FIGURE 26.1 Left-sided heart failure. Shaded areas indicate areas of congestion from blood back-up caused by the failing left side of the heart.

increased fluid and pressure in the pulmonary artery and lungs. Over time this additional strain eventually causes it to fail.

Conditions causing right-sided heart failure increase the work of the right ventricle. They increase the amount of contractile force needed or they require pumping of excess blood volume (**preload**). Among these conditions are disorders that (1) increase pulmonary pressures, such as emphysema or congenital heart defects; (2) restrict the outflow of blood from the right ventricle, as in pulmonary valve stenosis; and (3) allow left atrial blood to flow into the right atrium, thereby increasing blood volume in the right ventricle, as in septal defects. When the right ventricle hypertrophies or fails because of increased pulmonary pressures, it is referred to as **cor pulmonale**.

cor pulmonale: cor—heart + pulm—lung

TABLE 26.1 EXAMPLES OF CAUSES OF LEFT-SIDED HEART FAILURE

Cause	Primary Effect on Left Ventricular Workload
<i>Aortic Stenosis</i>	Increased volume to pump
<i>Cardiomyopathy</i>	Increased workload from poor contractility
<i>Coarctation of the Aorta</i>	Resistance increased from elevated pressure
<i>Hypertension</i>	Resistance increased from elevated pressure
<i>Heart Muscle Infections</i>	Increased workload from damaged myocardium
<i>Myocardial Infarction</i>	Increased workload from poor contractility
<i>Mitral Regurgitation</i>	Increased volume to pump

TABLE 26.2 CAUSES OF RIGHT-SIDED HEART FAILURE

Cause	Primary Right Ventricular Workload Effect
<i>Atrial Septal Defect</i>	Increased volume to pump
<i>Cor Pulmonale</i>	Resistance increased from elevated pressure
<i>Left-Sided Heart Failure</i>	Resistance increased from backup of fluid and elevated pressures
<i>Pulmonary Hypertension</i>	Resistance increased from elevated pressure
<i>Pulmonary Stenosis</i>	Increased volume to pump

When the right ventricle fails, it does not empty normally and there is a backward build-up of blood in the systemic blood vessels. As the blood backs up from the right ventricle, right atrial and systemic venous blood volume increases. The jugular neck veins, which are not normally visible, become distended and can be seen when the person is in a 45-degree upright position. Edema may occur in the peripheral tissues, and the abdominal organs can become engorged (Fig. 26.2). Congestion in the gastrointestinal tract causes anorexia, nausea, and abdominal pain. As the failure progresses, blood pools in the hepatic veins and the liver becomes congested, known as **hepatomegaly**. Pain in the right upper quadrant and impaired liver function are caused by this liver congestion. Systemic venous congestion also leads to engorgement of the spleen, known as **splenomegaly**.

LEARNING TIP

To understand the signs and symptoms of left-sided versus right-sided heart failure, remember that left-sided signs and symptoms are found in the lungs. Left begins with L, as does Lung: Left = Lungs, L = L.

Any signs and symptoms not related to the lungs (L) are caused by right-sided failure.

FIGURE 26.2 Right-sided heart failure. Shaded areas indicate areas of congestion from blood back-up due to the failing right side of the heart.

hepatomegaly: hep—liver + mega—large

splenomegaly: splen—spleen + mega—large

COMPENSATORY MECHANISMS TO MAINTAIN CARDIAC OUTPUT

Compensatory mechanisms help ensure that an adequate amount of blood is being pumped out of the heart. Although these mechanisms are designed to maintain cardiac output, they contribute to a cycle that instead of being helpful leads to further heart failure.

When the sympathetic nervous system detects low cardiac output, it speeds up the heart rate by releasing epinephrine and norepinephrine. Although this raises cardiac output (cardiac output = heart rate \times stroke volume), the increased heart rate also increases the oxygen needs of the heart. In response to low renal blood flow, the kidneys activate the renin-angiotensin-aldosterone system, and antidiuretic hormone is released from the pituitary gland to conserve water, causing decreased urine output. This adds to the fluid retention problem already found in heart failure.

Over time the heart responds to the increased workload by enlarging its chambers (dilation) and increasing its muscle mass (hypertrophy), referred to as remodeling. In dilation, the heart muscle fibers stretch to increase the force of myocardial contractions, which is known as the Frank-Starling phenomenon. In hypertrophy, the muscle mass of the heart increases, creating more contractile force. Both of these compensatory mechanisms increase the heart's oxygen needs, which further contributes to heart failure. Additionally, the heart walls stiffen, which further reduces pumping ability.

PULMONARY EDEMA (ACUTE HEART FAILURE)

Pulmonary edema, also known as acute heart failure, is severe fluid congestion in the alveoli of the lungs and is life threatening. Pulmonary edema occurs in an acute event such as a myocardial infarction (MI) or when the heart is severely stressed, causing the left ventricle to fail. Complications of pulmonary edema include dysrhythmias and cardiac arrest.

Pathophysiology

First, pressure rises in the lung's venous blood vessels and blood builds up. As pressures continue to rise, fluid moves into the interstitial spaces. Then, with continued pressure increases, fluid containing red blood cells moves into the alveoli. Finally, the alveoli and airways become filled with fluid, reducing gas exchange and oxygen levels.

Signs and Symptoms

Signs and symptoms of pulmonary edema are listed in Table 26.3. Pink, frothy sputum is a classic symptom of pulmonary edema caused by the increased lung congestion and pressures that allow leaking of fluid into the alveoli. Compensatory mechanisms increase the heart rate and blood

TABLE 26.3 ACUTE HEART FAILURE SUMMARY

Signs and Symptoms	Rapid respirations with accessory muscle use Severe dyspnea, orthopnea Crackles and wheezes Coughing Pink, frothy sputum Anxiety, restlessness Pale skin and mucous membranes Clammy, cold skin
Diagnostic Tests	Chest x-ray examination Arterial blood gases Electrocardiogram Hemodynamic monitoring
Therapeutic Interventions	Oxygen via cannula, mask, or mechanical ventilation Positioning in high or semi-Fowler's position Bedrest IV Drugs: morphine, diuretics, inotropic agents, vasodilators, human B-type natriuretic peptide (Nesiritide) Frequent vital signs, urinary output Pulmonary pressures Daily weights Treatment of underlying cause
Nursing Diagnoses	Impaired gas exchange Decreased cardiac output Excess fluid volume

IV = intravenous.

pressure; however, as pulmonary edema worsens, the blood pressure may fall.

Diagnosis

Diagnostic studies are listed in Table 26.3. The congested pulmonary system can be seen on x-ray examination. Arterial blood gases (ABGs) will show a decrease in PaO₂ that continues as the edema worsens and an increase in PaCO₂, causing respiratory acidosis (pH = 7.35). The pulmonary artery catheter will show elevated pulmonary pressures and a decreased cardiac output.

Therapeutic Interventions

Immediate treatment is necessary to prevent patients from drowning in their own secretions (see Table 26.3). The goal of therapy is to reduce the workload of the left ventricle in order to improve cardiac output and reduce the patient's anxiety. Care for the patient is usually provided in an intensive care unit. Treatment for the underlying cause occurs at the same time that the patient is being treated for the pulmonary edema.

Treatment includes positioning the patient upright to make breathing easier. In Fowler's position, the lungs can more easily expand. Ask the patient what position is preferred. Oxygen is given usually by mask to provide higher

amounts. In severe cases of pulmonary edema, endotracheal intubation and mechanical ventilation may be necessary. Medications are given intravenously to reduce anxiety, relax airways, and increase peripheral blood pooling to decrease preload (morphine); reduce fluid congestion; reduce preload; strengthen heart contractions; reduce arterial pressure and sodium and water retention to relieve dyspnea (nesiritide [Natrecor]). Nesiritide belongs to a newer drug class called human B-type natriuretic peptide (hBNP). hBNP is normally secreted by the ventricular myocardium in response to heart failure. It has been found to reduce symptoms of acute HF.

CHRONIC HEART FAILURE

Signs and Symptoms

The signs and symptoms of chronic heart failure are influenced by the patient's age, the underlying cause and severity of the heart disease, and the ventricle that is failing. Chronic heart failure is a progressive disorder, so signs and symptoms may worsen over time. Signs and symptoms caused by a specific failing ventricle are listed in Table 26.4.

Fatigue and Weakness

Fatigue and weakness are the earliest symptoms of heart failure. They occur from the decreased amount of oxygen reaching the tissues. Throughout the day the fatigue worsens, especially with activity.

Dyspnea

A failing left ventricle produces prominent respiratory effects. Dyspnea is a common symptom of left-sided heart failure. It occurs from the pulmonary congestion that impairs gas exchange between the alveoli and capillaries. Dyspnea stimulates compensatory mechanisms that produce short, rapid respirations. Dyspnea is classified in several ways:

- Exertional dyspnea is shortness of breath that increases with activity.
- **Orthopnea** is dyspnea that increases when lying flat. In an upright position, gravity holds fluid in the lower extremities. In a supine position, gravitational forces are removed, allowing fluid to move from the legs to the heart, which overwhelms the already congested pulmonary system. When orthopnea is present, two or more pillows are often used for sleeping, and the documentation should state the number of pillows used. For example, use of three pillows would be three-pillow orthopnea.
- **Paroxysmal nocturnal dyspnea (PND)** is sudden shortness of breath that occurs after lying flat for a time. PND results from excess fluid accumulation in the lungs. The sleeping person awakens with feelings of suffocation and anxiety. Relief is obtained

orthopnea: orth—straight + pnea—to breathe

TABLE 26.4 CHRONIC HEART FAILURE SUMMARY

<i>Signs and Symptoms</i>			
	<i>Right-Sided Heart Failure</i>		<i>Left-Sided Heart Failure</i>
	Jugular vein distention		Dyspnea on exertion
	Dependent peripheral edema		Dry hacky cough, especially supine
	Ascites		Crackles, wheezing
	Weight gain		Orthopnea
	Splenomegaly		Paroxysmal nocturnal dyspnea
	Hepatomegaly		Cheyne-Stokes respirations
	GI pain, anorexia, nausea		Cyanosis
	Fatigue, weakness		Tachypnea, tachycardia
	Tachycardia		Nocturia
	Nocturia		
<i>Diagnostic Tests</i>	<i>Complications</i>	<i>Therapeutic Interventions</i>	<i>Nursing Diagnoses</i>
History and physical examination	Hepatomegaly	<i>Noninvasive</i>	Impaired gas exchange
Electrocardiogram	Splenomegaly	Treat underlying cause	Decreased cardiac output
Chest x-ray examination	Pleural effusion	Oxygen by cannula or mask	Excess fluid volume
Exercise stress test, pharmacological stress test	Left ventricular thrombus and emboli	Drug therapy: See Table 26.5	
Nuclear imaging studies	Cardiogenic shock	Individualized activity plan	
Echocardiography, TEE		Dietary sodium restriction	
Coronary angiography		Fluid restriction	
Cardiac catheterization		Daily weights	
Serum laboratory tests:		<i>Invasive</i>	
ABGs, CBC, ProBNP, electrolytes, liver enzymes, BUN, creatinine, thyroid function		Resynchronization therapy	
Urinalysis		ICD	
Hemodynamic monitoring		Mechanical assistive devices	
		Intra-aortic balloon pump	
		Left ventricular assist device	
		Total artificial heart	
		Valvuloplasty	
		Heart valve replacement	
		Cardiac transplant	

ABGs = arterial blood gases; ACE = angiotensin-converting enzyme; BUN = blood urea nitrogen; CBC = complete blood count; ICD = implantable internal cardiac defibrillator; TEE = transesophageal echocardiography.

by sitting upright for a short time, which reduces the amount of fluid returning to the heart.

Cough

A chronic, dry cough is common in heart failure. The coughing increases when lying down from increased irritation of the lung mucosa. This irritation is due to the increase in pulmonary congestion that occurs when gravity no longer keeps fluid in the legs and more fluid returns to the heart and lungs.

Crackles and Wheezes

Pulmonary congestion causes abnormal breath sounds such as crackles and wheezes. These sounds indicate the presence of increased fluid in the lungs. Crackles are produced from fluid build-up in the alveoli resulting from increased pressure in the pulmonary capillaries. Wheezes occur from bronchiolar constriction caused by the increased fluid.

Tachycardia

The sympathetic nervous system compensates for the decreased cardiac output in heart failure by releasing epinephrine and norepinephrine to increase the heart rate. Normally, this is helpful because the increased heart rate

LEARNING TIP

To simulate the sound of crackles, open a piece of Velcro or rub hair together next to your ear. These sounds are similar to the sound of crackles heard with a stethoscope.

increases the amount of blood ejected by the heart to maintain an adequate cardiac output. However, whenever the heart works faster, it also requires more oxygen, which a failing heart finds it difficult to supply.

Chest Pain

Chest pain may occur from ischemia in the patient with heart failure. Decreased cardiac output results in decreased oxygen delivery to the heart itself via the coronary arteries. Compensatory mechanisms designed to maintain cardiac output increase the workload and oxygen needs of the heart and are counterproductive in heart failure. Tachycardia increases the oxygen needs of the heart. The kidneys compensate by retaining sodium and fluid, which increases the fluid volume returning to the heart (preload) and therefore

the heart's workload and oxygen needs. Pain also increases oxygen requirements, adding further to the cycle of heart failure.

Cheyne-Stokes Respiration

A breathing pattern of shallow respirations building to deep breaths followed by a period of apnea characterizes Cheyne-Stokes breathing. The apneic period occurs because the deep breathing causes carbon dioxide levels to drop to a level that does not stimulate the respiratory center. This apnea may last up to 30 seconds and is then followed by the shallow to deeper respiratory pattern of Cheyne-Stokes as carbon dioxide levels rise again.

Edema

Edema occurs in heart failure as a result of (1) systemic blood vessel congestion and (2) sympathetic compensatory mechanisms that cause the kidneys to activate the renin-angiotensin-aldosterone system, in which antidiuretic hormone is released from the pituitary gland, causing sodium and water to be retained. Systemic or pulmonary edema can occur in heart failure. The effect of backward build-up of pressure in the systemic blood vessels is seen with distention of the jugular veins, swelling of the legs and feet, sacral edema in the individual on bedrest, and increased fluid within the abdominal cavity and organs. An acute build-up of fluid in the lungs produces pulmonary edema.

Anemia

Many patients with heart failure are anemic due to decreased angiotensin-converting enzyme (ACE) action. This reduced ACE action decreases production of red blood cells, resulting in anemia and decreased hemoglobin levels.

Nocturia

Nocturia is an increase in urine output at night. After lying down, fluid in the lower legs returns to the circulatory system. Renal blood flow and filtration is increased, resulting in greater urine production and the need to urinate frequently during the night. Nocturia may occur up to six times per night, contributing to the patient's fatigue from lack of sleep.

Cyanosis

The skin, nailbeds, or mucous membranes may appear blue, or cyanotic, from decreased oxygenation of the blood.

NURSING CARE TIP

Patients often have to get up to void shortly after going to bed. This is due to fluid in the legs returning to the heart and then the kidneys for filtering after a person lies down. To help patients get as much undisturbed rest as possible, teach them to recline with legs at or above heart level for at least 30 minutes before going to bed. Then they can void before going to bed, instead of soon after going to bed.

Cyanosis is a late sign of heart failure. It is associated primarily with left-sided heart failure.

Altered Mental Status

Less cardiac output decreases the amount of oxygen delivered to the brain. As a result, restlessness, insomnia, confusion, and impaired memory may occur. A decrease in level of consciousness may occur.

Malnutrition

Several factors contribute to malnutrition in the person with chronic heart failure. Altered mental status, dyspnea, and fatigue interfere with the ability to eat. Anorexia and gastrointestinal (GI) upset occur from pressure exerted by excess fluid surrounding the GI structures. Absorption of food may also be impaired by this pressure.

