
Bupivacaine	0.1
2-Chloroprocaine	0.3

[a]Sodium bicarbonate 8.4% (1 mEq/mL) added to 10-mL local anesthetic solution.

Studies have evaluated neuraxial clonidine administration in humans as an analgesic adjunct for labor analgesia (see Chapter 23). When combined with local anesthetics and opioids, lower doses may be used, resulting in less hypotension and sedation. The FDA has issued a "black box" warning against the use of neuraxial clonidine in obstetric patients because of concerns about hemodynamic instability. Therefore, clonidine is rarely used for labor analgesia in North America; however, it is more widely used in some European countries. Clonidine may be particularly useful in women in whom other epidural analgesics are contraindicated or in those who have breakthrough pain with standard local anesthetic/opioid solutions despite a functioning epidural catheter. In this setting, the bolus administration of clonidine 75 μg without a local anesthetic is not usually associated with hypotension. It appears safe to add small doses of intrathecal clonidine (15 to 30 μg) to opioids or local anesthetics, but side effects must be treated promptly to avoid fetal compromise.

Epidural clonidine has been administered for analgesia after cesarean delivery (see Chapter 27). One study suggested that epidural clonidine (400 to 800 μg) provided postoperative analgesia, but a continuous infusion was required after 6 hours.[362] Others have demonstrated that the addition of epidural clonidine (75 to 150 μg) to neuraxial morphine lengthens the duration of postoperative analgesia without increasing the incidence of side effects.[363,364]

Neostigmine

Both nicotinic and muscarinic cholinergic receptors are present in the dorsal horn of the spinal cord. Acetylcholine stimulates muscarinic and possibly nicotinic receptors in the spinal cord.[365–367] Neostigmine prevents breakdown of acetylcholine. Stimulation of muscarinic receptors facilitates release of gamma-aminobutyric acid (GABA) in the dorsal horn of the spinal cord, resulting in analgesia.[357,368] Neostigmine appears to be more effective at alleviating somatic pain than visceral pain.[369,370] Visceral afferents are located deep within the spinal cord. Because neostigmine has low lipid solubility, it has a limited ability to traverse biologic membranes. When administered without other agents, it provides minimal analgesia because it is unable to reach the visceral afferents responsible for much of labor pain.[371]

Early studies of intrathecal neostigmine demonstrated analgesic efficacy and safety at the expense of dose-dependent nausea and vomiting that were unresponsive to standard antiemetics.[372] However, single and intermittent-dose epidural neostigmine administration has been found to significantly reduce local anesthetic consumption without increasing the risk to the mother or fetus. A systematic review of 16 randomized controlled trials including 1183 patients evaluated the efficacy of neuraxial neostigmine administration and its effect on local anesthetic dose for cesarean delivery and labor analgesia as well as the incidence of adverse events.[373] Although the dose of neostigmine varied across studies, a final analysis of 8 studies revealed that women randomized to receive epidural neostigmine required lower local anesthetic doses compared with women who received placebo, both for labor analgesia as well as for postcesarean analgesia. The incidence of pruritus was decreased, likely a result of decreased opioid consumption. Other findings included an increased risk for nausea in patients receiving intrathecal but not epidural neostigmine. There were no adverse effects on FHR patterns or Apgar scores, and the risk for hemodynamic instability, sedation, and dizziness were not increased.

A randomized controlled trial compared the effect of the addition of neostigmine and fentanyl to epidural bupivacaine on total hourly bupivacaine requirements when the study solutions were used for patient-controlled epidural analgesia (PCEA).[374] Parturients were randomized to receive epidural bupivacaine 0.125% with neostigmine 2, 4, or 8 μg/mL or fentanyl 2 μg/mL. No difference in the total hourly bupivacaine consumption was identified. Although the incidence of pruritus was higher in the group receiving fentanyl, there were no differences among groups in other adverse effects (maternal heart rate and blood pressure, neonatal Apgar scores, mode of delivery, motor block, nausea, sedation).[374]

Although not routinely used in clinical practice in the United States, collectively, studies suggest there may be a role for epidural neostigmine in laboring patients with opioid substance use disorders and patients with severe opioid-related nausea and vomiting. Neostigmine is not approved by the FDA for neuraxial use.

KEY POINTS

- Pregnancy enhances the effect of local anesthetic agents.
- Appropriate administration of epidural anesthesia does not adversely affect uterine tone or uterine or umbilical blood flow.
- Bupivacaine has greater cardiotoxicity than lidocaine because of its greater electrophysiologic effects, which predispose to ventricular arrhythmias.
- Single (levorotary) isomer formulations of amide local anesthetics, such as ropivacaine and levobupivacaine, have a lower potential for cardiotoxicity than racemic bupivacaine.
- Lipid emulsion therapy should be considered at the first sign of a serious local anesthetic systemic toxicity event.
- Fetal acidosis results in a greater accumulation of amide local anesthetic in the fetus.
- Local anesthetics, as used clinically, are not teratogenic.
- The elimination half-life of amide local anesthetics is longer in the newborn than in the adult because the former has a greater volume of distribution.
- The fetus and newborn seem to be no more vulnerable to the toxic effects of local anesthetics than the adult.

- Neonatal neurobehavior depends on many factors other than the choice of local anesthetic.
- Alkalinization of a local anesthetic solution shortens the latency of neural blockade but increases the risk for hypotension during administration of epidural anesthesia.
- Neuraxial opioid administration produces analgesia without loss of sensation or proprioception.
- The combination of a neuraxial local anesthetic and an opioid increases block density and allows for administration of a lower total dose of local anesthetic and a lower incidence of side effects.
- Spinal bioavailability of the hydrophilic drugs (e.g., morphine, hydromorphone) is greater than that of hydrophobic (lipophilic) opioids (e.g., fentanyl, sufentanil).
- The most common side effects of neuraxial opioid administration are pruritus and nausea and vomiting. Fetal bradycardia and maternal respiratory depression are the most serious complications.

Pharmacology during Pregnancy and Lactation

Tony Gin, MBChB, MD, FANZCA, FHKAM

CHAPTER OUTLINE

Drug therapy during pregnancy can be complex because the physiologic changes of pregnancy may alter drug disposition and effect. Maternal medications may have direct effects on the fetus after placental transfer, or indirect effects through changes in placental and uterine function. Even after delivery, drugs may affect breast-feeding, and drug transfer to breast milk is a concern. Nevertheless, pregnant women still require medications to treat many acute and chronic conditions. Worldwide, the use of medications during pregnancy has been increasing,[1] with pregnant women in the United States taking an average of 4.2 medications between 2006 and 2008.[2] Recent data from the United States showed that 97.1% of women took at least one medication during pregnancy, and 30.5% were taking at least five medications.[3] The most common medications were antiemetics, antibiotics, and analgesics. However, at least 10% were taking drugs with long-term effects on the central nervous system such as antidepressants, anticonvulsants, and antipsychotics. The challenge is to find the balance between the benefits and risks associated with therapy.

Maternal variation in drug effect is not usually difficult to manage, and a change in dosing regimen or the choice of drug may be all that is required. The greatest fear and concern is for potential fetal effects that may manifest as teratogenicity with fetal loss or congenital malformations, fetal growth restriction (also known as intrauterine growth restriction), preterm labor, and other complications of pregnancy. After delivery, immediate neonatal adaptation may be affected, and in the longer term there may be impaired neurodevelopment and behavioral problems in childhood.

The anesthesia provider should understand the implications of pregnancy on drug disposition and effect. Although not usually responsible for primary maternal drug therapy, the anesthesia provider will encounter women taking many different medications and may need to administer a variety of nonanesthetic drugs during the peripartum period, either for

maintenance of chronic therapy or for acute indications, especially when managing critically ill patients.

In this chapter, the way maternal physiology affects pharmacology is summarized, placental transfer and maternal and fetal effects of the main classes of drugs encountered during pregnancy are addressed, and drug transfer to breast milk is reviewed, with discussion of the effects of common perioperative drugs. Specific drugs used in the management of individual obstetric conditions are discussed in other chapters.

CHANGES IN DRUG DISPOSITION AND EFFECT

Pharmacogenetics

Genetic differences are responsible for some of the variation in drug response among individuals. Pregnancy does not obviously modify these pharmacogenetic differences, although some obstetric conditions such as preeclampsia are related to complex genetic factors. There are, however, some examples in which underlying genetic differences do affect obstetric management.[4]

The metabolism of **codeine** to **morphine** is greatly affected by polymorphisms of the cytochrome P450 (CYP) isoenzyme CYP2D6. It has been recognized only recently that mothers who are ultra-rapid metabolizers of codeine may produce and transfer sufficient morphine through breast milk to cause neonatal central nervous system (CNS) depression and even death.[5] Codeine is now not recommended in women who are breast-feeding.

Two of the possible changes at the β_2-adrenergic receptor are an arginine-to-glycine substitution at codon 16 (Arg-16Gly) and a glutamine-to-glutamic acid substitution at codon 27 (Gln27Glu). Women with Arg16 and/or Gln27 are less likely to have preterm delivery and more likely to have longer labor.[4] Conflicting results are reported for vasopressor requirements in the management of hypotension during spinal anesthesia for cesarean delivery. In North American studies, Gly16 homozygotes and Glu27 homozygotes required less ephedrine,[6] and Arg16 homozygotes required more phenylephrine.[7] However, no differences were detected in an Asian cohort,[8] and a Brazilian group found that Arg16 and Gln27 homozygotes required less ephedrine.[9]

The μ-opioid receptor gene may have an adenine-to-guanine substitution at nucleotide position 118 (A118G). There have been many studies of the effects of this polymorphism on opioid dose requirements and response. Studies in laboring women showed that AA homozygous carriers had an increased intrathecal fentanyl requirement for analgesia.[10] However, most studies of postoperative pain, including after cesarean delivery, have shown that AA polymorphism was associated with less pain.[4] Many other genetic factors influence opioid disposition and response, and even more factors influence pain perception. A meta-analysis found that A118G polymorphism only explained 7% of the variability in opioid requirements.[11] Currently, given the conflicting results and limited clinical effects of genetic polymorphisms, specific single nucleotide polymorphism (SNP) testing does not appear to be indicated in routine obstetric anesthesia practice.[12]

Pharmacokinetic Changes

The major physiologic changes during pregnancy alter drug disposition.[13–18] However, the magnitude and time course of these changes vary throughout pregnancy and among individuals. The results of many older studies are unreliable because the studies were often of low quality. Making generalizations about the effects of pregnancy on drug disposition can be difficult, and individualized dosing is important. Even though there is increased clearance of many drugs in pregnancy, the standard dosing regimens for many drugs have not been updated for pregnancy, consequently resulting in underdosing.[15,18]

Maternal Pharmacokinetics

Absorption and uptake. Oral absorption and bioavailability are not usually affected by pregnancy, although nausea and vomiting may limit oral intake. Intestinal motility is decreased during pregnancy, but gastric emptying is only delayed during labor or after opioid administration. Cardiac output is increased by 30% to 50% during pregnancy, and the increased blood flow to skin and mucous membranes will enhance absorption from these sites. Reduced functional residual capacity and increased minute ventilation lead to increased pulmonary uptake of inhalational anesthetic agents.

Distribution. The increased cardiac output during pregnancy increases distribution of drug to all tissues. Drugs acting peripherally (e.g., neuromuscular blockers) will be delivered to their site of action more quickly. However, the onset of intravenous and inhalational anesthetics is dependent on the time course of their cerebral drug concentration. A delay in the increase in arterial and brain anesthetic concentration will result from increased peripheral perfusion. However, increased peripheral perfusion will increase the return of drug during the elimination phase. During pregnancy, total body water increases on average by 8 L, and intravascular plasma volume is increased by 40%, whereas extravascular volume increases by a variable amount, depending on weight gain and edema. Thus, hydrophilic drugs, such as neuromuscular blockers, will have a small increase in the volume of distribution. Body fat is increased on average by 4 kg, but this is unimportant given the large volume of distribution of lipophilic drugs.

Changes in protein binding are more important clinically. Plasma albumin concentration is reduced to about 70% of normal, whereas α_1-acid glycoprotein concentration is largely unchanged. Protein binding of drugs may be reduced by increased concentrations of free fatty acids and other endogenous displacing substances. This leads to increased concentrations of free drug, but with chronic drug administration this is offset by increased clearance of that free drug. The total (free + bound) concentration of drug will decrease, and it may be necessary to reset the therapeutic target range lower to compensate. Thus, it is important to know whether monitored concentrations are for free or total drug. Only a few

drugs (e.g., theophylline, phenytoin) require monitoring and modification of dose because of changes in protein binding.

Metabolism. Most drugs are metabolized in the liver, and the rate of metabolism may depend on hepatic blood flow or intrinsic enzyme activity. Although cardiac output is increased in pregnancy, it is not clear whether blood flow to the liver is significantly increased.[16] Most cytochrome P450 isoenzymes (CYP3A4, CYP2D6, and CYP2C9) and uridine diphosphate glucuronosyltransferase (UGT) isoenzymes (UGT1A4 and UGT2B7) have increased activity during pregnancy,[14,16] which increases the metabolism of drugs such as **phenytoin** (CYP2C9), **midazolam** (CYP3A4), and **morphine** (UGT2B7). A few isoenzymes (CYP1A2 and CYP2C19) have decreased activity, which reduces the metabolism of drugs such as caffeine and theophylline (CYP1A2).

Elimination. Renal blood flow is increased by 60% to 80%, and glomerular filtration rate is increased by 50% in pregnancy; thus, the renal excretion of unchanged drugs such as **cephalosporin** antibiotics is increased. There is also increased activity of many transporter proteins such as renal P-glycoprotein.[16] Increased minute ventilation enhances elimination of inhalational anesthetic agents.

The physiologic changes of pregnancy will affect individual drugs depending on their physicochemical characteristics and metabolic pathways. Bioavailability is not usually changed significantly. Changes in volume of distribution as a result of changes in protein binding may affect drugs such as phenytoin, but monitoring and modification of therapy is usually straightforward. Drugs metabolized by the liver may require increases or decreases in dose, depending on the metabolic pathway involved. Drugs excreted unchanged by the kidneys often require an increased dose.

Placental Transfer and Metabolism

Our understanding of placental transfer and metabolism is rapidly improving (see Chapter 4).[19] Early research was often limited to measuring drug concentration in the umbilical vessels and maternal vein at delivery. Results were variable and difficult to interpret, especially for drugs such as anesthetic agents that are administered shortly before delivery. Umbilical blood samples are obtained at variable times after drug exposure, well before steady-state conditions are achieved. The theory of a placental barrier was proposed because maternal and fetal concentrations were often different. However, differences in concentration of binding proteins are mainly responsible for the fetal-maternal distribution of drugs at steady state.[20] The fetal concentration of albumin is slightly greater than that in the mother, but α_1-acid glycoprotein concentration is only one-third of the maternal value at term. Umbilical-to-maternal blood ratios of total drug may be misleading because it is the free drug that equilibrates across the placenta. Maternal-to-fetal ratios of drugs do not provide information on the rate of drug transfer or the amount of drug that has already been transferred to the fetus.

Drug transfer across the placenta was previously thought to occur mainly by diffusion. This would favor the movement of lipophilic drugs, and placental perfusion would be an important factor affecting transfer. Fetal pH is lower than maternal pH, so that weak bases become more ionized in the fetus, thus limiting their transfer back across the placenta. Normally, the difference in pH is only 0.1 and this "ion trapping" is irrelevant, but fetal acidosis can significantly increase the fetal concentration of drugs such as local anesthetics.

It is now known that the placenta contains many drug transporters that can modify fetal drug exposure.[14,16,19,21,22] In the treatment of sustained fetal tachyarrhythmia, placental P-glycoprotein, an adenosine triphosphate–dependent drug efflux pump, will reduce net transfer of substrates such as digoxin and verapamil from the mother. Although placental transport of immunoglobulin makes it possible to immunize the mother to protect the newborn, this transport also raises concerns when immunoglobulin tumor necrosis factor antagonists are used to treat maternal diseases.

The placenta contains many active enzymes responsible for Phase I and Phase II biotransformation.[21] Clearance of substrates by UGT in full-term placentas may be sufficient to contribute to overall maternal metabolism.

Fetal and Neonatal Elimination

The fetus and neonate metabolize drugs, but at a reduced rate compared with adults.[23,24] The fetal circulation guides drugs transferred across the placenta to undergo first-pass hepatic metabolism, but some drug will bypass the liver. Renal blood flow is minimal until near term, and any excreted products would just pass into the amniotic fluid to be swallowed. Elimination of drugs by the fetus is thus mainly reliant on placental transfer. It would seem prudent to minimize the amount of drug transferred to the neonate and choose drugs that are eliminated rapidly. Relatively large minute ventilation promotes neonatal elimination of inhalational anesthetic agents, and this may be further increased by assisted ventilation.

Pharmacodynamic Changes

Changes in the concentrations of various hormones may alter the response to other substances. In particular, progesterone and endorphins may enhance sedation and antinociception, respectively. A pharmacodynamic difference specifically refers to a change in response to a given effect-site concentration, but it is difficult during pregnancy to carry out the high-fidelity studies necessary for accurate pharmacokinetic-pharmacodynamic modeling. Thus, demonstration of pharmacodynamic changes in pregnancy has been limited to specific experimental designs in which there are large differences in effect.

General Anesthesia

Early animal studies showed that maternal anesthetic requirements were reduced during pregnancy. Minimum alveolar concentration (MAC) values for inhalational agents were reduced by 25% to 40% in pregnant ewes[25] and by 16% to 19% in pregnant rats.[26] Ethical and practical difficulties with research in pregnant women delayed confirmation of this finding in humans. Isoflurane MAC (determined using transcutaneous electrical stimulation instead of the classic skin

incision) was decreased by 28% in women undergoing termination of pregnancy at 8 to 12 weeks' gestation.[27] Similar reductions in MAC were found for **enflurane** (30%) and **halothane** (27%).[28] MAC was reduced by 30% in the immediate postpartum period, with a return to nonpregnant values by 12 to 72 hours after delivery (Fig. 14.1).[29,30]

Increased progesterone is probably the cause of the reduced anesthetic requirement during pregnancy; chronic progesterone administration reduced MAC in rabbits, dogs, and sheep.[31–33] Although human studies have not found a good correlation between progesterone concentration and the reduction in anesthetic requirement, a poor correlation may be expected if the effect of progesterone is not dose-dependent; it is possible that progesterone concentration only needs to exceed a low threshold to decrease anesthetic requirement. A lower concentration of sevoflurane was required to maintain anesthesia in nonpregnant women during the luteal phase of the menstrual cycle, when progesterone concentration is elevated, compared with during the follicular phase.[34] Progesterone concentration during pregnancy is much greater than that seen during the luteal phase of the menstrual cycle. The reduced MAC during pregnancy may also be a result of the increased endogenous endorphins that mediate the increase in nociceptive threshold during pregnancy; it is well known that opioids reduce MAC.

Pregnancy also alters other measures of anesthetic effect. In early pregnancy, the **isoflurane** concentration required for hypnosis was reduced by 31% and the bispectral index (BIS) was decreased at isoflurane concentrations over the range 0.1% to 2.0%.[35] During the second trimester, the **sevoflurane** concentration required to achieve a targeted BIS of 50 was reduced by 31%.[36] Both in early and term pregnancy, the median concentration of **nitrous oxide** required for loss of consciousness (MAC_{awake}) was reduced by 25% to 27%.[37] One study did not show any difference in electroencephalographic (EEG) measures between women having cesarean delivery or gynecologic surgery, but there were many confounding factors such as the study being conducted partly during and partly after surgery, the concurrent use of significant doses of fentanyl, large variations in EEG measures, and small sample size.[38]

Data for intravenous anesthetic agents are more variable, partly because of methodologic challenges. It is difficult to produce a stable effect-site concentration of intravenous drugs to allow accurate measurement of drug effect. Increased cardiac output usually results in an increase in intravenous anesthetic dose requirements to produce central effects, and this change would counter any decrease in requirements with pregnancy. The bolus dose of **thiopental** for hypnosis (failure to open eyes to command) was 17% lower, and that for anesthesia (no purposeful movement to a transcutaneous electrical stimulus) was 18% lower in early pregnancy compared with nonpregnant women (Fig. 14.2).[39] A similar reduction was found in the early postpartum period, less than 60 hours after delivery.[40]

Studies using target-controlled infusions may not be reliable because the pharmacokinetic models may not be accurate in pregnancy, and they are known to predict concentrations poorly at induction of anesthesia. These methodologic problems may be the reason one study found no differences in the concentration of **propofol** required for loss of consciousness

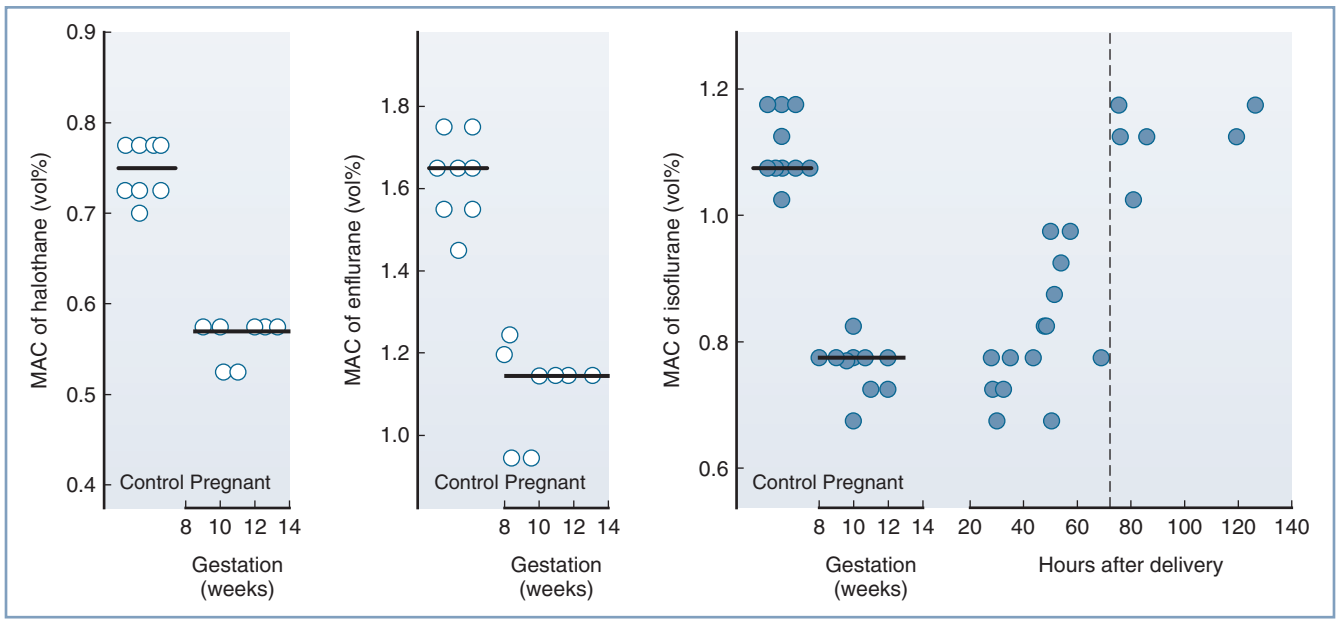

Fig. 14.1 Changes in minimum alveolar concentration (MAC), determined by response to transcutaneous electrical stimulation, for halothane, enflurane, and isoflurane in early pregnancy and for isoflurane in the early postpartum period. (From Gin T. Obstetric pharmacology. In: Evers AS, Maze M, Kharasch ED, eds. *Anesthetic Pharmacology: Basic Principles and Clinical Practice*. 2nd ed. Cambridge, Cambridge University Press; 2011:948–962. Original data from references 27, 28, and 29.)

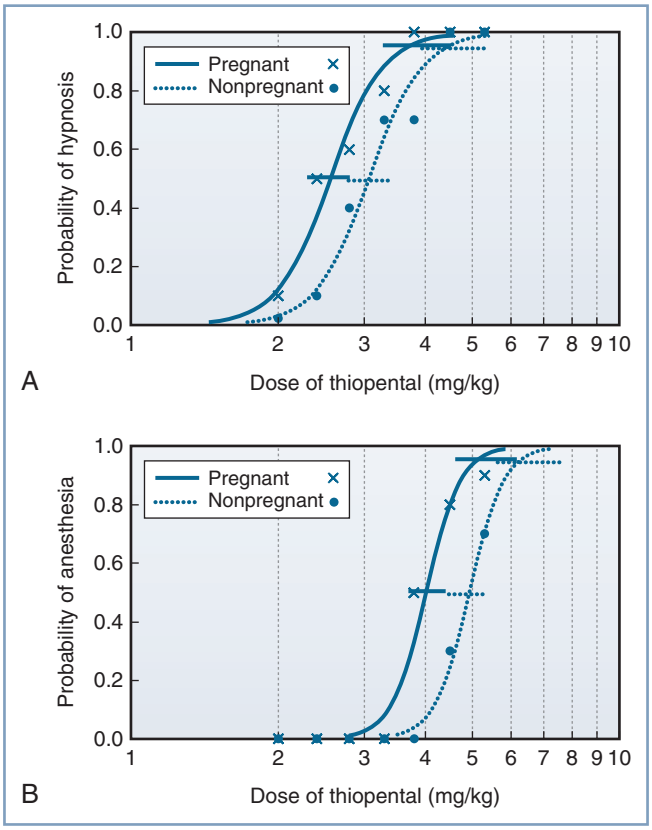

Fig. 14.2 Calculated dose-response curves (log [dose] scale) for thiopental for hypnosis (A) and anesthesia (B) in pregnant and nonpregnant women. The 95% confidence intervals for the values of ED50 and ED95 are also displayed, slightly offset for clarity. Raw data are shown for pregnant women (×) and nonpregnant women (•). (Modified from Gin T, Mainland P, Chan MTV, Short TG. Decreased thiopental requirements in early pregnancy. *Anesthesiology.* 1997;86:73–78.)

in early pregnancy.[41] Another study used a slow infusion of propofol for induction of anesthesia and found that the dose and calculated effect-site concentrations at loss of consciousness were 8% lower than in nonpregnant women.[42] The reduction in anesthetic requirement for intravenous agents appears to be less (8% to 18%) than that for inhalational agents (approximately 30%). It is not known whether this reflects real differences between the drugs or the methodologic problems just outlined.

Regional Anesthesia

The spread of neuraxial block is increased in pregnant women (see Chapter 2). This has been shown as early as the first trimester for epidural anesthesia[43] and the second trimester for spinal anesthesia.[44] One small study suggested that although the spread of epidural block was increased, the latency and density of sensory and motor block were not.[45] However, two more recent studies showed that the median effective dose of intrathecal **bupivacaine** for motor block was decreased by 13% to 35% in pregnant women at term.[46,47] Magnetic resonance imaging has confirmed that pregnant women have increased epidural blood volume, decreasing the capacity of the epidural space and decreasing the volume of lumbar cerebrospinal fluid.[48,49] These mechanical factors would explain the increased spread of local anesthetic. However, several studies have also shown that there is increased sensitivity to local anesthetics during pregnancy. The onset of conduction block in the vagus nerve with bupivacaine was faster in pregnant versus nonpregnant rabbits.[50,51] Sciatic nerve block was of longer duration and the **lidocaine** content in the nerves was lower at the time of return of deep pain in pregnant versus nonpregnant rats.[52] Sensory nerve action potentials were inhibited to a greater extent during median nerve block at the wrist with lidocaine in pregnant versus nonpregnant women.[53] The increased sensitivity may be caused by progesterone because exogenously administered progesterone increased the susceptibility of rabbit vagus nerves to bupivacaine.[54] One study found no changes in conduction block in pregnant rats and suggested that enhanced block may be caused by pregnancy-induced changes that facilitate diffusion of local anesthetic or an interaction with endogenous analgesic systems.[55]

Analgesia

Pregnancy is associated with increases in nociceptive response thresholds that are mediated by endogenous opioid systems.[56,57] The changes in threshold can be reproduced using exogenous progesterone and estrogen and appear to involve spinal cord kappa (κ) and delta (δ) opioid receptors and descending spinal α_2-noradrenergic pathways.[58] Neuropathic pain was also reduced in pregnant rats in a chronic constriction injury model.[59] Human studies continue to produce mixed results. Heat pain threshold was increased in term pregnant women, and this persisted during the first 24 to 48 hours after delivery.[60,61] However, a longitudinal study found that endogenous pain modulation evaluating both inhibitory and excitatory pain pathways did not change significantly during pregnancy.[62] Given the many different factors that influence pain behavior, especially those unique to pregnancy and delivery, it is difficult to determine how this change in pain threshold influences perioperative analgesic requirements.

DRUG USE DURING PREGNANCY

General Principles and Teratology

It would seem prudent to use only drugs considered safe in pregnancy. Unfortunately, the potential adverse effects of many drugs remain unclear. The U.S. Food and Drug Administration (FDA) approved 213 new medications between 2003 and 2012, and only 5% of them had human data in the pregnancy section of the label.[63] Pregnant women are not usually included in early clinical trials, and because of the low incidence of some complications, the first suggestion of adverse effects may be revealed only from postmarketing surveillance and registries of complications.[64] For long-term complications such as impaired neurodevelopment in children of mothers taking drugs acting on the central nervous system, it can be difficult to separate specific drug effects from

the influence of the underlying psychological disease and environment. There are often conflicting studies for many adverse events. This uncertainty about safety, and the difficulties in determining what public information is reliable, may convince mothers to refuse appropriate drug treatment. New improved drugs are available in many areas of therapeutics, but many prescribers prefer to use older drugs that have a longer empirical history of safety.

To avoid unnecessary exposure, nonpharmacologic techniques should be used when possible, and drugs should be used only when necessary. The risk-to-benefit ratio should justify the use of a drug given to a pregnant woman, and the minimum effective dose should be employed. Long-term effects of fetal drug exposure may not become apparent for many years. Therefore, physicians and patients should exercise caution in the use of any drug during pregnancy.

Sensitive serum pregnancy tests can diagnose pregnancy as early as 1 week after conception. Before drug therapy is started, a sensitive test should be used if there is any question about drug safety during a potential pregnancy.

Many resources on the safety of drugs in pregnancy are freely available online, in addition to the commercially available databases (Table 14.1). The FDA Office of Women's Health has created a pregnancy registry website that lists a variety of registries that women who have used specific medications during pregnancy can consult (see Table 14.1).

Teratology is the study of abnormal development or birth defects. Teratogens are substances that act to irreversibly alter growth, structure, or function of the developing embryo.[65] Ideally, preclinical studies would identify teratogens, but drug teratogenicity unfortunately can be markedly species-specific. For example, **thalidomide** produces phocomelia in primates but not in rodents.

In the United States, major malformations affect 2% to 3% of neonates.[66] A *major malformation* is defined as one that is incompatible with survival (e.g., anencephaly), one that requires major surgery for correction (e.g., cleft palate, congenital heart disease), or one that causes mental retardation. If all minor malformations (e.g., ear tags, extra digits) are included, the incidence of congenital anomalies may be as high as 7% to 10%. Exogenous causes of birth defects (e.g., radiation, infections, maternal metabolic disorders, drugs, environmental chemicals) account for almost 10% of all major birth defects and therefore affect only 0.2% to 0.3% of all births. Drug exposure explains only 2% to 3% of birth defects, and the majority of birth defects are of unknown etiology.

Drug teratogenicity is affected by the timing of exposure. Teratogen exposure in the first 2 weeks after conception is generally thought to be an all-or-nothing phenomenon (i.e., having either no effect or resulting in spontaneous fetal loss). Among women with a 28-day menstrual cycle, the classic period of susceptibility to teratogenic agents is during the period of organogenesis, which occurs primarily at 2.5 to 8 weeks after conception (31 to 71 days, or 4 to 10 weeks, after the first day of the last menstrual period) (Fig. 14.3). During organogenesis, each organ system has different critical periods of sensitivity, and there may be striking differences in effect. When administered between 35 and 37 days' gestation, thalidomide produces ear malformations; when administered between 41 and 44 days' gestation, it produces amelia or phocomelia. After this period, embryonic development is characterized primarily by increasing organ size; thus, the principal effect of exposure consists of growth restriction and/or effects on the nervous system and gonadal tissue. For example, diethylstilbestrol exposure during the second

trimester results in uterine anomalies that do not become apparent until after puberty.

It is also important to remember that the male partner may be taking teratogenic drugs and the drug may be present in semen at low concentrations. Although the magnitude of fetal risk is unclear, men are advised to avoid drugs such as **thalidomide, pomalidomide, ribavirin,** and **isotretinoin** if their partners could become pregnant.

U.S. Food and Drug Administration Categories

In 1979, the FDA introduced a five-tier alphabet drug classification system (ABCDX) to indicate the safety of medications used during pregnancy (Box 14.1). This system has been replaced but is discussed here because of its familiarity after nearly 40 years of use. The old system was oversimplified and confusing, and did not address the range of clinical situations or the range of possible effects. The categories implied a progressive fetal risk from Category A to X; however, the drugs in different categories may pose similar risks but may be listed in different categories on the basis of risk-to-benefit considerations. Category C included drugs with no well-conducted studies in humans, or drugs for which animal studies have demonstrated adverse effects, but the animal data may or may not be relevant to humans. The manufacturer's prescribing information for many drugs may state that the drug is not approved for use in pregnancy despite a long history of uncomplicated unlicensed or "off-label" use.[67] Although only 20 to 30 commonly used drugs are known teratogens, 7% of all the medications listed in the *Physicians' Desk Reference* were classified as Category X.[68] Use of potentially teratogenic drugs in pregnancy is surprisingly commonplace. In Canada, almost 8% of pregnant women received a prescription for a Category D or X medication.[69]

BOX 14.1 Previous U.S. Food and Drug Administration Drug Classification System

Category A
Controlled studies have shown no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.

Category B
No evidence of human fetal risk exists. Either animal reproduction studies have not demonstrated fetal risk but no controlled studies in pregnant women have been reported, or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of risk in later trimesters).

Category C
Risk cannot be ruled out. Either studies in animals have revealed adverse effects on the fetus (teratogenic, embryocidal, or other) but no controlled studies in women have been reported, or studies in women and animals are not available. These drugs should be given only if the potential benefit justifies the potential risk to the fetus.