CRITICAL THINKING

Mr. Shepard (1)

■ Mr. Shepard, age 66, has a family history of cardiac disease. He has been hypertensive for 10 years and takes captopril daily. His baseline vital signs are blood pressure 122/78, pulse 80, respiration 18, height 66 in, and weight 170 lb. During a visit to his physician, he states that he has been short of breath during his daily 2-mile walk and has been using two pillows at night for sleep. As he talks, the physician notes that he has an intermittent dry cough. His physical examination shows blood pressure 140/86, pulse 106, respiration 24, weight 178 lb, and bilateral crackles in the lung bases.

1. What signs and symptoms of heart failure does Mr. Shepard have?
2. Do the signs and symptoms reflect right- or left-sided heart failure?
3. Why are each of the signs and symptoms occurring?
4. Why is Mr. Shepard using two pillows for sleeping?

Suggested answers at end of chapter.

Complications of Heart Failure

Complications of heart failure are listed in Table 26.4. The liver and spleen enlarge from the fluid congestion, which causes impaired function, cellular death, and scarring. Pleural effusion, a leakage of fluid from the capillaries of the lung into the pleural space, can occur. The elevated pressures in the capillaries of the lung cause this leakage. Thrombosis and emboli can occur as a result of poor emptying of the ventricles, which leads to stasis of blood. Aspirin or anticoagulants are often prescribed to prevent thrombus formation in patients with heart failure. Cardiogenic shock, often caused by a myocardial infarction that damages the left ventricle, occurs when the left ventricle is unable to supply the tissues with enough oxygen and nutrients to meet their needs. Cardiogenic shock is a life-

threatening condition that requires immediate treatment (see Chapter 8).

Diagnostic Tests

Diagnostic tests are done to identify the cause of the failure and determine the degree of failure present (see Table 26.4):

- A chest x-ray examination shows the size, shape, and enlargement of the heart and congestion in the pulmonary vessels.
- Echocardiography measures the size of the heart chambers to detect enlargement and assess valvular function and motion of the ventricles.
- Cardiac dysrhythmias that precipitate and contribute to heart failure can be diagnosed with electrocardiogram (ECG; see Chapter 20). Chamber enlargement in the atrium from heart failure is shown by P-wave changes and in the left ventricle by increased voltage and deeper S waves in some V leads.
- Exercise stress testing and nuclear imaging studies provide information on activity tolerance, which is usually limited in heart failure.
- Cardiac catheterization and angiography are used to detect underlying heart disease that may be the cause of heart failure.
- Direct assessment of the heart's pressures is done with hemodynamic monitoring. A catheter is inserted into the heart and pulmonary artery to transmit pressures to a cardiac monitor. These cardiac and pulmonary pressures are then used to guide medical therapy.
- Serum laboratory tests may show elevated serum blood urea nitrogen (BUN) and elevated serum creatinine from renal failure and elevated liver enzymes from liver damage.

CRITICAL THINKING

Mr. Shepard (2)

■ Mr. Shepard's chest x-ray examination shows an enlarged heart (cardiomegaly).

1. Why is Mr. Shepard's heart enlarged?
2. What is the significance of an enlarged heart?

Suggested answers at end of chapter.

Therapeutic Interventions

The overall goal of medical treatment for chronic heart failure is to improve the heart's pumping ability and decrease the heart's oxygen demands. Treatment of heart failure focuses on (1) identifying and correcting the underlying cause, (2) increasing the strength of the heart's contraction, (3) maintaining optimum water and sodium balance, and (4) decreasing the heart's workload. Heart failure management requires a team approach that may involve physicians, case

managers, nurses, dietitians, physical therapists, occupational therapists, pharmacists, social workers, and clergy. Heart failure critical pathways (treatment guidelines), as well as heart failure clinics, are being used to ensure quality-based outcomes while reducing treatment costs.

The severity of heart failure determines the individualized therapy selected. Noninvasive approaches are usually tried first. If noninvasive treatment is not effective, invasive approaches may be used.

Oxygen Therapy

One of the major problems caused by heart failure is a reduction in oxygen delivered to the tissues. The heart failure signs and symptoms of this are fatigue, dyspnea, altered mental status, and cyanosis. Oxygen therapy assists in supplying the oxygen needs of the tissues. In mild heart failure, oxygen may be delivered via nasal cannula. For more severe cases, arterial blood gas values guide oxygen delivery, either via masks that provide high concentrations of oxygen or with mechanical ventilation.

Activity

Activity tolerance depends on the severity of heart failure signs and symptoms. Severe symptoms may require bedrest with restricted activity until treatment reduces the symptoms. For stable heart failure, a regular exercise program can be helpful in improving cardiac function and reducing heart failure effects. Patients should be encouraged to stay as active as possible within the parameters the physician has prescribed. An individualized walking program that increases activity over time is often prescribed. Patients should be taught how to exercise safely without causing symptoms and to understand that overexertion can produce fatigue the next day. Referral to a cardiac rehabilitation program can be helpful.

Nutrition

Dietary sodium is often restricted to decrease fluid retention. Restricting sodium is challenging. Compliance is often low because low-sodium foods are not very appealing. A referral to a dietitian is important. Diet counseling helps the patient and family understand the need for dietary compliance and the need to provide menus that are appealing and easy to use. Salt substitutes often use potassium in place of sodium, so the patient and physician should discuss their use. Spices, herbs, and lemon juice may be suggested to flavor unsalted

NURSING CARE TIP

In severe heart failure with abdominal discomfort present, malnutrition is a concern. The patient can be anorexic, but the weight gain that occurs with fluid retention can mask the weight loss occurring from the anorexia. Monitor food intake to ensure weight gain from fluid retention does not allow malnutrition to be undetected.

foods. Eating should remain pleasurable for the patient to avoid malnutrition. Focus on showing patients the foods that they like and can still have rather than talking about only the foods they cannot have.

Drug Therapy

Current guidelines generally recommend the use of three drug combination therapy for those with HF. These drug categories include angiotensin-converting enzyme inhibitors (ACEIs), or angiotensin receptor blockers (ARBs), diuretics, and beta blockers. Digoxin can be used as a fourth drug for symptom control. The major classifications of oral drugs used to treat heart failure are listed in Table 26.5. Potassium supplements, anticoagulants, and antidysrhythmics may be used as needed to prevent complications on an individualized basis.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS (ACEIs). ACEIs are considered the first-choice drug over angiotensin receptor blockers (ARBs). They are used for vasodilation. They also offer additional benefit by preventing remodeling. These remodeling changes lead to progressive cardiac deterioration, so inhibiting these changes is of great benefit. They decrease progression of chronic heart failure and hospitalization and improve survival.

LEARNING TIP

To help you identify ACE inhibitors, remember that their generic names end with *-pril*.

TABLE 26.5 ORAL MEDICATIONS FOR HEART FAILURE

Class	Drugs	Side Effects	Nursing Implications
ACE Inhibitor plus a Diuretic			
First-line therapy to decrease afterload.	Captopril (Capoten)	Cough, hypotension, altered taste, rash, proteinuria, hyperkalemia, angioedema (dyspnea, facial swelling), neutropenia (with captopril) Teach patient to change positions slowly to reduce orthostatic hypotension.	Check blood pressure before giving. Monitor WBC with captopril. Take captopril and moexipril on an empty stomach (1 hour before or 2 hours after meals). Teach to report development of cough, so drug can be changed Teach to check blood pressure weekly and report changes to physician. Teach to report rash, sore throat/mouth, fever, swelling of hands/feet/face/ tongue, difficulty breathing/swallowing, chest pain or irregular heartbeat.
Decreases cardiac hypertrophy.	Enalapril (Vasotec)		
	Fosinopril (Monopril)		
	Lisinopril (Prinivil, Zestril)		
	Moexipril (Univasc)		
	Perindopril (Aceon)		
	Quinapril (Accupril)		
	Ramipril (Altace)		
	Trandolapril (Mavik)		
Angiotensin II Receptor Inhibitor			
Decreases cardiac hypertrophy and apoptosis.	Candesartan (Atacand)	Headache, dizziness, angioedema (dyspnea, facial swelling)	Take blood pressure and pulse before giving. Correct dehydration before initiating therapy. Teach to change positions slowly to reduce orthostatic hypotension. Teach to report rash, sore throat/mouth, fever, swelling of hands/feet/face/tongue, difficulty breathing/swallowing, chest pain or irregular heartbeat.
May be used if ACE inhibitor not tolerated.	Irbesartan (Avapro)		
	Losartan (Cozaar)		
	Valsartan (Diovan)		
Diuretics			
Loop diuretics			
Decrease fluid overload.	Bumetanide (Bumex)	Hypokalemia, hyponatremia, hypochloremia, hypomagnesemia, dehydration, hypotension	Do not give loop or thiazide diuretics to sulfa-allergic patients. Take blood pressure and pulse before giving. Monitor electrolyte levels (especially potassium level and for those on digoxin), and fluid status (daily weight, intake, output, thirst, dry mouth, weakness, oliguria) throughout therapy. Administer per patient lifestyle (usually in AM) to avoid nocturia.
Potassium wasting	Furosemide (Lasix)		
	Torsemide (Demadex)		

(Continued on following page)

TABLE 26.5 ORAL MEDICATIONS FOR HEART FAILURE (Continued)

Class	Drugs	Side Effects	Nursing Implications
<p><i>Potassium-sparing</i></p>	Spironolactone (Aldactone)	Hyperkalemia, nausea, vomiting, anorexia, diarrhea, headache, clumsiness, gynecomastia	<p>Do not give potassium sparing diuretic if hyperkalemic.</p> <p>Teach to report signs of hyperkalemia: weakness, fatigue, confusion, dyspnea, arrhythmias, confusion.</p> <p>Older patients are at higher risk for electrolyte imbalances.</p>
<p>Thiazide diuretics <i>Potassium wasting</i> Decrease fluid overload.</p>	<p>Chlorothiazide (Diuril)</p> <p>Chlorthalidone (Hygroton, Thalitone)</p> <p>Hydrochlorothiazide (Hydro DIURIL, HCTZ, Microzide)</p> <p>Metolazone (Zaroxolyn)</p>	Hypokalemia, dizziness, hypotension, photosensitivity	<p>Teach about potassium supplements and, if on digitalis, about increased risk of toxicity with hypokalemia.</p> <p>Teach to monitor weight daily and report changes.</p> <p>Teach use of sunscreen to prevent photosensitivity reaction.</p>
<p>Beta Blockers Reduce sympathetic nervous system input, reduce cardiac remodeling, improve cardiac output, reduce symptoms, reduce disease progression and sudden death.</p>	<p>Bisoprolol (Zebeta)</p> <p>Carvedilol (Coreg), specific for heart failure, contains beta blocker plus antioxidant, effective in slowing progression of heart failure</p> <p>Metoprolol tartrate (Toprol XL, Lopressor)</p>	Dizziness, hypotension, hyperglycemia, fluid retention, diarrhea, bradycardia, heart blocks, impotence, bronchospasm (carvedilol)	<p>Avoid carvedilol in patients with asthma (causes bronchospasm).</p> <p>Check apical heart rate and blood pressure. If heart rate is below 50 or blood pressure below 100 systolic, contact physician before giving.</p> <p>Teach to take pulse daily and blood pressure biweekly and to contact physician before taking drug if pulse rate is below 60.</p> <p>Teach to change positions slowly to reduce orthostatic hypotension.</p> <p>Diabetic patients should closely monitor blood sugar.</p> <p>Teach to monitor for worsening of heart failure symptoms.</p>
<p>Inotropes—Cardiac Glycoside (positive inotrope and negative chronotrope) Increase the force and contraction of the myocardium, which increases cardiac output. Slows heart rate to reduce workload of heart and controls atrial fibrillation if present.</p>	Digoxin (Lanoxicaps, Lanoxin)	<p>Fatigue, nausea, vomiting, anorexia, headache, bradycardia, cardiac arrhythmias</p> <p>Toxicity: abdominal pain, anorexia, nausea, vomiting, visual changes (blurred, yellow-green halos, photophobia, diplopia) bradycardia, dysrhythmias</p>	<p>Take apical pulse for 1 minute; if below 60, contact physician before giving.</p> <p>Instruct patient to take medication exactly as directed, at the same time each day.</p> <p>Teach patient to take pulse and to contact health care professional before taking medication if pulse rate is below 60 or above 100.</p> <p>Therapeutic digoxin levels: 0.5 to 2 mg/mL. Older patients are more susceptible to toxicity.</p> <p>Teach signs and symptoms of digitalis toxicity to patient and family.</p> <p>Periodically monitor drug level and electrolytes (hypokalemia, hypomagnesemia, hypercalcemia make patients more susceptible to toxicity).</p> <p>Antidote for toxicity is digoxin immune FAB (Digibind).</p>

Class	Drugs	Side Effects	Nursing Implications
Vasodilators Decrease after-load, which increases cardiac output and reduces cardiac workload. Used for patients who cannot take ACE inhibitors.	Isosorbide dinitrate (ISDN, Isorbid, Isordil, Isonate) Hydralazine (Apresoline)	Headache, dizziness, hypotension, tachycardia	Take blood pressure and pulse before giving. Teach to change positions slowly to reduce orthostatic hypotension. Isosorbide dinitrate: Administer 1 hour before or 2 hours after meals for faster absorption. Chewable tablets should be chewed well before swallowing and held in the mouth for 2 minutes. Extended-release tablets and capsules should be swallowed whole. Do not chew, crush, or break. Sublingual tablets should be held under tongue until dissolved; no eating, drinking, or smoking until tablet is dissolved; replace sublingual tab if swallowed. Headache is common initially and is treated with aspirin. Hydralazine: Take with meals to enhance absorption. Teach to avoid sudden changes in position to avoid orthostatic hypotension. Teach to immediately report fatigue, fever, aching, rash, chest pain, sore throat, numbness, tingling, or weakness of hands/feet.

ACE = angiotensin-converting enzyme; WBC = white blood cell.

ANGIOTENSIN RECEPTOR BLOCKERS (ARBs). ARBs are an alternative to ACEIs for inhibiting the renin-angiotensin-aldosterone system. Several ARBs are available. They should be used carefully if ACEIs are also used as hyperkalemia and renal dysfunction risks increase.

DIURETICS. Diuretics are used to reduce fluid volume and decrease pulmonary venous pressure, so the heart does not have to work so hard. Since they are given to help prevent edema, edema does not need to be present for their use. Diuretics act on various areas of the kidneys to promote the excretion of edema fluid. A combination of diuretics may be used to achieve the desired effect. Electrolytes (especially potassium levels to prevent hypokalemia) and fluid balance (to prevent dehydration) should be carefully monitored during therapy. Potassium supplements are often given with potassium-wasting diuretics.

A potassium-sparing diuretic, spironolactone (Aldactone), blocks the effects of aldosterone and has a positive effect on sodium and potassium balance. Potassium must be monitored carefully, as spironolactone is a potassium-sparing agent and the risk of hyperkalemia increases if ACEIs or ARBs are also used.

BETA BLOCKERS. Initially the sympathetic nervous system (SNS) acts to compensate for HF. Long-term

NURSING CARE TIP

Always check potassium levels before giving a potassium-wasting diuretic such as loop diuretics furosemide (Lasix), bumetanide (Bumex), or torsemide (Demadex) or before giving a potassium supplement, which the patient may be taking due to diuretic therapy. Do not give a diuretic if the potassium level is low or a potassium supplement if the potassium level is high.

sympathetic effects, however, are not helpful in heart failure. Beta blockers block the adverse effects of the SNS. Improved cardiac output, reduced symptoms, reduced disease progression and reduced sudden death are benefits of this therapy.

LEARNING TIP

To help you identify beta blockers, remember that their generic names end with *-ol*.

INOTROPIC AGENTS. Inotropic drugs strengthen ventricular contraction to increase cardiac output. Inotropic agents include the cardiac glycosides (digitalis, digoxin), sympathomimetics (dopamine, dobutamine), and phosphodiesterase inhibitors (amrinone, milrinone). The sympathomimetics and phosphodiesterase inhibitors are usually used short term.

Digitalis. In addition to improving contraction strength, digitalis preparations decrease conduction time within the heart, which slows the heart rate to allow more complete emptying of the ventricles. Digitalis may increase myocardial oxygen needs, so it is used cautiously. Monitoring of serum drug levels is necessary to detect toxic levels of the drug. If toxic levels are present, the drug is stopped to allow digitalis levels to decrease over time. If life-threatening dysrhythmias occur, a digoxin antibody, digoxin immune FAB (Digibind), can be administered.

CRITICAL THINKING

Mr. Shepard (3)

■ During Mr. Shepard's visit, the physician tells him to continue the ACE inhibitor, the diuretic, and a 2-g sodium diet.

1. Why is the ACE inhibitor continued?
2. Will the ACE inhibitor affect preload or afterload?
3. Why is the diuretic ordered?
4. Why is a 2-g sodium diet ordered?
5. What is the overall goal of the ordered treatment?

Suggested answers at end of chapter.

Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CTR) is an option for some patients with heart failure and ventricular dyssynchrony. In heart failure, the ventricles do not always beat together. This ventricular dyssynchrony results in less effective pumping by the ventricles and reduced stroke volume. Cardiac resynchronization therapy restores normal contraction timing of both ventricles. Resetting the heartbeat reduces symptoms and improves quality of life. Cardiac resynchronization therapy uses a biventricular cardiac pacing system. An atrial lead senses or paces the atria as needed. A right and left ventricular lead stimulates the ventricles to synchronize their contractions in response to the atrial event. Left ventricular filling is then improved. Several types of CTR devices are available. CTR therapy is available with an implantable cardiac defibrillator therapy (CTR-D). One newer type of CTR device is also able to monitor fluid status within the thorax (chest). For more information and pictures of the InSync CRT devices, visit www.medtronic.com.

Mechanical Assistive Devices

Newer technology is improving treatment options for the failing heart. Mechanical assistive devices can provide tem-

porary support to patients in cardiogenic shock or be a bridge to transplantation or a long-term solution when other options are not available for the failing heart. These devices increase the cardiac output of the patient. They are used primarily in critical care settings and include the intra-aortic balloon pump, ventricular assist devices, and artificial heart. Technology in this area is continually being updated. For current information and to see pictures of artificial hearts and ventricular assist devices, visit the National Institutes of Health or a manufacturer's website at the following addresses:

<http://www.nlm.nih.gov/medlineplus/>

www.abiomed.com

www.syncardia.com

www.thoratec.com

www.worldheart.com

INTRA-AORTIC BALLOON PUMP. The purpose of using an intra-aortic balloon pump (IABP) is to increase circulation to the coronary arteries and reduce the work of the heart. The IABP catheter is inserted into the femoral artery and positioned in the descending aortic arch (Fig. 26.3). Then the IABP is attached to a computer that senses ventricular contraction and controls the balloon. While the heart is relaxed (diastole), the balloon is inflated, which sends more blood into the coronary arteries without having the heart work harder. Just before the heart contracts (systole), the balloon deflates to allow blood to flow past it. The deflation of the balloon also reduces pressure in the aorta which allows the blood to flow more easily from the

FIGURE 26.3 Intra-aortic balloon pump.

heart. The IABP is inserted in a cardiac catheterization laboratory, critical care unit, or surgery and is used short term for several days.

VENTRICULAR ASSIST DEVICES. Ventricular assist devices (VADs) are implanted mechanical devices that assist cardiac pumping. These devices maintain cardiac output and allow the failing ventricle to rest. VADs are used temporarily as a bridge to transplantation (while awaiting a donor heart), bridge to recovery (for hearts that potentially can recover), or as permanent, long-term therapy referred to as destination therapy for those who are not candidates for heart transplant. They may also be referred to as left ventricular assist devices (LVADs) if used in the left ventricle only, right ventricular assist devices (RVADs) if used in the right ventricle only, or bi-VADs (biventricular assist devices) if used in both ventricles. The types of VADs are shown in Figure 26.4. VADs can pump blood directly from either the right atrium to the pulmonary artery (right ventricular failure) or the left atrium to the aorta (left ventricular failure). Two devices can be used for biventricular failure.

Autologous Adult Stem Cell Therapy

Autologous adult stem cell therapy is a treatment option for some with heart failure that is available in other countries. The stem cells taken from a person's own blood are later injected or implanted into a coronary artery or the heart. These stem cells then stimulate the growth of new blood vessels or heart muscle to improve blood flow or cardiac function. For more information on stem cells, visit <http://stemcells.nih.gov/info/basics/>. For information on an example of this therapy, visit <http://www.vescell.com/index.php>.

Surgical Management

Many conditions can cause heart failure. Many of these causes may be treated surgically. Examples of surgical pro-

cedures include coronary artery bypass for coronary artery disease or valve replacement for valvular disease. Once these conditions are treated, heart failure symptoms should resolve.

LEFT VENTRICULAR RECONSTRUCTIVE SURGERY (DOR PROCEDURE). Left ventricular reconstructive surgery is done to remove areas of dead heart tissue or ventricular aneurysm. This returns the ventricle to a more normal shape to improve heart failure symptoms.

Ventricular Aneurysm Repair. Indications that a ventricular aneurysm requires surgery include persistent angina, symptoms of heart failure, large aneurysms impeding the function of the heart, left ventricular failure, or tachy-dysrhythmias. Once the patient is on CPB, an incision is made exposing the heart and then the aneurysm is resected (cut out), leaving a fibrous border (Fig. 26.5). The ventricle is wiped clean and irrigated to ensure all thrombi are removed. The opening is then closed with sutures or patched with a graft. Air that entered the ventricle while it was open is aspirated, and the surgery continues as described in the general surgery procedure section.

Treatments Being Researched

Several treatments are being studied for potential use in treating heart failure. Medications include oral phosphodiesterase III inhibitors, vasopressin receptor antagonists, and intermittent nesiritide infusions. Other therapies being studied include implantable hemodynamic monitors, external counterpulsation, internal cardiac support devices, stem cell transplantation, intravascular volume reduction, and surgical ventricular restoration.

HEART RESIZING PROCEDURES. Newer often minimally invasive surgical treatments are being explored to help reshape the heart so that it can function more normally as a

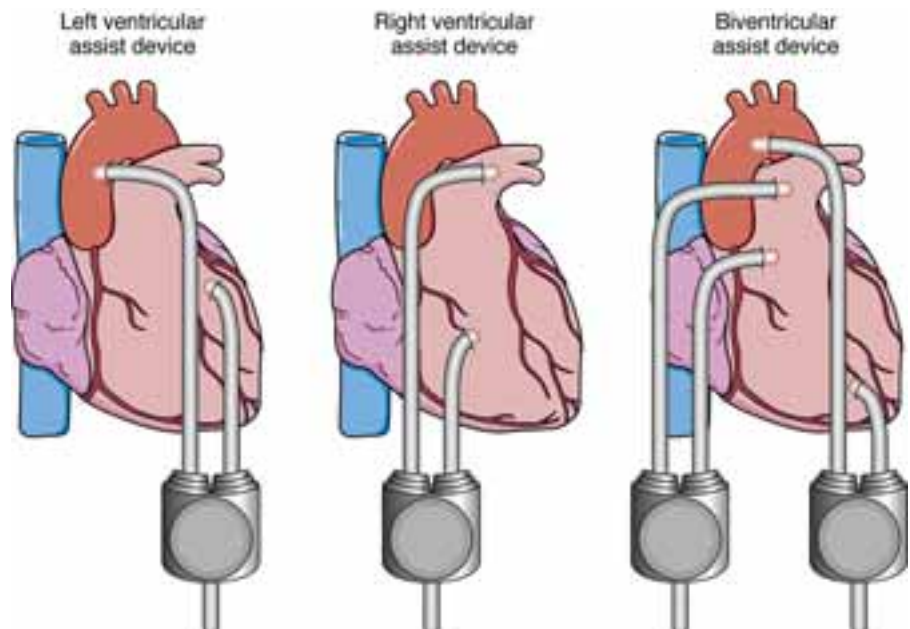

FIGURE 26.4 Different types of ventricular assist devices. (Modified from Ruppert, S, Kernicki, J, and Dolan, J: *Dolan's Critical Care Nursing*. F.A. Davis, Philadelphia, 1996, p 336.)

FIGURE 26.5 Ventricular aneurysm repair.

pump. The STICH trial began in 2002 and is evaluating this technique.

CARDIAC SUPPORT DEVICE. A meshlike support stocking for the heart is available in Europe and being studied in the United States. The stocking, the Corcap Cardiac Support Device (Acorn Cardiovascular A; St. Paul, Minn.), is implanted during surgery. It gives gentle support to the heart and permits normal function. In heart failure, increasing cardiac pressures dilate the heart. The stocking's goal is to help reduce this pressure thereby preventing the enlargement of the heart and improving the patient's quality of life. Visit <http://www.acorncv.com/> for more information.

CARDIOMYOPLASTY. Cardiomyoplasty is an experimental surgical procedure using the patient's own skeletal muscle (latissimus dorsi) to enhance the function of the heart and improve circulation. The muscle is wrapped

around the aorta or heart, and a cardiomyostimulator is implanted to stimulate muscle contraction. Cardiomyoplasty may reduce the need for heart transplantation by delaying or preventing end-stage heart failure.

Nursing Process for Chronic Heart Failure

Nursing Assessment/Data Collection

While obtaining data for the patient with heart failure, focus on areas that might indicate the presence of heart failure (Table 26.6).

Nursing Diagnosis, Planning, Interventions, and Evaluation

See Box 26.1 Nursing Care Plan for the Patient with Chronic Heart Failure for common nursing diagnoses.

The major focus of nursing care for chronic heart failure patients is to improve oxygenation and decrease the body's need for oxygen with rest, positioning, medications, fluid balance, and oxygen consumption control.

OXYGEN. Oxygen therapy is ordered by the physician and guided by blood gas analysis. Before starting oxygen therapy, explain the therapy to the patient. For chronic heart failure, oxygen is administered at 2 to 6 L/min via nasal cannula. The effects of the oxygen should be monitored carefully. Oxygen should be used cautiously in all patients, so that their stimulus to breathe is not diminished (especially if the patient has chronic obstructive pulmonary disease [COPD]).

Home Oxygen Therapy. If a patient will be using home oxygen therapy, instructions must be given on the proper use of the oxygen and safety precautions for oxygen use. The family must also understand oxygen safety precautions and be willing to comply with them. Smoking is prohibited when oxygen is in use.

REST AND ACTIVITY. Reduction of the body's oxygen demands decreases the workload of the heart. A balance of rest and activity that does not produce signs or symptoms of oxygen deprivation is essential. The activity level of the patient is determined by the severity of the heart failure. During times of exertion, monitor the patient's vital signs and respiratory effort for oxygen deprivation. If activity intolerance develops, the activity should be stopped.

POSITIONING. Semi-Fowler's or high-Fowler's position makes breathing easier. In upright positions, the lungs are able to expand more fully and gravity decreases the amount of fluid returned to the heart, thereby reducing the heart's workload.

FLUID RETENTION. Monitoring daily weights for weight gain is important in detecting fluid retention. Edema usually is not observed until there are 5 to 10 pounds of extra fluid present. A baseline weight should be obtained when heart failure is diagnosed. Daily weights should be measured on the same scale, at the same time of day, and with the same type of clothing worn to ensure accuracy. A good time to obtain a daily weight is in the morning after the bladder is

TABLE 26.6 NURSING ASSESSMENT FOR THE PATIENT WITH CHRONIC HEART FAILURE

Subjective Data	Objective Data
History	Respiratory
Respiratory	Tachypnea, crackles, wheezing, respiratory effort, dyspnea with exertion
Lung disease?	Cardiovascular
How many flights of stairs can be climbed without dyspnea?	Tachycardia, dysrhythmias, jugular vein distention, peripheral edema—degree of pitting
How many pillows used for sleeping?	Gastrointestinal
Dyspnea at rest or that awakens from sleeping?	Abdominal distention, ascites, hepatomegaly, splenomegaly
Cardiovascular	Neurological
Any cardiac disease history: hypertension, myocardial infarction, valvular problem, anemia, dysrhythmias, palpitations	Confusion, decreased level of consciousness, restlessness, impaired memory
Chest pain—precipitating factors, severity, relieving factors	Integumentary
Can activities of daily living be performed?	Cold, clammy skin; pallor; cyanosis
Can activities performed 6 months, 4 months, 2 months, 2 weeks ago still be done?	General
Any dizziness (vertigo) or fainting (syncope)?	Weight
Fluid retention	Diagnostic test findings
Daily sodium intake?	
Weight gain?	
Are shoes tight? Do ankles swell?	
Gastrointestinal	
Is appetite good?	
Any nausea, vomiting, or abdominal pain?	
Urinary	
Decrease in daytime urine output?	
How often does patient go to the bathroom at night (nocturia)?	
Neurological	
Any change in behavior?	
Medications	
Knowledge of condition	
Coping skills	

emptied. Documentation of daily weights should include the date and time of the weight, the scale used, the clothing worn, and the weight measurement. A weight journal can be kept by the patient. Tell patients to report weight gains of 2 to 3 lb over 1 to 2 days.

OXYGEN CONSUMPTION. Increased oxygen consumption by the heart should be avoided. Tachycardia increases the oxygen needs of the heart and should be reported promptly to the physician for treatment. Older patients are especially vulnerable to the effects of tachycardia because of their decreased reserves. Constipation should be prevented because straining during defecation, Valsalva's maneuver, increases the heart's workload by increasing venous return to the heart. Stool softeners should be administered, as ordered, to prevent straining.

Patients should be taught methods of saving energy while performing activities of daily living (ADL). Activities should be alternated with periods of rest. Fatigue should be avoided. A referral to occupational therapy and physical therapy can be helpful in developing techniques that allow

the patient to conserve energy during self-care. Some suggestions for conserving energy include placing frequently used objects at waist level to avoid reaching overhead, planning bathing activities to include rest periods, and using Velcro fasteners to make dressing easier.

MEDICATIONS. Because heart failure is a progressive, chronic condition, patients may require lifetime medications. Combination drug therapy is often needed. Taking many pills each day can be challenging. Financial resources, compliance, and ongoing monitoring are issues that must be considered.

Diuretics require monitoring of the patient's potassium levels and blood pressure. To prevent hypokalemia, potassium supplements may be prescribed during diuretic therapy, and a diet with high-potassium foods is encouraged. If too much fluid is removed, the patient may become hypotensive and orthostatic hypotension can develop. The patient may then be dizzy and at risk of falling. Caution the patient to change positions slowly to prevent falls during diuretic therapy.

Box 26.1 NURSING CARE PLAN for the Patient with Chronic Heart Failure

Nursing Diagnosis: Activity intolerance related to fatigue caused by oxygen imbalance

Expected Outcomes Patient will show increased activity tolerance with vital signs within normal limits (WNL) in response to activity.

Evaluation of Outcomes Does the patient participate in activities and maintain vital signs WNL?

Interventions

Provide rest, space activities, and conserve energy.

Assist as needed with activities of daily living (ADLs).
Teach use of assistive devices and lifestyle changes.

Rationale

Myocardial oxygen need is decreased with rest and energy conservation.
Conserve energy by assisting with ADLs.
Assistive devices can overcome limitations to increase activity.

Evaluation

Does patient participate in activity with no pulse rate or ECG changes?
Are patient's ADLs met?

Does patient incorporate assistive devices into lifestyle changes?

Geriatric

Increase time allowed to complete activities.

Independence and participation are increased if extra time is allowed for tasks.

Does patient report greater ability to complete activities with fewer symptoms?

Nursing Diagnosis: Excess fluid volume related to heart failure and the secondary reduction in renal blood flow for filtration

Expected Outcomes Patient remains free from edema and dyspnea, has clear lung sounds, and maintains baseline weight.

Evaluation of Outcomes Does patient have clear lung sounds with baseline weight maintained?