Category D
Positive evidence of human fetal risk exists. However, the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed for a life-threatening condition or for a serious disease for which safer drugs cannot be used or are ineffective).

Category X
Contraindicated in pregnancy. Studies in animals or human beings have demonstrated fetal abnormalities, or evidence exists of fetal risk based on human experience, or both, and the risk in pregnant women clearly outweighs any possible benefit. These drugs are contraindicated in women who are or may become pregnant.

Modified from Friedman JM. Report of the Teratology Society Public Affairs Committee symposium on FDA classification of drugs. *Teratology.* 1993;48:5–6.

In response to the many concerns, the FDA held a public meeting in 1997 to discuss labeling of drugs. After much consultation and discussion, the FDA produced a final guideline in 2014, the Pregnancy and Lactation Labeling Rule (PLLR),[70] with a webpage containing explanatory and guidance documents.[71,72] The PLLR was implemented on June 30, 2015, and it required drug and biologic data sheets to have increased narrative and detailed reporting of relevant risks and clinical considerations supported by data for each of three sections: pregnancy, lactation, and use of drugs by women and men with reproductive capability.

The **pregnancy** section is divided into four subsections:

1. *General Information:* This is a statement of background risk (without drug exposure for any complication subsequently mentioned), and contact details for any registry that is monitoring the drug.

2. *Risk Summary:* This is a narrative summary of all the fetal risks.
3. *Clinical Considerations:* This section provides a discussion about risks of not treating, dosing adjustments, adverse effects, and effects on the course of labor and the neonate. Recommendations are given on how to avoid adverse effects.
4. *Background Data:* This section provides more detail about all the research used to support the risk summary and clinical considerations.

The **lactation** section has three subsections:

1. *Risk Summary:* This reports the effect of the drug on lactation, the concentration of drug in breast milk, and the relative infant dose. The summary must include the statement that the drug is compatible with breast-feeding if that is supported by the available data.
2. *Clinical Considerations:* Recommendations are given to minimize adverse effects.
3. *Background Data:* This section provides detailed summaries of data used to support the above.

The **females and males of reproductive potential** section has three subsections that cover issues of pregnancy testing, contraception, and infertility that may be relevant to use of the drug.

Drugs approved before June 30, 2001, and over-the-counter drugs are exempted, and there is phased implementation by 2020 for more recently approved drugs. The information must be updated whenever new information is available, so the data sheets should be a reliable source of the best information available in a standardized format.

The following sections provide more detail for perioperative drugs commonly used or encountered by anesthesia providers. As the FDA requires the drug data sheets to be continually updated, the reader is advised to check those for the detailed information.

Anesthetic Drugs

Anesthetic drugs are discussed in Chapter 17. No anesthetic drugs have been shown to be teratogenic. There is continued debate about anesthetic neurotoxicity in neonates and infants, and these issues could also be applicable to the fetus of mothers receiving anesthesia. In December 2016, the FDA issued a safety announcement that repeated or lengthy anesthetics in women during their third trimester could affect subsequent neurodevelopment in the child. However, this was updated in April 2017, to state that any planned anesthesia (and surgery) in the third trimester was usually medically necessary and that pregnant women should not delay or avoid these procedures.[73]

Analgesics

There is no known teratogenic risk associated with the use of **acetaminophen (paracetamol)**,[74] which is the preferred mild analgesic and antipyretic agent during pregnancy.

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with an increased risk for some birth defects.[75,76] The use of NSAIDs and aspirin in the first trimester has increased risk for pregnancy loss (adjusted odds ratio [OR], 1.8 to 8.1).[75] In the third trimester, NSAIDs and **aspirin** are usually avoided because of fetal risks, such as renal injury, oligohydramnios, and intrauterine constriction of the ductus arteriosus. So although chronic use of NSAIDs is common in pain and rheumatology, they are not recommended for use during pregnancy.[77]

Opioids such as **propoxyphene** and **codeine** are not considered to have teratogenic risk,[78] but they have well-known potential for addiction. Excessive antepartum use can also lead to neonatal opioid-withdrawal symptoms.[79] However, recent studies have concluded that maternal opioid use was associated with an increased OR of 1.8 to 2.7 for various cardiac birth defects, spina bifida, and gastroschisis.[76,80]

Tramadol has analgesic effects from weak opioid activity and inhibition of serotonin and norepinephrine uptake. Despite availability in some countries for more than 30 years, few data are available regarding potential adverse effects in pregnancy. Tramadol exposure in early pregnancy was associated with a higher number of spontaneous abortions, and it should be avoided in the first trimester.[81] Chronic tramadol use in later pregnancy may result in neonatal withdrawal syndrome.

Sedatives

Some studies have suggested that first-trimester exposure to **diazepam** increases the risk for cleft lip with or without cleft palate, neural tube defects, intestinal atresia, and limb defects.[82] Other reports have *not* suggested an increase in rate of congenital abnormalities after fetal exposure to benzodiazepines. Perinatal use of diazepam has been associated with hypotonia, hypothermia, and respiratory depression.[83] Overall, it appears that the teratogenic risk associated with benzodiazepines is small at most,[84,85] but there may be a small risk for preterm birth and low birth weight.[86] Benzodiazepines should only be used in the first trimester if the perceived benefit offsets the possible teratogenic risks and later neonatal effects of continued use. Short-acting agents are preferred.

Anticonvulsants

Anticonvulsant drugs are now prescribed for a large number of indications other than epilepsy, so that women without epilepsy taking these medications greatly outnumber women with epilepsy. Most of this increase in prescriptions has been for the newer drugs for indications such as pain and psychiatric disorders.[87] However, most studies of adverse effects have been in women taking anticonvulsant drugs during pregnancy for epilepsy.

Valproate has the highest teratogenic risk, followed by **phenytoin, phenobarbitone,** and **topiramate.** Valproate alone or combined with other antiepileptic drugs has the highest risk for adverse neurodevelopment, and **oxcarbazepine** and **lamotrigine** were associated with increased autism.[88] **Gabapentin** and **pregabalin** are not prescribed for epilepsy and can often be stopped during pregnancy; the overall risk with these two drugs is low.

Epilepsy is the most common serious neurologic problem during pregnancy.[89] It has been estimated that 3 to 5 births per thousand will be to women with epilepsy.[90] If a patient first presents for care during pregnancy, most authorities agree that the benefits of anticonvulsant therapy during pregnancy outweigh the risks of discontinuing the drug. All anticonvulsants cross the placenta. The fetal congenital anomaly rate in pregnant women with epilepsy who ingest anticonvulsant drugs is 4% to 8%, compared with a background incidence in the general population of 2% to 3%.[91,92] A twofold higher risk for minor malformations also exists in this population.[92] Cleft lip, with or without cleft palate, and congenital heart disease are especially common. Administration of **valproate** or **carbamazepine** entails a 1% risk for neural tube defects and other malformations; thus, alpha-fetoprotein screening and targeted ultrasonography are appropriate for patients taking these agents. In addition, the offspring of epileptic women have a 2% to 3% incidence of epilepsy, which is five times that of the general population.

No congenital malformations appear to be unique to any one anticonvulsant. The characteristics of these syndromes are so similar that the broad term **fetal anticonvulsant syndrome,** consisting primarily of orofacial, cardiovascular, and digital malformations, has been applied to almost every anticonvulsant drug.[93]

Among women taking **phenytoin,** there is a 2% to 5% risk for major congenital anomalies, primarily midline heart defects, orofacial clefts, and urogenital defects.[91] **Fetal hydantoin syndrome** is a constellation of minor anomalies, such as craniofacial abnormalities (short nose, flat nasal bridge, wide lips, hypertelorism, ptosis, epicanthal folds, low-set ears, and low hairline) and limb anomalies (distal digital hypoplasia, absent nails, and altered palmar crease). In addition, neonatal growth and performance delays have been documented. The risk for fetal hydantoin syndrome for the child of a woman taking phenytoin is approximately 10%.[94] Phenytoin may act as a competitive inhibitor of the placental transport of vitamin K. In addition, phenytoin may induce fetal hepatic metabolism of the coagulation factors. The resulting reduction in fetal coagulation factors is associated with a higher risk for hemorrhagic disease of the newborn.[95] To help prevent this coagulopathy, some physicians advocate oral vitamin K supplementation (10 mg/day) for pregnant epileptic patients during the last month of pregnancy in addition to the parenteral administration of vitamin K to the neonate at birth.[96] Several anticonvulsant medications have metabolites that typically are eliminated by the enzyme epoxide hydrolase. In one study, all women with low enzyme activity in amniocytes had affected fetuses.[97]

Carbamazepine is commonly used in the treatment of psychomotor (temporal lobe) epilepsy and grand mal epilepsy. In one prospective study, there was an 11% incidence of craniofacial defects, a 26% incidence of fingernail hypoplasia, and a 20% incidence of developmental delay in the children of women treated with carbamazepine during pregnancy.[98] This constellation of fetal effects, named **fetal carbamazepine syndrome,** closely resembles the malformations seen in cases of fetal hydantoin syndrome. Fetal exposure to carbamazepine also carries a 0.5% to 1% risk for spina bifida.[99] Although it is generally agreed that the use of carbamazepine in pregnancy is associated with a risk for neural tube defects and other anomalies, the exact magnitude of the risk from use of carbamazepine alone is unclear.[100–102]

Fetal phenobarbital syndrome is characterized by minor dysmorphic features similar to those seen with fetal hydantoin syndrome.[91] Fetal exposure to phenobarbital has also been associated with decreased neurodevelopment in neonates and children. Maternal phenobarbital use during pregnancy can result in hemorrhagic disease of the newborn and neonatal withdrawal symptoms after delivery. The withdrawal symptoms consist mostly of irritability, begin at about 7 days of life, and usually last for 2 to 6 weeks.[103]

Valproate is used to treat mood and psychiatric disorders, migraine, and epilepsy. Infants exposed to valproate have a 1% to 2% risk for spina bifida. **Fetal valproate syndrome** has been described; it is characterized by dysmorphic features, including epicanthal folds, shallow orbits, hypertelorism, low-set ears, flat nasal bridge, upturned nasal tip, microcephaly, thin vermillion borders, downturned mouth, thin overlapping fingers and toes, and hyperconvex fingernails.[91] Jentink et al.[104] found a markedly increased risk for spina bifida (OR, 12.7), craniosynostosis, cleft palate, atrial septal defect, and hypospadias, and they concluded that valproate monotherapy should be avoided during pregnancy. In recent years, warnings against the use of valproate have increased, and it is labeled as requiring a pregnancy prevention program, contraindicated, or even banned in some countries.[105]

Psychotropic Drugs

Up to 10% of pregnant women are prescribed antidepressants. The **tricyclic antidepressants** do not appear to be associated with congenital abnormalities or neurodevelopmental problems,[106] but the **monoamine oxidase inhibitors (MAOIs)** should be avoided.[107] **Selective serotonin reuptake inhibitors (SSRIs)** and related **serotonin norepinephrine reuptake inhibitors (SNRIs)** are now the usual first-line therapy for depression (see Chapter 50). These drugs cross the placenta to varying degrees, greater for **venlaflaxine** and **citalopram** and less for **paroxetine** and **sertraline.** As a class, they increase the rate of cardiac malformations and risk for perinatal complications. Fetal echocardiography should be considered in monitoring the pregnancy. There is a high (30%) rate of neonatal adaptation problems, and at least double the risk for persistent pulmonary hypertension of the newborn. There are no effects on neurodevelopmental delay or autism.[108] The American College of Obstetricians and Gynecologists (ACOG) has recommended that use of paroxetine be avoided in pregnant women (and in women planning pregnancy), and that fetal echocardiography should be considered in women who have used it during early pregnancy.[109]

The antipsychotic drugs are generally not associated with increased congenital malformations, with the possible exception of **risperidone.**[106] There are more data for the older antipsychotic drugs such as **trifluroperazine** and **haloperidol**

than for the newer atypical antipsychotics. There appears to be an increased risk for poor neonatal adaptation, but no effects on short-term neurodevelopment.

Lithium therapy is associated with a small increased risk for cardiac defects, especially **Ebstein's anomaly.**[106] Women should be monitored with fetal echocardiography as well as serum concentrations because pregnancy accelerates the excretion of lithium.[110] There appear to be no effects on child neurodevelopment.[107]

Cardiovascular Drugs

Antihypertensive agents such as methyldopa, labetalol, calcium entry–blocking agents, and hydralazine are safe in pregnancy. The safety of beta-adrenergic receptor antagonists (apart from labetalol) is less clear, although atenolol and metoprolol are often used during pregnancy. They are probably not associated with congenital malformations, but there are reports of preterm birth, fetal growth restriction, and poor neonatal adaptation. Spironolactone should be avoided.

The **angiotensin-converting enzyme inhibitors (ACEIs)** and **angiotensin receptor blockers (ARBs)** should be avoided during pregnancy. It is clear that second- and third-trimester use can cause fetal renal failure and oligohydramnios, which may result in fetal limb contractures, craniofacial deformities, and pulmonary hypoplasia. During the first trimester, there is some debate about congenital malformations, but given that subsequent use is not recommended, it is logical to switch drugs or not use them in the first place.

There are no reports of teratogenicity related to the use of inotropic agents such as **dopamine, dobutamine,** or **digoxin.** Physicians should monitor the maternal digoxin level to ensure a therapeutic level of drug during pregnancy.

Amiodarone is structurally similar to thyroxine and contains 37% iodine by weight. In a review of 64 reported pregnancies in which amiodarone was administered to the mothers, there was no clear increase in the incidence of malformations. However, 11 (17%) infants had evidence of hypothyroidism, and two (3%) neonates had goiter.[111,112] The use of amiodarone in pregnancy was associated with mild abnormalities of neurodevelopment in some of the hypothyroid infants, although this was also observed in some euthyroid infants.[112] This agent is most often used during pregnancy to treat fetal arrhythmias, and first-trimester exposure is rare.

Respiratory Drugs

Maternal **asthma** is relatively common in pregnancy, affecting 4% to 12% of pregnant women. It is important to maintain appropriate treatment because asthma can increase the risk for adverse fetal and maternal outcomes.[113]

Inhaled **β_2-adrenergic receptor agonists, cromolyn sodium,** and **corticosteroids** have not been associated with congenital malformations. Currently, **albuterol (salbutamol)** is the preferred short-acting β_2-adrenergic receptor agonist, and **salmeterol** is the preferred long-acting β_2-adrenergic receptor agonist. **Budesonide** is the recommended inhaled corticosteroid because it has a long history of safe usage, but there is no evidence against the other options.

Severe persistent asthma may require systemic oral corticosteroid therapy, and this has been associated with low birth weight and a 3- to 5-fold increase in the relative risk for cleft lip and palate.[114,115] However, other studies have found no adverse effects and, given the risks from severe asthma, oral corticosteroids should be used if required.

The 5-lipoxygenase inhibitors such as **montelukast** and **zafirlukast** are considered safe.[116] Women using montelukast enrolled in several teratogen information services around the world showed no increased risk for birth defects in 160 live births.[117] The leukotriene receptor antagonist **zileuton** is not recommended because of adverse effects in animals, and there are no known adverse effects in pregnancy for the monoclonal antibody **omalizumab.**

Methylxanthines such as **theophylline** and **aminophylline** have no adverse fetal effects, but the protein binding and metabolism of theophylline are both reduced during pregnancy, making it necessary to monitor drug concentrations and adjust maintenance doses.

Anticoagulants

Pregnancy is a hypercoagulable state because of relative increases in many coagulation factors and increased venous stasis. Pregnant women have five times the normal risk for venous thromboembolism, and thrombosis is a significant cause of maternal death.[118,119]

Heparins are large water-soluble molecules that do not cross the placenta**. Low-molecular-weight heparin (LMWH)** is usually preferred over **unfractionated heparin (UFH)** because it is easier to administer, does not require monitoring for prophylactic dosing, and has a more predictable effect.[119–121] LMWH is also less likely to cause heparin-induced thrombocytopenia and osteoporosis. Therapeutic dosing of LMWH is weight-based and can be monitored by anti-Xa levels. The shorter half-life of UFH means that anticoagulation is easier to reverse, and so UFH is often used closer to the time of delivery or in any situation in which this flexibility is useful. As pregnancy progresses, pharmacokinetic changes require doses to be increased.

Warfarin is a vitamin K antagonist that can cause an embryopathy, especially with first-trimester exposure. Warfarin embryopathy is characterized by nasal bone hypoplasia, depressed nasal bridge (often with a deep groove between the alae and nasal tip), and stippled epiphyses. Second- and third-trimester exposures can result in neurologic complications probably from intracranial microhemorrhages.[120,121] Warfarin is thus not used in pregnancy except in patients with mechanical heart valves where warfarin therapy gives the best maternal outcomes at the expense of increased fetal loss and malformations.[122] Lower warfarin doses (less than 5 mg/day) are sometimes used in the first trimester. The lower doses appear to have less teratogenic potential, but the risk is not eliminated.

The indirect factor Xa inhibitor **fondaprinux** (administered subcutaneously) and the direct thrombin inhibitor **argatroban** (administered intravenously) appear to be safe alternative options in patients unable to take heparin.[121]

However the direct oral anticoagulants such as the factor Xa inhibitor **rivaroxaban** and the thrombin inhibitor **dabigatran** cross the placenta and are not recommended in pregnancy.[123] Patients who become pregnant while taking these drugs are usually switched to heparin.

Low-dose **aspirin** and **clopidogrel** are safe during pregnancy.[121]

Antiemetics

Most women in early pregnancy have nausea, with or without vomiting (see Chapters 2 and 16).[124] Complementary therapies such as **acupressure** and **ginger** may be effective, but more than 20% of women will still receive prescription drug therapy.[125] The ACOG recommends **vitamin B_6 (pyridoxine),** with or without the antihistamine **doxylamine** as the initial drug of choice.[126] A combination of vitamin B_6 with doxylamine was previously available as **Bendectin,** but this was withdrawn by the manufacturer in 1983 because of allegations of teratogenicity that were later found to be false. Other formulations are now available, and there is no evidence of teratogenicity with them or other antihistamines. If symptoms persist, the next suggestions are antihistamines such as **diphenhydramine, dimenhydrinate,** and **promethazine,** and dopamine antagonists such as **prochlorperazine** and **trimethobenzamide,** but they may all cause sedation. **Metoclopramide** is a nonsedating dopamine antagonist, but it has a "black box" warning because chronic usage has been associated with rare cases of tardive dyskinesia. There are no specific safety concerns during pregnancy. The 5-hydroxytryptamine receptor antagonists such as **ondansetron** are very effective antiemetics, and ondansetron is now the most popular antiemetic, being used in 22% of pregnancies in the United States in 2014 compared with just 1.8% for doxylamine/pyridoxine.[125] Initial suggestions that ondansetron was associated with septal defects and cleft palate have not been confirmed, and it is generally considered safe.[127,128]

Corticosteroids are now commonly used for postoperative and chemotherapy-induced nausea and vomiting, and **methylprednisolone** has been used for refractory nausea and vomiting during pregnancy. However, a meta-analysis concluded that the use of glucocorticoids before 10 weeks' gestation was associated with a 3- to 5-fold increased risk for cleft lip with or without cleft palate[114]; thus, they should not be used during this period.

Antihistamines

Over 25% of breast-feeding women have taken histamine type 1 (H_1)-receptor antagonists that are available as over-the-counter medications or prescribed for many indications such as nausea and vomiting, allergies, or upper respiratory tract infections. These drugs provide symptomatic therapy with no influence on the course of the disease. Topical nasal sprays result in less fetal exposure than systemic medication. They are generally considered safe,[129,130] but the nonsedating antihistamines with the longest history of use such as **cetirizine** and **loratadine** are considered the first choice.[131]

Antidiabetic Drugs

Treatment of gestational diabetes mellitus with **insulin, metformin,** or **glyburide** is safe, although there is some debate over which drug should be the first-line treatment[132,133] (see Chapter 43).

Anti-Infective Drugs

Antibacterial and Antiparasitic Agents

Approximately 25% of women will receive an antibiotic during pregnancy.[134] Sepsis is a leading cause of maternal mortality, and treatment is essential. When administering perioperative antibiotics, anesthesia providers should be aware of the considerations regarding their use during pregnancy.[15,135] Although **penicillins** and **cephalosporins** are considered first-line treatment because of their long safety record, therapy is ultimately guided by local microbiology policies and bacterial sensitivity. **Carbapenems, monobactams, macrolides,** and **glycopeptides** are also considered safe.

Short-term use of **aminoglycosides** is acceptable, but **streptomycin** is avoided because of the risk for congenital deafness after first-trimester exposure. **Metronidazole** is considered safe, but some recommend avoiding it during the first trimester. **Sulphonamides** and **nitrofurantoin** are also considered safe, but the combination of **sulphamethoxazole-trimethoprim** is usually avoided in the first trimester because of concerns with trimethoprim, which is a folate antagonist.[134]

Tetracyclines should not be administered after the fifth week of pregnancy. They bind to developing enamel and cause discoloration of the teeth. They affect deciduous teeth when administered between approximately 26 weeks' gestation and 6 months of age in the infant, and they affect permanent teeth only if administered to children between approximately 6 months and 5 years of age. In addition, tetracyclines deposit in developing osseous sites and inhibit bone growth beginning in the second trimester.[135]

Fluoroquinolones should not be used in pregnancy or in children. They have a high affinity for bone tissue and cartilage and may cause arthropathies in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed during the first trimester.[135]

Malaria is a significant cause of maternal and fetal death. Pregnant women should avoid traveling to malaria-endemic areas, but **chloroquine** or **mefloquine** can be used for malaria chemoprophylaxis. They are not associated with an increase in spontaneous abortions or congenital malformations. **Doxycycline, primaquine,** and **atovaquone-proguanil** are not to be used in pregnancy.

Drugs for Treatment and Prophylaxis of Viral Infections

Treatment of **herpes simplex** and **herpes zoster** infections in the first trimester with **acyclovir** or **valacyclovir** has not been associated with an increased risk for birth defects.[136] Combination antiretroviral therapy has not been associated with major infant toxicity, even when the therapy was initiated in the first trimester of pregnancy.[137] The Antiretroviral

Pregnancy Registry was established in 1989 to detect any major teratogenic effect of the antiretroviral drugs. Each year it enrolls approximately 15% of all **human immunodeficiency virus (HIV)**-positive women who give birth to live infants in the United States plus a small number from other countries. It depends on voluntary reporting of prenatal exposure; therefore, drug-associated adverse events may not necessarily reflect true rates. Results of retrospective and clinical studies are also reviewed. Through July 2017, no apparent increase in the frequency of birth defects after first-trimester exposure to antiretroviral drugs compared with population-based comparators was reported.[138] A modest but statistically significant elevation of defect rates with didanosine and nelfinavir was reported, the clinical relevance of which is unclear. For treatment of chronic **hepatitis B, pegylated interferon** has been used but is usually not recommended. Given that treatment of maternal hepatitis and HIV have been well-studied and generally safe, postexposure prophylaxis is also considered safe, although some specific drugs are avoided.

It is generally appropriate to administer vaccinations during pregnancy because the risk associated with the disease may outweigh the risk associated with the vaccine. No evidence exists of risk to the fetus from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. However, live vaccines pose a theoretical risk to the fetus, so vaccination with live attenuated virus (e.g., **varicella**, **measles-mumps-rubella [MMR]**) or **tuberculosis** (e.g., bacillus Calmette Guérin [BCG]) is considered contraindicated.[139] **Influenza** vaccination is recommended with the inactivated virus preparation.[140] Prevention and treatment of influenza with either **zanamivir** or **oseltamivir** is possible during pregnancy[141]; no adverse fetal effects have been reported.[142]

Caffeine

No evidence suggests that caffeine has teratogenic effects in humans. In 2010, the ACOG published a committee opinion that was reaffirmed in 2016.[143] They concluded that (1) daily intake of less than 200 mg of caffeine was not associated with an increased risk for miscarriage, but contradictory data did not allow for a recommendation regarding daily intake above this level; (2) moderate caffeine intake does not appear to contribute to preterm birth; and (3) the association between caffeine intake and fetal growth restriction was equivocal. A subsequent review concluded with more certainty that moderate or even high amounts of caffeine-containing foods and beverages did not increase the risk for congenital malformations, miscarriage, or fetal growth restriction.[144]

Cannabis

The prevalence of **marijuana** use in pregnancy usually ranges from 2% to 5%, but can be as high as 28% in some groups. Although marijuana may be prescribed for medical indications, most women taking marijuana do not have these indications. There do not appear to be any effects of marijuana on congenital defects, preterm birth, or perinatal mortality. Women are advised to stop marijuana because of the adverse effects of smoking and concerns regarding impaired neurodevelopment.[145]

Smoking Cessation Therapies

Smoking during pregnancy is clearly linked to multiple adverse fetal, neonatal, and childhood effects. The benefits and risks in pregnancy of nicotine replacement therapies and alternative forms of nicotine such as e-cigarettes and vaping are not known.[146] Other drugs such as **bupropion** and **varenicline** are not associated with congenital malformations. However, both drugs have an FDA warning about the risk for maternal psychiatric symptoms and suicide.

Specific Highly Teratogenic Drugs

Some drugs are so highly teratogenic that two simultaneous forms of reliable contraception are recommended or required during treatment of either partner, sometimes to be continued for months or years after stopping the drug. Some examples include (1) **thalidomide** (and analogues), which is still used for erythema nodosum leprosum and multiple myeloma; (2) the antiviral **ribavirin,** which is used for hepatitis C and viral hemorrhagic fevers; (3) **isotretinoin,** which is used for cystic acne; and (4) **acitretin,** which is used for severe psoriasis. In Europe, **valproate** now cannot be used unless there is a pregnancy prevention program.[105]

DRUG USE DURING LACTATION

With current recommendations to breast-feed exclusively for 6 months, and maintain breast-feeding for 2 years if possible, it is likely that most infants will be exposed to maternal medications through breast milk. Women on average take four medications during lactation.[147] Nursing mothers are understandably concerned about the transfer of drugs and chemicals to breast milk. Correct advice is important to prevent them from unnecessarily stopping breast-feeding or discontinuing appropriate drug treatment. Unfortunately, only about 5% of drugs have human data on breast-feeding.[63] It can be difficult to decide which of the many, sometimes conflicting, sources of public information to trust.

Pharmaceutical information leaflets from manufacturers often discourage the use of drugs during breast-feeding simply as a general precaution. The most comprehensive up-to-date information is found in the Drugs and Lactation Database (LactMed) of the National Library of Medicine's Toxicology Data Network (TOXNET).[148] The American Academy of Pediatrics (AAP) has published policy statements on the benefits of breast-feeding[149] and the use of drugs during lactation.[150] The Centers for Disease Control and Prevention (CDC) provides online information regarding breast-feeding and various toxins and infectious diseases.[151]

For the future, it is expected that the revised FDA Pregnancy and Lactation Labeling Rule (PLLR)[70] will lead to better information on drugs and breast-feeding. Human data

are used whenever possible, and animal data are purposefully omitted when human data are available. The lactation section has three parts that must be updated whenever new information is available. The risk summary outlines the drug absorption and transfer to milk, estimated infant exposure, effects on infant and possibly maternal milk production, and a risk/benefit statement including a statement that the drug is compatible with breast-feeding if human data are available to support that conclusion. The clinical considerations part gives advice on minimizing infant drug exposure and recommendations for monitoring possible drug effects. The data section gives more details about the available evidence to support the risk summary. Given the large knowledge gap, there are still many issues to resolve, such as the level of evidence required for the appropriate advice on the label, setting research priorities for the large number of older drugs still being used for which there is no information, and best research methods for human studies depending on the drug. These were discussed and summarized at a recent 2-day FDA meeting in June 2016.[152]

Only a few types of drugs such as cytotoxic and immunosuppressive drugs (e.g., **cyclophosphamide**, **methotrexate**) and radioactive compounds are strongly contraindicated during breast-feeding.[65] Mothers breast-feeding infants with **glucose-6-phosphate-dehydrogenase (G6PD) deficiency** should avoid **fava beans** and drugs such as **sulfonamides,** including the combination of **sulfamethoxazole and trimethoprim, nitrofurantoin, primaquine,** and **phenazopyridine.**

Maternal drugs may also affect lactation, and some are used therapeutically for this purpose.[150,153] Drugs that increase the secretion of prolactin can stimulate milk production; these include dopamine antagonists such as **phenothiazines, haloperidol,** and antipsychotics such as **sulpiride** and **risperidone. Metoclopramide** and **domperidone** are the drugs most commonly used off-label as galactagogues even though the FDA specifically warns against domperidone because of QT interval prolongation and the risk for cardiac arrhythmias.[154] Drugs that decrease the production of milk include **sympathomimetic vasoconstrictors, anticholinergics, diuretics, high-dose estrogen,** and dopamine agonists such as **bromocriptine** and **cabergoline. Bromocriptine** is no longer approved for postpartum lactation suppression because of its association with puerperal seizures, stroke, and myocardial infarction, so that **cabergoline** off-label is often the only choice.[155] Women who smoke also have lower milk production.

Transfer of Drugs to Breast Milk

Mammary epithelial cells form a barrier separating plasma from milk. For the first few days postpartum, larger molecules such as maternal immunoglobulins are able to pass to colostrum. The intracellular junctions gradually close so that by 1 week postpartum, only molecules less than 200 daltons readily pass across the membrane. However, mastitis may cause membrane disruption and allow larger molecules to pass into milk.

Drug transfer to breast milk occurs mainly by passive diffusion.[155] The rate of passive transfer into breast milk depends on the lipid solubility, molecular weight, degree of ionization, and protein binding of the drug. Nonionized molecules of small molecular weight (e.g., **ethanol**) are readily transferred into breast milk. The pH of milk is slightly acidic (pH approximately 7.1) but variable (pH 6.7 to 7.3), affecting the transfer of weak bases and acids with pKa near that range. Protein binding is one of the main determinants of drug transfer because human milk has a relatively low concentration of proteins (8 g/L) such as casein that do not bind drugs well. Drugs that have more than 85% maternal protein binding are often not detectable in the infant.[156] The fat composition of breast milk shows diurnal variation, and decreases after months of breast-feeding.

There are also a few active transport systems in humans, including the sodium iodide symporter that transports iodide, and the breast cancer resistance protein that transports a variety of drugs such as **acyclovir** and **methotrexate.**[155]

Animal studies are usually not useful indicators of human transfer because of large differences in anatomy, milk composition, and transport processes. Obtaining initial human data can be difficult. Pharmacokinetic modeling is now being used to provide preliminary predictions of milk transfer and to guide the appropriate pharmacokinetic study design in women.[157] Simple concentration data in breast milk may be sufficient to provide reassurance for some drugs not expected to have any adverse effect on infants. Otherwise, one can attempt to quantify infant exposure.

The amount of a drug in breast milk is a variable fraction of the maternal blood concentration, which is proportional to the maternal dose. Quoted maternal milk-to-plasma ratios can vary because drug transfer is a time-dependent process. Even when calculated under steady-state conditions, there can be large individual variation. **Absolute infant dose** (μg/kg/day) can be calculated as the product of the average concentration in milk and the estimated daily volume of milk intake, and **relative infant dose** can be estimated by dividing the absolute infant dose by the maternal dose. It has been suggested that a relative infant dose less than 10% is generally safe, but this will also depend on the oral bioavailability of the drug in the infant and the relative toxicity of individual agents.

However, physicians and patients should be aware of the following disclaimers. First, in the case of toxic drugs, any exposure may be inappropriate. Second, the infant may be allergic to a drug consumed by the mother. Third, there may be unknown, long-term effects of even small doses of drugs. Fourth, individual variability in drug disposition may lead to unexpectedly high maternal blood and breast milk concentrations. Finally, infants have immature enzyme systems and metabolic pathways, and some drugs are eliminated more slowly. The benefits of breast-feeding are well known, and the risk for drug exposure must be weighed against these benefits.

Lactation is not fully established during the first several days postpartum. The neonate receives only a small volume

of colostrum, and little drug is excreted through milk at this time. Thus, only very small amounts of drugs administered after vaginal or cesarean delivery would reach the neonate, and significant effects should be unlikely. However, neonatal metabolism and elimination are also poorly developed, and several days of maternal opioid analgesia may result in neonatal accumulation and side effects.

When a mother requires a daily dose of a drug during lactation, the minimum effective dose should be used. Some mothers requiring long-term therapy would already have been taking drugs during pregnancy, and the fetus would have been exposed to concentrations much greater than those achieved in the infant through breast-feeding. Thus, if a drug has been acceptable during pregnancy, it is often reasonable to continue it during breast-feeding unless there are drug-specific factors to the contrary.[158] For example, poor neonatal elimination of **lamotrigine** may eventually lead to drug accumulation in the infant and adverse effects. In general, medications should be taken after breast-feeding, and long-acting preparations should be avoided. If the infant nurses less frequently overnight, ingestion of a drug dose at night after nursing will decrease the infant's exposure.

The following sections provide more detail for perioperative drugs commonly encountered by anesthesia providers. As the FDA is continually updating information, the reader is advised to check the information on LactMed for the latest recommendations.[148]

Anesthetic Drugs

There is generally no concern regarding anesthetic drugs in the breast milk of women who require an anesthetic during delivery and the immediate postpartum period,[159] or in women with established breast-feeding well after delivery.[160,161] Hospitals should have a perioperative policy that supports mothers to continue breast-feeding. The short exposure time and rapid elimination of anesthetic drugs means that mothers can often breast-feed immediately following anesthesia or procedural sedation. However, the prolonged use of postoperative analgesics will increase the infant dose, and adverse effects have been described, particularly for opioids. Analgesics will be discussed in the subsequent section.

A variety of adjunct drugs are sometimes used as part of a multimodal analgesia regimen.[159] These include **ketamine, gabapentin** and **pregabalin, dexmedetomidine,** neuraxial **clonidine,** and **local anesthetics administered** by various routes. Postoperative infusions of ketamine are probably best avoided because limited safety data are available, and there is some concern for neurotoxicity. Gabapentin has less transfer to breast milk and is thus considered safer than pregabalin. Dexmedetomidine transfer is negligible, and a single dose of neuraxial clonidine is also unlikely to have any relevance to breast-feeding. Local anesthetics are large polarized molecules that do not transfer well to breast milk and are poorly absorbed orally. Other perioperative medications such as antiemetics are also considered safe, with nonsedating drugs such as **5HT3 receptor antagonists, dexamethasone,** and **metoclopramide** preferred, although drugs such as **promethazine** and **prochlorperazine** have a long history of safe use.