Interventions

Monitor for edema, weight gain, jugular vein distention (JVD), lung crackles.
Decrease sodium intake as ordered.
Administer diuretics or inotropics as ordered.

Monitor intake and output.

Rationale

Excess fluid is indicated by edema, sudden weight gain, JVD, and crackles in the lungs.
Sodium retains fluid.
Diuretics promote fluid excretion.
Inotropics increase cardiac contraction strength.
Intake and output will show imbalances.

Evaluation

Is edema, weight gain, JVD, or crackles present?

Does patient restrict sodium intake?
Is output increased and edema or dyspnea reduced?

Are intake and output balanced for 24 hours?

Nursing Diagnosis: Disturbed sleep pattern related to nocturia and inability to lie down and sleep comfortably

Expected Outcomes Patient awakens refreshed and is less fatigued during the day.

Evaluation of Outcomes Does patient wake up less frequently during the night and feel more refreshed with less fatigue during the day?

Interventions

Identify barriers to sleep.

Assist patient in identifying positions of comfort for sleeping.

Rationale

Anxiety, nocturia, diuretics, orthopnea, or paroxysmal nocturnal dyspnea can make sleep difficult.
Use of pillows or a recliner can decrease orthopnea.

Evaluation

Does patient identify sleep barriers?

Can patient identify a position of comfort?

Interventions

Teach patient cause of dyspnea at night.

Encourage patient to recline for 30 to 60 minutes before bedtime.

Encourage patient to take diuretics early in the day.

Rationale

Anxiety about falling asleep and waking up short of breath is reduced.

Reclining before bedtime redistributes fluid and increases voiding that can occur before going to sleep instead of after going to sleep.

Nocturia is reduced if diuretics are taken earlier in the day.

Evaluation

Can patient explain cause of dyspnea?

Is patient awakened to void after going to bed less often?

Does patient take diuretics early and report less nocturia?

Geriatric

Inotropic agents such as digitalis strengthen heart contractions and slow the heart rate. Before administration of a digitalis drug, the patient's apical pulse should be counted for 1 minute. If the pulse is below 60 beats per minute, notify the physician to determine if the drug should be given. Some patients are given digitalis even if their heart rates are between 50 and 60 beats per minute, as long as their heart's conduction system is normal or if it is due to other medications such as a beta blocker. When giving digitalis, be aware that hypokalemia increases the heart's sensitivity to digitalis. A patient can become toxic on a normal dose of digitalis when hypokalemia is present. This is important to note because many people on digitalis also take diuretics, which may lower potassium levels. Monitoring for signs and symptoms of digitalis toxicity should be done routinely during patient assessment. Early symptoms of digitalis toxicity are anorexia, nausea, and vomiting. Other signs and symptoms include bradycardia or other dysrhythmias, visual problems, and mental changes. The elderly are especially prone to toxic effects of this drug and may exhibit confusion when levels are toxic.

Medications with vasodilating effects reduce the heart's workload by decreasing vascular pressure. Blood pressure is monitored when administering vasodilators.

Medication Teaching. Patients and their families are taught the purpose, side effects, and precautions for prescribed medications. Teach them to report side effects to the physician. If dizziness occurs from drugs that reduce blood pressure, the drugs can be staggered so that they are not all taken at the same time. Patients taking a digitalis preparation should be taught to take their pulse. They should hold the medication and call their physician if their heart rate is less than 60 beats per minute or below the lower-limit heart rate set by their physician. Patients on diuretics should be taught the following:

- Take them during the day before 4 p.m. to decrease being awakened at night to void (if desired).

- Have a readily available and obstacle-free bathroom or commode to prevent incontinence and falls.
- Eat high-potassium foods if taking a potassium-wasting diuretic.
- Weigh themselves daily and report weight gains.

Patients should understand the importance of taking their medication as prescribed, even if they do not have symptoms. A schedule should be developed so patients remember to take their medications.

LOW-SODIUM DIET AND WEIGHT CONTROL. A diet assessment should include patient's food likes and dislikes, cultural influences, economic status, and food preparation resources (e.g., shopping ability, storage, refrigeration, and cooking equipment). It is helpful to include a dietitian in the planning process, as well as the food preparer or a support person, to increase diet compliance.

For overweight patients, weight reduction may help eliminate the underlying cause of heart failure. Diet counseling and support should be given to the obese patient to encourage weight loss. The body mass index (BMI) should guide weight loss. If anorexia occurs in the later stages of heart failure, the patient's intake should be evaluated. Several small meals rather than three large meals will decrease the heart's workload. If the patient's nutritional needs are not being met, the physician should be informed for a referral to a dietitian.

Patients should be taught to read food labels; foods that are high and low in sodium content and that salt substitutes may contain potassium. With this knowledge, patients can help design a daily meal plan using low-sodium foods that are appealing to them. Food preparers should be taught not to salt food during cooking, and table salt should be eliminated. Explaining seasoning alternatives such as spices, herbs, and lemon juice is helpful in making food taste better.

EDUCATION. Chronic management of heart failure requires patient and family understanding of the disease

process, management of home oxygen therapy, diet and weight control, need for immunizations such as the annual flu shot, and medications (see Home Health Hints). The patient and family must recognize the importance of each of these factors in order to foster a productive life for the patient with chronic heart failure. A discussion of heart failure and signs and symptoms to report to the physician using simple terms should be included in the teaching plan (Box 26.2 Patient and Family Education).

COPING. Living with a chronic illness can be frustrating for both patients and their families. An assessment of coping skills used by patients and their families can be used to develop a plan for coping with this current illness. Available support systems are explained to patients. Referrals to social workers, sexual counselors, telehealth management, and nurse-managed clinics can be helpful in providing resources that may make living with heart failure easier. Providing patients options for traveling can help maintain quality of life. Understanding the chronic nature of heart failure is important for patients, families, and caregivers to positively deal with the emotions and feelings that can result. Nurse-managed heart failure clinics have been shown to decrease hospitalization rates and increase effective management of the therapeutic regimen.

CRITICAL THINKING

Mr. Shepard (4)

■ The nurse meets with Mr. Shepard after the physician orders the ACE inhibitor to be continued, a diuretic, and 2-g sodium diet.

1. What information should the nurse teach Mr. Shepard based on the prescribed treatment?
2. What types of foods should be included in Mr. Shepard's diet?
3. Why does the nurse instruct Mr. Shepard to weigh himself daily?
4. Why does the nurse tell Mr. Shepard to weigh himself at the same time of day, on the same scale, and with the same type of clothing?

Suggested answers at end of chapter.

CARDIAC TRANSPLANTATION

Cardiac transplantation is reserved for patients with end-stage cardiac disease. Strict criteria for the selection of recipients and donors are applied to optimize survival (Box 26.3 Cardiac Transplant Criteria). Preoperative teaching is done once the recipient is accepted into the transplant program. For more information on heart transplantation, visit <http://www.nlm.nih.gov/medlineplus/hearttransplantation.html>.

Box 26.2

Patient and Family Education

Heart Failure Signs and Symptoms to Report to the Physician

- Shortness of breath
- Fatigue
- Dry cough
- Shortness of breath when lying down (orthopnea)
- Episodes of sudden awakening with shortness of breath (PND)
- Weight gain of 2 to 3 lb over 1 to 2 days
- Ankle or foot edema
- Nocturia
- Anorexia

Surgical Procedure

Once a donor heart is found, the recipient is notified, admitted to the hospital, and immediately prepared for surgery. The general procedures for this surgery are similar to those described in the cardiac surgery section. Two types of cardiac transplant procedures are performed: orthotopic and heterotopic. In the orthotopic procedure, once the patient is on CPB, the recipient's diseased heart is removed, leaving the posterior wall of the atria, superior vena cava and inferior vena cava, and pulmonary vein (Fig. 26.6). The aorta and pulmonary artery are cut. The donor's atria, aorta, and pulmonary artery are then anastomosed to the recipient's atria, aorta, and pulmonary artery. Surgery then continues as previously described. The heterotopic procedure joins the

Box 26.3

Cardiac Transplant Criteria

Donor Criteria

- Younger than 40 years of age
- No significant cardiac or malignant disease
- No active infections
- No severe hypertension or diabetes mellitus
- Only \pm 20 lb difference in weight between donor and recipient

Recipient Criteria

- Younger than 55 years of age
- Class IV cardiac disease (not treatable with other medical or surgical treatment, less than 6–12 months survival)
- No irreversible pulmonary hypertension
- No unresolved pulmonary infarcts
- No systemic disease limiting survival
- No drug addiction or peptic ulcer disease

donor heart and vessels to the recipient's heart and vessels without removing the recipient's heart. The donor heart rests in the right side of the chest.

Immunosuppressive therapy begins preoperatively with high loading doses of cyclosporine (Neoral, Sandimmune), azathioprine (Imuran), steroids, or other medications. The risk for rejection is highest immediately after surgery and decreases with time, so doses of immunosuppressive medication are also highest initially after surgery and decrease with time (Box 26.4 Nutrition Notes). Lifelong antirejection therapy is required.

Complications

Heart transplantation complications may include all those stated for cardiac surgery, as well as heart rejection, which is the major cause of death within the first year. Immunosuppressive therapy is required to prevent rejection of the heart. To detect rejection, biopsies of cardiac muscle are commonly performed weekly during the first 3 to 6 weeks

Box 26.4

Nutrition Notes

The potency of antirejection medications may be reduced if patients drink grapefruit juice with them. Grapefruit increases body metabolism.

Individuals who drink wine may not get the desired therapeutic effects of certain immunosuppressive medications.

after surgery, then every 3 months for 1 year, and then yearly. If a biopsy shows damaged cells, indicating rejection, antirejection drug therapy may be changed.

In addition, infection and malignancies may occur as a result of the immunosuppressive therapy. The medications used for immunosuppressive therapy also may cause adverse reactions. Cyclosporine is nephrotoxic and hepato-

FIGURE 26.6 Heart transplantation.

toxic. Azathioprine is also hepatotoxic and may cause bone marrow depression or skin sensitivity to the sun. Steroids can cause osteoporosis, hyperglycemia, sodium and water retention, gastritis, hypertension, and cataract formation. Muromonab-CD3 (Orthoclone OKT3), used to treat rejection reactions in spite of immunosuppressive therapy, can cause fever, malaise, and headaches.

Therapeutic Interventions

The patient receives a diuretic when CPB is stopped to aid in excretion of excessive circulating fluid. Intake and output are monitored hourly, and the patient is observed for fluid overload. Lung sounds are monitored frequently for crackle, and weight and electrolyte levels are checked daily.

Postcardiotomy syndrome (PCS) may occur from days 2 to 5 after surgery and last a few weeks. Patients may arouse normally and be oriented but exhibit mild confusion or psychosis. Pupillary reaction and motor response are assessed. The safety of the patient is maintained with side rails up, bed in low position, and nursing call light within reach. The patient is given as much rest and as little sensory stimulation as possible. The family is kept informed and involved in the patient's recovery.

Sleeping is difficult because of postoperative pain and the continuous level of activity in the intensive care unit (ICU). Sleep is promoted in 90-minute intervals by dimming lights and decreasing all sensory stimulation near the patient. Additionally, listening to a favorite soothing tape recording with earphones or the use of ordered narcotics for pain may also help sedate and relax the patient.

Temperature is monitored every 4 hours and complete blood cell count (CBC) and white blood cell (WBC) results are monitored for indications of infection. If oral thrush (white patches) develops, an antifungal agent is ordered. A urine culture to diagnose a urinary tract infection is ordered if cloudy urine or urinary tract burning occurs.

NURSING PROCESS FOR THE PREOPERATIVE CARDIAC TRANSPLANT PATIENT

General preoperative and postoperative surgical care is discussed in Chapter 11. Postoperative needs for the patient undergoing cardiac surgery are discussed here.

NURSING PROCESS FOR THE POSTOPERATIVE CARDIAC TRANSPLANT PATIENT

Assessment/Data Collection

The patient is accompanied to the ICU by the anesthesiologist, who gives the nurse a report of the procedure, compli-

cations, and hemodynamic and ventilatory management of the patient. The patient is connected to a cardiac monitor and mechanical ventilator. The mechanical ventilator is used for 4 to 24 hours. A temporary pacemaker is connected to the epicardial pacing wires if they were placed during surgery as a precaution to treat bradycardia. The patient is placed under a warming device, such as a light or blanket. The chest tubes are monitored, the nasogastric tube is placed to suction, and the urinary catheter is placed for gravity drainage. A head-to-toe assessment of the patient, including dressings, tubes, and IV lines, is performed. Of importance are signs of awakening, shivering, pain, lung and heart sounds, and palpation of the entire chest and neck to detect crepitus (air in the subcutaneous tissue from opening the chest). Blood is drawn for a CBC, electrolytes, coagulation studies, and arterial blood gases. Cardiac transplant patients may be in isolation for their own protection, depending on the agency's policy.

After the initial transfer assessment, vital signs, oxygen saturation, and cardiac pressures are monitored and recorded every 15 to 30 minutes, with decreasing frequency as the patient stabilizes. Body temperature is monitored continuously while warming measures are used. Intake and output are measured and vital signs are checked. An electrocardiogram (ECG) is done to detect perioperative myocardial infarction. A chest x-ray examination is done to check central line and endotracheal tube placement and to detect a pneumothorax or hemothorax, diaphragm elevation, or mediastinal widening from bleeding. At this point, the family may see the patient, and patient care is explained.

Nursing Diagnosis, Planning, Interventions, and Evaluation

Nursing diagnoses for postoperative cardiac surgery or transplant are discussed in Box 26.5 Nursing Care Plan for the Postoperative Patient Undergoing Cardiac or Transplant Surgery.

Coping with Cardiac Transplant

Cardiac transplant patients may have feelings of sadness and grief for the donor and his family. These feelings may be offset by great elation, relief, and hope after a long wait for the transplant. Patients should be told that these feelings are normal. They should be allowed to express their feelings when they are ready. Emotional support may be needed.

Transplant rejection is a possible complication of this surgery. Patients need to understand the importance of following instructions regarding medications and testing that are related to preventing or detecting rejection.

Cardiac transplant patients are followed in an exercise rehabilitation program that closely monitors their activity progression in relation to myocardial oxygen consumption and signs of activity intolerance. Most patients reach an activity level allowing them to participate in many recreational sports.

CRITICAL THINKING

Mrs. Eden

■ Mrs. Eden, age 45, a single mother of two, is transferred to a surgical unit 5 days after a cardiac transplant. She is withdrawn and has a poor appetite. Her vital signs are stable. However, on ambulating to the bathroom, she is very weak, requiring two nurses to help her. Her respiratory rate increases from 20 to 32 and is slightly labored, and her apical pulse increases from 88 to 103.

1. Is Mrs. Eden tolerating this activity? Why or why not?
2. List four reasons why Mrs. Eden has a poor appetite.
3. Give four nursing interventions for Mrs. Eden's poor appetite.
4. Give three reasons why Mrs. Eden is withdrawn.

Suggested answers at end of chapter.

Box 26.5 NURSING CARE PLAN for the Postoperative Patient Undergoing Cardiac or Transplant Surgery

Nursing Diagnosis: Acute pain related to sternotomy, leg incisions, internal mammary artery resection, or pericarditis

Expected Outcomes Patient will state pain is relieved or tolerable. Patient is able to rest and perform respiratory treatments.

Evaluation of Outcomes Does patient state pain is within acceptable levels? Is patient able to rest and perform respiratory therapies?

Interventions

- Obtain characteristics of pain with each episode.
- Splint chest incision with all movement and coughing and deep breathing.
- Encourage patient to report pain even when pain is mild.
- Turn, reposition every 2 hours.
- Offer back rubs frequently.
- Instruct patient to take a deep breath before movement and exhale slowly during movement.
- Explain that chest pain can occur from the surgical incision rather than the heart.

Rationale

A thorough description is needed to determine cause and plan actions. Stabilizes sternum and incision to increase comfort.

It is easier to keep pain under control when mild. Changes muscle position, relieving stiffness.

Relaxes tense muscles retracted during operation. Keeps muscles relaxed, minimizing tension with guarding and pain.

Chest pain after surgery can be frightening for patients as they may not associate surgical chest pain with the incision and instead think the pain is anginal or infarction pain.

Evaluation

Does patient describe pain on scale of 0 to 10?
Can patient splint chest incision independently?

Does patient report pain when mild?
Is patient comfortable without stiffness?
Is patient able to rest in comfort?

Can patient perform coughing and deep breathing techniques as instructed?
Does patient state understanding of pain sources?

(Continued on following page)

Box 26.5 NURSING CARE PLAN for the Postoperative Patient Undergoing Cardiac or Transplant Surgery (Continued)

Nursing Diagnosis: Decreased cardiac output related to myocardial depression, hypothermia, bleeding, unstable dysrhythmias, or hypoxemia

Expected Outcomes Patient will remain free of major side effects of pharmacological support. Patient will maintain vital signs within normal limits (WNL), palpable peripheral pulses, urine output greater than 30 mL/hr, and normal sinus rhythm.

Evaluation of Outcomes Is patient free of major side effects? Are vital signs WNL?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Monitor vital signs. • Monitor peripheral circulation. 	<p>Trends reflect problems.</p> <p>Mottling or weak pulses may indicate poor cardiac output (CO).</p>	<p>Are vital signs WNL?</p> <p>Do peripheral pulses remain strong with normal skin color, temperature, capillary refill?</p> <p>Does total intake equal output?</p>
<ul style="list-style-type: none"> • Monitor intake and output. 	<p>Fluid deficit or excess can alter CO.</p>	<p>Are lungs clear?</p>
<ul style="list-style-type: none"> • Listen to lung sounds and note character of sputum. • Monitor temperature closely while rewarming the patient. 	<p>Wet lung sounds may indicate heart failure or pulmonary edema.</p> <p>Febrile state increases heart rate and myocardial oxygen consumption.</p>	<p>Does temperature remain less than or equal to 98.6°F (37°C)?</p>
<ul style="list-style-type: none"> • Monitor for shivering. 	<p>Shivering increases the blood pressure, decreasing CO and increasing risk for bleeding.</p>	<p>Is patient's shivering controlled?</p>
<ul style="list-style-type: none"> • Monitor chest tube drainage for increase or sudden decrease. 	<p>Drainage >200 mL/hr may lead to hypovolemia and a decrease in CO.</p>	<p>Is patient free from cardiac tamponade and hypovolemia?</p>
<ul style="list-style-type: none"> • Monitor ECG. 	<p>Premature ventricular contractions and atrial fibrillation decrease CO.</p>	<p>Does patient remain in normal sinus rhythm or controlled dysrhythmia?</p>
<ul style="list-style-type: none"> • Monitor electrolytes. 	<p>Low calcium and magnesium and high potassium decrease contractility and CO.</p>	<p>Are electrolytes WNL?</p>
<ul style="list-style-type: none"> • Monitor ABGs. 	<p>Acidosis decreases heart function, and a low CO may lead to further acidosis.</p>	<p>Are ABGs WNL?</p>

Nursing Diagnosis: Risk for infection related to inadequate primary defenses from surgical wound or immunosuppression (transplants)

Expected Outcomes Patient will remain free from infection.

Evaluation of Outcomes Does patient remain free from infection?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Observe incision for signs and symptoms of infection. • Monitor drainage and maintain drains. 	<p>Redness, warmth, fever, and swelling indicate infection.</p> <p>Drains remove fluid from the surgical site to prevent infection development.</p>	<p>Are signs and symptoms of infection present?</p> <p>Are drainage amount and color normal for procedure? Are drains functioning?</p>

Interventions

- Maintain sterile technique for dressing changes.
- Monitor and report abnormal findings for temperature, lung sounds, sputum, and urine consistency.
- Encourage coughing and deep breathing and incentive spirometer use.

Rationale

Sterile technique reduces infection development.
Low-grade (immunosuppressed) or high-grade fever, crackles, yellow-green sputum color, or cloudy urine can indicate infection.
Lung infections can be prevented with lung expansion and secretion removal.

Evaluation

Is incision free of signs and symptoms of infection?
Is the patient's temperature WNL and are lung sounds, sputum, and urine clear?
Does patient perform coughing and deep breathing and use incentive spirometer?

Nursing Diagnosis: Deficient knowledge related to lack of prior experience with transplant.

Expected Outcomes Patient will demonstrate understanding of care post cardiac transplant.

Evaluation of Outcomes Does patient state understanding and ability to carry out care post cardiac transplant?

Interventions

Give information in small increments and use written materials and audiotapes.

Include families in teaching sessions and encourage them to promote self-care by the patient.

Address or refer sexual functioning questions with patients and their partners.

Discharge teaching includes treatment, complications, activity, medications, enhancing quality of life.

Rationale

Cardiac transplant patients commonly have memory deficits, cognitive dysfunction, and short attention spans resulting from long-term decreased cerebral perfusion.

Family involvement in teaching sessions is important to promote understanding and retention.

Patients usually have questions regarding sexual functioning. Referrals can be made to sexual counselors.

Patients need comprehensive information to comply with post transplant care.

Evaluation

Does patient state understanding of information?

Does family participate and state understanding of teaching sessions?

Does patient state questions have been addressed?

Does patient state understanding of discharge care?

Home Health Hints

- Some patients may not have a scale in their home. It may be necessary to assist them in obtaining one or to leave an agency scale in the home for daily weights.
- The most objective way to document edema is to use a tape measure on the abdominal girth, thigh, calf, and ankle in centimeters. Measure at the same place each visit, such as measuring the girth of the calf at a specified distance above the medial malleolus. Edema may be present if the patient's waistband is getting tighter or shoes and socks feel tighter.
- The sacrum, back, and sides of a bedridden patient should be checked to note edema. These are dependent areas in the bedridden patient, so fluid accumulates in these areas instead of the ankles.
- Blood drawn for potassium levels needs to be transported to the laboratory within 1 hour. Ice should not be put directly on the tube because this can cause destruction of the cells and a false elevation in the potassium level.
- Blood drawn for digoxin levels should be taken to the lab within 2 to 3 hours.

(Continued on following page)

Home Health Hints (Continued)

- Patients should use no salt added canned vegetables. Patients on sodium-restricted diets who already have canned vegetables in their home can still use them even though they are not the low-sodium type. They should be instructed to pour off the liquid and rinse the vegetables before heating them for serving. The use of herbs and spices helps make them more flavorful.
- For the patient on a low-sodium diet, an effective diet teaching technique is to have the patient name the foods highest in sodium. Asking the patient to rename the list on each visit helps knowledge retention and compliance.
- If patients have a poor appetite, ask their caregiver if they eat well when eating with others. Anorexia could be a sign of loneliness and depression if they eat well with others instead of an effect from the heart failure.
- Assist patients in taking medications at times that fit their lifestyle. A morning dose of a diuretic may limit what they can do for the next few hours. An afternoon dose might encourage compliance. Lack of compliance is a major factor in the rehospitalization of patients with heart failure. A dose of diuretic too late in the day may cause frequent awakenings during the night to void.
- The home health nurse should periodically check the contents of medicine bottles. If pills have been cut in half, ask about this. Often it is an attempt by the patient to “stretch” the medicine to decrease expenses. There are community or drug company programs that help purchase medicines for patients with financial need. Eligible Medicaid patients can apply for medication cards. The new Medicare Part D prescription program may be helpful, as well.
- Visual disturbances can occur from digitalis toxicity. If the patient sees halos around lights or red-green tinting on everything, report this to the physician.
- Troublesome side effects of an ACE inhibitor such as captopril (Capoten) are an intractable cough and hypotension. It should be noted how the patient is coughing. Teach the patient to report the cough.
- Oxygen concentrators are widely used in home care. Long tubing allows the patient ease in moving about the home. Patients need to be cautioned about keeping the tubing out of their way and not kinking it. If the patient also has chronic obstructive pulmonary disease (COPD), the oxygen flow rate is generally limited to 2 L/min, so the patient’s drive to breathe is not decreased. A note stating this should be placed near the gauge as a reminder to the patients.
- As the home health nurse becomes acquainted with the patient, it is easier to pick up on signs of oxygen deprivation and hypoxia, such as confusion, combativeness, or unusual expressions of anger.
- For patients with orthopnea, a foam wedge can be obtained from a medical equipment company to use under their head when sleeping instead of pillows.
- As patients with heart failure feel better, they may go back to the old habits that cause an increase in fluid. The home health nurse can help by providing information about the disease and help patients foster their own independence and ways of coping with the condition. Each home health visit is a teaching opportunity that empowers patients with a knowledge base to help them to take control of their health.

REVIEW QUESTIONS

1. A patient asks the nurse what heart failure is. Which of the following is the nurse’s best response?
 - a. “In heart failure the heart pumps too much blood into the pulmonary veins.”
 - b. “In heart failure the heart is unable to pump enough blood for the body’s oxygen needs.”
 - c. “Heart failure is a buildup of blood in the aorta from the heart’s left ventricle.”
 - d. “With a failing heart, the heart stops beating, so blood is not pumped out.”
2. Which of the following does the nurse understand is a major cause of left-sided heart failure?
 - a. Hypertension
 - b. Congenital heart defects
 - c. Pulmonary valve stenosis
 - d. Septal defects
3. A patient who has been treated for heart failure is being discharged from the hospital on 20 mg furosemide (Lasix) daily. Which of the following statements by the patient would indicate understanding of instructions for this medication?
 - a. “I will take the Lasix in the morning.”
 - b. “I will take the Lasix at bedtime.”

- c. "I will drink lots of fluids with the Lasix."
d. "I will take it with meals."
4. The nurse is caring for a patient receiving bumetanide (Bumex) to reduce preload for heart failure. While assessing the patient the nurse notes the patient has less ankle edema and jugular vein distention than earlier. The next dose of bumetanide is scheduled in 1 hour. Which of the following actions should the nurse take next?
- Notify the physician.
 - Hold the bumetanide.
 - Give the bumetanide as scheduled.
 - Give the bumetanide early.
5. Which of the following assessments should the nurse teach the patient to perform to monitor fluid status at home?
- Weigh daily.
 - Weigh weekly.
 - Weigh biweekly.
 - Weigh monthly.
6. A 160-lb patient is to receive cyclosporine (Neoral) 12.5 mg/kg daily in two divided doses. How many mg will the patient receive with each dose?
_____ mg

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. Shepard (1)*

1. Signs and symptoms of heart failure include shortness of breath, two-pillow orthopnea, dry cough, tachycardia (pulse 106), tachypnea (respiration 24), and bilateral crackles.
2. Left-sided heart failure is indicated by the findings.
3. Shortness of breath: fluid in the lungs impairs gas exchange; orthopnea: lying flat increases fluid accu-

mulation in the lungs, causing dyspnea; dry cough: fluid in the lungs irritates the mucosal lining of the lungs; tachycardia: sympathetic compensation to increase cardiac output; tachypnea: sympathetic compensation to increase blood oxygenation; bilateral crackles: fluid trapped in the lungs.

4. The two pillows help prevent orthopnea by using a more upright position, which allows gravity to decrease fluid accumulation in the lungs.

■ Mr. Shepard (2)

1. Mr. Shepard's heart is enlarged to compensate for the strain caused by increased peripheral vascular resistance from hypertension in order to maintain an adequate cardiac output.
2. An enlarged heart requires more oxygen, which often cannot be supplied in heart failure.

■ Mr. Shepard (3)

1. The ACE inhibitor is needed for vasodilation, which reduces peripheral vascular resistance and decreases the heart's workload, to prevent cardiac remodeling and improve functioning.
2. The ACE inhibitor will affect afterload.
3. The diuretic is ordered to decrease fluid volume, which reduces preload and decreases the heart's workload.
4. The diet is ordered to reduce water retention, which decreases preload and decreases the heart's workload.
5. The goal is to decrease the heart's workload and increase its efficiency by reducing preload and peripheral vascular resistance and to decrease progression of chronic heart failure and improve survival.

■ Mr. Shepard (4)

1. After assessment of Mr. Shepard's knowledge base, medication teaching should be given on the ACE inhibitor and diuretic that includes their purpose, side effects, and precautions. A schedule for taking the medications can be planned. An explanation of the purpose of a low-sodium diet and menu planning based on Mr. Shepard's likes and dislikes should be done.
2. Low-sodium foods should be selected to prevent fluid retention, and high-potassium foods should be

included to prevent hypokalemia from the diuretic if appropriate. Read food labels. Low-sodium foods include puffed rice, wheat cereals, fruits, chicken, beef, eggs, and potatoes. High-sodium foods include tomato juice, sauerkraut, softened water, buttermilk, cheese, smoked meats, canned tuna, canned soup, pickles, instant rice, and instant potatoes. High-potassium foods include salt substitutes, bran products, avocado, bananas, prunes, oranges, baked potato, sweet potato, spinach (cooked), chocolate, nuts, and molasses.

3. Daily weighing is necessary to detect a rapid weight gain that indicates fluid retention (2 lb in 24 hours) and to measure weight loss resulting from the diuretic.
4. These instructions ensure accuracy of the weight so that comparison to the baseline weight detects a weight gain or loss.

■ Mrs. Eden

1. No, Mrs. Eden is not tolerating this activity, as evidenced by her increased respiratory rate and apical rate.
2. Steroids, immunosuppressive therapy, depression, and fatigue could be causing her poor appetite.
3. Nursing interventions related to Mrs. Eden's poor appetite could include the following: offering small, frequent meals; having family bring favorite foods from home; allowing the patient to rest before meals; providing oral hygiene before meals; administering antiemetics before meals; giving a high-calorie meal at peak appetite.
4. Mrs. Eden could be withdrawn because of changes in her lifestyle as a result of her transplant, extreme fatigue and concerns regarding how she will raise her children, grieving for the donor, and fear that she will reject her new heart.

QUESTIONS TO GUIDE YOUR READING

1. What are the components of blood?
2. How are changes in the blood or blood-producing processes manifested as disease processes?
3. What is the sequence of events in the process of blood clotting?
4. What data should you collect when caring for a patient with a disorder of the hematological or lymphatic system?
5. What laboratory and diagnostic studies are used when evaluating the hematological and lymphatic systems?
6. What nursing care should you provide for patients undergoing each of the diagnostic tests?
7. What are common therapeutic measures for patients with hematological and lymphatic disorders?
8. What is the role of the licensed practical vocational nurse (LVN) in administering blood products?

NORMAL ANATOMY AND PHYSIOLOGY

Blood

The hematologic system comprises the bone marrow, blood, and blood components. The lymphatic system includes the lymph nodes and nodules that destroy pathogens, and lymph vessels that return lymph back to the blood.

The general functions of blood are transportation of oxygen, nutrients, and cellular waste products; regulation of body temperature, pH, and fluid balance; and production of cells that offer the body protection. Specific aspects of these functions are discussed further with the particular part of the blood that is responsible for each.

A human body holds 4 to 6 L of blood; 46 to 63 percent is plasma and the remainder is formed elements. The blood cells are the red blood cells (RBCs or erythrocytes) and white blood cells (WBCs or leukocytes); platelets (thrombocytes) are cell fragments. All of these formed elements are produced by the red bone marrow (RBM), a hematopoietic (blood-producing) tissue found in flat bones, irregular bones, and the epiphyses of long bones. The red bone marrow contains the undifferentiated stem cells that are the precursor cells for all blood cells. Final maturation and differentiation of T lymphocytes occur in the thymus. Table 27.1 shows normal blood cell counts.

Plasma

Plasma is the liquid portion of the blood and is about 91 percent water. It is the transporting medium for nutrients, wastes, hormones, enzymes, electrolytes, and gases. Plasma

proteins include clotting factors, albumin, and globulins. Clotting factors such as prothrombin and fibrinogen are synthesized by the liver and circulate until activated in the clotting mechanism. Albumin, also synthesized by the liver, helps maintain blood volume and blood pressure by pulling tissue fluid into the venous ends of the capillary networks. Alpha and beta globulins are synthesized by the liver to be carrier molecules for substances such as fats, and gamma globulins are the antibodies produced by lymphocytes.