Analgesics

Acetaminiophen (paracetamol) is the standard analgesic recommended for nursing mothers. The dose to the infant is less than 2% of the maternal dose and is considered safe.

NSAIDs are generally considered safe because they have low lipid solubility, high protein binding, and limited transfer to breast milk.[75] Some NSAIDs specifically recommended as compatible with breast-feeding are **ibuprofen, flurbiprofen, naproxen,** and **celecoxib. Ketorolac** previously had a "black box" warning that it was "contraindicated in nursing mothers," but current recommendations only say that it should be used with caution. Theoretically, NSAIDs with antiplatelet effects should be avoided by mothers who are breast-feeding neonates with platelet dysfunction, and all NSAIDs should be avoided in infants with ductal-dependent cardiac abnormalities. With **aspirin**, there is limited transfer of salicylic acid into breast milk because it exists mostly in the ionized form. After single oral doses, peak milk levels occur at approximately 3 hours with milk-to-plasma concentration ratios between 0.03 and 0.05.[162] However, maternal ingestion of *high doses* (e.g., more than 3 g per day) may result in maternal and breast milk concentrations sufficiently high to affect platelet aggregation in the infant. Reduced neonatal clearance of salicylic acid may lead to drug accumulation and toxic effects, even when repeated exposures are small.[163] Because of these concerns, the World Health Organization (WHO) Working Group on Human Lactation has classified salicylates as unsafe for use by nursing women.[164] Low doses of aspirin prescribed as antiplatelet therapy may be acceptable.[150]

It was thought previously that opioids used by nursing mothers were highly unlikely to have adverse effects on breast-fed infants. Normal maternal doses of **codeine, morphine, tramadol,** and **meperidine (pethidine)** do not have obvious adverse effects on most nursing infants.[81,150] The dose detectable in breast milk is 1% to 2% of the mother's dose and is unlikely to have significant pharmacologic activity.

Neonates are particularly vulnerable because their drug metabolism and elimination are poorly developed. Neonates of mothers receiving meperidine by intravenous patient-controlled analgesia after cesarean delivery had significant neurobehavioral depression by the third day.[166] The cumulative maternal meperidine dose at 48 hours postpartum was 14 mg/kg. No neonatal depression was seen in a morphine group in whom the cumulative maternal dose at 48 hours was 2.1 mg/kg. Both opioids and their major metabolites accumulated in colostrum. In a subsequent study,[167] the cumulative opioid doses at 48 hours were lower (meperidine 4.7 mg/kg and morphine 0.54 mg/kg), but infants in the morphine group were still more alert and oriented. With lower maternal morphine doses, concentrations in colostrum may even be undetectable.[168]

Recently, it has been recognized that infants of breast-feeding mothers taking **codeine** may have CNS depression. In 2006, the full-term 13-day-old infant of a mother taking a modest dose of codeine for episiotomy pain died of an apparent morphine overdose. It was discovered that the mother was heterozygous for a CYP2D6*2A allele with CYP2D6*2×2 gene duplication, making her an ultrarapid metabolizer of codeine. This condition resulted in a breast milk morphine concentration of 87 ng/mL, compared with the expected typical range of 1.9 to 20.5 ng/mL.[169] This case prompted the FDA to release a Public Health Advisory advising caution in the use of codeine-containing medications by breast-feeding women. The number of ultrarapid metabolizers is estimated to vary between 1 and 28 per 100 people. The updated warning notes that breast-feeding is not recommended when taking codeine because of the risk for serious adverse reactions.[170] In addition, genetic variability in UGT2B7 may increase the formation of active morphine-6-glucuronide. It is estimated that 1.4% of Western European women would have both the CYP2D6 and UGT2B7 variants promoting neonatal depression.[171]

Polymorphisms have less effect on the metabolism and analgesic effects of **oxycodone, hydrocodone,** and **tramadol** than **codeine.**[172] Maternal oxycodone has been associated with neonatal depression.[173] The FDA also gave a warning on April 20, 2017, against tramadol based on its CYP2D6 metabolism.[170] This is controversial because tramadol continues to be used in other parts of the world where it is considered safe. Tramadol also has a nonopioid mechanism of action, and proponents of tramadol argue that banning it will force prescribers to use other opioids that have greater inherent risk.[174]

Professional organizations differ in their recommendations for opioids, partly shaped by their normal clinical practice. Although anesthesia providers may be comfortable using tramadol, oxycodone, and hydrocodone in limited doses, the AAP recommends oral **morphine** and **hydromorphone.**[150] Nevertheless, breast-feeding babies of all mothers receiving opioids should be observed for sedation and respiratory depression.

Sedatives

The benzodiazepines are considered safe, although long-acting drugs such as **diazepam** are metabolized slowly in the infant, and accumulation can lead to sedation and poor feeding. Relatively short-acting agents with inactive metabolites, such as **oxazepam, lorazepam, alprazolam,** or **midazolam,** are preferred.[175]

Anticonvulsants

Some anticonvulsant drugs are used for many other indications apart from epilepsy, so that up to 80% of these drug prescriptions may be for patients without epilepsy. In contrast to use during pregnancy, congenital malformations are no longer a concern. **Carbamazepine** and **valproate** have low excretion into breast milk and are considered the safest choices.[176] Studies have detected only small amounts of **phenytoin, phenobarbital,** and **diazepam** in breast milk.[177,178] However, infants eliminate **phenobarbital** and **diazepam** slowly, so these agents may accumulate. Women taking a barbiturate or a benzodiazepine should observe their infants for evidence of sedation and withdrawal.[92,150] There are conflicting recommendations for the newer anticonvulsants. Lamotrigine concentrations in breast-fed infants can be very high, and some recommend that the drug should be avoided.[176] However, other authors note that the mother has usually been taking this drug throughout pregnancy already and that there is no evidence to recommend stopping the drug.[179] It has been suggested that breast-feeding may improve the development of children exposed to anticonvulsants during pregnancy.[107]

Cruikshank et al.[180] measured breast milk **magnesium** concentrations in 10 preeclamptic women who were receiving magnesium sulfate 1 g/h intravenously for 24 hours after delivery. The mean breast milk magnesium concentration was 6.4 ± 0.4 mg/dL, compared with 4.8 ± 0.5 mg/dL in controls. Breast milk calcium concentrations were not affected by magnesium sulfate therapy.

Psychotropic Drugs

Psychotropic agents may be of concern because many of these medications have long half-lives and the effect of even small doses on the developing nervous system is not known. Nevertheless, most antidepressants have low milk-to-plasma ratios and appear to have little if any immediate effect on the infant. Benefits of treatment usually outweigh any risks.[107]

The **SSRIs** are the most commonly prescribed antidepressants. Although they are found in breast milk, concentrations in infant plasma are very low and sometimes undetectable, especially with sertraline, which is often the preferred choice. The **SNRIs** and **norepinephrine reuptake inhibitors (NRIs)** have safety profiles similar to SSRIs, but fewer studies are available so they may be considered second-line. There are more data for venlafaxine, so this drug may be preferred. For the remaining antidepressants, there are concerns for neonatal seizures with **bupropion,** and **St John's wort** is considered safe.[175]

Data are available for only a few of the traditional antidopamine antipsychotics such as perphenazine and haloperidol, but there are no reported adverse effects on the infant. For the newer atypical antipsychotics, the most experience is with **olanzapine** and **quetiapine,** so they are considered the best choices.

Breast milk concentrations of **lithium** are one-third to one-half of maternal serum concentrations,[138,181] and infant serum concentrations during breast-feeding are much lower than fetal serum concentrations that occur when mothers take lithium during pregnancy. Neonatal clearance of lithium is reduced, and it may be useful to monitor neonatal lithium concentrations.

Cardiovascular Drugs

In general most of the first-line **antihypertensive** drugs are considered safe, although it would be prudent to use those

for which more safety information exists.[182] High-dose **thiazide diuretics** have been used to suppress postpartum lactation, but this should not be a problem with the normal antihypertensive doses. **Calcium entry–blocking agents** have been well studied, especially **nifedipine,** which has minimal transfer to breast milk. Except for **lisinopril,** most ACEIs are usually metabolized to the active drug, which is poorly absorbed orally. Lactation data are available for several ACEIs, including **captopril** and **enalapril,** so that these are often the recommended choices. There are currently no data for ARBs, and an alternative drug may be preferred, even though ARBs are all very highly protein bound and theoretically safe. **Beta-adrenergic receptor antagonists** are a diverse group, and it is best to avoid those with low protein binding and thus have a relatively higher transfer to breast milk, and those that are excreted renally, which are more likely to accumulate in neonates. Both **atenolol** (10% protein binding and 85% renal excretion) and **acebutalol** have been associated with neonatal cyanosis, bradycardia, hypotension, tachypnea, and hypothermia. However, these beta-adrenergic receptor antagonists are usually better tolerated by the mother than those with poor transfer to breast milk such as **propranolol. Labetalol** and **metoprolol** are often used as they lie between these two extremes. Among second-line drugs, **central alpha-adrenergic agonists** can cause sedation and have mixed effects on serum prolactin, and so they are probably best avoided.[182]

Amiodarone concentrations in the infant are unpredictable but may be sufficiently high to cause cardiac effects. Iodine released during its metabolism may cause thyroid dysfunction. Amiodarone has a very long half-life and is still excreted in breast milk weeks after stopping the drug.

Maternal protein binding of **digoxin** limits infant drug exposure; after a maternal dose of 0.25 mg, a peak breast milk concentration of 0.6 to 1.0 ng/mL occurs and the milk-to-plasma concentration ratio at the 4-hour peak is between 0.8 and 0.9 ng/mL. In 24 hours, an infant might receive approximately 1% of the maternal digoxin dose,[183] and no adverse effects have been reported in nursing infants of mothers taking this drug.

There are no safety data for **statins,** but they are not recommended during breast-feeding because of concerns that they may disrupt infant lipid metabolism.

Respiratory Drugs and Corticosteroids

Albuterol (**salbutamol**), **terbutaline,** and **salmeterol** inhalers are considered compatible with breast-feeding. Maximum milk concentrations of **theophylline** are achieved between 1 and 3 hours after an oral dose. It has been calculated that the nursing infant receives less than 1% of the maternal dose. Such exposure appears to have no adverse effects.

Inhaled and oral **corticosteroids** are also considered safe. Katz and Duncan[184] obtained breast milk 2 hours after an oral dose of 10 mg of **prednisone** in one nursing mother. They detected breast milk concentrations of prednisone and prednisolone that would be unlikely to result in any deleterious effect on the infant. McKenzie et al.[185] administered 5 mg of radioactive prednisolone to seven patients and found that 0.14% (a negligible quantity) of the radioactive label was secreted in the milk in the subsequent 60 hours. Thus, breast-feeding is not contraindicated in mothers taking corticosteroids. Even at a maternal dosage of 80 mg/day, the nursing infant would ingest a dose equivalent to less than 10% of its endogenous cortisol production.[186]

Anticoagulants

Heparin is not excreted into breast milk because of its high molecular weight and charge, and **LMWHs** behave similarly. In addition, these drugs are not active when given orally, and so they are all considered safe during breast-feeding.[187] **Warfarin** is highly (98%) protein bound and only appears in breast milk in insignificant quantities, so is also considered safe[188] There are no data for the **direct thrombin inhibitors,** and their package inserts recommend that they should not be used during breast-feeding. On first principles, significant transfer is unlikely, although there are differences among these drugs. **Dabigatran** has a low molecular weight and is likely to have the greatest oral bioavailability, but this is still only about 7%. The newer **direct factor Xa drugs** are orally active, and they are currently not recommended for use during breast-feeding. However, data for **rivaroxaban** show that the infant only receives about 1% of the maternal weight-adjusted dose. Antiplatelet drugs such as **clopidogrel** and **dypyridamole** are not recommended during breast-feeding, but low-dose **aspirin** is considered acceptable.

Antihistamines

No harmful effects have been noted with maternal use of antihistamines.[189] These drugs do not appear to affect the milk supply. Little antihistamine is excreted into breast milk, further confirming safety of use during lactation.[190]

In theory, histamine type 2 (H_2)-receptor antagonists might suppress gastric acidity or cause CNS stimulation in the infant, but these effects have not been confirmed in published studies. **Famotidine, nizatidine,** and **roxatidine** are less concentrated in breast milk and may be preferable to cimetidine.[191]

Antidiabetic Drugs

Of the antidiabetic drugs,[192] **insulin** is normally present in breast milk and not absorbed by the infant. Insulin-dependent mothers should continue insulin with close monitoring of glucose. **Metformin** is found in low doses in maternal milk, and infants are exposed to less than 0.5% of the maternal dose. Nevertheless it should be used with caution while nursing preterm infants and neonates. Second-generation **sulphonylureas** are falling out of favor, but there are data for **glyburide** and **glipizide.** Although glyburide was not detected in human milk, monitoring of infant blood glucose is still advised. The **thiazolidonediones** are greater than 99% bound to plasma proteins and so should not affect the infant, but **rosiglitazone** is labeled as contraindicated, leaving only **pioglitazone** to be used in this class. There are no data for the **dipeptidyl peptidase-4 inhibitors** or the **glucagon-like**

peptide-1 receptor agonists, but the current recommendation is to use with caution rather than avoid. **Saxagliptin** currently has the highest protein binding and shortest half-life, and so it is probably the best choice among the dipeptidyl peptidase-4 inhibitors. The **sodium-glucose cotransporter-2 inhibitors** are not currently recommended because of theoretical risk to the developing kidney, even though no data are available.

Anti-Infective Drugs

Penicillin and its derivatives are considered safe in nursing mothers. With the usual therapeutic doses of **ampicillin,** the milk-to-plasma concentration ratio is 0.2 or less and no adverse effects have been noted in nursing infants.[193] Theoretically, infant diarrhea or candidiasis might occur with prolonged therapy. **Cephalosporins** appear in trace amounts in breast milk and are also considered safe.

Sulfonamides displace bilirubin from binding sites on albumin, so these drugs are best avoided during the first 5 days of life or in mothers of preterm infants with hyperbilirubinemia. Sulfonamides appear in breast milk in small amounts. **Sulfasalazine** has been associated with diarrhea and bloody diarrhea in an infant.[150] Sulfonamides should be avoided in infants with G6PD deficiency.

Tetracyclines are normally avoided during breast-feeding because of the potential for tooth staining and delayed bone growth. The breast milk concentration of tetracycline is about one-half the maternal plasma concentration, but tetracycline has a high affinity for both calcium and protein, and the amount of free tetracycline available for systemic absorption is very small. Thus, some references consider a short course of tetracyclines to be compatible with breast-feeding. **Fluoroquinolones** are usually avoided in pregnancy, but there is disagreement over their safety during breast-feeding.

Use of drugs for treatment and prophylaxis of viral infections is a controversial area requiring specialist consultation, and recommendations may depend on the resources available. Infants should have been immunized against hepatitis B. Breast-feeding is usually not a contraindication to the mother receiving various drugs to treat hepatitis B such as **tenovir** and **lamivudine.** Hepatitis C is not transmitted through breast milk, and breast-feeding is not a contraindication to the use of the various anti–hepatitis C drugs.[194] In the United States, where mothers have access to clean water and affordable infant formula, the CDC and the AAP recommend that women being treated for HIV should not breast-feed. In countries with limited resources, the World Health Organization recommends that patients being treated for HIV should breast-feed their infants.[a] In the case of postexposure prophylaxis, some authorities recommend discontinuing breast-feeding until the risk for HIV infection is better known. Except for yellow fever and smallpox, most vaccines, including influenza, can be administered during breast-feeding.[150]

Alcohol

About 50% of nursing mothers consume alcohol. The alcohol concentration in breast milk is similar to that in maternal blood, but it is estimated that the infant dose is only about 5% of the weight-adjusted maternal dose. Neonates take twice as long as adults to metabolize alcohol, but neither short-term behavioral changes nor long-term effects of alcoholic milk have been established. Advice on alcohol varies widely. Occasional maternal alcohol consumption within normal recommendations (approximately 10 to 20 g/day) should not affect the breast-fed infant,[195] although some advise not breast-feeding for 2 hours after alcohol intake to be prudent.[151]

Caffeine

Moderate maternal intake of caffeine does not adversely affect the breast-fed infant. One study noted that breast milk contains only 1% of the total maternal dose of caffeine.[196] If a mother drinks excessive amounts of coffee, caffeine might accumulate in the infant and the infant might show signs of caffeine stimulation (e.g., irritability, poor sleeping pattern). Nursing mothers should limit their intake to a moderate level of caffeinated beverages (e.g., 2 to 3 cups per day).[150]

Cannabis

The prevalence of **marijuana** use during pregnancy is 2% to 5%, but may be as high as 28% in some demographic groups.[197] Apart from the possible effects of cannabis on the infant, an additional concern is the possible effect of the drug on the mother affecting her ability to care for the child. Women who smoke marijuana have a lower prolactin level, and tetrahydrocannabinol (THC) can alter the mother's perception of the environment. Passive smoking is another route for drug exposure. There are regulatory and methodologic issues complicating interpretation of data on the effects of THC and non-THC cannabinoids such as **cannabidiol.**[198] The percentage of THC in marijuana has also been rising steadily in recent years. THC is lipophilic and will be transferred to the breast-feeding infant who will test positive for the substance. Although oral bioavailability of THC is low, there are few data for the effects of THC on the newborn and infant. In general there have been more studies that show possible adverse effects to the infant than those that show no effect.[197] Thus the prevailing medical opinion is that cannabis should not be used during breast-feeding.[145] However, in mothers determined to continue cannabis, the benefits of breast-feeding may outweigh the effects of cannabinoids in breast milk.

KEY POINTS

- Appropriate maternal treatment is essential to maintain fetal health.
- On average, women take over four drugs during pregnancy.
- Few drugs have detailed safety information for pregnancy and breast-feeding.
- The basis of safety for many drugs during pregnancy is a long history of uneventful use.
- Potential adverse fetal outcomes of the use of drugs during pregnancy include teratogenic effects, fetal loss, and fetal growth restriction. After delivery, there may be problems with neonatal adaptation and neurodevelopment.
- The U.S. Food and Drug Administration has implemented the Pregnancy and Lactation Labeling Rule.
- Physiologic changes of pregnancy can alter drug disposition and drug effect.
- Anticonvulsants and antidepressants have a high risk for adverse fetal effects.
- Acetaminophen is the safest analgesic for use during pregnancy, and NSAIDs should probably be avoided during pregnancy.
- Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) should be avoided during pregnancy.
- LactMed is an up-to-date resource for safety of drugs during breast-feeding.
- Oral opioids such as codeine and tramadol are not recommended during breast-feeding.

In Vitro Fertilization and Other Assisted Reproductive Technology

Lawrence C. Tsen, MD

CHAPTER OUTLINE

In 1978, Steptoe and Edwards[1] reported the first live birth of an infant produced from *in vitro* fertilization (IVF) techniques. Initiated with a single oocyte recovered laparoscopically just before ovulation and inseminated *in vitro,* the resulting embryo was grown in culture media for 2.5 days to the eight-cell stage and transferred to the uterine cavity (i.e., embryo transfer [ET]).

Conceived as a treatment for infertility secondary to chronic fallopian tube disease, current indications for these techniques, which as a group are referred to as assisted reproductive technology (ART), include (1) inadequate oocyte quality or number (donor oocyte therapy), irreparability or absence of the uterus (surrogate uterus programs), and significant comorbidities (embryo and ovarian tissue cryopreservation) in women; (2) sperm deficiencies in men; and (3) certain genetic aberrations in couples.[2]

In 1981, Edwards[3] estimated that 15 to 20 infants would be born worldwide through the use of IVF and ET techniques. Scientific advances, coupled with ethical and moral acceptance of ART, have resulted in dramatic global increases in the number of infants born (Fig. 15.1).[4] Within the United States (Fig. 15.2), the initiation of 231,936 ART cycles resulted in the birth of 72,913 infants in 2015.[5]

Despite the application of ART procedures to a greater diversity of infertility causes, the probability of a live birth after a cycle of hormonal stimulation has increased from 6% in 1985 to 37% in 2014 in women younger than 35 years of age.[5] Attention to subtle differences in culture media as well as improvements in laboratory methods, retrieval routes, and transfer techniques are primarily responsible for these improved results.[6] Given the importance of small alterations to the overall success of ART, coupled with the costs (i.e., approximately $13,000 for each cycle that progresses to transfer) and limited insurance coverage for these procedures,[7] it is prudent for anesthesia providers to be aware of the potential effects that anesthetic agents may have on gametes or embryos.

ASSISTED REPRODUCTIVE TECHNOLOGY PROCEDURES

Hormonal Stimulation

Limited initially by the *single* preovulatory oocyte generated with each natural menstrual cycle,[1] the introduction of follicular hormonal stimulation has significantly increased the probability of a live birth through the retrieval of *multiple* oocytes per cycle. Hormonal regimens typically initiate a cycle with a gonadotropin-releasing hormone agonist to induce pituitary and ovarian suppression, followed by follicle-stimulating hormone and human menopausal gonadotropin to stimulate the development and growth of multiple ovarian follicles. Human chorionic gonadotropin (hCG) is later added to induce maturation and demargination of the oocyte from the follicular wall before retrieval. Although the goal of these regimens is

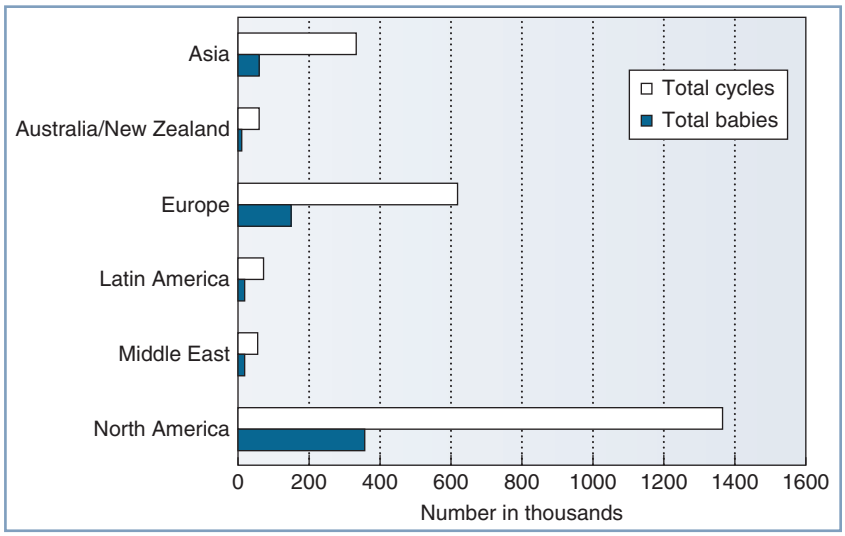

Fig. 15.1 Numbers of initiated assisted reproductive technology *(ART)* cycles and infants born worldwide by region in 2010 (from data accumulated by 61 countries) as reported by the International Committee for Monitoring Assisted Reproductive Technology (ICMART). (Data from Dyer S, Chambers GM, deMouzon J, et al. International Committee for Monitoring Assisted Reproductive Technology (ICMART) world report. Assisted Reproductive Technology 2008, 2009, 2010. *Hum Reprod.* 2016;31:1588–1609.)

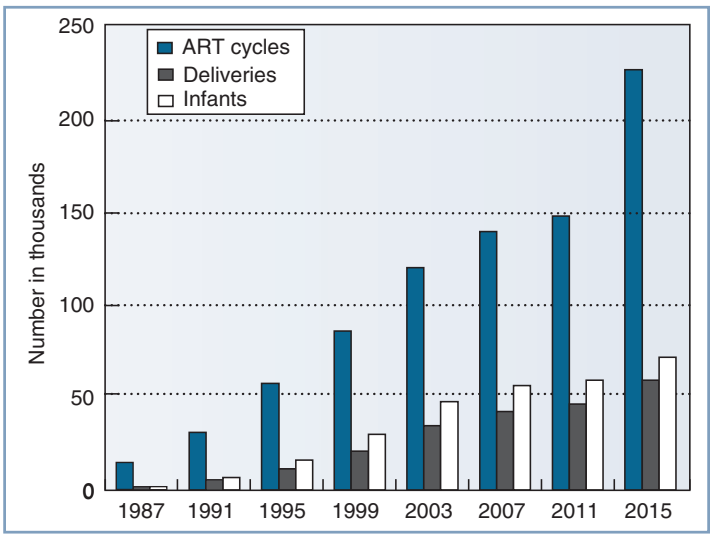

Fig. 15.2 Numbers of assisted reproductive technology *(ART)* cycles performed, live-birth deliveries, and infants born in the United States using ART from 1987 to 2015, as reported to the Centers for Disease Control and Prevention, Division of Reproductive Health, and the Society for Assisted Reproductive Technology Registry. (Data from U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, Division of Reproductive Health. 2014 Assisted Reproductive Technology [ART] Report. Atlanta, CDC/DRH, 2017.)

the generation of 10 to 15 oocytes, the physiologic responses to hormonal manipulation can be unpredictable, particularly with primary cycles, resulting in either failed or superovulation. All visible ovarian follicles are aspirated (see later discussion), with each follicle usually containing a single oocyte.

After oocyte retrieval, pituitary function is usually insufficient to provide adequate hormonal support for the growing corpus luteum. For this reason, parenteral progesterone is administered until either the first pregnancy test results are known or the first trimester of pregnancy is completed.

Oocyte Retrieval

Originally conducted with direct visualization of the ovarian follicles through pelvic laparoscopy,[1] the majority of oocyte retrievals are currently performed through a transvaginal approach with ultrasonographic guidance (Fig. 15.3).[8] Laparoscopic oocyte retrieval is typically reserved for situations in which tubal transfer is planned (i.e., gamete intrafallopian transfer [GIFT] or zygote intrafallopian transfer [ZIFT]; see later discussions).

Oocyte retrieval is performed promptly between 34 to 36 hours after hCG administration to prevent spontaneous ovulation from occurring. With the use of a needle introduced through the vaginal fornix and affixed to a channel on the side of a transvaginal ultrasound probe, the ovary is punctured and follicular fluid is aspirated. Oocytes are identified in the aspirated fluid, immediately washed in culture media, and microscopically examined to determine their stage of meiosis. Oocytes are classified as postmature metaphase II, mature metaphase II, metaphase I, or prophase I based on their nuclear, cytoplasmic, and extracellular composition.

In vitro Fertilization

Although the term *in vitro fertilization* is often used synonymously with any aspect of ART, technically it applies only to the process of oocyte fertilization with spermatozoa in culture media. After a microscopic examination, oocytes are incubated for 4 to 6 hours in culture media that resembles human fallopian tube fluid and are then inseminated. The insemination process is sometimes delayed with immature oocytes

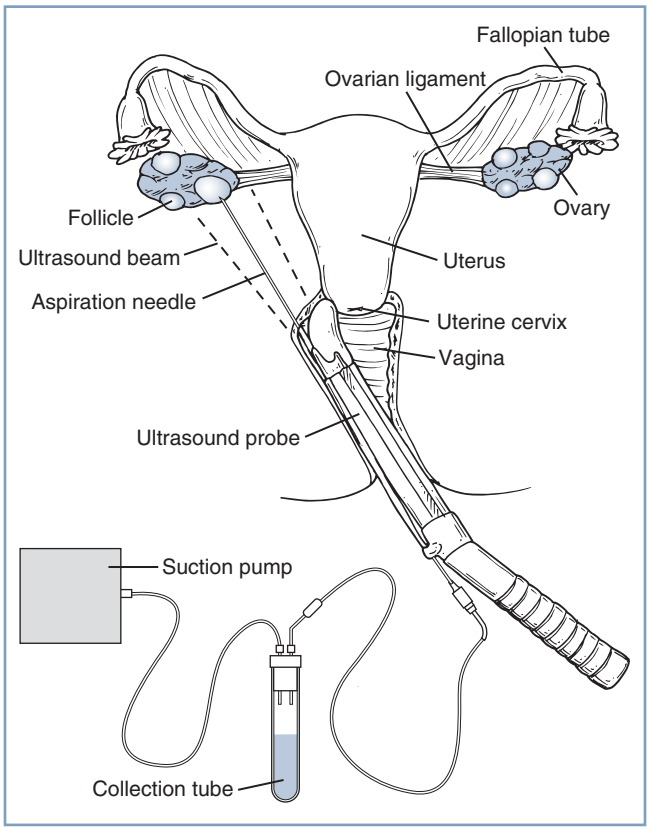

Fig. 15.3 Transvaginal ultrasound-guided oocyte retrieval. The ultrasonographic probe is placed in the vagina and advanced into the posterior fornix. The needle, previously inserted through the needle guide, is advanced through the vaginal wall and ovarian capsule. (Redrawn from Steinbrook R. Egg donation and human embryonic stem-cell research. *N Engl J Med* 2006;354:324–326. Copyright © 2006 Massachusetts Medical Society. All rights reserved.)

(e.g., metaphase I) to increase the probability of normal (i.e., monospermic) fertilization.

At 16 to 20 hours after insemination, the oocytes are examined for evidence of fertilization (i.e., the presence of two pronuclei and two polar bodies in the perivitelline space) (Fig. 15.4).[9] The advantages of IVF include the ability to document the process of fertilization and to enhance sperm motility or penetration (e.g., intracytoplasmic sperm injection). IVF followed by ET represents approximately 99% of the ART procedures used in the United States[5]; less than 1% occur via GIFT or ZIFT procedures (see later discussions). Male factor infertility is present in approximately 35% of the couples seeking ART procedures, with intracytoplasmic sperm injection being the most frequently used therapeutic intervention.[5]

Embryo Transfer

Following incubation for 3 to 5 days, embryos resulting from IVF may be transferred via a catheter into the fallopian tubes (i.e., ZIFT) or, more commonly, into the uterine cavity (IVF-ET). The advantages of transcervical ET are (1) simplicity—it does not require laparoscopy or anesthesia; (2) low cost, especially compared with laparoscopic intrafallopian transfer procedures; and (3) the ability to proceed without patent fallopian tube(s).

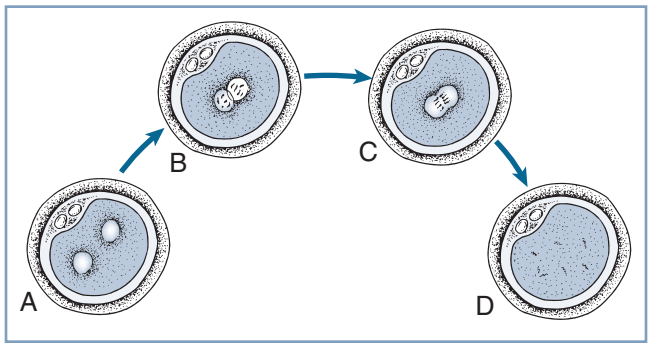

Fig. 15.4 Pronuclear stage prezygote. (A) At 8 to 10 hours after insemination, pronuclei are barely visible and may be spaced slightly apart. (B) After 12 hours, pronuclei have migrated to the center of the cell and are clearly seen. (C) At 20 to 22 hours, nuclear envelopes break down and pronuclei begin to fade from view. (D) The one-cell zygote before the first cleavage. (Redrawn from Veeck LL. *Atlas of the Human Oocyte and Early Conceptus*. Baltimore, MD: Williams & Wilkins; 1991:43.)

The primary disadvantage of transcervical ET is that the probability of successful pregnancy is slightly less than that with ZIFT. Embryos in excess of those required for transfer may be frozen in 1,2-propanediol or glycerol and stored for possible later transfer.

Gamete Intrafallopian Transfer

GIFT procedures consist of the transabdominal or transvaginal collection of oocytes followed by a microscopic inspection of the oocytes' quality and maturation in a laboratory adjacent to the operating room. Mature oocytes are aspirated into a transfer catheter with washed partner or donor sperm, and the contents (gametes) are injected into the distal 3 to 6 cm of one or both fallopian tubes. The catheter is subsequently inspected microscopically to verify that oocytes have not been retained. The GIFT procedure does not involve IVF, because fertilization occurs *in vivo* in the natural milieu of the fallopian tube.

Specific advantages of the GIFT procedure include (1) the convenience of oocyte retrieval and ET occurring within a single operative event, (2) the elimination of IVF, and (3) the embryos reaching the uterine cavity at a potentially more appropriate (i.e., later) stage of development than with IVF-ET.[10] The primary disadvantage is that fertilization cannot be documented, a critical factor when this capacity is in question (e.g., couples with male or immunologic factors). Normally, 50% to 70% of inseminated oocytes become fertilized[11]; however, lower fertilization rates are often observed in couples with severe male factor infertility or in women with antisperm antibodies. Other limitations are the required presence of at least one patent fallopian tube and the requirement for laparoscopic surgery.

Zygote Intrafallopian Transfer

ZIFT (also known as pronuclear stage transfer [PROST]) consists of oocyte retrieval followed by IVF. At 16 to 20 hours after insemination, the oocytes are examined for the presence

of two distinct pronuclei (i.e., the pronuclear stage; see Fig. 15.4), which indicates that fertilization has occurred. The patient is anesthetized for laparoscopy, and pronuclear stage embryos (usually no more than four) are transferred through a catheter into the distal portion of a fallopian tube (as described for GIFT). Advantages of ZIFT include (1) the documentation of fertilization, (2) the avoidance of laparoscopy if fertilization is not successful (approximately 13% of inseminations),[5] (3) a shorter exposure to the laboratory environment than with IVF-ET, and (4) the potential for embryos to reach the uterine cavity at a more appropriate stage of development than with IVF-ET (i.e., approximately the fifth day after insemination). Its disadvantages and limitations include (1) the added inconvenience and cost of a two-stage procedure, (2) the requirement for laparoscopic surgery, and (3) the requirement for at least one patent fallopian tube.