Plasma is also important in maintaining body temperature because blood carries heat. The water of plasma is warmed by passage through active organs, such as the liver or skeletal muscles, and this heat is distributed as blood circulates throughout the body. This process may be visible in people with light skin. The flush of fever or vigorous exercise is caused by vasodilation in the dermis, allowing blood to circulate near the body surface and lose heat. A person in a cold environment may be pale, as vasoconstriction in the dermis keeps blood circulating in the core of the body to preserve heat.

The normal pH range of blood is 7.35 to 7.45, which is slightly alkaline. Chemical buffer systems in the blood prevent sudden fluctuations in pH and contribute to the body's acid-base balance.

Red Blood Cells

Mature RBCs are biconcave disks without nuclei; they carry oxygen bonded to the iron in hemoglobin (Hgb). Oxyhemoglobin is formed in the pulmonary capillaries where the hemoglobin combines with the oxygen in the lungs. Once hemoglobin gives up its oxygen to the cells of the body, it becomes reduced hemoglobin. The amount of hemoglobin

TABLE 27.1 REVIEW OF BLOOD CELL VALUES AND DISORDERS

Test	Normal Value	Significance of Abnormal Findings
Red Blood Cells		
Red blood cells (RBCs)	Male: 4.6–6.2 million/mm ³ Female: 4.2–5.4 million/mm ³	Increased in chronic hypoxia; decreased in anemia or blood loss
Hematocrit (cellular portion of blood)	Male: 40%–54% Female: 38%–47%	Increased in dehydration or chronic hypoxia; decreased in anemia or blood loss
Hemoglobin (reflects oxygen carrying capacity of blood)	Male: 13.5–18.0 g/100 mL Female: 12–16 g/100 mL	Increased in chronic hypoxia; decreased in blood loss or anemia
Reticulocytes (number of circulating immature RBCs)	0%–1.5%	Increased in hypoxia or anemia; decreased in RBC maturation defect
White Blood Cells		
White blood cells (WBCs)	5000–10,000/mm ³	Increased in infection
Neutrophils	54%–75%	Increased in infection
Eosinophils	1%–4%	Increased in allergic response, some leukemias
Basophils	0.5%–1.0%	Increased in hyperthyroidism, some bone marrow disorders, ulcerative colitis
Lymphocytes	25%–40%	Increased in viral infections, chronic bacterial infection, some leukemias
Monocytes	2%–8%	Increased in chronic inflammatory disorders, some leukemias
Platelets		
Thrombocytes/Platelets	150,000–450,000/mm ³	Increased from trauma; decreased with blood disorders; low platelet count causes risk for bleeding.

in RBCs, the amount of iron in that hemoglobin, and the number of RBCs are the determining factors for the amount of oxygen the blood can carry. A lack of iron, hemoglobin, or RBCs can cause anemia, which results in symptoms such as shortness of breath and weakness.

The rate of RBC production by the red bone marrow is most influenced by the blood oxygen level. Hypoxia stimulates the kidneys to secrete erythropoietin, which increases the rate of RBC production and thus the oxygen-carrying capacity of the blood. At such times, immature RBCs (reticulocytes) may be found in greater abundance in peripheral blood. A reticulocyte becomes a mature RBC when it ejects its nucleus. This causes the characteristic biconcave disk shape. Reticulocytes usually remain in the red bone marrow until they mature; their presence in large numbers in peripheral blood indicates an insufficient amount of mature RBCs to meet the oxygen demands of the body.

Sufficient dietary intake of protein and iron to synthesize hemoglobin is also required for normal production of RBCs. The vitamins folic acid and vitamin B₁₂ are necessary for DNA synthesis in the stem cells of the red bone marrow. The continuous mitosis of these cells depends on their ability to produce new sets of chromosomes. Vitamin B₁₂ is also called *extrinsic factor* because it comes from an extrinsic source: food. The parietal cells of the stomach lining produce *intrinsic factor*, which is a chemical that combines with vitamin B₁₂ to promote its absorption in the small intestine.

Red blood cells live for about 120 days and then become fragile and are phagocytized by fixed macrophages in the liver, spleen, and red bone marrow. The iron is returned to the red bone marrow for synthesis of new hemoglobin or is stored in the liver. The heme portion of the hemoglobin is converted to bilirubin, a bile pigment that the liver excretes into bile for elimination in the feces. Diseases such as malaria and sickle cell anemia cause an accelerated destruction of red blood cells. This hemoglobin release may cause the blood level of bilirubin to rise. When the bilirubin level is elevated, it discolors the sclerae, skin, and mucous membranes bright yellow to dark orange, depending on the bilirubin levels. This is known as jaundice.

Each person has a hereditary blood type, which refers to the antigens present on the RBCs. The two most important type categories are the ABO group and the Rh factor. The ABO type (A, B, O, or AB) indicates the antigens present (or not present, as in the case of type O) on the RBCs. In the plasma are antibodies for antigens that are not present in the blood. These antibodies can interact with antigens in transfused blood if the donor's blood does not match the recipient's blood (Table 27.2). To be Rh positive means that the D antigen is present on the RBCs; Rh negative means that the antigen is not present. Rh-negative people do not have natural antibodies to the D antigen but will produce them if given Rh-positive blood.

White Blood Cells

White blood cells are larger than RBCs and have nuclei when mature. The granular WBCs (neutrophils, eosinophils, and basophils) are produced only in the red bone marrow.

TABLE 27.2 ABO BLOOD TYPES

Type	Antigens Present on RBCs	Antibodies Present in Plasma
A	A	Anti-B
B	B	Anti-A
AB	Both A and B	Neither anti-A nor anti-B
O	Neither A nor B	Both anti-A and anti-B

The agranular WBCs (lymphocytes and monocytes) are also produced in the red bone marrow; however the T lymphocytes complete their development in the thymus. The T lymphocytes and B lymphocytes become activated, proliferate, and differentiate in the lymph nodes, spleen, and lymphatic nodules. Table 27.1 shows normal values and percentages for each type of WBC in a differential count. WBCs carry out their functions in tissue fluid, as well as the blood, and all are involved in the immunity or inflammatory response to injury.

Monocytes become macrophages, which phagocytize pathogens and dead tissue; neutrophils are more numerous but phagocytize only pathogens. Eosinophils combat the effects of histamine, detoxify foreign proteins during allergic reactions, and respond to parasitic infections. Basophils release histamine as part of inflammatory reactions. There are two groups of lymphocytes: T cells and B cells. T cells may be helper, suppressor, killer, or memory T cells. B cells become plasma cells, which produce antibodies to foreign antigens and also become memory cells.

Platelets

Platelets are formed in the red bone marrow; they are fragments of large cells called megakaryocytes. Platelets are involved in all mechanisms of hemostasis: vascular spasm, platelet plugs, and chemical clotting.

When a blood vessel is damaged, platelets release serotonin, which promotes contraction of smooth muscle and thereby vasoconstriction of an artery or a vein. Such constriction makes the break smaller; perhaps small enough to be covered by a clot. Constriction also allows the clot to adhere and stop any continued bleeding because it has to cover a smaller area. Capillaries have no smooth muscle and cannot constrict but are so small that breaks can be closed by platelet plugs. Platelets become sticky, adhering to the rough edges of the broken capillary and to one another, eventually forming a platelet plug that stops the bleeding.

Platelets also produce platelet factors, chemicals whose release is stimulated by contact of blood with a rough surface such as a broken or damaged vessel lining. Platelet factors are necessary for the first of the three stages of chemical clotting. In stage 1, platelet factors, clotting factors from the liver, tissue factor (thromboplastin), and calcium ions react to form prothrombinase (also called prothrombin activator). In stage 2, prothrombinase converts prothrombin (synthesized by the liver) into thrombin. In stage 3, throm-

bin converts soluble fibrinogen (also from the liver) to insoluble fibrin, strands which form the clot. Calcium ions are also required for stages 2 and 3.

Excessive clotting in the vascular system is prevented in several ways. The very smooth endothelial lining of blood vessels repels platelets so that they do not stick to intact vessel walls. Heparin produced by mast cells inhibits the clotting mechanism. Antithrombin (synthesized by the liver) inactivates excess thrombin to prevent the clotting mechanism from becoming a vicious cycle.

Lymphatic System

The lymphatic system consists of lymph, the system of lymph vessels, the lymph nodes and nodules, the spleen, and

the thymus. Functions of the lymph system are to return tissue fluid to maintain blood volume and to protect the body against pathogens and other foreign material. (Immunity is covered in Unit 4).

Lymphatic Vessels

Lymph is tissue fluid that has entered lymph capillaries. Lymph must be returned to the blood to maintain blood volume and blood pressure. Lymph capillaries are found in most tissue spaces; they anastomose, forming larger and larger lymph vessels, which have valves to prevent backflow of lymph. Lymph from areas below the diaphragm and the upper left quadrant enters the thoracic duct (in front of the vertebral column) and is returned to the blood in the left subclavian vein (Fig. 27.1). Lymph from the upper right quad-

FIGURE 27.1 System of lymph vessels and major groups of lymph nodes. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA Davis, Philadelphia, 2007.)

rant enters the right lymphatic duct and is returned to the blood in the right subclavian vein.

Lymph Nodes and Nodules

Lymph nodes are masses of lymphatic tissue along the pathways of the lymph vessels. They form activated lymphocytes and monocytes. Nodes are scattered both superficially and deep. As lymph flows through the nodes, the WBCs enter the lymph. Foreign materials are phagocytized by fixed macrophages, and fixed plasma cells produce antibodies to foreign antigens. The major paired groups of lymph nodes are the cervical, axillary, and inguinal nodes. These areas are located at the junction of the head (cervical) and extremities (axillary and inguinal) with the trunk to remove pathogens in the lymph from the extremities before the lymph is returned to the blood.

Lymph nodules are small masses of lymphatic tissue found just beneath the epithelium of all mucous membranes. They are often referred to as mucosa-associated lymphatic tissue (MALT). The body tracts lined with mucous membranes are those that have openings to the environment: the respiratory, digestive, urinary, and reproductive systems. Any natural body opening is a potential portal of entry for pathogens; any pathogens that penetrate the epithelium usually are destroyed by the macrophages in the lymph nodules. The tonsils, which protect the oral and nasal portions of the pharynx, are familiar examples of lymph nodules, although most lymph nodules do not have names.

Spleen

The spleen is located in the upper left quadrant of the abdominal cavity, just below the diaphragm, behind the stomach. The lower rib cage protects the spleen from mechanical injury. In the fetus, the spleen produces red blood cells, a function assumed by the red bone marrow after birth. The spleen has several functions after birth.

The spleen contains B cells and T cells, which conduct immune responses. It also contains fixed macrophages that phagocytize pathogens and worn or defective blood cells and platelets. The heme unit from RBC destruction forms bilirubin. Bilirubin is sent to the liver by way of portal circulation for excretion in the bile. The spleen also stores up to one-third of the body's platelets.

The spleen is not considered a vital organ because other organs compensate for its functions if the spleen must be removed. A person without a spleen is, however, somewhat more susceptible to certain bacterial infections such as pneumonia and meningitis. The liver and red bone marrow remove worn RBCs from the circulation, and the many lymph nodes and nodules produce lymphocytes and monocytes and phagocytize pathogens (as does the liver).

Thymus

The thymus is located inferior to the thyroid gland and anterior to the trachea. With increasing age, the thymus atrophies; relatively little thymic tissue is found in adults. The thymus contains T lymphocytes, or T cells, that mature and proliferate. Thymic hormones contribute to the maturation of the T cells. (Immunity is covered in Unit 4.)

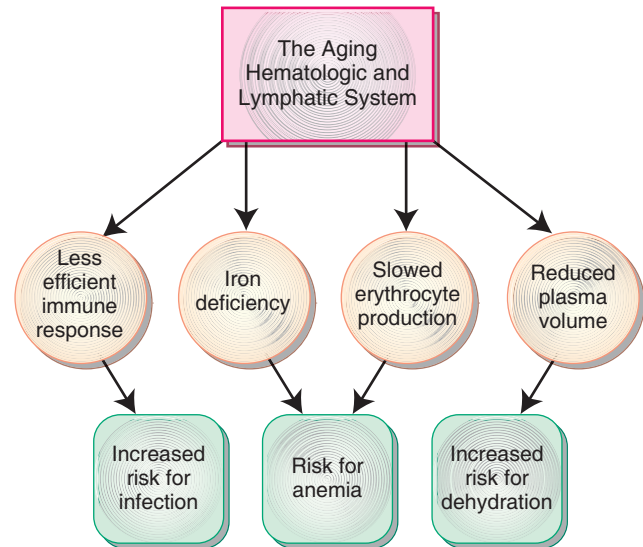

FIGURE 27.2 Effects of aging on the hematologic and lymphatic systems.

Aging and the Hematopoietic and Lymphatic Systems

Older people undergo a number of changes in the hematological and lymphatic systems (Fig. 27.2).

NURSING ASSESSMENT

History

A thorough nursing assessment starts with an in-depth patient history (Table 27.3). Specific problems that might be seen in patients with hematological disorders include abnormal bleeding, **petechiae** (small purplish hemorrhagic spots under the skin), **ecchymoses** (larger areas of discoloration from hemorrhage under the skin), and **purpura** (hemorrhage into the skin, mucous membranes, and organs), as well as fatigue, weakness, shortness of breath, and fever. Fatigue, malaise, and weight loss can accompany cancers of the lymphatic system.

Begin by obtaining the patient's biographical data, marital status, occupation, religion, age, sex, and ethnic background. This information can give you valuable clues to risk factors. For example, even though hemophilia almost always occurs in males, females may carry the gene. Sickle cell anemia occurs mostly in African Americans but also affects people of Mediterranean or Asian ancestry. Pernicious anemia occurs most often in people of northern European ancestry. By carefully collecting this information, you may be obtaining important clues that will help pinpoint the patient's problem. Finally, focus on the assessment of symptoms by using the WHAT'S UP? format presented in Chapter 1.

A complete review of past illnesses and family history is always indicated and can provide some valuable information. The social history is also useful. After developing good

TABLE 27.3 SUBJECTIVE ASSESSMENT OF THE HEMATOLOGIC AND LYMPHATIC SYSTEMS

Category	Questions to Ask During History/Assessment	Rationale/Significance
Reason for seeking health care	<ul style="list-style-type: none"> • Why are you seeking health care? • What has brought you in to see the doctor today? 	Signs and symptoms of hematological/lymphatic disorders may be nonspecific. Any body system can be involved.
Family History	<ul style="list-style-type: none"> • How is the health of your blood relatives? • Does anyone in your family have any blood-related diseases? 	Some blood and immune disorders are hereditary.
Diet History	<ul style="list-style-type: none"> • Describe your usual diet. 	Dietary deficiencies can lead to anemia or altered immune responses.
Medications/Supplements	<ul style="list-style-type: none"> • What medications do you take? • What herbs or alternative therapies do you use? • How much alcohol do you drink each day? 	Herbs and drugs can cause adverse reactions in the blood and immune system. Excess alcohol intake can lead to folic acid–deficiency anemia.
Occupational/Exposure History	<ul style="list-style-type: none"> • What is your occupational history? • What is your military history? 	Exposure to certain hazardous substances can lead to leukemias, other cancers, or anemias.
Fatigue	<ul style="list-style-type: none"> • Have you noticed any change in your energy level? 	Anemia and many cancers are associated with fatigue.
Bleeding Tendency	<ul style="list-style-type: none"> • Have you experienced nosebleeds or any other unusual bleeding? • Have you had bloody or black bowel movements? 	Bleeding may indicate low platelet levels or a clotting factor deficiency.
Respiratory	<ul style="list-style-type: none"> • Do you experience shortness of breath or faintness? 	These are symptoms of anemia.
Integumentary	<ul style="list-style-type: none"> • Have you noticed any changes in your skin? 	Bleeding into the skin or mucous membranes can indicate a bleeding disorder.
Lymphadenopathy	<ul style="list-style-type: none"> • Have you noticed swelling in your neck, armpits, or groin? 	Swollen lymph nodes may indicate inflammation, infection, or some cancers.

rapport with the patient, explore dietary and alcohol intake habits, any drug use or abuse, and sexual habits, all of which may cause changes in the hematological system.