SUCCESS OF ASSISTED REPRODUCTIVE TECHNOLOGY

The Society for Assisted Reproductive Technology (SART) and the American Society for Reproductive Medicine (ASRM) collaborate with the Centers for Disease Control and Prevention (CDC) to maintain a data registry and analyze the results of all ART cycles initiated during each calendar year in the United States.[5]

Maternal age is the dominant factor in predicting successful pregnancy after an ART procedure (Fig. 15.5), affecting the ovarian response to fertility medications and rates of fertilization, implantation, miscarriage, and live birth. For example, in 2014, 37% of ART cycles in women younger than 35 years of age, compared with 1% in women older than 44 years of age, led to the delivery of one or more infants.[5] In 2014, the average age of a woman having an ART procedure in the United States was 36 years.

Although pregnancy and delivery rates have historically been greater for tubal transfers (i.e., GIFT, ZIFT) than for transcervical uterine transfers (IVF-ET), greater parity in these rates has developed in recent years.[5,11] The early postovulatory uterine environment has been postulated to be unfavorable to early embryo growth.[11] Tubal transfer procedures allow embryos 3 to 5 days to reach the uterine cavity, when the environment for implantation may be more receptive. Lower implantation rates after transcervical ET may also be explained by (1) adverse uterine effects produced by the transfer procedure, (2) uterine contractions expelling transfer fluid and embryos,[12] and (3) the absence of yet undiscovered tubal factors that promote early embryo growth and implantation.[11,13]

OBSTETRIC COMPLICATIONS

ART hormonal stimulation regimens are associated with increased coagulation and decreased fibrinolysis when evaluated by individual hemostatic markers and global assessment tools (i.e., thromboelastography).[14,15] These alterations are especially significant in the setting of the most common ovarian stimulation complication, a phenomenon termed *ovarian hyperstimulation syndrome* (OHSS). Mild cases of OHSS may manifest as abdominal discomfort, bilateral ovarian enlargement, and ascites, whereas severe cases may result in follicular rupture and hemorrhage, pleural effusion, hemoconcentration, oliguria, and thromboembolic events.[16–18] In the presence of OHSS, the oocyte retrieval may be triggered earlier, and in severe cases, the embryo transfer may be delayed to limit exposure to exogenous and endogenous hormones. Anesthetic

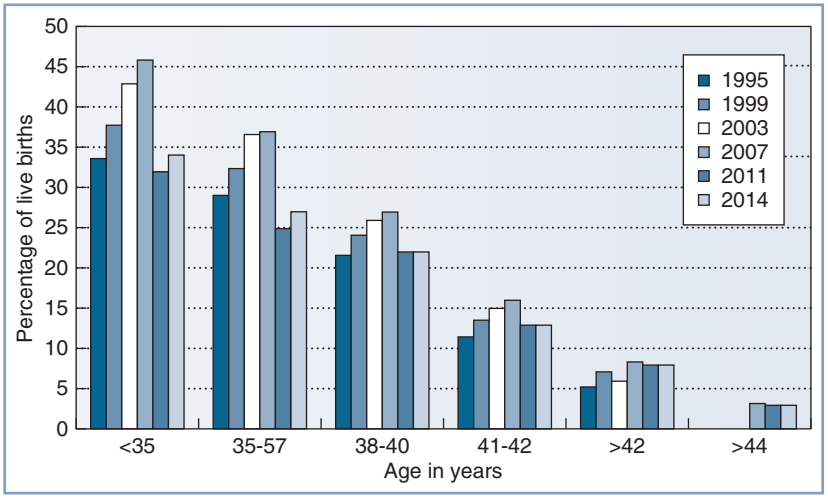

Fig. 15.5 Percentage of transfers that resulted in live births with assisted reproductive technology *(ART)* cycles using fresh nondonor eggs or embryos, according to the women's age in the years from 1995 to 2014, as reported to the Centers for Disease Control and Prevention, Division of Reproductive Health, and the Society for Assisted Reproductive Technology Registry. The first year in which data for women older than 42 years of age were subdivided into 43 to 44 years of age and older than 44 years of age was in 2007. (Data from U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, Division of Reproductive Health. 2014 Assisted Reproductive Technology (ART) Report. Atlanta, CDC/DRH, 2017.)

implications of OHSS include increased free drug concentrations (see later discussion) and greater perioperative pain from larger follicle numbers. Rarely, an emergency laparoscopy or laparotomy is required for excision of an ovarian cyst rupture or release of an ovarian pedicle torsion.[18] Abdominal paracentesis and thoracentesis may be necessary before the induction of general anesthesia in patients with respiratory compromise caused by massive ascites or pleural effusions.

Multiple-gestation pregnancies represented 25% of the deliveries that followed ART procedures in the United States in 2014, of which 96% were twins.[5] Although the transfer of a greater number of embryos or oocytes increases both the probability of a live birth and the likelihood of a multifetal pregnancy, maternal and perinatal morbidity and mortality for multiple versus singleton gestation pregnancies are at least doubled,[19] but are no different than spontaneously conceived pregnancies.[20] In an effort to reduce the incidence and sequelae of multifetal pregnancies, many ART programs and societies, and even some countries, have mandated a limit on the number of embryos or oocytes that are transferred.[21] In the presence of triplet or higher-order gestation pregnancies, selective reductions can be performed; however, these procedures are subject to a number of medical and ethical considerations.

Ectopic pregnancies occur up to five times more frequently in ART pregnancies than with natural pregnancies (2%), primarily owing to the greater prevalence of fallopian tube disease among infertility patients.[22] The transfer site (uterine versus fallopian tube) *per se* does not appear to be a predisposing factor in the development of ectopic pregnancies; however, a greater number occur after uterine transfer, because women with bilateral tubal disease are not candidates for GIFT or ZIFT procedures. In approximately 10% of ectopic pregnancy cases, the ectopic embryo develops in conjunction with an ongoing intrauterine pregnancy and requires a termination or surgical removal within the first trimester.[22]

Preterm, low-birth-weight, and small-for-gestational-age infants are more common with ART singleton pregnancies than with natural pregnancies, although the prevalence of admission into the neonatal intensive care unit, duration of infant hospital stay after birth, and the incidence of infant death appear similar (Fig. 15.6).[23] The difference appears to be a result of infertility *per se* rather than the ART procedures, because previously infertile women who conceive independent of ART also are at greater risk for preterm delivery.[23]

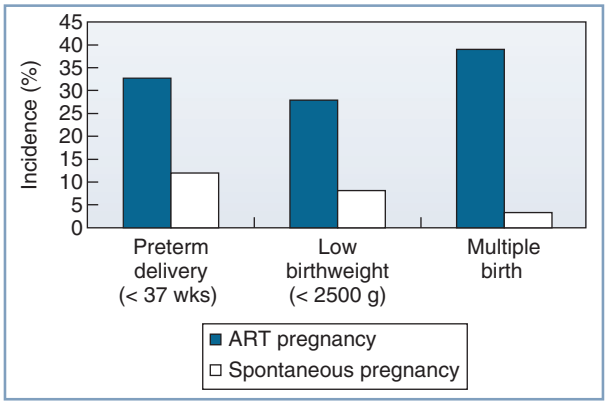

Fig. 15.6 Outcomes associated with births from assisted reproductive technology *(ART)* and spontaneous pregnancies in the general population. (Data from Sunderam S, Kissin DM, Crawford SB, et al. Assisted Reproductive Technology Surveillance-United States, 2014. *MMWR Surveill Summ.* 2017;66:1–24.)

EFFECTS OF ANESTHESIA ON REPRODUCTION

General Considerations

In 1987, Boyers et al.[24] reported that oocytes recovered by laparoscopic techniques in patients who had received general anesthesia (isoflurane or enflurane with a 50% nitrous oxide–oxygen mixture) were less likely to be fertilized if the duration of the procedure was prolonged. Specifically, fertilization rates for the first- and last-recovered oocytes were 69% and 54%, respectively, when the difference in exposure time exceeded 5 minutes. The investigators advanced the following two plausible explanations for this difference: (1) the acidification of follicular fluid by intraperitoneal carbon dioxide and (2) the effects of anesthesia.

The potential association between anesthetic techniques and agents, and outcomes of ART procedures must be interpreted with caution. For example, one study concluded that oocyte cleavage rates were significantly lower with general anesthesia than with epidural anesthesia.[25] However, a laparoscopic (instead of transvaginal) retrieval method was used in the general anesthesia group, and carbon dioxide pneumoperitoneum may significantly decrease both follicular fluid pH and oocyte fertilization rates. Another report commented on the effects of different anesthetic techniques, but failed to disclose the actual anesthetic agents that were administered.[26] In addition, conclusions based on animal data may not reflect the human experience owing to significant interspecies and assay method differences.[27]

Assessment of specific anesthetic drugs must also be interpreted in context; relevant factors include (1) the method of administration, (2) dose of anesthetic agents, (3) combination with other drugs, (4) timing of administration, and (5) duration of exposure. For example, local anesthetic agents yield dissimilar pharmacokinetic profiles when administered via paracervical, epidural, and intrathecal techniques. Anesthetic agents may also affect unfertilized oocytes and fertilized embryos differently; thus, studies of anesthetic agents used for a GIFT (prefertilization) procedure should not be directly compared with studies of agents used for a ZIFT (postfertilization) procedure. Finally, significantly greater free concentrations of certain agents (e.g., bupivacaine) exist during ART stimulation because of a decrease in plasma protein binding capacity associated with hormonal manupulation.[28] Thus, when selecting anesthetic techniques or agents for an ART procedure, the clinician should weigh their known benefits (e.g., greater hemodynamic stability, less nausea, less psychomotor impairment) and potential risks (e.g., lower delivery rates).

Local Anesthetic Agents

In animal models, the effect of local anesthetic agents on reproductive physiology appears to be related to the agent, timing, and dose of exposure. Using mouse oocytes incubated for 30 minutes in culture media with known concentrations of lidocaine, bupivacaine, or 2-chloroprocaine, Schnell et al.[29] demonstrated that lidocaine and 2-chloroprocaine adversely affected both fertilization and embryo development at concentrations of 1.0 and 0.1 μg/mL, respectively (Figs. 15.7 and 15.8). In contrast, bupivacaine produced adverse effects only at the highest concentration studied (100 μg/mL). Similarly, Del Valle and Orihuela[30] demonstrated that after 48 hours of culture, 24% of mouse embryos exposed to lidocaine 10 μg/mL, in comparison with none in the control group, showed evidence of degeneration. Finally, Ahuja[31] observed that hamster oocytes exposed to procaine or tetracaine had impaired zona reactions, potentially allowing additional sperm to enter the oocyte and create abnormal chromosomal numbers (polyploidy).

These *in vitro* findings may have limited clinical relevance, however, given the lower anesthetic concentrations that are administered in clinical practice and the washing and screening procedures that oocytes undergo before fertilization and transfer. Human trial data appear to indicate minimal oocyte and embryo alterations with local anesthetic agents used during oocyte retrieval, GIFT, or ZIFT procedures. Wikland et al.[32] reported that the incidence of oocyte fertilization and clinical pregnancy was not reduced among women who received a modified paracervical block with lidocaine for transvaginal oocyte retrieval (Fig. 15.9). Favorable pregnancy rates have also been reported after GIFT procedures performed during epidural anesthesia with lidocaine.[25]

Opioids and Benzodiazepines

Fentanyl, alfentanil, remifentanil, and meperidine do not appear to interfere with either fertilization or preimplantation embryo development in animal and human trials.[33,34] When given during oocyte retrieval, fentanyl and alfentanil

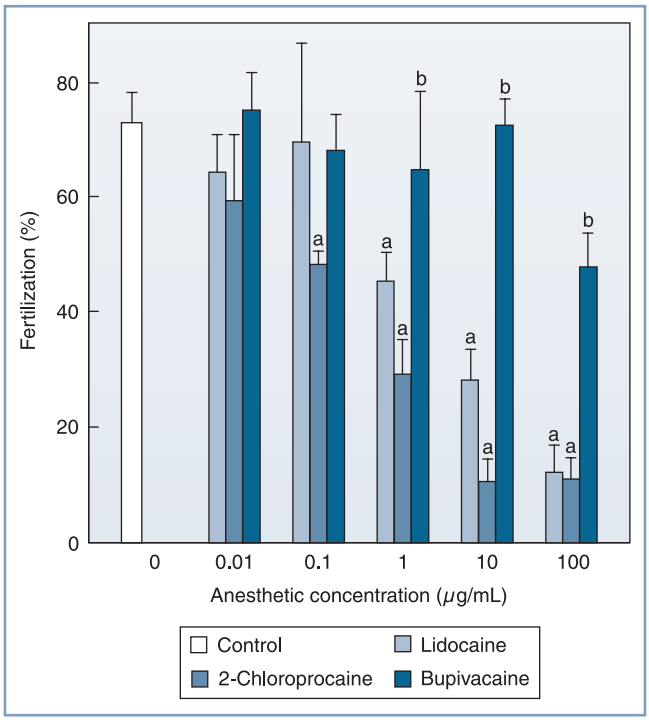

Fig. 15.7 Fertilization of mouse oocytes at 48 hours (mean ± SD) for each anesthetic exposure group. *a, P* < .05 (anesthetics compared with control); *b, P* < .05 (lidocaine and 2-chloroprocaine compared with bupivacaine). (Modified from Schnell VL, Sacco AG, Savoy-Moore RT, et al. Effects of oocyte exposure to local anesthetics on in vitro fertilization and embryo development in the mouse. *Reprod Toxicol.* 1992;6:323–327.)

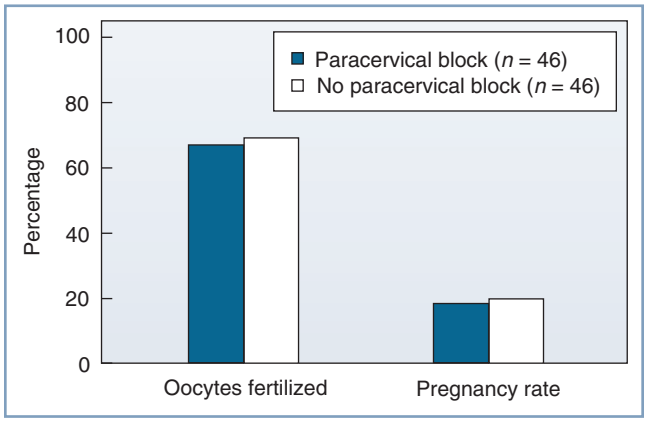

Fig. 15.9 Fertilization and pregnancy rates after transvaginal oocyte retrieval with and without lidocaine paracervical block. Fertilization and cleavage rates did not differ in the two groups. (Modified from Wikland M, Evers H, Jakobsson AH, et al. The concentration of lidocaine in follicular fluid when used for paracervical block in a human IVF-ET programme. *Hum Reprod.* 1990;5:920–923.)

were detected in extremely low (or undetectable) follicular fluid concentrations.[35] With alfentanil, a 10:1 ratio between serum and follicular fluid was observed 15 minutes after the initial bolus dose.[36] Morphine appears unique in terms of adverse effects; when sea urchin eggs were incubated in morphine (equivalent to a human dose of 50 mg), more than one sperm entered approximately 30% of the oocytes.[37]

Midazolam administered systemically in preovulatory mice did not impair fertilization or embryo development *in vivo* or *in vitro,* even when given in doses up to 500 times those used clinically.[38] When used in small bolus or infusion doses for anxiolysis and sedation for ART in humans, midazolam has not been detected in follicular fluid and does not appear to be teratogenic.[39,40]

Propofol, Thiopental, and Ketamine

Most animal and human trials suggest minimal to no detrimental effects of propofol on fertilization and early embryo development,[41–45] despite accumulating in a dose- and duration-dependent manner within the follicular fluid.[46–48] General anesthesia provided with propofol and a 50% oxygen-air mixture was associated with fertilization, embryo cleavage, and implantation rates similar to those produced by a paracervical block with mepivacaine.[44] Hamster oocytes exposed to very high concentrations of propofol (20 µg/mL) demonstrated no DNA damage—even through two metaphases—when evaluated by sister chromatid exchange assays, a sensitive index of genotoxic effects.[49] These concentrations were 40 times greater than those detected clinically in the follicular fluid of patients undergoing oocyte retrieval.[46,47] The induction and maintenance of general anesthesia with propofol for GIFT procedures demonstrated negligible differences in reproductive outcomes from women receiving other forms of anesthesia.[42] By contrast, a smaller incidence of ongoing pregnancies was observed among women given propofol–nitrous oxide anesthesia for ZIFT procedures compared with thiopental–nitrous oxide–isoflurane anesthesia.[50] Further investigation is necessary to further elucidate the full effects of propofol on various reproductive outcomes.

Both thiopental and thiamylal (5 mg/kg) can be detected in follicular fluid as early as 11 minutes after their administration for induction of general anesthesia in patients undergoing GIFT procedures.[51] No adverse reproductive effects have been observed with these agents, and when they were specifically compared with propofol (2.7 mg/kg) for GIFT procedures, no differences in clinical pregnancy rates were noted.[43]

Ketamine (0.75 mg/kg), administered with midazolam (0.06 mg/kg), has been reported to be an acceptable alternative to general anesthesia with isoflurane for oocyte retrieval.[52] No differences in reproductive outcomes were observed; however, the study was not powered to adequately assess this result.

Nitrous Oxide

Nitrous oxide reduces methionine synthetase activity, nonmethylated folate derivatives, and DNA synthesis in animals and humans.[53,54] Nitrous oxide also impairs the function of mitotic spindles in cell cultures.[55] Although Warren et al.[56] reported that two-cell mouse embryos exposed to nitrous oxide within 4 hours of the expected onset of cleavage were less likely to develop to the blastocyst stage (Fig. 15.10), this difference had resolved by later stages of embryo development.

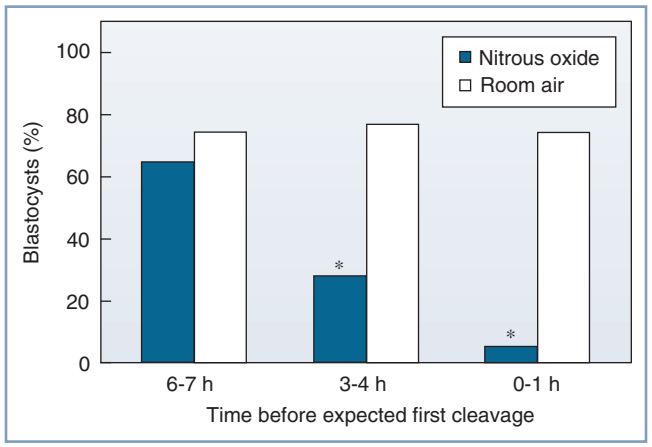

Fig. 15.10 Developmental outcome of two-cell mouse embryos exposed to 60% nitrous oxide/40% oxygen for 30 minutes *in vitro.* Administration of nitrous oxide within 4 hours of anticipated cleavage decreased the percentage of embryos reaching the blastocyst stage. $*P < .05$ compared with the room air (i.e., control) group. (Modified from Warren JR, Shaw B, Steinkampf MP. Effects of nitrous oxide on preimplantation mouse embryo cleavage and development. *Biol Reprod.* 1990;43:158–161.)

Clinical studies of anesthesia for laparoscopic ART procedures support the administration of nitrous oxide during GIFT and ZIFT procedures.[42,50,57] In a multicenter study, Beilin et al.[42] observed a delivery rate of 35% among women given nitrous oxide for GIFT procedures, compared with 30% among women who did not receive nitrous oxide. In women undergoing oocyte retrieval, Handa-Tsutsui and Kodaka[58] reported lower target-controlled propofol doses with a 50% nitrous oxide–oxygen mixture than with an oxygen-air mixture. The authors reported that there were no alterations in pregnancy rates, but the study was not adequately powered to identify a difference.

Volatile Halogenated Agents

Volatile halogenated agents have been observed to depress DNA synthesis and mitosis in cell cultures.[59,60] Sturrock and Nunn[59] noted that volatile halogenated agents prevent cytoplasmic cleavage during mitosis, leading to a greater number of abnormal mitotic figures (e.g., tripolar and tetrapolar nuclear phases). Isoflurane adversely affects embryo development *in vitro.*[34,61] Warren et al.[61] reported that two-cell mouse embryos exposed to 3% (but not 1.5%) isoflurane for 1 hour were less likely to develop to the blastocyst stage (Fig. 15.11), but only when isoflurane was given within 4 hours of the predicted onset of cleavage.

Volatile halogenated agents may also affect ART outcomes through an increase in prolactin levels. High prolactin levels have been associated with diminished oocyte development

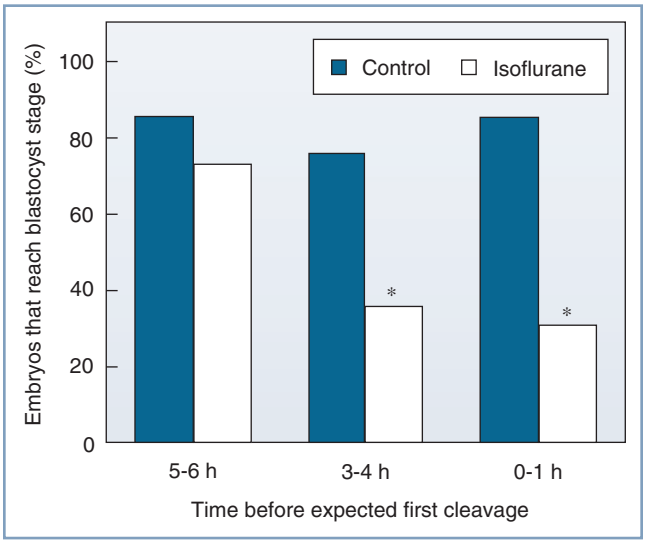

Fig. 15.11 Developmental outcome of two-cell mouse embryos exposed *in vitro* to 3% isoflurane for 30 minutes at various times in relation to expected onset of the first cleavage in vitro. *$P < .01$. (Modified from Warren JR, Shaw B, Steinkampf MP. Inhibition of preimplantation mouse embryo development by isoflurane. *Am J Obstet Gynecol.* 1992;166:693–698.)

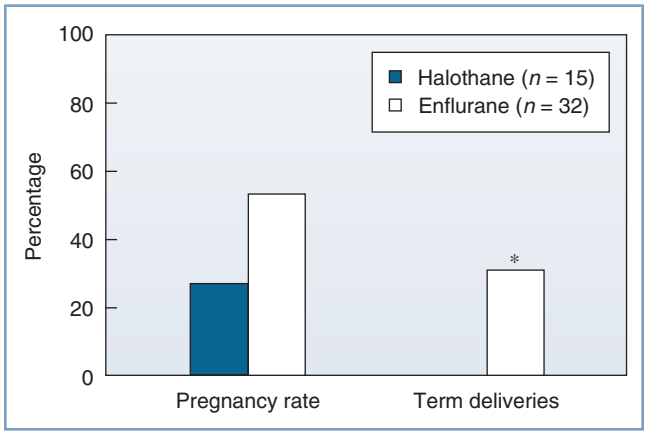

Fig. 15.12 Pregnancy and term delivery rates after halothane and enflurane anesthesia for gamete intrafallopian transfer (GIFT). The percentage of term pregnancies after GIFT was greater after enflurane–nitrous oxide anesthesia than after halothane–nitrous oxide anesthesia. *$P < .05$ compared with the halothane group. (Modified from Critchlow BM, Ibrahim Z, Pollard BJ. General anaesthesia for gamete intra-fallopian transfer. *Eur J Anaesthesiol.* 1991;8:381–384.)

and uterine receptivity (see later discussion); whether volatile halogenated agents can affect mature oocytes in the process of being retrieved, however, is questionable. Critchlow et al.[62] observed dramatic rises in plasma prolactin levels with an enflurane in nitrous oxide–oxygen technique for GIFT procedures, although these changes did not occur until 4 to 10 minutes after induction and did not affect follicular fluid prolactin levels or fertilization rates.

Volatile anesthetic agents have been compared in clinical studies. Fishel et al.[63] reported that pregnancy rates were significantly lower among women given halothane anesthesia for ET than in a similar group of women given enflurane; of interest, the anesthesia was administered in an attempt to decrease uterine activity during ET. Similarly, Critchlow et al.[62] reported lower pregnancy and delivery rates among women who received halothane for GIFT procedures than in women who received enflurane (Fig. 15.12). In a retrospective sequential study design, Wilhelm et al.[33] noted lower pregnancy rates in patients undergoing oocyte retrieval with general anesthesia (isoflurane or propofol in combination with 60% nitrous oxide in oxygen) than in subsequent patients who received analgesia with a remifentanil-based technique. The investigators acknowledged that the success rates of ART programs have improved over time and that it is possible that physician-related factors may have improved the outcomes in the later sedation analgesia phase of the study.[33]

Although these data suggest that specific volatile halogenated anesthetic agents can affect ART outcomes, the mechanisms remain incompletely evaluated. For example, compound A, the metabolic byproduct of sevoflurane, has been associated with genotoxic ovarian cell effects, although reproductive outcomes have not been assessed.[64] As a consequence, caution is advised in the selection of newer agents, such as sevoflurane and desflurane, until further work has been done.

Antiemetic Agents

At least one study noted that droperidol and metoclopramide rapidly induce hyperprolactinemia with subsequent impairment of ovarian follicle maturation and corpus luteum function.[65] Moreover, Forman et al.[66] demonstrated that low plasma prolactin concentrations during ART procedures were associated with a higher incidence of pregnancy. In contrast, when a single dose of intravenous metoclopramide 10 mg was given the day preceding oocyte retrieval, a prolactin level increase of greater, versus less, than 200% yielded larger follicles, more mature oocytes, and improved IVF success rates.[67] The effect of agents that do not affect prolactin levels, such as ondansetron, have not been studied.

ANESTHETIC MANAGEMENT

Because most patients undergoing ART procedures are young and otherwise healthy, many institutions do not require preoperative laboratory studies, electrocardiograms, or chest radiographs before the procedure. However, the use of ART procedures in patients with a growing spectrum of pathologic processes, such as morbid obesity, cancer (with oocyte retrieval performed before chemotherapy or radiation therapy), and severe cardiac, pulmonary, or renal morbidities (with oocyte retrieval performed for ET in surrogate gestational carriers), has created special concerns that should be addressed in individual patients.

All patients should follow the fasting guidelines typically used for patients undergoing ambulatory surgery. In patients with risk factors for pulmonary aspiration of gastric contents, a nonparticulate antacid should be given before the procedure. On occasion, a patient may not adhere to strict fasting

guidelines; although delay or cancellation of the procedure is an option, the decision should be made after careful analysis of the potential risks and benefits. If the window for maximal oocyte retrieval (34 to 36 hours after hCG administration) is missed, ovulation with loss of oocytes can occur, invalidating the considerable effort and expense that have been incurred to that point. Moreover, if oocyte retrieval is not performed, the patient is at increased risk for OHSS, with its potential for significant morbidity. In contrast, the risk for pulmonary aspiration of gastric contents is low, particularly when spinal anesthesia is administered (see later discussion).

As with other ambulatory surgery cases, the ideal anesthetic technique provides effective pain relief with minimal postoperative nausea, sedation, pain, and psychomotor impairment.

Ultrasound-Guided Transvaginal Oocyte Retrieval

Although transvaginal oocyte retrievals can be performed under paracervical, spinal, epidural, and general anesthetic techniques, conscious or deep sedation analgesia (often administered by an anesthesia provider as a component of monitored anesthesia care[68]) is the most commonly used technique.[69,70] Although usually adequate for surgical analgesia, deep sedation analgesia may need to progress to loss of consciousness (i.e., general anesthesia) to prevent patient movement at critical points in the procedure.[71] The need for additional pain relief should be anticipated when the needle penetrates the cul-de-sac and, later, each ovary. A greater rate of hospital admission after oocyte retrieval, mostly secondary to intra-abdominal bleeding, has been reported with sedation analgesia compared with general anesthesia.[72]

Because paracervical anesthesia incompletely blocks sensation from the vaginal and ovarian pain fibers, additional analgesia is required.[73] Epidural and spinal techniques provide excellent anesthesia with minimal oocyte exposure to anesthetic agents. Compared with sedation using propofol and mask-assisted ventilation with nitrous oxide, epidural bupivacaine anesthesia resulted in fewer complications, especially nausea and emesis.[74] Spinal anesthesia may be preferable to epidural anesthesia owing to the reduced anesthetic failure rate, reduced systemic and follicular concentrations of anesthetic agent, and faster recovery profile.[75] Spinal administration of 1.5% hyperbaric lidocaine (60 mg) is associated with significantly shorter recovery times than spinal administration of 5% hyperbaric lidocaine (60 mg) in patients undergoing ART procedures.[76] The addition of intrathecal fentanyl 10 μg to lidocaine 45 mg improves postoperative analgesia for the first 24 hours, with no increase in time to urination, ambulation, and discharge compared with intrathecal lidocaine alone.[77] Given the frequent association of spinal lidocaine with postoperative transient neurologic symptoms (see Chapter 31), low-dose spinal bupivacaine represents a viable alternative, with recognition of the prolonged time to urination and discharge.[78]

General anesthesia can be provided by total intravenous anesthesia (TIVA) using propofol (titrated) and an opioid (e.g., fentanyl 50 to 100 μg). Midazolam (1 to 2 mg) can be used as an optional premedication. Most patients can be managed with spontaneous ventilation.[40] (Individuals with significant risk factors for aspiration should undergo tracheal intubation with a cuffed endotracheal tube.) This anesthetic technique can produce mean bispectral index scores that range from 47 to 53 and modified Ramsay sedation scores that are consistent with general anesthesia[79] and results in greater patient satisfaction than sedation analgesia, owing to better pain relief and less awareness during the surgical procedure.[40] Alternatively, tracheal intubation and maintenance of anesthesia with a volatile halogenated agent has been used successfully; however, greater rates of nausea and emesis and more unplanned admissions have been observed with this technique than with a propofol, alfentanil, and air-oxygen mixture.[80]

Novel analgesic measures have been investigated during oocyte retrieval. One study evaluated electroacupuncture as an alternative to intravenous alfentanil, although both groups also received a paracervical block, and the acupuncture group experienced greater degrees of preoperative stress and longer periods of discomfort during oocyte aspiration.[81]

Embryo Transfer

Described as relatively painless, transcervical ET procedures are most commonly performed without analgesia or anesthesia; however, on rare occasion, intravenous sedation analgesia or regional or general anesthesia may be requested. In contrast, transabdominal gamete or embryo transfer procedures (i.e., GIFT, ZIFT) are usually performed via laparoscopy under local, neuraxial, or general anesthesia. The anesthetic management for these procedures and the associated concerns with regard to the laparoscopic technique and the Trendelenburg position are described here. Major intraoperative complications associated with laparoscopy are rare but include gastric or intestinal perforation, hemorrhage, pneumothorax, pneumopericardium, mediastinal emphysema, gas embolism, and cardiac arrest.[82]

Pneumoperitoneum and the Trendelenburg Position

Carbon dioxide is the gas most commonly used to establish pneumoperitoneum. The high blood solubility of carbon dioxide facilitates absorption from the peritoneal cavity after laparoscopic surgery and may represent a life-saving property of the gas in the rare but potentially catastrophic event of gas embolization. For example, rapid intravenous injection of 5 to 10 mL/kg of carbon dioxide produces only transient (< 1 minute) hypotension in anesthetized dogs (Fig. 15.13),[83] whereas intravascular administration of a similar volume of a less soluble gas (e.g., helium, oxygen, nitrogen) is usually fatal.

Signs of embolization of large quantities of carbon dioxide (or any other gas) in anesthetized patients may include hypocapnia, hypotension, hypoxemia, ST-segment and T-wave changes, arrhythmias, and audible changes in heart sounds.[84] Initial treatment of carbon dioxide embolism should include release of the pneumoperitoneum and pharmacologic support of the circulation. If initial resuscitation efforts are

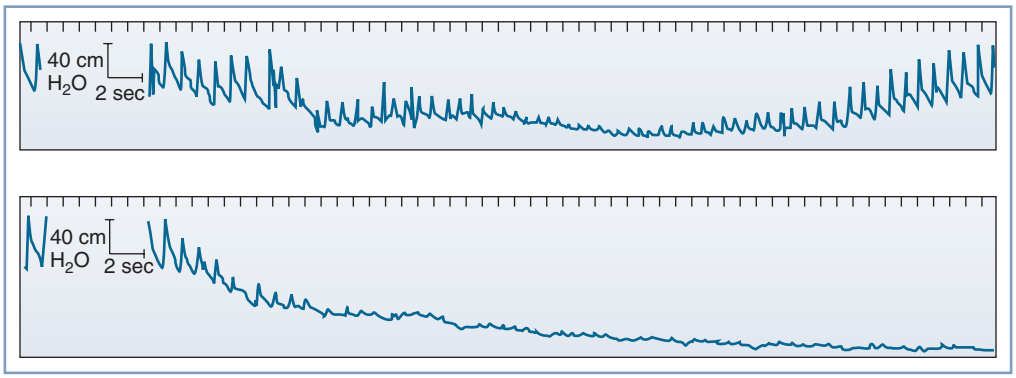

Fig. 15.13 Arterial tracings after rapid intravenous injection of 7.5 mL/kg of carbon dioxide *(top)* and helium *(bottom).* Recovery occurs within 1 minute after the carbon dioxide injection, but complete cardiovascular collapse occurs after the helium injection. (Modified from Wolf JS, Carrier S, Stoller ML. Gas embolism: helium is more lethal than carbon dioxide. *J Laparoendosc Surg.* 1994;4:173–177.)

unsuccessful, aspiration of gas from the right atrium (using a multi-orifice central venous catheter) should be considered. Although the use of the left lateral recumbent position (Durant's maneuver), with or without head-down positioning, has been suggested to facilitate removal of the postulated air lock from the right side of the heart,[85] laboratory evidence suggests that this maneuver may have a detrimental effect on cardiac function after venous gas embolism.[86]

Nearly as soluble in blood as carbon dioxide, nitrous oxide is associated with less peritoneal and diaphragmatic irritation[87] and has been suggested for the establishment of pneumoperitoneum in awake patients undergoing laparoscopy. A major disadvantage of nitrous oxide is its ability to support combustion, which could increase the possibility of an explosion if the surgeon uses electrocautery.

GIFT and ZIFT procedures are often performed with the patient in the Trendelenburg position to facilitate visualization of the fallopian tubes and other pelvic structures. Positioning strategies to prevent the patient from moving cephalad on the operating table and to prevent brachial plexus damage should be used. The adduction of the patient's arms against her trunk has been suggested to reduce the risk for brachial plexus injury, but the efficacy of this precaution is unproven.

Both pneumoperitoneum and the Trendelenburg position produce physiologic changes. Hemodynamic effects of moderate pneumoperitoneum (< 20 mm Hg) in a patient in the Trendelenburg position include increased mean arterial and central venous pressures, increased systemic vascular resistance, and decreased stroke volume and cardiac output.[88] Heart rate usually does not change, but in some patients pneumoperitoneum may elicit sinus bradycardia, heart block, or even cardiac arrest. Finally, pneumoperitoneum aggravates the respiratory effects of the Trendelenburg position (e.g., reduced chest wall compliance, increased venous admixture). Overall, most healthy patients easily tolerate the cardiovascular and pulmonary effects of intra-abdominal pressures lower than 20 mm Hg.

Laparoscopic-Assisted Reproductive Technology

The anesthetic plan for GIFT procedures is typically dictated by the method (i.e., transabdominal or transvaginal) of oocyte retrieval. Many ART programs harvest oocytes transabdominally during pelvic laparoscopy; the principal advantage is that the patient is positioned and anesthetized once for both the retrieval and transfer portions of the procedure. The major disadvantage of this technique is that oocytes are exposed to both carbon dioxide pneumoperitoneum and anesthetic agents. The induction of general anesthesia for GIFT procedures can be delayed until just before the skin incision in an effort to minimize unnecessary exposure to these agents. Induction is usually performed with intravenous propofol, lidocaine, fentanyl, and either succinylcholine or rocuronium. After tracheal intubation, the anesthesia provider may decompress the patient's stomach with a suction catheter or Salem sump tube to reduce the risk for gastric perforation during instrumentation. Subsequently, a volatile halogenated agent in oxygen and air, with or without a short-acting muscle relaxant, is given to maintain anesthesia. The use of a propofol–nitrous oxide technique has been associated with less postoperative sedation, lower pain scores, and less emesis than an isoflurane–nitrous oxide technique.[50]

Alternatively, oocytes can be retrieved transvaginally and transferred—as oocytes or embryos—laparoscopically. This technique is most commonly used with ZIFT procedures, whereby oocyte retrieval and IVF occur on the preceding day. Advantages to the combined transvaginal/transabdominal approach include (1) the avoidance of laparoscopy in the 1% to 2% of cases in which oocyte quality or number is inadequate to justify proceeding with a tubal transfer[4] and (2) the elimination of oocyte exposure to the carbon dioxide pneumoperitoneum. Disadvantages of this method include (1) the need to reposition the patient before laparoscopy and (2) a prolonged total operative time if performed on the same day (GIFT) or the need for a second procedure if performed on consecutive days (ZIFT).

A few patients prefer spinal or epidural anesthesia for GIFT procedures.[89,90] Healthy, nonobese patients have been reported to successfully undergo laparoscopic surgery in the Trendelenburg position with high thoracic (i.e., T2 to T4) spinal or epidural anesthesia.[89–92] Limiting intraperitoneal pressure to less than 10 mm Hg may facilitate the use of neuraxial anesthesia

for these procedures. Obese women are not ideal candidates for neuraxial anesthesia in laparoscopic surgery.

Adequate analgesia for laparoscopic ART procedures has also been reported with the use of local anesthesia supplemented with intravenous sedation analgesia.[93–96] Padilla et al.[93] observed that the quality of intraoperative analgesia can be improved by limiting maximal intra-abdominal pressure to less than 10 mm Hg, reducing the rate of carbon dioxide insufflation to 1 L/min, and minimizing ovarian manipulation. The difficulty and discomfort frequently associated with cannulation of the fallopian tubes, however, may make local anesthesia an unwise choice for laparoscopic ART procedures.[94] The use of local anesthesia should not be interpreted as being devoid of risk for serious complications (e.g., bradycardia, cardiac arrest). These life-threatening complications are rare, but the management and outcome are greatly assisted by the presence of individuals skilled in airway management and cardiopulmonary resuscitation.[97]

Postoperative Management

The incidence of anesthetic or surgical complications requiring hospital admission after ART procedures is low. Oskowitz et al.[72] reported admission rates after oocyte retrieval and GIFT procedures of 0.16% and 0.18%, respectively. The most common indications for hospitalization were hemoperitoneum and syncope after oocyte retrieval, and nausea, vomiting, and bowel injury after laparoscopic GIFT procedures. Abdominal pain and uterine cramping occur commonly after oocyte retrieval. Incisional pain and referred shoulder pain as a result of diaphragmatic irritation can also occur after laparoscopic ART procedures. Postprocedural discomfort is related primarily to the number of follicles retrieved (rather than the hormonal alterations induced by the stimulation cycle) and can be effectively managed with the use of a heating pad and small doses of intravenous fentanyl (25 to 50 μg) or oral analgesic agents (acetaminophen 500 mg to 1 g).[98] The use of nonsteroidal anti-inflammatory drugs should be avoided because changes in the prostaglandin milieu can affect embryo implantation.[99]

Nausea and emesis can also occur; however, exposure to droperidol and metoclopramide should be limited (see earlier discussion); treatment with nondopaminergic agents can be considered. Before discharge, patients should be able to drink and retain liquids, ambulate, and void. Patients undergoing anesthesia for an ART procedure should be called 24 hours after the procedure to allow assessment of recovery and potential complications.

FUTURE CONSIDERATIONS

The use of ART procedures has been extended to include patients within a broader range of ages and comorbidities. Check et al.[100] reported the successful delivery of infants through the use of donor oocytes, IVF, and ET in two postmenopausal women who were 51 years of age; women in the seventh decade have also successfully delivered infants. In addition, more programs are participating in the preservation of ovarian tissue as a means of extending reproductive capability. Future studies should assess the short- and long-term maternal and perinatal consequences of ART procedures as well as the obstetric and anesthetic implications.[101]

Technical improvements in ultrasonography as well as fiberoptic methods of oocyte retrieval and fallopian tube cannulation could potentially make laparoscopic interventions less invasive or unnecessary. For example, small-diameter laparoscopes with optical views comparable to conventional instruments have allowed "mini-laparoscopic" procedures to be performed for GIFT procedures.[96] These alterations may allow for changes in anesthetic options.

The identification of agents and techniques that provide optimal analgesia or anesthesia with negligible impact on ART success is an important process to which anesthesia providers can and should contribute.

KEY POINTS

- Assisted reproductive technology (ART) includes techniques that are being applied to an increasingly diverse population of patients with a wide range of comorbidities.
- ART procedures usually involve a regimen of hormonal stimulation and oocyte retrieval followed by either *in vitro* fertilization with embryo transfer (IVF-ET) or gamete intrafallopian transfer (GIFT) procedures.
- Hormonal stimulation creates a number of oocytes for retrieval. On occasion, ovarian hyperstimulation syndrome can occur, with severe cases being associated with ascites, pleural effusion, hemoconcentration, oliguria, and thromboembolic events.
- Oocyte retrieval must be performed promptly, or ovulation will reduce the number of mature oocytes available for harvesting. Embryo transfer usually occurs transcervically; however, laparoscopic techniques (zygote intrafallopian transfer [ZIFT]) can be used.
- Sedation analgesia, neuraxial anesthesia, and general anesthesia have all been used successfully to anesthetize women for ART procedures. Deep sedation may have to progress to loss of consciousness (i.e., general anesthesia) to prevent patient movement at critical times during the procedure.
- Laboratory studies have suggested that local anesthetic agents, nitrous oxide, and the volatile halogenated agents interfere with some aspects of reproductive physiology *in vitro*. However, few clinical data show that brief administration of any contemporary anesthetic agent for an ART procedure adversely affects live-birth rates.
- The identification of agents and techniques that provide optimal analgesia or anesthesia with negligible impact on ART success is an important process to which anesthesia providers can and should contribute.

Problems of Early Pregnancy

Katherine W. Arendt, MD, Margaret E. Long, MD

CHAPTER OUTLINE

Obstetric disease of early pregnancy may result in significant maternal morbidity and even mortality. Safe care of patients with obstetric disease involves a thorough understanding of the physiologic changes of early pregnancy as well as the specific issues associated with each pathologic condition.

PHYSIOLOGIC CHANGES OF EARLY PREGNANCY

Respiratory System

The respiratory system undergoes profound physiologic changes during early pregnancy. Increased progesterone concentration stimulates respiratory efforts by increasing the sensitivity of the respiratory center to carbon dioxide. Minute ventilation increases by at least 15% by 12 weeks' gestation and by 25% by 20 weeks' gestation. This results from an increase in tidal volume (respiratory rate is unchanged) and exceeds the increase in oxygen consumption. The result is a respiratory alkalosis with maternal arterial partial pressure of carbon dioxide decreasing to 30 to 33 mm Hg (4.0 to 4.4 kPa) by 10 to 12 weeks' gestation. Moreover, maternal arterial partial pressure of oxygen increases to 106 to 108 mm Hg (14.1 to 14.4 kPa) in the first trimester. Decreased bicarbonate concentration partially compensates for the modest respiratory alkalosis that results from the physiologic hyperventilation, leading to a maternal pH that is slightly above normal (i.e., approximately 7.44). There is little or no change in lung capacities during the first half of pregnancy. Women in early pregnancy who undergo mechanical ventilation require increased minute ventilation.

Cardiovascular System

The cardiovascular system also undergoes profound changes early in pregnancy.[1] During the first trimester, cardiac output increases by about 15% above prepregnancy values; by the early third trimester, cardiac output is about 30% above prepregnancy values. Systemic vascular resistance decreases 30% by 8 weeks' gestation. Maternal mean arterial pressure decreases approximately 6 mm Hg at 16 to 24 weeks' gestation and returns to normal near term.

In a typical pregnancy, aortocaval compression could begin to occur after 18 to 20 weeks' gestation, when the uterine fundus reaches the umbilicus and is potentially large enough to compress the aorta and vena cava when the patient is supine. Of note, the frequency of aortocaval compression in pregnant women in the supine position has recently been questioned with a magnetic resonance imaging study showing no aortocaval compression in 10 healthy full-term pregnant women in the supine position.[2] Nonetheless, most experts agree that when the uterine size is equivalent to an 18- to

20-week gestation, the application of left uterine displacement should be performed if possible. This can be achieved by elevating the right hip approximately 15 degrees off midline with a wedge or blankets. The need for left uterine displacement may occur earlier in gestation in the presence of multiple gestation, polyhydramnios, or gestational trophoblastic disease.

Blood volume increases throughout pregnancy. The average prepregnancy blood volume of 4350 mL (76 mL/kg) increases to 4700 mL (81 mL/kg) at 12 weeks' gestation, to 5500 mL (89 mL/kg) at 20 weeks' gestation, and to approximately 6600 mL (97 mL/kg) at term. The increase in blood volume is primarily the result of greater plasma volume because red blood cell volume increases to a smaller degree (27 mL/kg). Because pregnant women have an expanded blood volume, most can typically tolerate a blood loss of 500 to 1500 mL in early pregnancy without requiring blood transfusion, if the blood loss is replaced with an adequate volume of crystalloid or colloid.

Gastrointestinal System

An increased progesterone level causes relaxation of the lower esophageal sphincter tone as early as the first trimester. Fasting gastric volume is approximately 30 mL in both nonpregnant women and women in early pregnancy. Metoclopramide 10 mg, administered intravenously 15 to 30 minutes before anesthesia, can reduce this volume by 50%.[3] Obesity does not delay gastric emptying in nonlaboring pregnant women.[4] In a study of 100 pregnant women undergoing general anesthesia by mask at 6 to 22 weeks' gestation, a pH electrode showed reflux of gastric contents into the esophagus in 17% of patients.[5] Most episodes of reflux occurred in patients who experienced hiccups. Only 2% had regurgitation of gastric contents into the pharynx, and no patient demonstrated clinical evidence of pulmonary aspiration.

General anesthesia may be safely administered by means of a mask or a laryngeal mask airway (LMA) by experienced anesthesia providers in selected obstetric patients during early pregnancy. Many anesthesia providers are comfortable managing an airway without tracheal intubation until 18 to 20 weeks' gestation, when the uterus moves out of the pelvis. The latter movement leads to anatomic and intragastric pressure changes that predispose to gastroesophageal reflux. Some anesthesia providers prefer to intubate the trachea of pregnant women who require general anesthesia as early as 12 to 14 weeks' gestation, given that hormonal changes leading to sphincter relaxation are present early in pregnancy. Patients who receive general anesthesia during the first half of pregnancy should be intubated if they are at increased risk for gastric content aspiration (e.g., history of gastroesophageal reflux, morbid obesity, solid food ingestion within 8 hours). Pharmacologic prophylaxis (e.g., sodium citrate, a histamine-2 (H_2) receptor antagonist, and/or metoclopramide) is likely to further reduce the risk for aspiration pneumonia (see Chapter 28). Neuraxial anesthesia is associated with a lower risk for aspiration than general anesthesia.

Nervous System

During early pregnancy, the nervous system is more sensitive to general and local anesthetic agents. The minimum alveolar concentration (MAC) for volatile anesthetic agents is decreased by approximately 30%, although the underlying mechanism for this change is unclear. A study that compared patients undergoing cesarean delivery with nonpregnant patients undergoing elective gynecologic surgery found no difference between groups in electroencephalographic (EEG) measures during general anesthesia with similar end-tidal concentrations of sevoflurane.[6] Because it is well-proven that MAC decreases in pregnancy, this study implies that MAC in pregnant women may not correlate well with depth of anesthesia. Conversely, another study found that pregnant women with elevated baseline serum progesterone concentrations had lesser sevoflurane consumption when the anesthetic was titrated to vital signs and a bispectral index (BIS) value.[7] Further research is needed to clarify the effects of pregnancy and progesterone on MAC and depth of anesthesia as measured by BIS or EEG.

ECTOPIC PREGNANCY

Ectopic pregnancy occurs when the fertilized ovum implants outside the endometrial lining of the uterus. Death, infertility, and recurrent ectopic pregnancy are possible sequelae. The frequency of ectopic pregnancy is difficult to determine accurately but in the United States is approximately 5 to 20 per 1000 pregnancies.[8]

Hemorrhage from ruptured ectopic pregnancy is the leading cause of pregnancy-related maternal death during the first trimester and accounted for 2.7% of all pregnancy-related maternal deaths in the United States from 2011 to 2013.[9] More than 30% of women who have had an ectopic pregnancy subsequently suffer from infertility, and 5% to 23% have a second ectopic pregnancy.[10]

The number of deaths from ectopic pregnancy has decreased in the United States since the 1970s. The case-fatality rate decreased from 35.5 deaths per 10,000 ectopic pregnancies in 1970 to 3.8 per 10,000 in 1989,[11] and the ectopic pregnancy mortality ratio decreased from 1.15 deaths per 100,000 live births from 1980 to 1984 to 0.5 death per 100,000 live births from 2003 to 2007.[12] The U.S. Centers for Disease Control and Prevention (CDC) attributes this decline to "improvements in the sensitivity, accuracy, and use of pregnancy testing, ultrasound for diagnosis, and improvements in therapeutic modalities, including laparoscopic surgery and medical management of ectopic pregnancy."[13] Maternal death from ectopic pregnancy is more common in women with less access to obstetric care including teens, racial minorities, and women with poor socioeconomic status.

Factors that alter the risk for ectopic pregnancy include (1) previous ectopic pregnancy; (2) treatment for infertility (e.g., *in vitro* fertilization); (3) prior pelvic infection (e.g., pelvic inflammatory disease and ruptured appendix); (4) prior tubal surgery (e.g., tubal ligation or occlusion); and

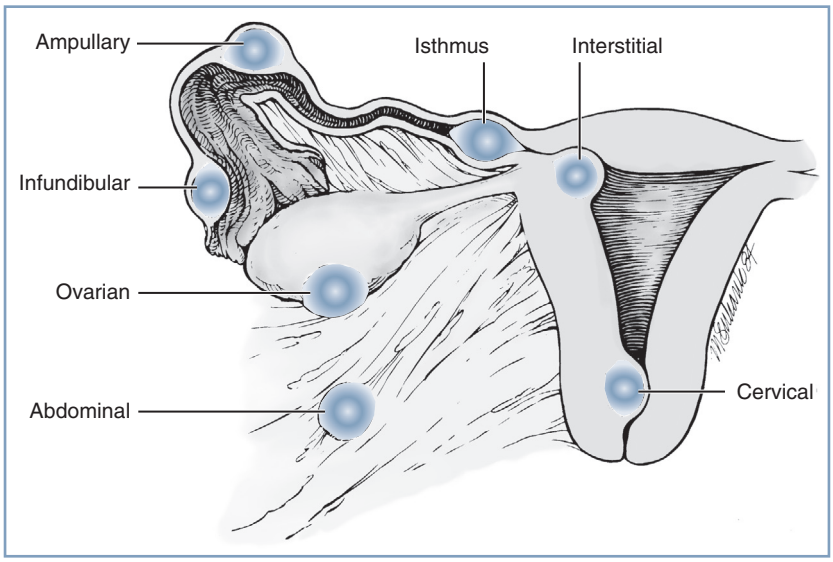

Fig. 16.1 Potential locations of ectopic pregnancies. The majority occur in the ampullary portion of the fallopian tube. (Modified from DeCherney AH, Seifer DB. Ectopic pregnancy. In Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics: Normal and Problem Pregnancies,* 2nd ed. New York, NY: Churchill Livingstone; 1991:811.)

(4) advanced maternal age.[14] However, one-third of patients with ectopic pregnancies have no identifiable risk factors. In women with an intrauterine device (IUD), the risk for ectopic pregnancy is lower than in the general population at 0 to 0.5 per 1000 women-years. However, in the rare event that a pregnancy occurs with an IUD present, the likelihood that it is ectopic is increased.[15]

The fertilized ovum can implant anywhere along the path of migration or in the abdominal cavity (Fig. 16.1). Most ectopic pregnancies (98%) are **tubal** (infundibular or fimbrial, 6%; ampullary, 78%; isthmic, 12%; interstitial or cornual, 2%). The remaining 2% implant on the **cervix, vagina,** or **ovary** or elsewhere in the **abdomen.**[16] An increasing number of **cesarean scar** ectopic pregnancies, which may be on a continuum with **early placenta accreta,** are being reported.

In patients who undergo advanced reproductive technology (ART) procedures, ectopic pregnancies have been reported in approximately 2% of pregnancies.[17] Most of these pregnancies are tubal; however, approximately 6% are ovarian, abdominal, or cervical, and 12% to 15% are **heterotopic** (see later discussion).[16]

Clinical Presentation

The clinical presentation of the patient with an ectopic pregnancy depends on the gestational age, site of implantation, and extent of hemorrhage. Before rupture, the signs and symptoms are often subtle. Classic clinical signs of impending rupture or a ruptured tubal pregnancy include abdominal or pelvic pain (95%), delayed menses (75% to 95%), and vaginal bleeding (60% to 80%). Vaginal bleeding results from the breakdown and shedding of the decidual lining of the uterine wall, which is probably associated with decreased hormone production by the corpus luteum and inadequate human chorionic gonadotropin (hCG) production by the ectopic trophoblast. Pain often precedes vaginal bleeding. Patients with hemorrhage (with or without tubal rupture) may experience dizziness or syncope, may have the urge to defecate because of the effect of blood in the cul-de-sac, and may have shoulder pain from diaphragmatic irritation by intra-abdominal blood.

Physical findings include abdominal tenderness with or without rebound (80% to 95%), a uterus that is smaller than expected for dates (30%), and a tender adnexal mass (30% to 50%). A bulging cul-de-sac suggests hemoperitoneum. With significant hemorrhage, there may be signs of shock, but some patients may appear hemodynamically stable despite a hemoperitoneum volume of 1000 to 1500 mL. As with many young women, compensation for blood loss can occur with minimal symptoms initially followed by rapid decompensation.

Diagnosis

Ectopic pregnancy should be excluded in any patient who has pelvic pain and a positive pregnancy test. In a woman of reproductive age, the symptoms of ectopic pregnancy must be differentiated from (1) a threatened, inevitable, or incomplete pregnancy loss; (2) infection after attempted abortion; (3) pelvic inflammatory disease; (4) a degenerating fibroid; (5) appendicitis and other gastrointestinal diseases; (6) ovarian torsion; (7) a ruptured or bleeding ovarian cyst; (8) a trapped retroverted uterus in pregnancy; and (9) nephrolithiasis.

Pregnancy of unknown location (PUL) exists when the hCG is positive and presumed due to pregnancy but the site of implantation has yet to be determined. Ultrasonography can reliably confirm the presence of an intrauterine pregnancy; however, the ectopic pregnancy itself may be difficult to visualize.[18] **Transvaginal ultrasonography** is the current modality of choice. A gestational sac with a yolk sac is the earliest confirmation of an intrauterine pregnancy,[19] while ultrasonographic visualization of an adnexal mass and free fluid with absence of an intrauterine pregnancy is specific for

ectopic pregnancy. Unfortunately, ultrasonographic visualization of an ectopic pregnancy has poor sensitivity.[20]

Despite the challenges of early diagnosis of ectopic pregnancy, prompt treatment decreases morbidity and mortality. If concern exists for ectopic pregnancy with a PUL, serial hCG measurements spaced 48 hours apart can help clarify the viability of the pregnancy regardless of location. For a viable pregnancy, the increase in hCG over 48 hours should be at least 53%.[21] A decrease in hCG by at least 10% suggests a nonviable pregnancy. In these scenarios, the decision to intervene or manage the nonviable pregnancy conservatively is based on the clinical situation and the woman's preference. An abnormal rise (< 53% in 48 hours) or a plateau in the hCG value often indicates a nonviable pregnancy, but can also be seen with a vanishing twin where a viable pregnancy remains.[22] Serial hCG measurements and transvaginal ultrasonography along with symptoms are considered when determining viability versus nonviability of a PUL.[19]

A serum progesterone concentration greater than 25 ng/mL is usually associated with a viable pregnancy. A concentration less than or equal to 5 ng/mL usually indicates a nonviable pregnancy but cannot distinguish a spontaneous pregnancy loss from an ectopic pregnancy.[23] Most ectopic pregnancies are associated with progesterone levels between 5 and 25 ng/mL, a fact that limits the usefulness of this test.

Uterine curettage can be performed when nonviability of a PUL is established. Identification of trophoblastic villi confirms loss of an intrauterine pregnancy. Absence of villi signals either a complete spontaneous pregnancy loss (confirmed by rapidly decreasing hCG concentration) or an ectopic pregnancy. Culdocentesis has been replaced in most all instances by transvaginal ultrasonography for detection of hemoperitoneum.

Obstetric Management

Management options for ectopic pregnancy are expectant, medical, and surgical. Management choice depends on the "activity" of the ectopic pregnancy, which is determined by symptoms and diagnostic findings.[24]

Expectant management is preferred in "very less active" ectopic pregnancy or PUL with no symptoms, an hCG less than 1500 mIU/mL, and a plateauing trend in hCG values. Treatment with methotrexate does not improve resolution and is reserved for women in whom hCG levels fail to resolve. Very low positive hCG levels can have etiologies other than pregnancy. Very less active ectopic pregnancy may be difficult to localize surgically.

Medical management with methotrexate is a preferred option in "less active" ectopic pregnancy. Less active ectopic pregnancy is characterized by an hCG less than 5000 mIU/L and no fetal cardiac activity in an asymptomatic woman who is hemodynamically stable. Methotrexate, a folate antagonist, interrupts DNA synthesis and thus inhibits the growth of trophoblastic cells. It can be administered intramuscularly in one or more injections to women who screen negative for kidney, liver, and hematologic disease.

From day 4 to day 7 after methotrexate treatment, a decrease in hCG level of 15% must be present to consider the treatment successful. Otherwise, repeat methotrexate treatment or surgical intervention is required. Follow-up and close monitoring until the hCG level reaches nonpregnant values is imperative because of the risk for rupture and hemorrhage. Side effects of methotrexate can be severe and include abdominal pain, vomiting, stomatitis, severe neutropenia, and pneumonitis. Compared with surgical management, medical management of ectopic pregnancy provides no difference in overall tubal preservation, tubal patency, risk for repeat ectopic pregnancy, or success of future pregnancies.

Surgical management depends on the location of the pregnancy, the hemodynamic stability of the patient, the availability of equipment, and the surgeon's expertise. Most often, laparoscopy is performed to confirm the diagnosis by locating the ectopic pregnancy and then proceeding with treatment. For tubal ectopic pregnancies, a salpingostomy, salpingotomy, or salpingectomy (usually partial) is performed by means of laparoscopy or laparotomy. To aid hemostasis during laparoscopic removal of the ectopic pregnancy, some obstetricians inject dilute vasopressin into the surface of the fallopian tube. This agent causes marked blanching of the tube and results in a relatively bloodless surgical field. If the vasopressin is mixed incorrectly or accidentally injected intravenously, a marked increase in maternal blood pressure may occur.

A laparotomy is indicated if the surgeon is not trained in operative laparoscopy, laparoscopic removal is anticipated to be difficult (e.g., tube diameter greater than 6 cm or an interstitial location of the ectopic pregnancy), or there is uncontrolled bleeding. Laparotomy should be performed immediately if there is hemodynamic instability; these cases often require a partial or total salpingectomy. If a partial salpingectomy is performed, tubal repair may be performed primarily or during a second operation. Although some experts have noted that outcomes from randomized trials comparing salpingostomy and salpingectomy are lacking,[25] the risk for persistent ectopic pregnancy may be higher after salpingostomy than after salpingectomy.[26]

Interstitial, cervical, cesarean scar, and abdominal ectopic pregnancies as well as early placenta accreta may present significant diagnostic and therapeutic challenges, resulting in delay of diagnosis and treatment. There is potential for massive hemorrhage because of disruption of organs and adjacent tissues. The desire to preserve fertility may result in greater blood loss as tissue and organ preservation are attempted.

Interstitial pregnancy often goes unrecognized and may manifest as uterine wall rupture, massive hemorrhage, and shock. Conservative surgery (e.g., cornual resection) may be attempted, but hysterectomy may be required if uterine damage is severe.

Cervical pregnancy can result in massive hemorrhage because of the inability of the cervix to contract. In the past, most cervical pregnancies necessitated hysterectomy to control hemorrhage. More current management options that are more likely to maintain fertility include (1) methotrexate therapy; (2) local excision; (3) cerclage and tamponade; (4) ligation of the hypogastric arteries or the cervical branches of

the uterine arteries; and (5) angiographic embolization of the uterine arteries followed by a dilation and curettage procedure (see later discussion).[27]

Cesarean scar pregnancy occurs when a gestational sac implants in the uterine scar defect (niche) at the site of a previous cesarean delivery. Cesarean scar pregnancy has a high complication rate. Although relatively rare, its incidence is rising with increasing cesarean delivery rates and currently may be as high as 1 in 1800 pregnancies.[28] Jurkovic et al.[28] described two types of cesarean scar pregnancies: (1) implantation on the scar with enlargement into the uterine cavity and (2) implantation into a scar defect with growth into the myometrium. Depending on its progression, the former type may grow normally or may be treated medically. Scar implantation results in an increased risk for early uterine rupture and severe hemorrhage at delivery. Growth into the myometrium may lead to eventual rupture and bleeding in the first trimester; prompt surgical intervention is preferred over medical management in this situation.[29]

The incidence of **early placenta accreta** is also rising because of increasing cesarean delivery rates. It is defined as penetration of the placenta into the myometrium, which is discovered in the first or early second trimester. Because of similarities in pathogenesis, it is thought—although not confirmed—that early placenta accreta may develop from cesarean scar pregnancy. A review found that 15 of 47 (32%) patients with early placenta accreta had spontaneous uterine rupture, in most cases followed by bleeding and shock, which resulted in laparotomy, hysterectomy, or uterine artery embolization.[30] Although the gestational age is early, it is imperative that the anesthesia team is aware of the risk for hemorrhage during surgical intervention for cesarean scar pregnancy and early placenta accreta.

Abdominal pregnancy is defined as implantation in the peritoneal cavity, not including the fallopian tubes, ovaries, or ligaments, and is associated with a high incidence of maternal morbidity and fetal demise. In a series of advanced extrauterine pregnancies, Worley et al.[31] identified 10 women who presented with extrauterine pregnancies beyond 18 weeks' gestation, of whom three met the diagnostic criteria for abdominal pregnancy. All patients had difficult surgery, nine patients required blood transfusion, and only five fetuses survived after complicated courses.

Diagnosis of abdominal pregnancy can be difficult, historically being missed in as many as one of nine cases.[32] The diagnosis was missed before delivery in four of the ten cases in the series of Worley et al.[31] Abdominal pain, vaginal bleeding, symptoms consistent with partial bowel obstruction, shock, or death may be the first indication of this unusual type of pregnancy. Ultrasonography is useful but may miss the diagnosis in more than 50% of cases. Magnetic resonance imaging may prove to be a more sensitive diagnostic tool.

If an extrauterine pregnancy is suspected in early gestation, laparoscopy can be used to diagnose and remove gestational products. If the extrauterine pregnancy is not identified until late gestation, it is associated with decreased placental perfusion (which typically results in fetal growth restriction) and oligohydramnios (which often results in pulmonary hypoplasia and anatomic deformities). In 1993, Stevens[33] reviewed published cases of abdominal pregnancy since 1809 and found that 63% of infants survived when born after 30 weeks' gestation.

Management of an advanced extrauterine pregnancy consists of laparotomy and delivery of the fetus. Once the fetus is delivered, management of the placenta is controversial and fraught with hazard. Removal of the placenta is associated with massive hemorrhage, prolonged and complicated surgery (e.g., bowel resection), and an increased risk for maternal mortality. A decision to leave the placenta *in situ* results in a higher risk for infectious morbidity as well as a potential greater need for additional surgery.[33,34] In the series of Worley et al.,[31] the placenta was left *in situ* in two patients, both of whom developed serious complications. The site of placental implantation and the ability to adequately ligate the blood supply often dictates the obstetrician's decision about management of the placenta.

Heterotopic pregnancy describes the simultaneous occurrence of an ectopic and an intrauterine pregnancy. Historically, it was thought to occur in 1 in 30,000 spontaneous pregnancies.[35] However, in patients utilizing assisted reproductive technologies, 0.2% to 3% of pregnancies may be heterotopic.[16,36] Difficulty visualizing the entire fallopian tube on ultrasonography, combined with normal or slightly elevated hCG measurements (i.e., low serum levels from the ectopic pregnancy combined with normal levels from the intrauterine pregnancy), make the early diagnosis of heterotopic pregnancy difficult.[37] This diagnosis should be suspected in cases in which clinical signs of an ectopic pregnancy and a confirmed intrauterine pregnancy coexist. In most cases, the ectopic pregnancy is removed surgically. Alternatively, transvaginal ultrasonography-guided injection of potassium chloride into the ectopic pregnancy has been performed successfully; however, as many as 55% of patients may require subsequent surgery.[38] The patient often retains the normal intrauterine pregnancy to term. Patients with ectopic pregnancies who are Rh-negative should receive Rh_0(D) immune globulin.[19]

Anesthetic Management

Patients with an unruptured tubal pregnancy usually have normal intravascular volume, minimal bleeding before and during surgery, and low anesthetic and surgical risk. Anesthetic considerations for laparoscopy or laparotomy are summarized in Box 16.1. Although most patients may prefer general anesthesia, neuraxial anesthesia with an upper sensory level to at least T4 may be an alternative in selected patients. Shoulder pain from diaphragmatic irritation may occur and can be treated with intravenous analgesics (e.g., fentanyl 1 to 2 μg/kg).

A ruptured ectopic pregnancy may be associated with significant preoperative blood loss, but estimation of the extent of this is difficult because young women may have normal blood pressure despite a markedly reduced circulating blood volume. General anesthesia, with preparation for

BOX 16.1 Suggested Anesthetic Techniques for Laparoscopy or Laparotomy for Patients with Ectopic Pregnancy

General Considerations

- Blood typing and antibody screening
- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- Large-bore peripheral intravenous catheter
- Urinary catheter
- If major bleeding has occurred or is expected to occur (e.g., ruptured tubal, interstitial, cervical, uterine scar, or abdominal ectopic pregnancy):
  - Two or more intravenous catheters
  - Typing and cross-matching of blood
  - Consideration of invasive hemodynamic monitoring (e.g., arterial catheter, central venous catheter)
  - Consideration of intraoperative cell salvage
- Although general anesthesia is usually preferred, neuraxial (spinal or epidural) anesthesia may be considered for hemodynamically stable patients with a low likelihood of significant hemorrhage (i.e., unruptured tubal pregnancy):
  - Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated.

General Anesthesia

- Rapid-sequence induction with cricoid pressure if the patient has a full stomach
- Induction: propofol or thiopental (ketamine or etomidate should be considered if patient is hemodynamically unstable)
- Muscle relaxant
- Tracheal intubation
- Maintenance: volatile or intravenous anesthetic agents
- Placement of an oral gastric tube, performance of suctioning, and removal of the tube
- Reversal of neuromuscular blockade and extubation when the patient is awake and responds to verbal commands

Spinal Anesthesia

- Single injection with a small-gauge pencil-tip spinal needle: hyperbaric bupivacaine 12 mg with fentanyl 10 to 25 µg to achieve T4 sensory blockade

Epidural Anesthesia

- Placement of mid-lumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 µg/mL (1:200,000), approximately 20 mL, and fentanyl 100 µg, injected incrementally, to achieve T4 sensory blockade

hemorrhage, is preferred if significant bleeding has occurred (e.g., ruptured tubal pregnancy) or is likely to occur (e.g., cervical, interstitial, cornual, cesarean scar, or abdominal ectopic pregnancy, or early placenta accreta). Intraoperative autologous blood transfusion can be used, and it may be useful especially in developing countries, where blood bank supplies are limited and women typically present late with significant hemoperitoneum and/or hypovolemic shock.[39] The desire to preserve fertility often results in greater blood loss as tissue and organ preservation are attempted.

EARLY PREGNANCY LOSS, ABORTION, AND INTRAUTERINE FETAL DEMISE

Abortion refers to a pregnancy loss or termination, either before 20 weeks' gestation or when the fetus weighs less than 500 g. Changing terminology now refers to spontaneous, incomplete, and missed abortions as **early pregnancy loss (EPL).** The term *abortion* is now limited to medical or surgical procedures to terminate a pregnancy that may be performed electively or for medical reasons.