An occupational review may reveal exposure to some hazardous substances that can cause bone marrow dysfunction. Certain occupations, such as working in a paint factory, tool and dye processing, and even dry cleaning can be related to the formation of some hematological cancers. Military information may also reveal sources of exposure that can help during the diagnostic phase for hematological and lymphatic disorders.

Physical Examination

Hematological and lymphatic disorders can involve almost every body system, so each system must be carefully assessed. First, assess vital signs, which can reveal important clues. For example, frequent fevers indicate a poorly functioning immune system. Markedly subnormal temperatures may indicate an overwhelming gram-negative infection when combined with other abnormal assessment data. Heart and respiratory rate abnormalities may indicate decreased blood volume or decreased oxygen supply. Finally, check the level of consciousness; changes may occur with hypoxia, fever, and intracranial bleeding.

An inspection of physical structures most relevant to the blood and lymph systems includes the skin, mucous membranes, fingernails, eyes, lymph nodes, liver, and spleen.

Observe the patient's skin color, noting pallor (indicating anemia), cyanosis (indicating poor oxygenation of RBCs), or jaundice (indicating liver disease or hemolysis). Observe the face, neck, and hands for areas of local inflammation, enlargements, or obvious sites of infection. Check the entire skin surface for purpura or other signs of bleeding, and examine the oral mucosa for color changes and petechiae or ecchymoses. These findings may indicate a bleeding disorder. Other important findings can be obtained with careful examination of the skin to look for dryness and coarseness, which can indicate anemia. Inquire about itching, which may also indicate blood or lymph disorders.

Fingernails can give important clues about the patient's health. For instance, long striations (lines) on the nails or spoon-shaped nails may indicate anemia. Clubbed fingertips and raised nailbeds may indicate long-term hypoxia, which can be caused by anemia or heart disease.

Abdominal assessment should include the use of auscultation, or listening with the stethoscope. Listen intently and try to identify high-pitched, tinkling sounds, which might indicate intestinal obstruction, versus the regular, gurgling, and lower pitched noises normally heard in the intestines. In some cases, you will measure the abdominal girth and record the measurement in the nurse's notes. This baseline measurement might be useful if the patient begins to exhibit abdominal enlargement secondary to ascites or bleeding.

Next, progress to palpation, making sure that the patient is comfortable and that the patient's privacy is protected. Make sure to warm your hands. You can start with an examination of the lymph nodes, although this is more commonly done by a primary care practitioner. The nodes of the neck can be gently palpated with one or two fingers while the patient is sitting. When examining the axillary nodes, the patient may lie down. Nodes that are palpable, with or without **lymphedema**, are not usually normal. Occasionally, normal superficial nodes of 1 cm or less may be palpable. Note the location, size, tenderness, texture, and fixation of the node groups. Enlarged or tender nodes indicate current or previous inflammation. Sternal tenderness may or may not be present. If present, this finding indicates that the bone marrow may be "packed" with an abnormal number and type of cells.

NURSING CARE TIP

If abdominal girth must be monitored for changes, use a marker to identify the site where you measure so it can be measured at the same spot each time.

DIAGNOSTIC TESTS

A number of diagnostic tests can help rule out or confirm a suspected diagnosis based on the analysis of the formed elements of the blood and the bone marrow. Specific studies include a complete blood cell count (CBC), coagulation studies, agglutination studies, bone marrow aspiration, and needle biopsy.

Blood Tests

Examples of laboratory studies routinely done for patients with hematological disorders include CBC, total hemoglobin concentration (Hgb), hematocrit levels (Hct), and platelet levels. (See normal values in Table 27.1.)

Coagulation Tests

Tests in this category include bleeding times, capillary fragility test, prothrombin time (PT), international normalized ratio (INR), partial thromboplastin time (PTT), and thrombin clotting time (TCT) (Table 27.4). Agglutination tests include ABO blood typing, Rh typing, cross matching blood samples, and direct antiglobulin tests (also known as a Coombs' test).

Bone Marrow Biopsy

Biopsy information may be obtained through removal of a small amount of bone marrow with a needle, which in most

lymphedema: lymph—fluid found in lymphatic vessels + edema—swelling

LEARNING TIP

When a patient has a bacterial infection, the neutrophils, which are one type of WBC, rise in number to help fight it. There are two forms of neutrophils: *segmented* (mature) and *bands* (immature). Initially the number of *segmented* neutrophils goes up. Then, as the infection becomes more severe, the number of immature *bands* begins to rise.

An easy way to remember this is that the WBCs are part of the body's defenses, just like the military is part of a country's defenses. When needed, sergeants who are fully trained or mature are called to battle first. If they are unable to fight off the invading enemy, new recruits being trained in boot camp are called in to help.

So *segmented* neutrophils (**S**egs) are like the **S**ergeants, fully mature and ready to fight. The **B**ands are like **B**oot camp recruits, immature and not fully trained. However, in an acute infection, bands are necessary to prevent the body from being overwhelmed by the infection and losing the battle.

As you look at the differential WBC count, if the segs are elevated but the bands are normal, it is probably a new infection. If the bands are also elevated, the infection is worsening. The more elevated they are, the more severe the infection.

Lymphocytes fight viral infections and are elevated during a virus. A common pattern in the WBCs is produced for either a bacterial or viral infection. If the infection is acute bacterial:

Segs ↑ Bands ↑ Lymphocytes ↓

If the infection is viral:

Segs ↓ Bands ↓ Lymphocytes ↑

This can be remembered as the bone marrow producing the cells most needed during the time of viral infection and reducing production of those cells least needed. When the infection is resolved, all the cells should return to their normal production levels.

states must be obtained by a physician. Aspiration of liquid and biopsy of the solid portion of the bone marrow is done to obtain a specimen that can be viewed under the microscope. Purposes of this test include the diagnosis of hematological disorders; monitoring the course of treatment; discovery of other disorders, such as primary and metastatic tumors, infectious diseases, and certain granulomas; and isolation of bacteria and other pathogens by culture.

TABLE 27.4 COAGULATION STUDIES

Test	Normal Value	Significance of Abnormal Findings
Prothrombin time (PT) (affected by activity of clotting factors V, VII, X, prothrombin, and fibrinogen)	Men 9.6–11.8 seconds Women 9.5–11.3 seconds Therapeutic range 1.5–2.0 times normal for patient on warfarin (Coumadin) therapy.	Abnormalities in these values when the patient is not receiving anticoagulant therapy can indicate liver malfunction and bleeding tendency.
International normalized ratio (standardized test adopted by World Health Organization)	<1.3 Therapeutic range 2.0–3.0 for patient on warfarin (Coumadin) (3.0–4.5 for recurrent problems).	
Partial thromboplastin time (PTT) (affected by activity of clotting factors, prothrombin, and fibrinogen)	30–45 seconds Therapeutic range 1.5–2.0 times normal for patient on heparin therapy	
Thrombin clotting time (TCT) (measures time for fibrin clot to form after addition of thrombin)	10–15 seconds Therapeutic range 1.5–2.0 times normal for patient on heparin therapy.	Prolonged TCT indicates fibrinogen deficiency.
Bleeding time (measures time for small puncture wound to stop bleeding)	2.5–9.5 minutes	Prolonged bleeding time indicates a platelet disorder.
Capillary fragility test	Fewer than 10 petechiae appearing in a 2-inch circle after application of a blood pressure cuff at 100 mm Hg for 5 minutes	Tests ability of capillaries to resist rupture under pressure. More than 10 petechiae could be related to fragile capillaries or thrombocytopenia.

CRITICAL THINKING

Mrs. Brown

■ Mrs. Brown is on warfarin (Coumadin) therapy because of a blood clot in her leg. She has a PT drawn at the lab, and the result is 12 seconds. Will the physician most likely increase her daily dose of warfarin, decrease it, or leave it the same? (Use Table 27.4 to figure out the answer.)

Suggested answer at end of chapter.

An accurate bone marrow specimen in an adult can be obtained from the sternum, the spinous processes of the vertebrae, or the anterior or posterior iliac crest. Bone marrow biopsy is considered a minor surgical procedure, and is carried out under aseptic conditions. For iliac crest aspiration, the patient is placed comfortably on the side with the back slightly flexed. The posterior iliac crest is cleansed and covered with antiseptic solution. The skin, the subcutaneous tissue, and the periosteum are anesthetized using 1 or 2 percent lidocaine (Xylocaine). A 2- to 3-mm incision is made to facilitate penetration with a 14-gauge, 2- to 4-cm bone marrow needle. The incision is made to avoid introducing a skin plug into the marrow cavity, which can cause infection.

The nurse's role in bone marrow biopsy is multifaceted. You may need to help coordinate between the laboratory and the physician, establishing a time to do the procedure and determining who obtains the supplies, such

as the disposable bone marrow aspiration tray and specialized needles, from the central supply department. Be sure to obtain an order for an analgesic and administer it before the procedure. You may also help position the patient before and during the procedure, help the patient maintain the necessary position, and observe the aspiration site for bleeding and infection. You can also provide emotional support to the patient before, during, and after the procedure.

SAFETY TIP

Prior to the start of any invasive procedure, conduct a final verification process to confirm the correct patient, procedure, site, and availability of appropriate documents. This verification process uses active, not passive, communication techniques (2006 National Safety Goals from www.jcaho.org).

Lymphangiography

Disorders of the lymph system can be evaluated using lymphangiography. This procedure involves injection of a dye into the lymphatic vessels of the hand or foot. Various x-ray views are then taken to determine lymph flow or blockages. X-ray examinations are repeated in 24 hours to assess lymph node involvement.

Following the procedure, the physician may order a pressure dressing and immobilization of the injected limb to prevent leakage at the site. Continue to monitor the limb for

swelling, circulatory status, and changes in sensation. Warn the patient that the skin, urine, or feces may be blue tinged from the dye for about 2 days.

Lymph Node Biopsy

If a lymph node is enlarged, it may be biopsied to determine whether the cause is infection or malignancy. A biopsy may be done with a needle aspiration or surgical incision. A small dressing or Band-Aid is applied to the site. Following the procedure, review with the patient signs of bleeding and infection that should be reported to the physician.

THERAPEUTIC MEASURES

Blood Administration

Blood may be administered by a registered nurse (RN) or licensed practical/vocational nurse (LPN/LVN), depending on the state in which you practice. Some states require that only RNs administer blood. As an LPN/LVN, you may be called on to assist with proper identification procedures and monitoring of vital signs during the transfusion. Table 27.5 lists blood components that may be ordered. The main goal is to administer them safely and avoid mistakes. Make sure to use proper identifying information to ensure that the right patient is receiving the right blood products. A careful system most often used in health care institutions is outlined next.

Safety Steps

BASELINE ASSESSMENT. Prior to the blood transfusion, it is important to assess the patient's vital signs and history of transfusions or transfusion reactions. Vital signs provide baseline data. If the patient has had a reaction in the past, be sure to alert the physician and the lab before proceeding.

IDENTIFICATION. Safety is the first priority. This includes checking and double checking the patient's identity. Great care is taken in the blood bank to match the donor's blood type with the recipient's blood type. After obtaining the unit of blood from the blood bank but before hanging the unit,

two nurses (according to the state's guidelines) will check the following information at the patient's bedside (Fig. 27.3). Do not take this identification step for granted, because if you make an error and accidentally transfuse blood that does not match the patient's blood type, the results can be fatal.

- Ask the patient to state his or her name and birth date aloud if alert and able to speak.
- Use the patient's identification band to confirm the identity and compare it with the information on the paperwork obtained from the blood bank.
- Examine the blood bag and verify that the patient information and any other information, such as the ABO type, Rh type, and unit number, all match.
- Finally, check the expiration date on the blood bag.

Do not give the unit of blood if any of the information does not match. Notify the blood bank immediately of any discrepancies, and delay the transfusion until the differences are cleared up. Remember, there is no room for error when transfusing blood products.

SAFETY TIP

Use at least two patient identifiers (neither to be the patient's room number) whenever administering medications or blood products (2006 National Safety Goals www.jcaho.org).

FILTERING. Filters are used with blood administration tubing to prevent potentially harmful particles from entering the patient. Most often, the filter that comes with the transfusion tubing is sufficient for each unit of packed RBCs. In some situations, special filters may be needed to remove leukocytes or microaggregates. The blood bank can advise in these situations.

WASHED OR LEUKOCYTE-DEPLETED BLOOD. There are instances when packed RBCs (PRBCs) are ordered as "washed"; often arriving from the blood bank in a round bag.

TABLE 27.5 BLOOD PRODUCTS

Product	Use
Packed red blood cells	Severe anemia or blood loss
Frozen red blood cells	Autotransfusion (blood taken from patient and saved for future surgery), prevention of febrile reactions
Platelets	Bleeding caused by thrombocytopenia
Albumin	Hypovolemia caused by hypoalbuminemia
Fresh frozen plasma	Provides clotting factors for bleeding disorders; occasionally used for volume replacement
Cryoprecipitates	Bleeding caused by specific missing clotting factors

FIGURE 27.3 Two nurses check a patient's identification before administering a unit of blood.

The washing process removes almost all the plasma and can decrease the risk or severity of a febrile reaction. In addition, leukocyte filters may be used to completely remove all WBCs. This removal process is used in cases in which many transfusions are anticipated, and decreases the chance of antigen sensitization. It can also reduce transmission of certain viruses, such as cytomegalovirus.

WARMED BLOOD. If the patient has had a severe bleeding episode and the nurses are helping to give replacement therapy through rapid, multiple transfusions, the physician may consider ordering a blood warmer. It works just as the name implies, warming the cold blood from the blood bank to the standard body temperature of 98.6° F (37.0°C). This warming helps prevent hypothermia, which can cause heart dysrhythmias, or shivering, which can destroy blood cells and platelets.

Administration

GUIDELINES. It is important to use the correct intravenous needle size to infuse blood. The best sizes are 18- and 20-gauge catheters to prevent hemolysis of red blood cells. Make sure to use only normal saline solution to help dilute the blood and to flush the intravenous lines before and after the transfusions. Any other type of fluid or medication may cause the blood product to clump, clot, or not infuse at all. Generally, 2 hours is a good time frame to transfuse each unit of packed cells. If it must transfuse more slowly because of the patient's condition, make sure that the unit does not hang longer than 4 hours to prevent deterioration and bacterial proliferation.

MONITORING. Carefully monitor the patient's response to the transfusion to prevent complications or to detect and treat them quickly if they occur. Stay with the patient for the first 15 minutes of the blood transfusion to assess for any immediate reactions. The 15 minutes begins when the blood enters the vein. If saline is in the tubing, it may take several minutes before the blood reaches the patient. Check and document vital signs before starting the transfusion, after the blood has begun to infuse, and after the infusion is complete. Some institutions require vital sign monitoring every 15 to 30 minutes during the earliest part of the transfusion and then slightly less often for the duration of the infusion. Always follow institution guidelines. During the transfusion, assess the patient for signs and symptoms of transfusion reactions.

Complications

Quick detection of complications may be lifesaving. It is easy to think of transfusing blood components as a routine procedure because it is a common activity. Do not be fooled. It is a serious procedure that can be life threatening if errors occur. Complications include febrile reactions, hypersensitivities, hemolytic reactions, anaphylaxis, circulatory overload, and even death. Regular monitoring according to institution policy can help detect complications early when treatment is most effective.