A total of 664,435 legal abortions were reported in the United States in 2013, a rate of 12.5 abortions per 1000 women and a ratio of 200 abortions per 1000 live births.[40] The total number of abortions and rate of abortions (number of abortions per 1000 women) in the United States are at historic lows since surveillance began by the CDC in 1969.[40] In 2013, 67.9% of induced abortions were performed by dilation and curettage by 13 weeks' gestation, 22.2% by early medical abortion before 8 weeks' gestation, and 8.6% by curettage after 13 weeks' gestation.[40] From 2011 to 2013 in the United States, 2.4% of maternal deaths were associated with early pregnancy loss or induced abortion.[9] Maternal death from abortion is usually the result of sepsis, hemorrhage, or embolism.[41] The case fatality rate from 2008 to 2014 for legal induced abortions was 0.08 per 100,000.[40]

From a global perspective, unsafe abortion is a significant cause of maternal death. A global study of unsafe abortions estimated that 25.1 million abortions performed each year between 2010 and 2014 were unsafe, according to World Health Organization (WHO) definitions, of which 97% occurred in developing countries.[42] A review of causes of maternal death from 2010 to 2014 by the WHO reported that 4.7% to 13.2% of maternal deaths were attributed to unsafe abortion. These unsafe abortions are performed by an untrained person or in conditions lacking minimal medical standards or both.[43]

EPL occurs in 10% to 15% of clinically recognized pregnancies; when subclinical pregnancies are also considered, the incidence of spontaneous pregnancy loss may be as high as 60%.[44] Although most spontaneous pregnancy losses manifest clinically at 8 to 14 weeks' gestation, ultrasonography suggests that fetal demise usually occurs before 8 weeks' gestation.

The etiology of EPL varies among patients. Chromosomal abnormalities are responsible for at least 50% to 80% of all spontaneous early pregnancy losses.[45] Other causes include (1) immunologic mechanisms; (2) maternal infections; (3) endocrine abnormalities (e.g., poorly-controlled diabetes mellitus); (4) uterine anomalies; (5) debilitating maternal disease; (6) maternal clotting disorders; (7) trauma; and possibly (8) environmental exposures (e.g., irradiation, smoking, certain drugs).

Although some studies (conducted before scavenging of anesthetic gases was routine) suggested a higher incidence of EPL among women who were exposed to trace concentrations of anesthetic agents in operating rooms,[46] reevaluation of these data demonstrated significant flaws in study design, casting doubt on the original conclusions.[47] Later studies have

shown no increased incidence of spontaneous EPL in women working in operating rooms.[48]

Clinical Presentation

The clinical presentation and management of spontaneous pregnancy loss vary. A **threatened early pregnancy loss** is defined as uterine bleeding without cervical dilation before 20 weeks' gestation. Bleeding may be accompanied by cramping or backache. While historically recommended, alteration in daily activities does not impact outcome. Approximately 25% of pregnancies are complicated by first-trimester bleeding; approximately one-half of affected women progress to a spontaneous pregnancy loss, with the percentage increasing to about 80% if cramping and bleeding are present.[49,50]

An **inevitable pregnancy loss** is defined as cervical dilation or rupture of membranes without expulsion of the fetus or placenta. Spontaneous expulsion of the uterine contents usually occurs, but infection or hemorrhage can be complications. A **complete pregnancy loss** is defined as a total, spontaneous expulsion of the fetus and placenta. Partial expulsion of the uterine contents (i.e., an **incomplete pregnancy loss**) is more common after 8 weeks' gestation. Persistent bleeding and cramping after expulsion of tissue are signs of an incomplete pregnancy loss.

Fetal death may go unrecognized for several weeks in a patient with a **first-trimester pregnancy loss.** Symptoms may not start until the late first trimester, with diagnosis occurring at first-trimester screening ultrasonography. Ultrasound and hCG criteria for diagnosing early pregnancy loss have become more conservative based on observational data and a desire to avoid intervening in pregnancies that are viable. Follow-up ultrasonography is indicated when the ultrasound criteria are not definitive initially. Once an intrauterine site of pregnancy is confirmed by ultrasonography, hCG is no longer helpful in determining viability.

Fetal death in the second trimester or later is termed **intrauterine fetal demise** and is more likely to require medical intervention. Occasionally, coagulation defects such as disseminated intravascular coagulation (DIC) may complicate intrauterine fetal death with longer retention of fetal tissue and at more advanced gestational ages. The risk of DIC with first-trimester losses is minimal.

Recurrent or habitual pregnancy loss refers to the occurrence of three or more consecutive spontaneous pregnancy losses. These patients have a greater potential for a recurrent etiology of pregnancy loss, and thereby have an increased risk for future losses. With fewer or nonconsecutive pregnancy losses, the recurrence rate for pregnancy loss is the same as the general population rate.

Obstetric Management

First-trimester pregnancy losses can be managed expectantly, medically, or surgically. Clinical scenario, patient preference, availability, and cost can all impact management, but long-term outcome is similar. A woman who is asymptomatic or minimally symptomatic may utilize any management option. Active vaginal bleeding (especially if heavy) typically requires surgical intervention to prevent excessive blood loss and potential shock. Infection and medical disorders that would increase the patient's risk for bleeding or decrease maternal tolerance of blood loss are other indications for surgical management.

Conservative management incurs the least medical intervention and cost. While most pregnancy losses occur in the early first trimester, spontaneous expulsion of tissue may not occur until the late first trimester. An 80% complete expulsion rate occurs within 8 weeks of diagnosis. Nonetheless, some women will require surgical intervention for bleeding. Early gestations have higher success with conservative management.

Medical management provides more control over timing of tissue expulsion without surgery. A vaginal dose of misoprostol is effective in initiating expulsion of a pregnancy loss, although it is an ineffective method for terminating a viable pregnancy. For incomplete pregnancy loss, a 71% expulsion rate within 3 days with a single dose can increase to 84% with a second dose if needed. Use of medical management in a woman with an incomplete pregnancy loss does not clearly improve complete expulsion rates. Medical management success is greater if the crown rump length of the fetus is 8-week size or less.

For second-trimester intrauterine fetal demise, medical management may involve high-dose intravenous oxytocin, multiple doses of misoprostol, or vaginal prostaglandin E_2. About 8% of women will require surgical management for removal of residual placental tissue.

Choice of technique for surgically emptying the uterus after an incomplete or minimally symptomatic pregnancy loss primarily depends on the quantity of tissue that needs to be removed, the gestational age, and the amount of vaginal bleeding. Initial cervical dilation can be facilitated with vaginal misoprostol or intracervical laminaria if needed. A dilation and curettage (D & C) procedure refers to dilation of the cervix (if needed), followed by suction curettage with subsequent sharp curettage only if needed. When a smaller quantity of tissue requires removal, a manual vacuum aspirator may be used. Ossified fetal bones occur around 13 to 15 weeks' gestation and often require grasping with forceps for complete removal. After 13 to 15 weeks' gestation, a dilation and evacuation (D & E) procedure will be required; this involves greater cervical dilation followed by evacuation of the uterus with suction and the aid of surgical forceps. Oxytocin and/or an ergot alkaloid (e.g., methylergonovine) increases uterine tone and may be administered intraoperatively and/or postoperatively to decrease the amount of uterine bleeding. To prevent massive maternal blood loss during a vaginal delivery, D & E is the procedure of choice for second-trimester fetal demise with placenta previa.

Obstetric Complications

Complications of D & C and D & E procedures include cervical laceration, uterine perforation, hemorrhage, retained products of conception, and infection. The risk for these complications is increased in pregnancies that have progressed

beyond the first trimester. Medical and surgical management of fetal demise in the second trimester have similar complication rates. Uterine perforation, vasovagal events, delayed hemorrhage, retained products of conception, DIC, and unrecognized ectopic pregnancy can occur. Management of uterine perforation may involve simple observation or immediate laparotomy with repair. Management depends on the suspected severity of injury to the uterus and adjacent structures.

Serious infection (e.g., **septic pregnancy loss**) complicates approximately 1 in 200,000 spontaneous pregnancy losses. It is more common after induced abortion, particularly illegal abortion.[51] Septic abortion causes significant morbidity and is life-threatening. Blood cultures should be taken, and broad-spectrum intravenous antibiotics should be administered promptly. Patients with hemodynamic instability may require invasive hemodynamic monitoring to guide fluid, blood, and vasoactive drug therapy. Lower genital tract or bowel injury should be excluded, and the uterus should promptly be re-evacuated. Occasionally, hysterectomy is necessary and may be lifesaving.

$Rh_0(D)$ immune globulin should be administered to prevent Rh sensitization in Rh-negative woman who have a pregnancy loss because of a sensitization risk of 1.5% to 2% with a spontaneous loss and 4% to 5% after a D & C procedure.[52] $Rh_0(D)$ immune globulin should also be given to Rh-negative women with first-trimester bleeding because of the possibility of sensitization.[52]

Women who suffer spontaneous pregnancy loss and especially recurrent losses are at increased risk for depressive disorders during the 6 months after pregnancy loss[53] (see Chapter 50).

Anesthetic Management

Several anesthetic techniques are appropriate for D & C and D & E procedures (Box 16.2). The choice depends on several factors (e.g., whether the cervix is dilated; the gestational age and ossification of the fetus; the presence of significant blood loss, sepsis, or a full stomach; and the emotional state and preference of the patient). Dilation of the cervix is relatively painful, whereas suction and curettage are less painful. If the cervix is dilated and the products of conception can be

BOX 16.2 Suggested Anesthetic Techniques for Dilation and Uterine Suction Curettage (D & C) or Evacuation (D & E) for Early Pregnancy Loss or Induced Abortion

General Considerations

- Blood typing and antibody screening or typing and cross-matching in patients with a large blood loss or those with advanced gestation
- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- One peripheral intravenous catheter
- Administration of a short-acting benzodiazepine (e.g., midazolam) may be indicated for patients who prefer anxiolysis, sedation, and/or amnesia
- Monitored Anesthesia Care (natural airway) is an option for D & C procedures in healthy, stable patients who have appropriately fasted. If the cervix is closed, then a paracervical block can facilitate this anesthetic
- Neuraxial (spinal or epidural) anesthesia is an option for hemodynamically stable patients without sepsis
- General anesthesia may be most appropriate for patients with anticipated blood loss or for patients requiring a D & E procedure (e.g., gestation greater than 15 weeks with large fetal size and fetal ossification)
- Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated
- Oxytocin and/or an ergot alkaloid available
- In patients with significant blood loss: observation of the patient on the operating table for evidence of hypotension for at least 5 minutes after the legs have been lowered from the lithotomy to the supine position

Monitored Anesthesia Care (Well Tolerated When the Cervix Is Dilated and Gestational Age Is First Trimester)

- Intravenous analgesia with fentanyl or remifentanil and sedation with midazolam or propofol
- Paracervical block if needed

Spinal Anesthesia

- Single injection with a small-gauge spinal needle: lidocaine 40 mg or hyperbaric bupivacaine 7.5 mg, with fentanyl 10 to 20 μg, to achieve sensory blockade from T10 to S4

Epidural Anesthesia

- Placement of mid-lumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 μg/mL (12 to 15 mL) and fentanyl 100 μg, injected incrementally, to achieve sensory blockade from T10 to S4

General Anesthesia

- Rapid-sequence induction with cricoid pressure if the patient has a full stomach
- Induction: propofol or thiopental (ketamine or etomidate in cases of severe hemorrhage)
- Mask anesthesia or laryngeal mask airway during early pregnancy if stomach is empty and the patient is hemodynamically stable; otherwise tracheal intubation with a muscle relaxant
- Maintenance: volatile or intravenous anesthetic agents
- High concentration (greater than 0.5 MAC) of a volatile anesthetic agent should be avoided if there is significant bleeding or evidence of uterine atony
- Insertion and removal of an oral gastric tube (if trachea is intubated) to evacuate the stomach
- Tracheal extubation when the patient is awake and responds to verbal commands

curettaged and suctioned, sedation with or without a paracervical block may suffice. If the cervix is not dilated, paracervical block and sedation, spinal or epidural anesthesia (with sensory blockade from T10 to S4), or general anesthesia should be used. General anesthesia may be most appropriate if the patient is emotionally upset or if the gestational age is 13 to 15 weeks or greater (which requires a greater degree of cervical dilation for a D & E procedure). Selected patients may benefit from premedication with a short-acting benzodiazepine (e.g., midazolam).

Typically, the cervix is already dilated in patients who have had significant preoperative bleeding; rarely does a patient with a closed cervix have significant bleeding. In the presence of significant bleeding, intravascular volume should be restored first. A paracervical block and sedation may then be adequate. Substantial hemorrhage represents a relative contraindication to the use of spinal or epidural anesthesia, which probably should also be avoided in patients with evidence of sepsis.

General anesthesia may be induced with propofol or thiopental, although ketamine or etomidate may be preferred in patients with significant bleeding. Large doses (1.5 to 2.0 mg/kg) of ketamine may increase uterine tone,[54] which may be advantageous in patients who require evacuation of the uterus.

Drugs administered for general anesthesia may influence blood loss during the procedure. Volatile anesthetic agents cause dose-dependent relaxation of uterine smooth muscle[55] and have been associated with increased uterine bleeding.[56,57] In two studies that compared blood loss during general anesthesia for elective first-trimester abortion, blood loss was greater when anesthesia was maintained with isoflurane compared with propofol.[56,57] However, the differences were small. Some obstetricians contend that relaxation of the uterus (caused by administration of a volatile anesthetic agent) increases the risk for uterine perforation, and they prefer that administration of a volatile anesthetic agent during a D & C or D & E procedure be avoided.

For D & E procedures, general anesthesia is commonly maintained with oxygen, a propofol infusion, and an opioid. Nitrous oxide or a low concentration (less than 0.5 MAC) of a volatile agent may be added. The volatile agent should be avoided or discontinued if there is any evidence of uterine atony. In most cases, oxytocin is administered intravenously to increase uterine tone and decrease blood loss. Although some anesthesia providers simply dilute oxytocin in a bag of crystalloid solution, many are moving to administering oxytocin via a controlled infusion pump to achieve more accurate titration. Oxytocin receptor expression increases with gestation. Therefore, uterine atony in early pregnancy may require other uterotonics that do not act on the oxytocin receptor such as misoprostol, carboprost, or methylergonovine. The D & C or D & E procedure is performed with the patient in the lithotomy position. After the procedure is completed and the patient's legs are lowered, hypotension may develop in patients who have lost a substantial amount of blood, especially if neuraxial anesthesia has been used.

CERVICAL INSUFFICIENCY OR INCOMPETENCE

Cervical insufficiency is the inability of the cervix to hold a pregnancy in the uterus through the second trimester in the absence of labor. The definition and diagnostic criteria for cervical insufficiency have changed over time because of difficulty in separating it from other processes that lead to preterm delivery syndrome. Cervical insufficiency is a clinical diagnosis. Vaginal bleeding, rupture of membranes, and labor may result from cervical insufficiency, but to meet the diagnostic criteria these cannot be antecedent events. The etiology of cervical insufficiency remains unclear, and acquired factors such as obstetric cervical laceration, treatment of cervical intraepithelial lesions, or mechanical dilation for a gynecologic procedure may contribute to an increased risk. Congenital factors may include collagen disorders, Müllerian disorders, and biologic variation.[58]

The U.S. *National Vital Statistics Report* for 2008 cited a rate of 3.0 cervical cerclages performed per 1000 live births, indicating a general decrease from prior rates likely as a result of more limited indications for the procedure.[59] National statistics on cerclage incidence are no longer collected.[60]

Diagnosis

Symptoms of cervical insufficiency include altered vaginal discharge, lower abdominal or back pressure or discomfort, vaginal fullness, and urinary frequency. The diagnosis is definitive if delivery occurs in the second trimester before 24 weeks' gestation in the absence of bleeding, infection, or labor as the initial symptom. Cervical dilation or prolapse of membranes through the cervix in the absence of other findings or symptoms provides sufficient certainty of cervical insufficiency. As success of cerclage is less when the cervix is dilated or membranes are prolapsed, screening of asymptomatic women is also utilized.[58]

Obstetric Management

Cervical cerclage may be placed based on prior obstetric history, current symptoms and findings, or both. For women with two or more second-trimester losses that suggest cervical insufficiency, a history-indicated cerclage may be placed at 12 to 14 weeks' gestation. A rescue or emergency cerclage is placed in the setting of symptoms such as pelvic pressure, cramping, or altered vaginal discharge and evidence of cervical insufficiency before 25 weeks' gestation. A dilated or short cervix found on visual or digital examination or a short cervix on transvaginal ultrasonography provide evidence of cervical insufficiency. Rescue or emergency cerclage carries greater risk for complications and a lower success rate. Some women will be found to have a short cervix during routine screening anatomy ultrasonography, while others with risk factors may have serial ultrasonographic examinations to detect development of a short cervix. With a history of prior preterm birth at less than 34 weeks' gestation along with a short cervix noted on ultrasonography before 24 weeks' gestation, cerclage placement is associated with improved outcome.[61] In these

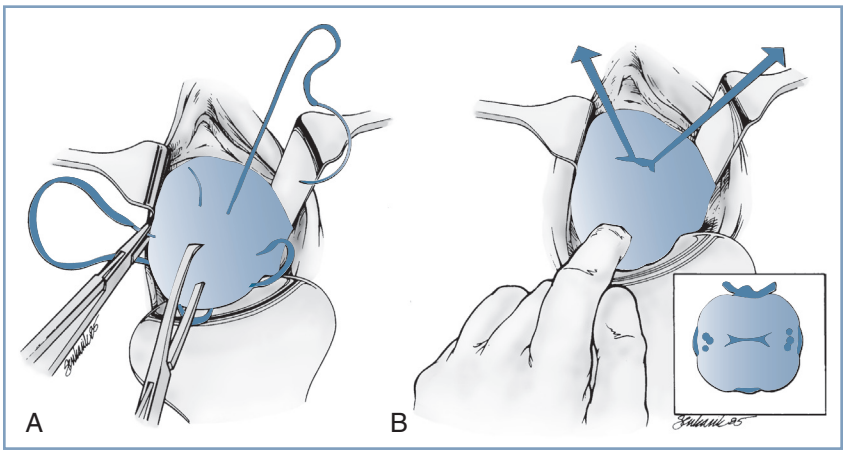

Fig. 16.2 Placement of sutures for McDonald cervical cerclage. (A) A double-headed polyester fiber (Mersilene®) band with four "bites" is placed in the cervix, avoiding the vessels. (B) The suture is placed high up on the cervix, close to the cervical-vaginal junction, approximately at the level of the internal os. (Modified from Iams JD. Preterm birth. In Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics: Normal and Problem Pregnancies,* 4th ed. New York, NY: Churchill Livingstone; 2002:803.)

women, an estimated 20 cerclages are needed to prevent one perinatal death, and more than 6500 infants per year could be saved in the United States by this management.[62] In contrast, cerclage placement appears to worsen outcome in women with a multifetal gestation regardless of cervical length.

The most common cerclage procedures are the modified **Shirodkar cerclage** and the **McDonald cerclage,** both of which are performed transvaginally. A ligature (e.g., polyester fiber [Mersilene®] tape or a large gauge nonabsorbable suture) is placed around the cervix at or near the level of the internal cervical os. In the more invasive modified Shirodkar procedure, the cervical mucosa is incised anteriorly and posteriorly with dissection of the bladder and rectum off the cervix. The ligature is placed submucosally and then tied, and the mucosal incisions are closed. The cervical mucosa is left intact with the McDonald cerclage; a purse-string ligature is placed around the cervix and then tied (Fig. 16.2). These two procedures result in comparable rates of fetal survival in patients with no history of a previous cerclage.[63] In one study, a more favorable outcome (i.e., more advanced gestational age) was obtained when a Shirodkar cerclage was performed in patients who had a previous cerclage.[64]

Transvaginal cerclage can be performed in most patients with an incompetent cervix. However, if no substantial cervical tissue is present (e.g., severe cervical laceration, shortening or scarring) or if two previous transvaginal cerclages have failed, a **transabdominal cerclage** may be performed, either before or during pregnancy.[65] Most patients with transabdominal cerclage undergo cesarean delivery. The transabdominal cerclage can remain *in situ* if further pregnancies are desired, or it can be removed at the time of cesarean delivery. Although the efficacy of perioperative antibiotics and/or tocolytic drugs has not been confirmed, some obstetricians may choose to use them.[66]

Contraindications to cerclage procedures include preterm labor, vaginal bleeding, fetal anomalies, fetal death, rupture of membranes, placental abruption, and evidence of intrauterine infection. Some obstetricians obtain specimens for culture of the amniotic fluid and/or cervix before placement of a cerclage.

The greatest risk during the performance of emergency cerclage is rupture of the membranes. Several techniques have been described to facilitate replacement of the bulging fetal membranes into the uterus. Uterine relaxation is essential, which can be facilitated by administration of a volatile anesthetic agent. Alternatively, a uterine relaxant like nitroglycerin may be administered. The steep Trendelenburg position allows for gravity assistance.

To assist in reduction of herniated membranes, some obstetricians fill the urinary bladder with sterile saline. Insertion of a 16-mm Foley catheter into the cervical canal with subsequent inflation of the balloon with 30 to 60 mL of saline has also been described.[67] The balloon is deflated and the catheter is removed at the end of the procedure.

Cervical cerclage is associated with a 0.6% risk for perioperative complications.[68] Immediate complications include rupture of the fetal membranes, hemorrhage, and preterm labor. Delayed complications include infection, suture displacement, cervical stenosis secondary to scarring, and cervical lacerations and uterine rupture if labor proceeds with the cerclage in place. Rarely, sepsis may result in death. Overall, patients who have had a cerclage have a higher rate of cesarean delivery. The Shirodkar procedure is associated with a rate of cesarean delivery almost double that associated with a McDonald cerclage (31% versus 17%, respectively).[64]

Anesthetic Management

Transvaginal cervical cerclage is usually performed under spinal, epidural, or general anesthesia (Box 16.3). The degree of cervical dilation may influence the choice of anesthesia. If the cervix is not dilated, spinal, epidural, or general anesthesia may be administered. Spinal anesthesia provides a rapid,

BOX 16.3 Suggested Anesthetic Techniques for Transvaginal Cervical Cerclage

General Considerations

- Aspiration prophylaxis if patient has a full stomach
- Routine noninvasive monitors
- One peripheral intravenous catheter
- Neuraxial anesthesia (spinal or epidural):
  - Intravenous fluids, vasopressors, supplemental oxygen, and minimal sedation given as clinically indicated
- Left uterine displacement if the pregnancy is greater than 18 to 20 weeks' gestation
- Consideration of fetal heart rate (FHR) monitoring:
  - Less than 24 weeks' gestation: FHR checked before and after procedure
  - Greater than 24 weeks' gestation: continuous FHR monitoring during and after the procedure

Spinal Anesthesia

- Single injection with a small-gauge spinal needle: lidocaine 40 mg or bupivacaine 7.5 mg, with fentanyl 10 to 20 µg, to achieve sensory blockade from T10 to S4
- If patient is in the Trendelenburg position for emergency cerclage, avoid hyperbaric local anesthetic

Epidural Anesthesia

- Placement of mid-lumbar epidural needle and catheter
- Lidocaine 2% with epinephrine 5 µg/mL (12 to 15 mL) and fentanyl 100 µg, injected incrementally, to achieve sensory blockade from T10 to S4

General Anesthesia (if Cervix Is Dilated and Uterine Relaxation Is Needed)

- Induction: propofol or thiopental
- Tracheal intubation is preferable in patients with a full stomach or at greater than 18 to 20 weeks' gestation; otherwise, mask anesthesia or laryngeal mask airway may be acceptable
- Maintenance: volatile or intravenous (a volatile anesthetic agent may be useful to provide uterine relaxation)
- Avoidance of large increases in intra-abdominal and intrauterine pressures (e.g., patient coughing on endotracheal tube, vomiting)

predictable onset of sacral anesthesia, which is desirable for these procedures. Sensory blockade from sacral dermatomes to T10 is necessary, because both the cervix (L1 to T10) and vagina and perineum (S2 to S4) require anesthesia.

If the cervix is dilated—and especially if the fetal membranes are bulging—the choice of anesthesia is less straightforward. The advantages and disadvantages of each anesthetic technique must be weighed carefully. It is important to produce adequate analgesia for the mother and to prevent an increase in intra-abdominal and intrauterine pressure that may lead to further bulging and possible rupture of the fetal membranes.

General anesthesia may be preferred in the patient with a dilated cervix and bulging fetal membranes. Administration of a volatile anesthetic agent relaxes uterine smooth muscle and results in a decrease in intrauterine pressure. A decrease in intrauterine pressure facilitates replacement of the bulging membranes and placement of the cerclage. On occasion, an amniocentesis may be performed before or during a cerclage procedure in an attempt to decrease intrauterine pressure and facilitate reduction of the fetal membranes. During induction and maintenance of general anesthesia, it is important to avoid endotracheal tube–induced coughing, which might raise intrauterine pressure. In addition, vomiting significantly raises intrauterine pressure.

Administration of neuraxial anesthesia obviates the need for tracheal intubation and the possibility of coughing on the endotracheal tube. Although some physicians worry that the acute dorsiflexion needed during initiation of the neuraxial blockade may raise intrauterine pressure, many prefer the avoidance of general anesthesia during pregnancy whenever possible.

Few clinical studies have compared obstetric outcomes after administration of neuraxial anesthesia and general anesthesia for cerclage. One retrospective study observed no difference in fetal outcome after administration of either general anesthesia (375 cases) or epidural anesthesia (114 cases).[69] Another study found no significant difference in plasma oxytocin levels or postoperative uterine activity between women who received either spinal or general anesthesia for a Shirodkar cerclage.[70]

Fetal heart rate monitoring should be considered during the procedure if the pregnancy is sufficiently advanced to allow monitoring to be performed easily. In theory, it is possible that replacement of bulging membranes and closure of the cervix may raise intrauterine pressure with a subsequent reduction in placental blood flow. In this case, it would be reasonable to give a tocolytic agent to help reduce intrauterine pressure.

The transvaginal cerclage is removed at 37 to 38 weeks' gestation, or earlier if rupture of membranes or onset of labor occurs. Removal of a McDonald cerclage often requires no anesthesia. Anesthesia (e.g., paracervical block, spinal anesthesia, epidural anesthesia) is usually necessary for removal of a Shirodkar cerclage. If the Shirodkar cerclage is epithelialized, some obstetricians elect to leave it intact and perform an elective cesarean delivery.

Labor often begins within a few hours or days after suture removal. If an epidural catheter was placed for cerclage removal, the epidural anesthetic can be allowed to regress while the patient is observed for evidence of cervical dilation and the onset of labor. When labor begins, epidural labor analgesia can be initiated by injection of drugs through the *in situ* catheter.

GESTATIONAL TROPHOBLASTIC DISEASE

In normal pregnancy, trophoblastic tissue forms the placenta. Abnormal trophoblastic proliferation results in **gestational trophoblastic disease** (GTD). When GTD persists after the pregnancy is concluded (diagnosed by persistent elevation of

hCG), it is called persistent gestational trophoblastic disease (PGTD).

Before 1970, most cases of GTD persisting after pregnancy were fatal. Early diagnosis and effective chemotherapy have reduced the mortality rate to 0.1% in the United Kingdom and the Netherlands and to 1% in the United States.[71,72] This improvement may be related to the fact that trophoblastic cells produce hCG, which provides an easily assayed biochemical marker to aid in detection and to monitor treatment. Further, cytotoxic chemotherapeutic drugs may be particularly effective against PGTD because the latter arises from a genotype that is not entirely that of the patient, thus facilitating rejection of the trophoblastic cells and leaving them vulnerable to this therapy.[73]

However, some women still die of GTD, often as a result of late presentation and drug resistance or concomitant human immunodeficiency virus infection.[74] Risk factors for GTD include advanced or very young maternal age, previous molar pregnancy, and Asian or Native American ancestry.

Categorization and Etiology

The classification and terminology applied to GTD are varied and can be confusing because GTD encompasses a heterogeneous group of diseases. **Gestational trophoblastic neoplasia** is a subset of GTD.

Classification of GTD continues to be in flux. Current terminology supported by the Society of Gynecologic Oncology and the American College of Obstetrics and Gynecology is listed (Box 16.4). The pathologic and clinical features of GTD are summarized in Table 16.1.[75] The spectrum from the most benign to the most malignant form of GTD is as follows: (1) **partial hydatidiform mole,** (2) **complete hydatidiform mole,** (3) **invasive mole,** and (4) **gestational choriocarcinoma.** Complete molar pregnancies have a higher rate of associated complications and a higher rate of persistent GTD than partial molar pregnancies. Approximately 20% of patients with complete molar pregnancy have postmolar nonmetastatic GTD (70% to 90%) or malignant GTD (10% to 30%) and require chemotherapy; in contrast, less than 5% of patients with partial molar pregnancy require chemotherapy.[76]

GTD can also be classified according to the genetic makeup of the trophoblastic cells; further details are available elsewhere.[73] Typically, the genetic makeup of trophoblastic cells in complete hydatidiform molar pregnancy is **androgenic,** meaning nearly all of the genome of the trophoblastic cell arises from the sperm. **Diploid** (46,XY) or **triploid** (e.g., 69,XXY) versions are possible. No fetus develops. Approximately 90% of hydatidiform moles are complete.[77] Most invasive moles result from complete moles. In contrast, the genetic makeup of a partial hydatidiform molar pregnancy is **diandric,** meaning the chromosomes arise from both the

BOX 16.4 Classification of Gestational Trophoblastic Disease

- Hydatidiform mole:
  - Complete
  - Partial
- Malignant gestational trophoblastic disease
  - Invasive mole
  - Gestational choriocarcinoma
  - Placental site trophoblastic tumor

TABLE 16.1 Pathologic and Clinical Features of Gestational Trophoblastic Disease

Gestational Trophoblastic Disease	Pathologic Features	Clinical Features
Hydatidiform mole, complete	46,XX (mainly); 46,XY Absent fetus/embryo Diffuse swelling of villi Diffuse trophoblastic hyperplasia	15%–20% trophoblastic sequelae hCG often > 100,000 mIU/mL Medical complications
Hydatidiform mole, partial	Triploid (69,XXY; 69,XYY; 69,XXX) Abnormal fetus/embryo Focal swelling of villi Focal trophoblastic hyperplasia	< 5% trophoblastic sequelae hCG usually < 100,000 mIU/mL Rare medical complications
Invasive mole	Myometrial invasion Swollen villi Hyperplastic trophoblast	15% metastatic, to lung/vagina Most often diagnosed clinically, rather than pathologically
Choriocarcinoma	Abnormal trophoblastic hyperplasia and anaplasia Absent villi Hemorrhage, necrosis	Vascular spread to distant sites: lung/brain/liver Malignant disease
Placental site trophoblastic tumor	Tumor cells infiltrate myometrium with vascular/lymphatic invasion Intermediate cells/absent villi Less hemorrhage and necrosis Tumor cells stain positive for hPL	Extremely rare hCG levels less reliable indicator Relatively chemoresistant Mainly surgical treatment

hCG, Human chorionic gonadotropin; *hPL,* human placental lactogen.

From Lurain JR. Gestational trophoblastic disease. I. Epidemiology, pathology, clinical presentation and diagnosis of gestational trophoblastic disease, and management of hydatidiform mole. *Am J Obstet Gynecol.* 2010;203:531–539.

egg and the sperm but is complicated by triploid conception (69,XXX or 69,XXY). Because both maternal and paternal chromosomes are present, a fetus may form with a partial mole. As a result, patients with partial mole may have a preoperative diagnosis of incomplete or missed pregnancy loss.

Specific care of GTN is beyond the scope of this chapter. Classification of GTN has been moving more toward a clinically based system that may better predict outcome and direct treatment. **Gestational choriocarcinoma** can occur after a molar pregnancy, a normal pregnancy, or even a pregnancy loss. In summary, GTN always involves trophoblastic cells with resultant positive hCG, often presents with bleeding sequela, and metastatic forms can appear in any organ but most frequently lung, brain, or liver.

Complete and Partial Hydatidiform Mole

The reported incidence of hydatidiform mole varies. In the United States, it is detected in 1 in 600 elective abortions and 1 in 1500 pregnancies. Rates of 1 in 400 pregnancies are reported in Korea and Indonesia and among Native Americans.[71,78,79] Coexistence of an intact fetus with molar components is extremely rare, occurring in 1 in 22,000 to 1 in 100,000 pregnancies.[78]

Patients may have a complete molar pregnancy diagnosed during first-trimester ultrasonography, or they may have vaginal bleeding after delayed menses, suggestive of a threatened, missed, or incomplete pregnancy loss. They may spontaneously pass hydropic vesicles. The absence of fetal cardiac activity, a uterus large for gestational age, and a marked elevation of hCG strongly suggest the diagnosis of hydatidiform mole. Diagnosis may be made after a D & C for an incomplete pregnancy loss[78]; baseline chest radiography and quantitative hCG levels should be obtained promptly after surgery in such cases.

Molar pregnancies produce hCG in amounts proportional to the neoplastic volume. Excessive uterine size is associated with a marked elevation of serum hCG concentration (greater than 100,000 mIU/mL) secondary to a large tumor volume. Large ovarian cysts, hyperemesis gravidarum, and early onset of gestational hypertension are also strongly suggestive of GTD. Ultrasonography may show characteristic multiechogenic regions that represent hydropic villi or hemorrhagic foci.[75]

Persistent and Malignant Gestational Trophoblastic Disease

Persistent and malignant GTD can develop after any gestational event, including normal pregnancy, spontaneous pregnancy loss, induced abortion, ectopic pregnancy, and molar pregnancy. Diagnosis of persistent GTD is made when hCG levels plateau or rise.[78,79]

The subtle signs and symptoms of malignant GTD after a nonmolar gestational event may delay diagnosis. A quantitative hCG measurement should be performed in any patient with continued or abnormal vaginal bleeding 6 weeks after the end of gestation. In any woman of reproductive age with metastatic disease from an unknown primary tumor, the diagnosis of gestational choriocarcinoma should be considered. Metastases of gestational choriocarcinoma can occur anywhere. The vagina, liver, lung, and brain are the most frequently involved sites, and imaging may show signs of local hemorrhage. Signs and symptoms are related to the affected site. Biopsy of metastases is rarely needed and can result in profuse bleeding. The diagnosis of metastatic GTD is suggested with a positive hCG result and no identifiable pregnancy. Details on staging and risk-factor scoring of GTD and their implications for therapy and prognosis are available elsewhere.[78]

Medical Complications

Routine use of ultrasonography has led to earlier diagnosis of molar pregnancy, which has reduced the incidence of medical complications. However, excessive uterine size occurs in up to one-half of patients with complete molar pregnancy and is associated with a higher incidence of medical complications. Medical complications occur in about 25% of patients with uterine size of more than 14 to 16 weeks' gestation and include ovarian theca-lutein cysts, hyperemesis gravidarum, gestational hypertension with anemia, hyperthyroidism, DIC, and sepsis (Table 16.2).

Ovarian theca-lutein cysts occur primarily in patients with an extremely high serum hCG concentration (greater than 100,000 mIU/mL).[80] They typically regress over 2 to 3 months. Rarely, torsion, rupture, or infarction may necessitate oophorectomy. Patients with theca-lutein cysts and a uterus more than 4 weeks larger than expected (for dates) have a 50% likelihood of development of postmolar GTN.[71]

Hyperemesis gravidarum can lead to significant electrolyte disturbances and volume depletion, all of which should be corrected before surgery.

Gestational hypertension is more likely to occur in women with molar pregnancy. **Preeclampsia** may be diagnosed if proteinuria accompanies hypertension. Although early presentation does not fit usual definitions (see Chapter 35), preeclampsia in the first trimester suggests the presence of GTD. Although it is thought that convulsions rarely occur in these patients,[80] prophylactic use of magnesium sulfate

TABLE 16.2 Complications of Complete Molar Pregnancies

Complication	Incidence (%)
Excessive uterine size	28
Ovarian theca-lutein cysts, bilateral	15
Hyperemesis gravidarum	8
Gestational hypertension	1
Other complications less common due to earlier diagnosis and treatment: anemia, hyperthyroidism, disseminated intravascular coagulation, and sepsis	Rare

From Lurain JR. Gestational trophoblastic disease. I. Epidemiology, pathology, clinical presentation and diagnosis of gestational trophoblastic disease, and management of hydatidiform mole. *Am J Obstet Gynecol.* 2010;203:531–539.

should be considered if severe features of preeclampsia are present. Antihypertensive therapy (e.g., hydralazine, nifedipine, labetalol) should be administered to reduce blood pressure, similar to the management of preeclampsia without GTD.

Anemia can complicate a complete molar pregnancy. The visible vaginal bleeding may underrepresent the total amount of hemorrhage. Occult bleeding into and around the tumor results in multiple hemorrhagic foci. Because blood loss may occur gradually, the patient may have a normal intravascular volume despite the presence of severe anemia. In any patient with suspected GTD, blood typing and antibody screening should be performed preoperatively.

Although infrequent, **hyperthyroidism** may result from a marked elevation of hCG,[81] which can have a thyrotropin-like effect. Alternatively, hyperthyroidism may result from some other thyrotropic substance produced by the neoplasm.[81] Anesthesia or surgery can precipitate thyroid storm (i.e., sinus tachycardia, atrial fibrillation, hyperthermia, cardiovascular collapse).

Historically, **acute cardiopulmonary distress** was observed after evacuation of molar pregnancy in as many as 27% of patients.[80,82,83] A higher risk for cardiopulmonary complications occurs in patients with a uterine size of 16 weeks or greater.[82] Therefore, with earlier diagnosis, cardiopulmonary distress after molar evacuation is far rarer. For patients with poor prenatal care who present late in pregnancy, it is important to be prepared for such an event. Signs and symptoms include chest pain, cough, tachycardia, tachypnea, hypoxemia, diffuse rales, and chest radiographic evidence of bilateral pulmonary infiltrates. **Trophoblastic embolization** may be the etiology of cardiopulmonary distress in more than one-half of cases.[83,84] Other causes include (1) high-output cardiac failure from thyrotoxicosis; (2) pulmonary congestion from severe anemia; (3) gestational hypertension or preeclampsia; (4) aspiration pneumonitis; and (5) iatrogenic fluid overload.[83,84] Symptoms usually develop within 12 hours of uterine evacuation.[83] Some patients require tracheal intubation, mechanical ventilation, and invasive hemodynamic monitoring. Symptoms usually subside within 72 hours; however, massive embolization or adult respiratory distress syndrome may result in death. If the patient survives trophoblastic embolization, malignant sequelae often develop.[83,85]

Obstetric Management

The following preoperative tests are recommended for patients with suspected hydatidiform mole: (1) complete blood count including platelet count; (2) coagulation studies; (3) thyroid, renal, and liver function studies; (3) blood typing and antibody screening; (4) quantitative hCG level; and (5) chest radiography.[78,79] Prompt molar evacuation should be instituted, because a delay in uterine evacuation may increase the risk for complications. Once the patient is stabilized, suction curettage is performed to evacuate the uterus in patients who want to preserve fertility. Hysterectomy may be performed in patients who have completed childbearing, especially if the uterus is markedly enlarged. Hysterotomy or medical induction of labor are not recommended because they are associated with increased blood loss and a higher incidence of persistent PGTD.[79] Rh_0(D) immune globulin should be administered to Rh-negative patients.[52]

After uterine evacuation, the hCG level should be measured every 1 to 2 weeks until it is undetectable in three tests in a row, and then every 2 months for an additional 6 months. Frequent pelvic examinations are performed while hCG levels remain high. Thorough evaluation of the patient with GTD includes screening for evidence of metastasis (e.g., vagina, liver, lung, brain) and other potential complications. Prevention of pregnancy is recommended for 6 months after the hCG is normalized.[71,78]

Malignant GTD should be managed by an experienced team in a trophoblastic center to minimize mortality.[71,78,79,86] Chemotherapy is indicated in patients with (1) histologic evidence of choriocarcinoma; (2) an increase in hCG levels of 10% or greater in three or more samples taken over at least 2 weeks; (3) a plateau of hCG levels in four or more samples taken over 3 consecutive weeks; (4) persistence of measurable hCG levels 6 months after molar evacuation; or (5) evidence of metastasis. Some patients may require additional surgery or radiation to manage lung, liver, or brain metastasis or resistant uterine disease.[87]

Anesthetic Management

Preoperative assessment of the patient with a molar pregnancy consists of evaluation for specific complications of molar pregnancy, including hyperemesis gravidarum, gestational hypertension and preeclampsia, anemia, and thyrotoxicosis. The main anesthetic considerations are the potential for rapid and significant blood loss and the risk for cardiopulmonary distress with uterine evacuation. The anesthesia provider should establish adequate intravenous access, and blood products should be immediately available. Invasive arterial pressure and/or central venous pressure monitoring may be indicated in the patient with hypoxemia, severe anemia, hemorrhage, severe gestational hypertension or preeclampsia, hyperthyroidism, or a uterus of more than 16 weeks size.[88]

Although neuraxial anesthesia has been described, general anesthesia is often preferred because of the potential for rapid, substantial blood loss and cardiopulmonary distress during evacuation of the uterus (Box 16.5). For patients with acute hemorrhage and hypovolemia, induction with propofol may cause marked hypotension. In hyperthyroid patients, ketamine may result in marked tachycardia.[89] Etomidate is an excellent choice for patients with preoperative bleeding and preoperative evidence of hyperthyroidism. Anesthesia can be maintained using either an inhalational or intravenous technique, although it may be necessary to avoid volatile anesthetic agents in some patients to optimize uterine contractility,[90] and care should be exercised with the use of a propofol infusion in hemodynamically unstable patients.

An intravenous oxytocin infusion (6 to 15 IU per hour) should begin either before[80,82] or during[86] uterine evacuation. Oxytocin helps the uterus contract, facilitating safe curettage

BOX 16.5 Suggested Anesthetic Technique for Patients with Gestational Trophoblastic Disease

Preoperative Evaluation

- Evaluation for complications of molar pregnancy
- Baseline arterial blood gas measurements

General Anesthesia

- Routine noninvasive monitors
- Consideration of invasive hemodynamic monitoring in patients with hypoxemia, gestational hypertension or preeclampsia, severe anemia, hyperthyroidism, or a uterine size greater than 16 weeks.
- Two large-gauge peripheral intravenous catheters
- Immediate availability of blood
- Induction: etomidate if evidence of hemorrhage or hemodynamically unstable
- Tracheal intubation with a muscle relaxant
- Maintenance: inhalation or intravenous technique; avoid volatile agents if optimization of uterine contractility is required, and exercise caution with the use of a propofol infusion in hemodynamically unstable patients
- Oxytocin infusion (6 to 15 IU per hour) after cervical dilation or after partial uterine evacuation

and reducing blood loss. Some obstetricians have speculated that oxytocin may decrease trophoblastic embolization by constricting the uterine veins.[82] Postoperatively, the patient should be monitored closely for any evidence of uterine hemorrhage or cardiopulmonary distress.

HYPEREMESIS GRAVIDARUM

As many as 50% to 80% of women experience nausea and vomiting during pregnancy; this is the most common indication for admission to the hospital during the first trimester of pregnancy.[91] Symptoms can be worse during the morning hours, thus the term *morning sickness,* though symptoms can occur at any time of the day. Symptoms typically improve or resolve by the end of the first trimester.

On rare occasions (0.3% to 3% of pregnancies), women experience a persistent and severe form of nausea and vomiting called **hyperemesis gravidarum.**[91] This is believed to be an extreme form of normal nausea and vomiting of pregnancy, although there is no single accepted definition. These women may develop dehydration, ketonuria, nutritional compromise, weight loss, electrolyte abnormalities, and/or transient hepatic and renal dysfunction. Intravenous rehydration, correction of electrolyte abnormalities, antiemetics, and, rarely, hyperalimentation are indicated. Gastroesophageal reflux disease may exacerbate vomiting especially after the first trimester.

Hyperemesis gravidarum may be associated with multiple gestation, thyrotoxicosis, and/or GTD. Diagnosis is by exclusion, and if symptoms begin after 9 weeks' gestation, many other underlying diseases should be ruled out including: gastrointestinal diseases (e.g., hepatitis, cholecystitis, pancreatitis, gastroparesis, partial bowel obstruction, appendicitis), genitourinary diseases (e.g., pyelonephritis, uremia, ovarian torsion, kidney stones), metabolic disorders (diabetic ketoacidosis, hyperthyroidism, Addison disease), neurologic disorders (pseudotumor cerebri, migraine headaches), psychiatric disorders, acute fatty liver of pregnancy, drug toxicity, and preeclampsia, among others.

Serious maternal complications may include Wernicke encephalopathy, acute tubular necrosis, esophageal rupture, and splenic avulsion.[91]

CORPUS LUTEUM CYSTS

Symptomatic corpus luteum cysts occasionally occur during early pregnancy. Typically, they resolve over several weeks. In some cases, hemorrhage or ovarian torsion necessitates ovarian cystectomy or oophorectomy. After the cyst is removed, the fetus usually is not affected, provided that supplemental progesterone is administered until 10 to 12 weeks' gestation.

KEY POINTS

- Aortocaval compression does not develop until the uterine fundus reaches the umbilicus (i.e., 18 to 20 weeks' gestation in a normal singleton pregnancy, or earlier in conditions with an enlarged uterus). Left uterine tilt should be initiated when the potential for aortocaval compression exists.
- General anesthesia may be administered by mask or laryngeal mask airway (LMA) for selected extra-abdominal procedures during the first 18 to 20 weeks of pregnancy, provided that the patient fulfills the criteria for an empty stomach and there is no difficulty with mask ventilation. Some anesthesia providers prefer to limit the use of mask anesthesia or the LMA to the first 12 to 14 weeks of pregnancy.
- During pregnancy, the nervous system is more sensitive to local anesthetics and perhaps general anesthetic agents. Lower doses of these drugs should be considered, although it is important to be aware of the greater risk for intraoperative awareness during cesarean delivery.
- Most ectopic pregnancies are located in one of the fallopian tubes. Ruptured tubal pregnancies, as well as interstitial, cervical, cesarean scar, and abdominal ectopic pregnancies as well as pregnancies with early placenta accreta, may result in substantial hemorrhage.
- The most painful part of a dilation and uterine evacuation procedure is the dilation of the cervix. If the cervix is already dilated and the fetal size is first trimester, sedation (with or without paracervical block) often suffices. If the

cervix is closed, either a paracervical block with sedation or neuraxial or general anesthesia may be necessary. If the fetal size is advanced (greater than 13 to 15 weeks' gestation), many anesthesia providers prefer general anesthesia because of the greater surgical stimulation and risk for bleeding complications.

- Neuraxial anesthesia is an excellent choice for prophylactic cervical cerclage. In a patient who requires emergency cervical cerclage, it is important to prevent a marked increase in intra-abdominal and intrauterine pressures, which might cause rupture of bulging fetal membranes.
- The patient with a molar pregnancy may have hyperemesis gravidarum, gestational hypertension, severe anemia, and/or hyperthyroidism. These complications are more common in patients with excessive uterine size.
- Rapid and profound blood loss is possible with uterine evacuation of a molar pregnancy, and acute cardiopulmonary distress can develop after uterine evacuation.

Nonobstetric Surgery during Pregnancy

Jeanette R. Bauchat, MD, MS, Marc Van de Velde, MD, PhD, EDRA

CHAPTER OUTLINE

Estimates of the frequency of nonobstetric surgery performed during pregnancy range from 0.3% to 2.2%,[1,2] accounting for approximately 100,000 cases per year in both the United States and the European Union. Pregnancy may be unrecognized at the time of surgery. The incidence of positive pregnancy tests in women of childbearing age presenting for orthopedic and elective sterilization procedures have ranged from 0.002%[3] to 2.6%.[4] Medical history alone may not be a reliable means of excluding pregnancy in women presenting for elective surgery[5,6]; however, the practice of mandating pregnancy testing for every woman of childbearing age is controversial. A number of concerns have been raised; mandatory testing does not fully consider patient autonomy and likely disproportionately affects the most vulnerable patient populations, including minorities and women of lower socioeconomic status.[7,8] Moreover, the medicolegal and health implications of a false-positive or false-negative pregnancy test have not been fully explored; litigation has occurred as a result of failure to follow-up on routine preoperative pregnancy tests and pregnancy loss following surgery.[9]

The American Society of Anesthesiologists (ASA) has stated: "Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management. Informed consent or assent of the risks, benefits, and alternatives related to preoperative pregnancy testing should be obtained."[10] In 2016, the UK National Institute for Health and Clinical Excellence (NICE) issued updated preoperative screening guidelines recommending the development of institutional protocols that include "… criteria for enquiry or consented testing, what information is provided to patients, how pregnancy status is recorded, and the procedures for management of consent and disclosure, particularly for groups who may find discussion of pregnancy a sensitive issue."[11]

Surgery may be necessary during any stage of pregnancy. Indications for pregnancy-related surgery include cervical incompetence, the presence of ovarian cysts, and conditions amenable to fetal surgery (see Chapter 7). Indications for nonpregnancy-related surgery include the presence of acute abdominal disease (most commonly appendicitis and cholecystitis), malignancies, and trauma. Among 5405 Swedish women who had operations during pregnancy, 42% occurred during the first trimester, 35% during the second trimester, and 23% during the third trimester.[1] Laparoscopy for gynecologic indications and appendectomy were the most common procedures during the first trimester (34%) and the remainder of pregnancy, respectively.[1]

When caring for pregnant women undergoing nonobstetric surgery, anesthesia providers may need to modify standard anesthetic protocols to accommodate pregnancy-induced maternal physiologic changes and the presence of the fetus. The Global Burden of Disease Maternal Mortality Collaborators[12] and other maternal mortality databases, such as the Confidential Enquiries into Maternal and Child Health in the United Kingdom,[13] have demonstrated that mothers may die, even in early pregnancy, of hemorrhage, hypertensive disorders, thromboembolism, and sepsis. In developed countries, many maternal deaths are considered preventable; multidisciplinary care should ideally follow protocols and guidelines developed for specific scenarios,

which can occur during or after nonobstetric surgical procedures.[14,15] Two studies retrospectively analyzed data from the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database for pregnant women undergoing surgery.[16,17] The rate of major complications (e.g., infections, reoperation, wound complications, respiratory complications, venous thromboembolism, blood transfusion, maternal death) for antenatal nonobstetric surgery was approximately 7%, which was not different from the rate in nonpregnant women.[16]

Possible fetal risks of antenatal surgery include (1) the effects of the disease process itself, or related therapy; (2) the teratogenicity of anesthetic agents or other drugs administered during the perioperative period; (3) intraoperative perturbations of uteroplacental perfusion and/or fetal oxygenation; and (4) preterm delivery or fetal demise.

MATERNAL PHYSIOLOGY: ANESTHETIC IMPLICATIONS

During pregnancy, profound changes in physiology result from increased concentrations of various hormones, mechanical effects of the gravid uterus, greater metabolic demand, and the hemodynamic consequences of the low-pressure placental circulation. Hormonal changes are likely responsible for most of the changes that occur during the first trimester. Mechanical effects become apparent when the uterus emerges from the pelvis during the second half of gestation (see Chapter 2).

Respiratory System and Acid-Base Balance Changes

Alveolar ventilation increases by 30% or more by mid-pregnancy. This increase results in chronic respiratory alkalosis with a $Paco_2$ of 28 to 32 mm Hg, a slightly alkaline pH (approximately 7.44), and decreased levels of bicarbonate and buffer base. Although oxygen consumption is increased, Pao_2 usually increases only slightly or remains within the normal range. Functional residual capacity (FRC) diminishes by approximately 20% as the uterus expands, resulting in decreased oxygen reserve and the potential for airway closure. When FRC is decreased further (e.g., from morbid obesity; perioperative intra-abdominal distention; placement of the patient in the supine, Trendelenburg, or lithotomy position; or induction of anesthesia), airway closure may be sufficient to cause hypoxemia.

Weight gain during pregnancy and capillary engorgement of the respiratory tract mucosa lead to more frequent problems with mask ventilation and tracheal intubation (see Chapter 29). Difficult airway management and failed intubation (a leading cause of anesthesia-related maternal death) is as much a risk during early pregnancy with nonobstetric surgery as it is during cesarean delivery.[13] In 2015, the Obstetric Anaesthetists' Association and the Difficult Airway Society developed a difficult airway algorithm that was designed for the unique challenges of managing an obstetric patient, including considerations of the fetal status and urgency of a cesarean delivery; this algorithm is relevant to airway management for women with a viable fetus undergoing nonobstetric surgery (see Figs. 29.12, 29.13, 29.14).[18]

Decreased FRC, increased oxygen consumption, and diminished buffering capacity result in the rapid development of hypoxemia and acidosis during periods of hypoventilation or apnea. Moreover, induction of inhalation anesthesia occurs more rapidly during pregnancy because alveolar hyperventilation and decreased FRC allow faster equilibration of inhaled agents. Combined with the reduction in the minimum alveolar concentration (MAC), subanesthetic concentrations of analgesic and anesthetic agents can induce unconsciousness quickly and unexpectedly in the pregnant woman.

Cardiovascular System Changes

Cardiac output increases by up to 50% during pregnancy because of increases in heart rate and stroke volume; diminished systemic and pulmonary vascular resistances occur from increased production of endothelial prostacyclin, relaxin, and nitric oxide. By 8 weeks' gestation, 57% of the increase in cardiac output, 78% of the increase in stroke volume, and 90% of the decrease in systemic vascular resistance that are typically achieved by 24 weeks' gestation have already occurred.[19]

During the second half of gestation, compression of the inferior vena cava by the gravid uterus reduces venous return and cardiac output; in 10% of pregnant women, these effects can precipitate significant vasovagal symptoms and signs, which are collectively known as the "supine hypotension syndrome of pregnancy."[20] During mid-pregnancy, patient movement from the supine to the left lateral position reduces vena caval compression, resulting in a significant increase in left ventricular ejection fraction (8%), end-diastolic volume (25%), and stroke volume.[21] By late pregnancy, the same patient movement results in even greater increases in these parameters; for example, cardiac output increases by up to 24%.[21] In the supine position, pregnant women may maintain upper extremity blood pressure by compensatory vasoconstriction and tachycardia; however, these effects may be attenuated by neuraxial or general anesthesia. Moreover, uteroplacental blood flow and venous return can be compromised.

Although magnetic resonance imaging (MRI) studies of vena caval compression indicate virtually no compression with 30 degrees of left lateral tilt,[22] most surgeries cannot be performed in this position. Therefore, after 18 to 20 weeks' gestation, some degree of left lateral tilt should be applied, acknowledging that maternal or fetal hemodynamic instability may warrant a further increase in tilt, if necessary.

Vena caval compression can result in distention of the epidural venous plexus, which increases the likelihood of intravascular injection of local anesthetic during the administration of epidural anesthesia. The reduced capacity of the epidural space most likely contributes to the enhanced spread of epidural local anesthetic solution that is observed during pregnancy.

Changes in Blood Volume and Blood Constituents

Blood volume expansion begins as early as the first trimester and ultimately achieves a 30% to 45% increase by term gestation. The smaller increase in red blood cell than plasma volume results in dilutional anemia, allowing moderate blood loss to be well tolerated. However, when accompanied by anemia from other causes, a patient's reserve during significant hemorrhage is decreased. The need for perioperative transfusions in pregnant women with iron-deficiency anemia is reduced by the intravenous administration of iron. Hemoglobin levels increase more rapidly (2 weeks) with intravenous compared with oral (greater than 6 weeks) iron therapy.[23,24] Pregnancy is associated with benign leukocytosis; thus the white blood cell count is an unreliable indicator of infection. In general, pregnancy induces a hypercoagulable state, with increases in fibrinogen; factors VII, VIII, X, and XII; and fibrin degradation products.

Pregnancy is associated with enhancement of platelet turnover, clotting, and fibrinolysis; although a wide variation in the platelet count has been observed, functionally some pregnant women with thrombocytopenia may still be hypercoagulable. Pregnancy represents a state of accelerated but compensated intravascular coagulation. Given the high risk and mortality associated with thromboembolism, thromboprophylaxis management should be applied to pregnant surgical patients (see later discussion).[25,26]

Gastrointestinal System Changes

Incompetence of the lower esophageal sphincter and distortion of gastric and pyloric anatomy during pregnancy increase the risk for gastroesophageal reflux, despite similar gastric emptying rates in pregnant and nonpregnant patients.[27] It is unclear at what gestational age the risk for aspiration becomes significant; gastroesophageal reflex starts early in the first trimester, and other mechanically induced factors become more relevant later in pregnancy. Investigators have studied the feasibility of assessing gastric contents using ultrasonography.[28] Further study is warranted to determine if assessing gastric contents before the induction of anesthesia can be used to inform anesthetic management and reduce the risk for aspiration. It seems prudent to consider the pregnant patient as having a higher risk for aspiration from the beginning of the second trimester.[29]

Altered Responses to Anesthesia

A 30% to 40% decrease in the MAC of volatile anesthetic agents has been observed in pregnancy, correlating with higher serum progesterone levels.[30] Although thiopental requirements begin to decrease in early pregnancy,[31] the effects of pregnancy on propofol requirements are conflicting and appear unrelated to progesterone levels.[31,32] Higuchi et al.[31] determined that the median effective dose (ED_{50}) of propofol required to achieved loss of consciousness was unchanged in pregnancy, whereas Mongardon et al.[32] reported that lower propofol doses were required in early pregnancy compared with the nonpregnant state. The relatively high risk for intraoperative awareness (estimated risk 1 in 670 general anesthetics) observed during cesarean delivery is attributable, in part, to the need for rapid-sequence induction of general anesthesia, omission or reduction in analgesic (opioids) and anesthetic medications, and need for urgent surgery.[33,34] These circumstances are also commonly encountered during nonobstetric surgery in pregnancy.[33,34]

Plasma cholinesterase levels decrease by approximately 25% from early in pregnancy until the seventh postpartum day. However, prolonged neuromuscular blockade with succinylcholine is uncommon, because the larger volume available for drug distribution offsets the impact of decreased drug hydrolysis.[35] The anesthesia provider should monitor all forms of neuromuscular blockade with a nerve stimulator to ensure adequate muscle relaxation as well as reversal before extubation of the trachea.

Decreased protein binding associated with lower albumin and alpha-glycoprotein concentrations during pregnancy may result in a larger fraction of unbound drug, with the potential for greater drug toxicity during pregnancy.[36] Pregnancy-associated changes in volume of distribution (caused by changes in body composition and/or plasma protein–binding capacity), metabolic activity, and hepatic or renal elimination (caused by changes in glomerular filtration rate and tubular transport processes) may contribute to changes in drug effects and metabolism, including a higher initial loading dose of any given medication.[37] For example, in pregnant women, cefazolin clearance is approximately twice as high between 20 and 40 weeks' gestation and acetaminophen (paracetamol) clearance is increased, compared with nonpregnant women.[37]

Pregnant surgical patients may require drugs for which limited pharmacokinetic and pharmacodynamic information during pregnancy is available; judicious use of such agents is advisable. In addition to the altered response to systemic drugs, more extensive neuraxial and peripheral neural blockade may occur in pregnant than nonpregnant patients (see Chapter 12). Pregnancy may be associated with lower 48-hour postsurgical analgesic drug consumption,[38] but this decrease has not been consistently demonstrated across studies.

FETAL CONSIDERATIONS

Risk for Teratogenicity

Although severe maternal hypoxia and hypotension pose the greatest risk to the fetus, considerable attention has focused on the role of anesthetic agents as abortifacients and teratogens. *Teratogenicity* has been defined as any significant postnatal change in function or form in an offspring after prenatal treatment. Concern about the potential harmful effects of anesthetic agents stems from their known effects on mammalian cells, which include reversible decreases in cell motility, prolongation of DNA synthesis, and inhibition of cell division. Despite these concerns, no data specifically link any of these cellular events with teratogenic changes. Unfortunately, prospective clinical studies of the teratogenic effects of

anesthetic agents are impractical; such studies would require significant numbers of patients exposed to the drug being evaluated. Therefore, investigations of anesthetic agents have taken one of the following directions: (1) small animal studies of the reproductive effects of anesthetic agents, (2) epidemiologic surveys of operating room personnel routinely exposed to subanesthetic concentrations of inhalation agents, and (3) outcome studies in women who have undergone surgery while pregnant.

Principles of Teratogenicity

Like other toxicologic phenomena, a number of important factors influence the teratogenic potential of a substance, including species susceptibility, dose of the substance, duration and timing of exposure, and genetic predisposition (Fig. 17.1).[39] Most teratologists accept the principle that any agent can be teratogenic when given at a specific dose and time. A teratogen may cause malformations following the single administration of a high dose, or the long-term administration of a low dose; however, this does not mean that a single, short exposure of a "normal" dose (e.g., during a typical anesthetic) would incur similar risk. In addition, a small dose of a teratogen may cause an effect in susceptible early embryos, whereas a much larger dose in the fetus may prove harmless, as was shown with thalidomide. Finally, the results of studies performed predominantly in small animals (e.g., chick embryos, mice, rats) cannot necessarily be extrapolated to other species, especially humans. Only a very small minority of drugs or agents listed in catalogs of teratogenic agents are proven teratogens in humans, although many more have teratogenic effects in animals.[39]

Manifestations of teratogenicity include death, structural abnormality, growth restriction, and functional deficiency.[39] Depending on when it occurs, death is referred to as abortion, fetal death, or stillbirth in humans, and as fetal resorption in animals. Structural abnormalities can lead to death if they are severe, although death may occur in the absence of congenital anomalies. Growth restriction is a manifestation of teratogenesis and may relate to multiple factors, including placental insufficiency and genetic and environmental factors. Functional deficiencies include behavioral and learning abnormalities, the study of which is called *behavioral teratology*. The stage of gestation at which exposure occurs determines the target organs or tissues, the types of defects, and the severity of damage. Most structural abnormalities result from exposure during the period of organogenesis, which extends from approximately day 31 to day 71 after the first day of the last menstrual period. Fig. 17.2 shows the critical stages of development and the related susceptibility of different organs to teratogens. Functional deficiencies are usually associated with exposure during late pregnancy or even after birth because the human central nervous system (CNS) continues to mature until the second year of life.

Consideration of the possible teratogenicity of anesthetic agents must be viewed against the naturally high occurrence of adverse pregnancy outcomes. Roberts and Lowe[40] estimated that as many as 80% of human conceptions are ultimately lost; many are lost even before pregnancy is recognized. The rates of spontaneous miscarriage from 5 to 20 weeks' gestation range from 11% to 22%.[41] The incidence of congenital anomalies among humans is approximately 3%, most of which are unexplained, and of these, only 1% are attributable to exposure to drugs and environmental toxins (Table 17.1). There are several criteria for determining that an agent is a human teratogen, including the following: (1) proven exposure to the agent at the critical time of development; (2) consistent findings in two or more high-quality epidemiologic studies; (3) careful delineation of the clinical cases, ideally with the identification of a specific defect or syndrome; and (4) an association that "makes biological sense."[39] Documentation of teratogenicity in experimental animals is important but not essential. The agents or factors that are proven human teratogens do not include anesthetic agents (which are listed as "unlikely teratogens") or any drug routinely used during the course of anesthesia (Box 17.1) (see Chapter 14).

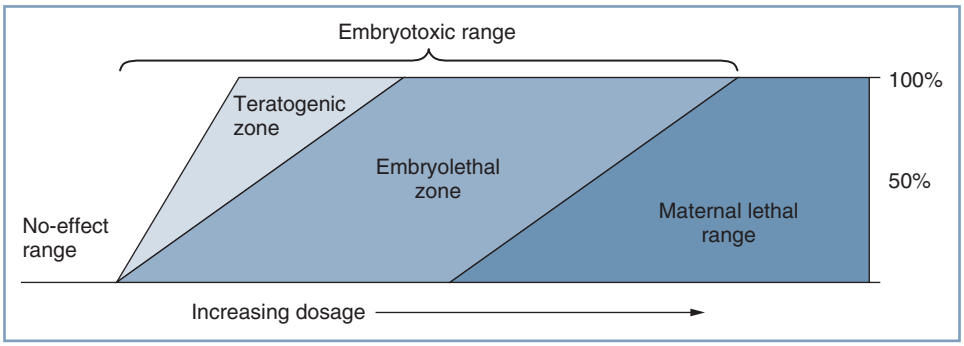

Fig. 17.1 Toxic manifestations with increasing dosage of a teratogen. A no-effect range of dosage occurs below the threshold, at which embryotoxic effects abruptly appear. Teratogenesis and embryolethality often have similar thresholds and may increase at roughly parallel rates as dosage increases to a point at which all conceptuses are affected. Increasing dosage causes increased embryolethality, but teratogenicity appears to decrease, because many defective embryos die before term. A further increase in dosage reaches the maternal lethal range. (Modified from Wilson JG. *Environment and Birth Defects*. New York: Academic Press; 1973:31.)

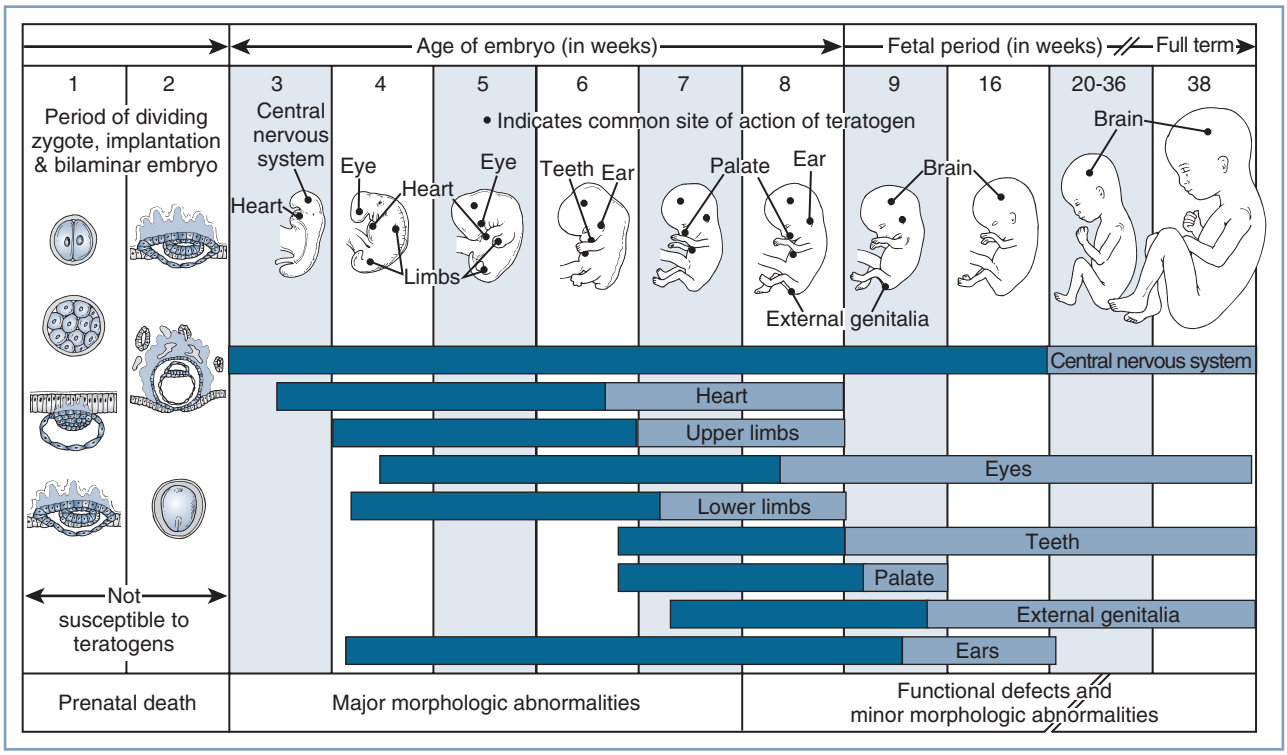

Fig. 17.2 Critical periods in human development. During the first 2 weeks of development, the embryo typically is not susceptible to teratogens. During these predifferentiation stages, a substance either damages all or most cells of the embryo, resulting in its death, or damages only a few cells, allowing the embryo to recover without development of defects. The dark bars denote highly sensitive periods, whereas the light bars indicate periods of lesser sensitivity. The ages shown refer to the actual ages of the embryo and fetus. Clinical estimates of gestational age represent intervals beginning with the first day of the last menstrual period. Because fertilization typically occurs 2 weeks after the first day of the last menstrual period, the reader should add 14 days to the ages shown here to convert to the estimated gestational ages that are used clinically. (Redrawn from Moore KL. *The Developing Human.* 4th ed. Philadelphia: WB Saunders; 1993:156.)

TABLE 17.1 Etiology of Human Developmental Abnormalities

Causes of Developmental Defects in Humans	Percentage
Genetic transmission	15–20

Nondrug Factors Encountered in the Perioperative Period

Derangements of normal physiology. Anesthesia and surgery can cause derangements of maternal physiology that may result in hypoxia, hypercapnia, stress, and abnormalities of temperature and carbohydrate metabolism. These states can increase oxidative stress and be teratogenic themselves, or they may enhance the teratogenicity of other agents.[42,43]

Severe hypoglycemia and prolonged hypoxia and hypercarbia have caused congenital anomalies in laboratory animals, but there is no evidence to support teratogenicity

BOX 17.1 Teratogenic Agents in Humans

Radiation
Atomic weapons, radioiodine, therapeutic uses

Infections
Cytomegalovirus, *Herpesvirus hominis,* parvovirus B19, rubella virus, syphilis, toxoplasmosis, Venezuelan equine encephalitis virus

Maternal Metabolic Imbalance
Alcoholism, cretinism, diabetes, folic acid deficiency, hyperthermia, phenylketonuria, rheumatic disease and congenital heart block, virilizing tumors

Drugs and Chemicals
Aminopterin and methylaminopterin, androgenic hormones, busulfan, captopril, chlorobiphenyls, cocaine, warfarin anticoagulants, cyclophosphamide, diethylstilbestrol, phenytoin, enalapril, etretinate, iodides (goiter), lithium, mercury (organic), methimazole (scalp defects), penicillamine, 13-cis-retinoic acid (Accutane), tetracyclines, thalidomide, trimethadione, valproic acid

Modified from Shepard TH, Lemire RJ. *Catalog of Teratogenic Agents.* 13th ed. Baltimore, MD: Johns Hopkins University Press; 2010.

after brief episodes in humans. Prolonged exposure to hyperglycemia is a known teratogen causing cardiac, CNS, and skeletal abnormalities, but any organ system can be affected.[44] Anomalies are tightly linked with duration and degree of hyperglycemia, particularly in the first trimester,[44] but it is unlikely that a brief period of intraoperative hyperglycemia has any teratogenic effects. Although severe hypoxemia causes structural teratogenesis in animals and humans, the chronic hypoxemia experienced by mothers at high altitudes results in the delivery of infants with lower birth weights but with no increase in the rate of congenital defects.[45] Maternal stress and anxiety have been associated with poor fetal neurocognitive development (behavioral teratogenicity).[46] Studies following obstetric outcomes in women in war zones demonstrate that maternal emotional trauma and posttraumatic stress disorder may affect fetal growth[47] and increase the risk for miscarriage and hypertensive disorders of pregnancy,[48] but these studies may be confounded by the lack of infrastructure to meet basic prenatal health care needs. Hypothermia is not teratogenic, whereas hyperthermia is teratogenic in both animals and humans.[49] Congenital anomalies, especially involving the CNS, have repeatedly been associated with maternal fever during the first half of pregnancy. It must be remembered that fetal temperature is on average 0.5° C to 1° C higher than maternal temperature. Embryonic oxidative stress from reactive oxygen species has been implicated as one of the mechanisms involved in teratogenicity of many agents.[43]

Diagnostic procedures. **Ionizing radiation** is a human teratogen that can result in an increased, dose-related risk for malignant disease, genetic disease, congenital anomalies, and/or fetal death.[50] The effects of radiation are often classified as being *deterministic* or *stochastic*. Deterministic effects are dose related and are observed above a certain threshold dose (e.g., pregnancy loss, growth restriction, mental retardation, organ malformation). In contrast, stochastic effects are possible at any level of exposure with no minimum threshold but with the likelihood of worsening effects at higher doses. An increased risk for childhood cancer is a stochastic effect when fetuses are exposed to ionizing radiation *in utero*.

Radiation is expressed as grays (Gy) or milligrays (mGy) (1 Gy = 100 rad) and is evaluated as cumulative dose (i.e., background radiation and medical diagnostic radiation) throughout the entire pregnancy. No dose of radiation is considered safe, but the type and severity of effects vary with the radiation exposure to the uterus and fetus and with the gestational age of the fetus (Table 17.2). Background radiation during gestation is 1.3 to 5.8 mGy.[51] There is no evidence that radiation exposure less than 50 mGy is associated with a teratogenic effect in either humans or animals.[51] In contrast with the negligible risk for teratogenicity, observational studies suggest that there is a slightly higher risk for childhood cancer at radiation doses greater than or equal to 10 mGy.[51] The relative risk for childhood malignancy after maternal abdominal radiation exposure has been estimated to be 2.28 (95% confidence interval, 1.31 to 3.97).[51] The absorbed *fetal dose* for all conventional radiographic imaging inside or outside the abdomen and pelvis is negligible and is well below 50 mGy, with most falling under 5 mGy (Table 17.3). However, direct radiographic examination using computed tomography or fluoroscopy of the abdomen and pelvis may result in significant fetal radiation exposure, with doses that may approach 100 mGy.[50-52] Interventional radiologic procedures (e.g., cerebral angiography, cerebral embolization, endoscopic retrograde cholangiopancreatography) are frequently complex and prolonged, particularly when surgery is not an option. These procedures, especially the abdominal interventions, expose the fetus to a significant radiation dose, sometimes greater than 50 mGy; thus, professional societies

TABLE 17.2 Radiation Exposure by Gestational Age and Outcomes

Radiation Dose (cGy)	Gestational Age	Fetal Effects
< 5	All stages	No fetal effects
10	< 8 weeks	Miscarriage
5–50	8–15 weeks	Growth restriction Mental retardation
5–50	16 weeks–birth	Increase childhood cancer (0.3%–6%)
> 50	16 weeks–birth > 25 weeks	Childhood cancer (> 6%) Death

have developed guidance for the use of these technologies during pregnancy (Table 17.4).[53,54]

If the mother's condition necessitates diagnostic testing and radiation exposure, and no other acceptable imaging modality is available, testing should not be withheld if the benefits to the mother (and, by extension, the fetus) are judged to outweigh the risks. Delayed diagnosis of a critical condition may result in significant harm to the maternal/fetal dyad. The consultation with the radiologist should include discussion of the optimal diagnostic modality that adheres to the ALARA principle (*as low as reasonably achievable*) for radiation and minimizes the absorbed dose, through abdominal shielding, scan length reduction, and milliampere modulation. The avoidance or minimization of intravenous radiopaque **iodinated contrast media,** which crosses the placenta and theoretically can cause neonatal hypothyroidism, should be considered as well.[54]

Diagnostic **ultrasonography** during pregnancy has long been considered devoid of embryotoxic effects. In animals, ultrasound intensities up to 20 W/cm^2 have been found to be safe.[55,56] However, in rat models, when higher intensities (greater than 30 W/cm^2) have been used, or when repeated exposure has occurred during early pregnancy, postnatal neurobehavioral effects have been described.[56,57] Ultrasound waves produced by modern diagnostic equipment can induce significant increases in fetal temperature, especially when imaging is prolonged. Although Miller et al.[58] concluded that the range of temperatures produced could be teratogenic, no biologic effects have been documented from diagnostic ultrasonographic examinations in the pregnant patient, despite widespread use over several decades. Nonetheless, it must be stressed that these epidemiologic studies were conducted in an era when ultrasound equipment was less potent and associated with lower increases in temperature. Doppler interrogation emits significantly more acoustic intensity, and subsequently more heat, than pulse-echo imaging equipment. Therefore, ultrasonographic examinations should be used judiciously, keeping the exposure time and acoustic output to the lowest level possible.

Gadolinium-based MRI contrast agents readily cross the placenta, enter the fetal circulation, and are excreted by the fetal kidneys into the amniotic fluid, where they may be swallowed by the fetus or resorbed by the mother. A large retrospective study designed to evaluate the effects of MRI exposure interrogated a Canadian universal-health care database of all births after 20 weeks' gestation from 2003 to 2015.[59] The relative risk for stillbirth was higher (1.68) among those pregnancies in which the fetus was exposed to gadolinium-MRI in the first trimester ($n = 1737$) compared with no MRI ($n = 1{,}418{,}451$); no conclusion could be made for MRI with and without gadolinium because of small sample sizes.[59] The American College of Radiology and the American College of Obstetricians and Gynecologists (ACOG) recommend that intravenous gadolinium be avoided during pregnancy and used only if absolutely essential.[54,60]

Systemic Agents

Animal studies. Early rodent studies documented teratogenicity (CNS malformations, skeletal abnormalities, and growth restriction) after exposure to a variety of opioids; however, these conclusions have been challenged because opioids given in large bolus injections can cause respiratory depression and impaired feeding, which may be teratogenic. In a rat study designed to avoid such problems, Fujinaga and Mazze[61] maintained clinically relevant concentrations of morphine throughout most of pregnancy by means of continuously implanted osmotic mini-pumps. Structural anomalies were not observed at any morphine dose, although fetal growth restriction was present, and offspring mortality was increased. Using the same methodology, Fujinaga et al.[62,63] found fentanyl, sufentanil, and alfentanil completely devoid of teratogenic effects. Additional mouse studies have confirmed the absence of structural teratogenicity with opioids.[64]

Use of tranquilizers and anxiolytics in pregnancy has been investigated less rigorously than opioids. Animal studies have demonstrated structural or behavioral teratogenesis after exposure to some of the barbiturate, phenothiazine, and tricyclic antidepressant agents.[65,66] The reader is referred to standard teratology reference sources and package inserts for animal and human data related to specific drugs.[39]

Studies in rodents and nonhuman primates indicate that exposure of the immature brain to anesthetic agents such as propofol, thiopental, and ketamine (i.e., agents classified as *N*-methyl-D-aspartate [NMDA] antagonists and gamma-aminobutyric acid [GABA] agonists) are associated with brain cell apoptosis and functional learning deficits (see Chapter 10).[67] In animal models, neurodegeneration increases with longer duration, greater dosage, and higher frequency of propofol exposure.[68] Whether these effects occur in humans remains to be determined. These observed changes may represent indirect effects, such as hypoxia or hypoglycemia, as well as direct effects of the anesthetic agent on the developing brain.

Human studies. Teratogenesis has not been associated with any of the commonly used induction agents, including barbiturates, ketamine, and benzodiazepines, when administered in clinical doses during anesthesia.[39]

Although human data relating to long-term sedative-hypnotic therapy have raised questions about the possible teratogenicity of some agents, positive studies were retrospective and suffer from a variety of methodologic flaws. In a prospective evaluation of children with birth defects, a higher risk for cleft lip was not found when mothers ingested diazepam during the first trimester.[69] Although the present consensus among teratologists is that diazepam is not a proven human teratogen,[39] it is appropriate to consider the risk-to-benefit ratio before initiating long-term benzodiazepine therapy during the first trimester. No evidence suggests that a single dose of a benzodiazepine (e.g., midazolam) during the course of anesthesia is harmful to the fetus.

Obstetric complications of prenatal opioid exposure are well-documented and include preterm birth, small-for-gestational age, low birth weight (LBW), reduced head circumference, and sudden infant death (see Chapters 42 and 53).[70] The evidence supporting structural teratogenicity of opioids in humans is of low quality, but in a systematic review of case-control and cohort studies, Lind et al.[70] found a positive association between fetal opioid exposure and congenital anomalies (e.g., cleft lip, cleft palate, atrial septal defects, clubbed feet) in 17 of 30 studies. Neonatal opioid withdrawal syndrome,[71] and impaired cognition, psychomotor skills, and behavioral development have been observed in infants and children exposed to opioids *in utero*.[72,73] However, many studies did not correct for socioeconomic or environmental factors that might also influence neurobehavioral development.

Attempts should be made to reduce the amount of opioid medications prescribed to pregnant women while ensuring adequate pain management. Preference for analgesic techniques such as regional, peripheral nerve, and field blocks, and surgical techniques such as laparoscopy that reduce the need for postoperative opioids, should be used preferentially in pregnant women. Multimodal analgesia, including maximizing the use of nonopioid medications that are considered safe in pregnancy (e.g., acetaminophen) should be considered.

Local Anesthetics

No evidence supports morphologic or behavioral teratogenicity with lidocaine administration in rats,[74] or with the clinical administration of local anesthetic agents, with the exception of cocaine. Maternal cocaine abuse is associated with adverse reproductive outcomes, including abnormal neonatal behavior and, in some reports, a higher incidence of congenital defects of the genitourinary, cardiac, facial, and gastrointestinal tracts.[75] The greatest risk to the fetus most likely results from the high incidence of placental abruption and preterm delivery associated with maternal cocaine use (see Chapter 53).

Muscle Relaxants

Testing muscle relaxants for teratogenicity using standard *in vivo* animal study techniques is complicated by the requirement for very low drug doses or the need for mechanical ventilation (a complex undertaking in rodents). Fujinaga et al.[76] used a whole-embryo rat culture system to investigate the reproductive toxicity of high doses of D-tubocurarine, pancuronium, atracurium, and vecuronium. Although dose-dependent toxicity was manifested, these effects occurred only at concentrations 30-fold greater than those encountered in clinical practice. Given that fetal blood concentrations of muscle relaxants are only 10% to 20% of maternal concentrations, these drugs appear to have a wide margin of safety when administered to the mother during organogenesis. Many women have received muscle relaxants for several days during late gestation without adverse effect on the neonate.

Inhalation Anesthetics

Animal studies. Under certain conditions, the volatile halogenated anesthetic agents can produce teratogenic changes in chicks or small rodents. Basford and Fink[77] observed skeletal abnormalities but no increase in fetal loss when rats were exposed *in utero* to 0.8% halothane for 12 hours on days 8 and 9 of pregnancy (i.e., the "critical period" in the 21-day rat gestation). Long-term exposure to subanesthetic concentrations of halothane caused fetal growth restriction in rats but no increase in the incidence of congenital anomalies,[78] whereas isoflurane had no adverse effects.[79]

Significant reproductive effects have occurred with anesthetic concentrations of volatile anesthetic agents, including fetal skeletal abnormalities or death, following repeated or prolonged maternal exposure in mice.[80] Teratogenicity in these studies was most likely caused by the physiologic changes (e.g., profound hypothermia, hypoventilation) associated with anesthesia rather than by the anesthetic agent itself. Moreover, some strains of mice are especially likely to demonstrate anomalies, such as a cleft palate. Mazze et al.[81] exposed rats to 0.75 MAC of halothane, isoflurane, or enflurane, or 0.55 MAC of nitrous oxide, for 6 hours daily on 3 consecutive days at various stages of pregnancy. The animals remained conscious throughout the study, and normal feeding and sleep patterns were preserved. Under these conditions, no teratogenic effects were associated with any of the volatile agents. The only positive finding was a threefold increase in the rate of fetal resorption with nitrous oxide. No evidence has suggested reproductive toxicity with either sevoflurane or desflurane in clinical concentrations.

In contrast with the volatile halogenated agents, nitrous oxide is a weak teratogen in rodents under certain conditions, even when normal homeostasis is maintained. Rats continually exposed to 50% to 70% nitrous oxide for 2 to 6 days (starting on day 8 of gestation) had an increased incidence of congenital abnormalities.[81,82] To exclude the possibility that adverse effects were a consequence of the anesthetic state, Lane et al.[83] exposed rats to 70% nitrous oxide or to a similar concentration of xenon (a slightly more potent anesthetic

devoid of biochemical effects) for 24 hours on day 9 of gestation; abnormalities occurred only in the nitrous oxide group. With the exception of one study in which extremely prolonged exposure to a low concentration of nitrous oxide had some minor effects,[84] at least 50% nitrous oxide has been required to consistently produce anomalies.[82] The threshold exposure time has not been rigorously determined, although exposure for at least 24 hours typically was necessary.

In vivo and embryo culture studies in rats have confirmed that nitrous oxide has several adverse reproductive effects, each of which results from exposure at a specific period of susceptibility.[85,86] Fetal resorptions occurred after exposure on days 8 and 11 of gestation, skeletal anomalies after exposure on day 8 or 9, and visceral anomalies (including *situs inversus*) only when exposure occurred on day 8.[87]

Initially, teratogenicity associated with nitrous oxide was thought to result from its oxidation of vitamin B_{12}, which interferes with its function as a coenzyme for methionine synthase.[88] Transmethylation from methyl-tetrahydrofolate to homocysteine, with subsequent production of tetrahydrofolate (THF) and methionine, is catalyzed by methionine synthase (Fig. 17.3). Thus, methionine synthase inhibition could cause a decrease in THF (with a resultant decrease in DNA synthesis) and lower methionine levels (with resultant impairment of methylation reactions). Nitrous oxide rapidly inactivates methionine synthase in both animals[89] and humans.[90] Prolonged human exposure to nitrous oxide leads to adverse neurologic and hematologic outcomes, the latter probably resulting from diminished DNA synthesis.[88]

Considerable evidence indicates that methionine synthase inhibition and a consequent lack of THF are not solely responsible for the teratogenic effects of nitrous oxide. Additional studies have implicated alpha$_1$-adrenergic receptor stimulation in the production of *situs inversus* by nitrous oxide.[86,91,92] Postulated mechanisms by which sympathetic stimulation might have adverse reproductive effects include a decrease in uterine blood flow and overstimulation of G protein–dependent membrane signal transduction pathways.[93] There is also evidence that nitrous oxide may cause neuronal apoptosis in rats, in part, as a result of oxidative stress.[94]

In summary, evidence suggests that the etiology of nitrous oxide teratogenicity in rats is complex and multifactorial. Determination of the relative roles of methionine deficiency and sympathetic stimulation or other mechanisms awaits further study. Although nitrous oxide is considered a weak teratogen in rats and mice, reproductive effects occur only after prolonged exposure to high concentrations that are unlikely to be encountered in humans during clinical anesthesia. Whether nitrous oxide administration is associated with neuronal apoptosis and learning impairments in humans remains to be determined.

Human studies

Occupational exposure to waste anesthetic agents. Epidemiologic surveys dating to the early 1970s suggested that reproductive hazards (e.g., spontaneous abortion, congenital anomalies) were associated with exposure to trace anesthetic agents, principally nitrous oxide, in the operating room and during dental surgery. Critical reviews of these studies questioned their conclusions, noting that response bias, inappropriate control groups, lack of verification of medical data, and exposure to multiple environmental factors made definitive conclusions impossible.[95–97] Studies in the late 1970s and 1980s have not confirmed an association between operating room work and higher reproductive risk.[98,99] Pregnancy outcomes were comparable in exposed and nonexposed operating room nurses when questionnaire information was matched with objective data obtained from medical records and registries of abortions, births, and congenital anomalies.[98] Similarly, in a 10-year prospective study of all female physicians in the United Kingdom, Spence[99] found no differences in reproductive outcome when anesthesiologists were compared with other working female physicians. Although these studies may have missed a higher incidence of very early abortion, their data do not support a statistically demonstrable reproductive hazard resulting from operating room exposure to anesthetic agents.

The Nurse's Health Study-II ($n = 8461$), published in 2012, compared the risk for spontaneous abortion in nurses exposed to anesthetic gases (e.g., nitrous oxide, halothane, enflurane, and isoflurane) with those who were not exposed after correcting for age, parity, shift work, and hours worked.[100] The odds for abortion were not different between groups. Dimich-Ward et al.[101] studied the risk for fetal anomalies in live and stillborn births in an offspring cohort study of registered nurses ($n = 22{,}611$) in the British Columbia Vital Statistics Registry (1986 to 2000). In nurses exposed to the operating room environment, an increased risk for congenital anomalies was associated with exposure to halogenated gases (odds ratio [OR], 1.49) or nitrous oxide (OR, 1.42).[101,102] A major limitation of these studies[100–102] was the failure to correct for tobacco use or alcohol consumption; the relative risk for spontaneous abortion is increased with cigarette smoking (1.8), one or two alcoholic drinks per day (1.98), and more than three drinks per day (3.53).[103]

Using a questionnaire-based survey of 744 pregnancies in 2028 female veterinarians, Shirangi et al.[104] observed that the prevalence of preterm birth (before 37 weeks' gestation) was higher in female veterinarians exposed to unscavenged anesthetic gases (7.3%) compared with the general Australian population (5.7%) during the same period. The identity of

the specific anesthetic gas used was not requested; however, halothane, nitrous oxide, enflurane, and methoxyflurane were commonly used during the study period. A hazards model predicted a 2.5-fold increase in preterm delivery risk in women exposed to unscavenged gas for one or more hours per week compared with an unexposed group.[104]

It is possible that the higher waste levels of nitrous oxide encountered in dentists' offices compared with operating rooms pose a reproductive risk.[105,106] In 1980, Cohen et al.[105] reported a doubling of the spontaneous abortion rate among exposed female chairside assistants and the wives of exposed male dentists. The incidence of birth defects among the children of exposed dental assistants was slightly higher than that for nonexposed assistants. However, the validity of this finding is doubtful; the incidence of anomalies among the offspring of nonexposed dentists was similar to that of the exposed assistants. Moreover, the expected dose-response relationship did not exist. In another study,[106] reduced fertility was reported among female dental assistants working with nitrous oxide in an unscavenged environment for more than 5 hours per week; the affected group consisted of only 19 individuals, making it difficult to draw firm conclusions from these data. Overall, the epidemiologic data do not support an increased risk for congenital anomalies with long-term occupational exposure to nitrous oxide.

Studies of operations performed during pregnancy. In 1963, Smith[107] reviewed the obstetric records of 18,493 pregnant women. Sixty-seven (0.36%) had had an operation during pregnancy; only 10 procedures occurred during the first trimester. Fetal mortality was 11.2%, with the poorest survival occurring after operations for appendiceal abscess and cervical incompetence. In 1965, Shnider and Webster[108] examined the records of 9073 obstetric patients; 147 (1.6%) of this group had had operations during pregnancy. Preterm delivery followed operation in 8.8% of patients, and the incidences of perinatal mortality and LBW were increased in patients who had surgery during pregnancy. Brodsky et al.[2] surveyed 12,929 pregnant dental assistants and wives of male dentists; those who were exposed to surgery had higher rates of spontaneous abortion than those in the control group (8% and 5.1% during the first trimester, and 6.9% and 1.4% during the second trimester, respectively). None of these three studies reported a higher incidence of congenital anomalies among infants of women who underwent surgery during pregnancy. A case-control study of infants born in Atlanta between 1968 and 1980 gathered information regarding first-trimester exposure to general anesthesia from the mothers of 694 infants with major CNS defects and 2984 control mothers.[109] A significant association was found between general anesthesia exposure and hydrocephalus in conjunction with another major defect (the strongest association was with hydrocephalus and eye defects). Limitations of this study include its retrospective nature and a lack of information about the types of surgery, the anesthetic agents used, and the presence or absence of complications. The investigators cautioned that further studies are necessary to confirm their observations.[109] Two additional studies[110,111] from the 1980s focused on the risks associated with nitrous oxide anesthesia during early pregnancy; no increase in the incidence of spontaneous abortion or congenital abnormalities was identified.

Duncan et al.[112] investigated obstetric outcomes based on anesthesia type using health insurance data from the entire Manitoba, Canada population between 1971 and 1978. They matched 2565 women who had operations during pregnancy with similar controls who did not undergo surgery. Type of anesthesia was classified as nil (18%), general (57%), spinal/nerve block (2%), or local (24%). Although the incidence of congenital anomalies was similar in the surgical and control groups, spontaneous abortion was more common among women who had general anesthesia for surgery during the first or second trimester. This was true for both gynecologic procedures (relative risk [RR], 2.00) and nongynecologic procedures (RR, 1.58). Unfortunately, no conclusions regarding the relationship between anesthetic technique and fetal loss could be drawn because most of the gynecologic and other major procedures were performed with general anesthesia. As in most studies, it is difficult to separate the effects of the anesthetic technique from those of the surgical procedure.

In the largest study to date investigating anesthesia type and pregnancy outcomes, Mazze and Källén[1] linked data from three Swedish health care registries—the Medical Birth Registry, the Registry of Congenital Malformations, and the Hospital Discharge Registry—for the years 1973 to 1981. Among the population of 720,000 pregnant women, 5405 (0.75%) had nonobstetric surgery, including 2252 who had procedures during the first trimester. (Cervical cerclage was excluded from analysis.) Of the women who had surgery, 54% received general anesthesia, which included nitrous oxide in 97% of cases. The researchers examined the following adverse outcomes: (1) congenital anomalies, (2) stillbirths, (3) neonatal death within 7 days, and (4) LBW or very-low-birth-weight (VLBW) infants. There was no difference between surgical and control patients in the incidence of stillbirth or the overall incidence of congenital anomalies (Fig. 17.4). Although the overall rate of anomalies among infants of women who had first-trimester operations was not higher, this group did have a higher-than-expected incidence of neural tube defects (6.0 observed versus 2.5 expected).[113] Five of the 6 women whose infants had these defects were among the 572 women who had had surgery during gestational weeks 4 to 5, which is the period of neural tube formation; the researchers cautioned that this finding could have been a chance association.[113] However, if a true causal relationship exists between neural tube defects and anesthesia at this stage of gestation, it could represent an 8- to 9-fold increase in the risk for this anomaly (i.e., an absolute risk of almost 1%). Other positive findings were a higher incidence of LBW and VLBW infants in the surgical group, which resulted from both preterm delivery and fetal growth restriction.[1] A predictable consequence of preterm delivery was a higher number of deaths of live-born infants within the first 7 days of life. Finally, no anesthetic technique or operation was associated with a significantly higher number of adverse outcomes.

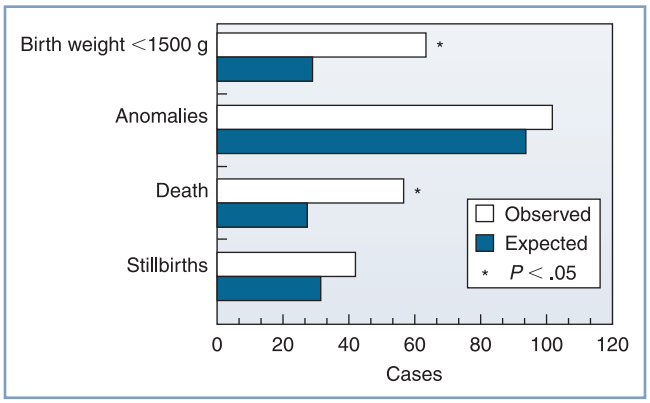

Fig. 17.4 Total number of observed and expected adverse outcomes among women having nonobstetric operations during pregnancy. The incidence of infants with a birth weight less than 1500 g and of infants born alive who died within 7 days of birth were significantly increased. (Modified from Mazze RI, Källén B. Reproductive outcome after anesthesia and operation during pregnancy: a registry study of 5405 cases. *Am J Obstet Gynecol.* 1989;161:1178.)

Most recently, a cohort study of 19,926 pregnant women in the Nationwide Inpatient Sample, which accounted for 20% of patients discharged from U.S. community hospitals from 2003 to 2012, sought to analyze risk factors for adverse outcomes associated with appendectomy and cholecystectomy; these surgeries are the most common emergency abdominal procedures performed during pregnancy.[114] Among the 4.8% of women who experienced an adverse obstetric outcome, the most common were preterm delivery (35.4%), preterm labor without preterm delivery (26.4%), and miscarriage (25.7%).[114] Preexisting obstetric risk factors were the largest contributors to adverse pregnancy outcomes, including cervical incompetence (adjusted OR, 24.29), prior preterm labor in pregnancy (adjusted OR, 18.34) and vaginitis/vulvovaginitis (adjusted OR, 5.17).[114] Other risk factors associated with adverse obstetric outcomes included non-Caucasian ethnicity, multiple gestation, open surgical technique, and increased disease severity (e.g., peritonitis, sepsis). Specific anesthetic techniques or agents could not be determined from the database.

In summary, although nonobstetric anesthesia and surgery are associated with a higher incidence of abortion, fetal growth restriction, and perinatal mortality, these adverse outcomes can often be attributed to the procedure, the site of surgery (i.e., proximity to the uterus), and/or the underlying maternal or obstetric conditions. Evidence does not suggest that anesthesia during pregnancy results in an overall increase in congenital abnormalities, or that a relationship between type of anesthesia provided and adverse pregnancy outcomes exists.

Behavioral Teratology

Some teratogens produce enduring behavioral abnormalities without any observable morphologic changes. The CNS may be especially sensitive to such influences during the period of major myelination, which in humans extends from the fourth intrauterine month to the second postnatal month (see Chapter 10). Several studies have shown that brief intrauterine exposure to halothane adversely affects postnatal learning behavior and causes CNS degeneration and decreased brain weight in rats.[115–117] The rat fetal nervous system is most susceptible to the effects of halothane during the second trimester.[115] Maternal administration of systemic drugs—including barbiturates, meperidine, and promethazine—has also resulted in behavioral changes in offspring,[118–120] whereas no effect has been noted with the administration of lidocaine.[74]

Currently used general anesthetic agents act by one of two principal mechanisms: (1) the potentiation of $GABA_A$ receptors (benzodiazepines, volatile halogenated agents, and barbiturates) or (2) the antagonism of NMDA receptors (nitrous oxide and ketamine). Drugs that act by either of these mechanisms appear to induce widespread neuronal apoptosis in the developing rat brain and behavioral abnormalities when administered during the period of synaptogenesis (i.e., the brain growth-spurt period).[94,121–123] Jevtovic-Todorovic et al.[94] observed that the administration of a general anesthetic "cocktail" (midazolam, isoflurane, and nitrous oxide), in doses sufficient to maintain general anesthesia for 6 hours in 7-day-old infant rats, resulted in widespread apoptotic neurodegeneration in the developing brain, deficits in hippocampal synaptic function, and persistent memory/learning impairments. They concluded that these deficits are "subtle enough to be easily overlooked" but may persist into adolescence and adulthood.[94] Ikonomidou et al.[122] described neurodegeneration in rat pups after exposure to NMDA receptor antagonists. These data suggest that prolonged exposure to anesthetic agents at a critical period in brain development may accelerate the normal developmental process of apoptotic neurodegeneration, potentially resulting in long-term behavioral deficits.[124] Whether the duration or total dose of exposure, or both, contribute to the outcome is yet to be determined. In a rat model, Hayashi et al.[125] observed that repeated administration of ketamine over several hours, but not a single dose, resulted in apoptotic neurodegeneration.

Using validated postoperative neurodevelopmental testing in human children, the Pediatric Anesthesia and Neurodevelopment Assessment (PANDA) trial[126] and the General Anesthesia versus Spinal Anesthesia (GAS) trial[127] determined that a brief, single exposure to general anesthesia did not lead to poorer neurodevelopmental outcomes in children exposed to general anesthesia compared with control groups.[126,127] The international, multicentered GAS trial randomized infants (younger than 60 weeks postmenstrual age, born at greater than 26 weeks' gestation) who were undergoing inguinal herniorrhaphy to awake-regional ($n = 238$) or sevoflurane-based general anesthesia ($n = 294$). No difference was found in the secondary outcome, the composite cognitive score of the Bayley Scales of Infant and Toddler Development III, assessed at 2 years of age.[127] The result of the primary outcome, the 5-year IQ, has not been published. The sibling-matched cohort design PANDA trial evaluated whether a single exposure to general anesthesia in healthy children younger than 3 years of age (determined retrospectively) was associated with a risk for impaired global cognitive function (IQ) or other neurocognitive functions and behaviors in children between 8 and 15 years of age (assessed prospectively).[126] No differences were found in global cognitive function or

neurodevelopmental outcomes in 105 sibling-matched pairs. No studies have assessed neurocognitive outcomes after *in utero* exposure to general anesthetic agents during the critical period of synaptogenesis during human maternal nonobstetric surgery.

On December 14, 2016, the U.S. Food and Drug Administration (FDA) issued a "Drug Safety Communication" warning that "…repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains."[128] Because most repeated or lengthy procedures in pregnant women and in children younger than 3 years of age are urgent or necessary, and alternative anesthetic techniques are not feasible for many of these surgical procedures, the implications for anesthetic and surgical practice will primarily be to discuss the timing and the relative advantages and risks of different procedures.

Surgery may result not only in exposure to anesthetic agents, but also in derangements in maternal physiology (e.g., hypoxia, stress, hypoglycemia) that can lead to apoptosis during the critical period of neuronal development.[129] It is also important to remember that painful stimuli *per se* can cause long-term behavioral changes.[130]

Fetal Heart Rate Monitoring during Surgery

Continuous fetal heart rate (FHR) monitoring (using transabdominal Doppler ultrasonography) is feasible beginning at 18 to 20 weeks' gestation, although technical problems may limit its use until after 22 weeks' gestation.[131] Transabdominal monitoring may not be possible during abdominal procedures or when the mother is very obese; the intraoperative use of transvaginal Doppler ultrasonography may be considered in selected cases.

The ACOG and ASA have jointly published guidelines for fetal monitoring during nonobstetric surgery.[132] In the previable fetus, it is generally sufficient to ascertain the FHR by Doppler before and after the procedure. At a minimum, in patients with a viable fetus, simultaneous electronic FHR and contraction monitoring should be performed before and after the procedure to assess fetal well-being and the absence of contractions.[132] The ACOG/ASA guidelines[132] state that intraoperative electronic FHR monitoring "may be appropriate when all of the following apply: (1) the fetus is viable; (2) it is physically possible to perform intraoperative electronic [FHR] monitoring; (3) a health care provider with obstetric surgery privileges is available and willing to intervene during the surgical procedure for fetal indications; (4) when possible, the woman has given informed consent to emergency cesarean delivery; and (5) the nature of the planned surgery will allow the safe interruption or alteration of the procedure to provide access to perform emergency delivery."[132] Responses to a survey sent to members of the Association of Professors of Gynecology and Obstetrics indicated that only 43% routinely used intraoperative FHR monitoring.[133]