FEBRILE REACTION. By far the most common reaction is fever (febrile reaction); occurring up to 2 percent of the time. The risk of a febrile reaction goes up with each unit of blood product given to the patient. Many times, febrile reactions occur after the transfusion is completed, but they can occur at any time. This is the reason for obtaining a set of baseline vital signs, including the patient's temperature. Once a febrile reaction begins, the most common signs are an increasing fever and shaking chills, which can be severe. Other symptoms may include headache and back pain. If febrile symptoms occur, stop the transfusion and notify the physician. Acetaminophen may be ordered. If a hemolytic reaction is not suspected, the physician may order the transfusion to continue once the patient is more comfortable. Make sure that the 4-hour hang rule is not violated. Future febrile reactions can usually be prevented by administering leukocyte-depleted blood as described previously.

URTICARIAL REACTION. Urticarial (hive) reactions are considered to be minor allergic reactions and are usually associated with antigens in the plasma accompanying the transfusion. There may be a fever, but the cardinal sign is the appearance of urticaria, a hive-like rash. On discovery of this reaction, stop the transfusion and notify the physician immediately. Expect that the patient will be given a dose of an antihistamine such as diphenhydramine (Benadryl). If the transfusion is restarted, continue to monitor the patient closely. Again, make sure the 4-hour hang rule is not violated.

HEMOLYTIC REACTION. The most deadly and, fortunately, the rarest of the possible reactions is an acute hemolytic reaction. The cause of this reaction is transfusion of incompatible blood. The result is hemolysis (destruction) of RBCs. Generally, this type of serious reaction is noticed within minutes of starting the transfusion. The patient may report back pain, chest pain, chills, fever, shortness of breath, nausea, vomiting, or a feeling of impending doom. As the reaction progresses, the patient begins to show signs of shock, hypotension, oliguria, and decreased consciousness. Late signs and symptoms include those associated with disseminated intravascular coagulation: uncontrollable bleeding from many different sites at the same time, usually ending in death. At the first sign of this type of reaction, immediately stop the transfusion and stay with the patient. Institute emergency procedures to notify the charge nurse, the physician, and the blood bank. The vein is kept open with normal saline using a new administration set (ensuring that no more incompatible blood is administered) so that emergency drugs can be administered. High volumes of fluids are administered to decrease shock and hypotension, and high doses of diuretics are given to promote urine flow because the kidneys are the most likely organs to be damaged. Dialysis may be instituted.

ANAPHYLACTIC REACTION. Anaphylactic reactions are not common but may be seen more often in patients who have received many transfusions or have had many

pregnancies. Usually the source of the anaphylaxis is from sensitization to immune globulins passed from the donor's unit of blood product. In this type of reaction the very first milliliters of blood containing the allergens to pass into the patient's system may be enough to cause the patient to develop respiratory or cardiovascular collapse. Other more common symptoms include severe gastrointestinal cramping, instant vomiting, and uncontrollable diarrhea. If the patient exhibits these signs and symptoms, stop the transfusion at once and stay with the patient. Have someone else notify the registered nurse and the physician, using institutional emergency procedures. Emergency resuscitation measures, including cardiopulmonary resuscitation if necessary, must be instituted until the code team arrives. Expect the patient to be intubated and receive oxygen, steroids, and other drugs as needed for life support. After the emergency has passed, this patient will likely need to receive transfusions from frozen, deglycerolized blood cells.

CIRCULATORY OVERLOAD. Circulatory overload is caused by rapid transfusion in a short period, particularly in older and debilitated patients. Usual signs and symptoms

Box 27.1

Gerontological Issues

Older patients have less cardiac and renal ability to adapt to changes in blood volume, so they have a much higher risk of fluid overload when receiving blood transfusions. Carefully monitor lung sounds and vital signs both before and during a transfusion. New onset of dyspnea, crackles, hypertension, or bounding pulse should be reported to the registered nurse or physician immediately.

include chest pain, cough, frothy sputum, distended neck veins, crackles and wheezes in the lung fields, and increased heart rate. If symptoms occur, stop the transfusion and notify the physician. Anticipate administration of diuretics, which help get rid of the excess fluid. The transfusion may be restarted later at a slower rate (Box 27.1 Gerontological Issues).

REVIEW QUESTIONS

- Clotting factors such as prothrombin are produced by which structure?
 - Red bone marrow
 - Liver
 - Spleen
 - Lymph nodes
- Which of the following best describes the function of erythropoietin?
 - Increase production of platelets to promote clotting
 - Decrease production of platelets to prevent abnormal clotting
 - Increase RBC production to correct hypoxia
 - Decrease RBC production to prevent hypoxia
- Why is the return of tissue fluid to the blood important?
 - To maintain blood clotting
 - To maintain blood volume
 - To promote white blood cell formation
 - To promote red blood cell formation
- Which of the following is the portion of the blood in which cellular elements are suspended?
 - Cytoplasm
 - Platelets
 - Plasma
 - Hemoglobin
- Which of the following actions should the nurse take when caring for a patient with a platelet count of $23,000/\text{mm}^3$?
 - Request an order for an anticoagulant.
 - Protect the patient from injury.
 - Encourage the patient to drink plenty of fluids.
 - No action is necessary. This is a normal level.
- The nurse is assessing a patient and finds small red-purple dots over most of his skin surfaces. The patient says that he has not noticed them before. Which action should the nurse take first?
 - Report the findings immediately to the registered nurse or physician.
 - Document the findings objectively in the medical record.
 - Assist the patient to apply lotion.
 - Administer an antihistamine as needed.
- Which of the following checks should be done prior to initiating a blood transfusion? Choose all that apply.
 - Ask the patient to state his or her name.
 - Verify the correct room number.
 - Check the patient's arm band.
 - Check the identifying information on the unit of blood.
- The nurse is monitoring a patient during a blood transfusion. After the blood has been hanging for 30 minutes, the patient's temperature rises from 98.6°F (37.0°C) at baseline to 101.0°F (38.3°C). The patient also complains of severe chills. Which action should the nurse take first?
 - Document the vital signs in the medical record.
 - Administer acetaminophen for the fever.
 - Notify the physician of the change.
 - Stop the transfusion and hang normal saline.

SUGGESTED ANSWERS TO**CRITICAL THINKING****■ Mrs. Brown**

The physician will most likely increase Mrs. Brown's warfarin dose. Note in Table 23.4 that the PT for a patient on warfarin should be 1.5 to 2.0 times normal.

That is the reason the warfarin is ordered—to prolong the time it takes for blood to clot. If a normal PT is 9.5 to 11.3 seconds, a therapeutic PT for Mrs. Brown would be 14.25 seconds (9.5×1.5) to 22.6 (11.3×2.0). Her result of 12 seconds is not therapeutic.

Nursing Care of Patients with Hematological and Lymphatic Disorders

QUESTIONS TO GUIDE YOUR READING

1. What is the pathophysiology of each of the disorders discussed in this chapter?
2. What are the etiologies, signs, and symptoms of each disorder?
3. What are current therapeutic interventions for each disorder?
4. What data should you collect when caring for patients with disorders of the hematological or lymphatic systems?
5. What nursing care will you provide for patients with hematological disorders?
6. What nursing care will you provide for patients with lymphatic disorders?
7. How will you know if your nursing interventions have been effective?
8. What precautions should you institute to prevent bleeding in patients with clotting disorders?
9. What nursing care and teaching will you provide for patients undergoing a splenectomy?

HEMATOLOGICAL DISORDERS

Patients with hematological disorders have problems related to their blood. Some problems are caused by too many cells, others by too few or defective cells. When red blood cells (RBCs) are affected, oxygen transport is also affected, causing symptoms of poor oxygenation. When white blood cells (WBCs) are affected, the patient is unable to effectively fight infections. If platelets or clotting factors are affected, bleeding disorders occur.

DISORDERS OF RED BLOOD CELLS

Anemias

The term **anemia** describes a condition in which there is a deficiency of RBCs, hemoglobin, or both, in the circulating blood. Because hemoglobin carries oxygen, this results in a reduced capacity to deliver oxygen to the tissues, producing symptoms such as weakness and shortness of breath, which lead the patient to seek medical help.

Pathophysiology

A decrease in the numbers of RBCs can be traced to three different conditions: (1) impaired production of RBCs, as in **aplastic** anemia and nutrition deficiencies; (2) increased destruction of RBCs, as in **hemolytic** or sickle cell anemia; or (3) massive or chronic blood loss. Some anemias are related to genetic problems in certain cultures (Box 28.1 Cultural Considerations). It is important to remember that the general term *anemia* refers to a symptom or a condition secondary to another problem and is not a diagnosis in itself. Different types of anemia are discussed later in this chapter.

Etiologies

DIETARY DEFICIENCIES. Iron, folic acid, and vitamin B₁₂ are all essential to production of healthy RBCs. A deficiency of any of these nutrients can cause anemia. Pernicious anemia is associated with a lack of intrinsic factor in stomach secretions, which is necessary for absorption of vitamin B₁₂. See Box 28.2 Nutrition Notes for more information.

HEMOLYSIS. Hemolysis is the destruction, or lysis, of RBCs. Destruction of RBCs leads to a type of anemia called hemolytic anemia. This may be a congenital disorder or it may be caused by exposure to certain toxins.

OTHER CAUSES. Thalassemia anemia is a hereditary anemia found in persons from Southeast Asia, Africa, Italy, and the Mediterranean islands. Individuals with thalassemia do not synthesize hemoglobin normally. Individuals with

anemia: a—not + emia—blood

aplastic: a—not + plastic—develop

hemolytic: heme—blood + lytic—break down

hemolysis: heme—blood + lysis—dissolution

Box 28.1

Cultural Considerations

In the past, Iranian cross-cousin marriages have resulted in an increased incidence of several forms of anemia and hemophilia. These marriages are now being addressed through genetic counseling and premarital screening for carriers.

A sex-linked genetic disease common in the Chinese is glucose-6-phosphate dehydrogenase (G6PD) deficiency, an enzyme deficiency affecting the person's red blood cells and resulting in anemia. Mediterranean G6PD is common, causing a hemolytic crisis when fava beans are eaten, when aspirin or certain other drugs are taken, or in acidotic or hypoxemic states. Mediterranean-type G6PD deficiency is an inherited disorder most fully expressed in males, with a carrier state in females.

Among Asian Indians, sickle cell disease is highly prevalent; the gene is detected in 16.5 percent of selected populations. Sickle cell anemia is the most common genetic disorder among African American populations. Sickle cell anemia also is found in individuals who live in areas where malaria is endemic, such as the Caribbean, the Middle East, the Mediterranean region, and Asia.

chronic disease also develop anemia (Box 28.3 Gerontological Issues). Additional causes of anemia are discussed under the separate headings of aplastic and sickle cell anemias.

Signs and Symptoms

Symptoms of anemia include pallor, tachycardia, tachypnea, irritability, fatigue, and shortness of breath (Table 28.1). In addition to these symptoms, the patient with pernicious (vitamin B₁₂) anemia may experience numbness of the hands or feet and weakness because vitamin B₁₂ is necessary for normal neurological function. Pernicious anemia is also associated with a sore, beefy red tongue. Patients with iron deficiency may have fissures at the corners of the mouth, an inflamed tongue (**glossitis**), and spoon-shaped fingernails.

Diagnostic Tests

A complete blood cell count (CBC) is done to determine the number of RBCs and WBCs per cubic millimeter. The size, color, and shape of the blood cells are determined by microscopic examination. Hemoglobin and hematocrit are below normal in anemia. Serum iron, ferritin, and total iron-binding capacity measurements are done to diagnose iron deficiency anemia. Serum folate is measured if folic acid deficiency is suspected. A bone marrow biopsy and analysis may also be done.

glossitis: glos—tongue + itis—inflammation

**Box 28.2****Nutrition Notes****Understanding Common Nutritional Anemias**

Nutritional deficiencies can produce some forms of anemia. Nutrients vital to the construction of red blood cells include iron, folic acid, and vitamin B₁₂. Even if the cause of the anemia is dietary, other therapies may be employed in addition to nutritional interventions.

MICROCYTIC ANEMIA. Iron deficiency anemia, the most common nutrient deficiency in the world, is characterized by smaller than normal RBCs. Insufficient intake of iron, excessive blood loss, or lack of stomach acid can lead to iron deficiency anemia. Individuals at greatest risk of iron deficiency are women of childbearing age and young children. Even before frank anemia is seen, cognitive abilities can be impaired. In early iron deficiency, serum transferrin, a blood protein that carries iron, rises in an attempt to increase iron-carrying capacity. Later the hemoglobin and hematocrit levels drop.

Relatively good sources of iron that are commonly included in Western diets are red meat; dark green leafy vegetables; dried fruits; and enriched, fortified, or whole grain products. Foods rich in vitamin C can be used to enhance absorption of iron from nonmeat sources. Likewise, stewing acidic foods such as tomatoes in iron cookware increases their iron content. If iron supplements are given to treat iron deficiency, they should be continued for several months after hemoglobin and hematocrit levels return to normal to enable the body to rebuild iron stores.

MACROCYTIC ANEMIA. Folic acid or vitamin B₁₂ deficiencies produce anemias characterized by larger than normal RBCs. Both these vitamins are necessary for normal RBC production. Folic acid aids in the formation of DNA and heme, the iron-containing portion of hemoglobin. Conditions that increase the metabolic rate increase the need for folic acid. Many drugs, including alcohol, anticonvulsants, and oral contraceptives, interfere with its absorption, metabolism, or excretion and can lead to anemia. Good food sources of folic acid include liver, green

leafy vegetables, legumes, and enriched grain products. Because folic acid markedly decreases the occurrence of fetal neural tube defects such as spina bifida, women capable of becoming pregnant are advised to consume 400 µg of synthetic folic acid from fortified foods or supplements in addition to the folic acid furnished by a varied, balanced diet.

Vitamin B₁₂ is essential for the manufacture of RBCs and for synthesis and maintenance of myelin, the fatty covering of nerves that facilitates rapid transmission of impulses. Vitamin B₁₂ requires a highly specific protein-binding factor called intrinsic factor, secreted by glands in the stomach, to be absorbed. Intrinsic factor and vitamin B₁₂ (also called extrinsic factor) combine in the proximal small intestine to form a complex to transport vitamin B₁₂ to the ileum, where it is absorbed. Extrinsic factor (vitamin B₁₂) is found in foods from animal sources such as meat, fish, shellfish, poultry, and milk. A healthy person eating these foods regularly is not at risk of vitamin B₁₂ deficiency, but strict vegetarians are at risk. Because the deficiency here is dietary, a dietary supplement is the treatment.

In contrast, pernicious anemia is a disease caused by lack of intrinsic factor. Pernicious anemia occurs more frequently in older persons and is attributed to antibodies against gastric parietal cells and intrinsic factor. Extensive gastric resection surgery can also result in insufficient intrinsic factor. Because the deficiency is not dietary, neither is the treatment. Pharmaceutical vitamin B₁₂ is usually given by injection to circumvent the absorption problem. Symptoms of vitamin B₁₂ deficiency are, in usual order of appearance, numbness and tingling in hands and feet followed by RBC changes. Moodiness, confusion, depression, delusions, and overt psychosis appear next. Finally, irreparable nerve damage occurs and eventually death occurs. Because of the neurological damage, vitamin B₁₂ deficiency should be considered in a person being evaluated for dementia.

Patients with pernicious anemia have low gastric acid levels, and many have antibodies to intrinsic factor. Both abnormalities are associated with poor absorption of vitamin B₁₂. If blood loss is suspected, additional tests are done to determine the source of bleeding.

Therapeutic Interventions

Treatment begins with elimination of contributing causes. Intake of the deficient nutrient can sometimes be increased in the diet or administered as a supplement. Changing cooking habits, taking dietary supplements, decreasing alcohol intake, and controlling chronic diarrhea can help correct

folic acid deficiency. If symptoms of anemia are acute, a blood transfusion may be necessary.

Nursing Process for the Patient with Anemia

ASSESSMENT/DATA COLLECTION. Monitor hemoglobin and hematocrit levels and other laboratory studies as ordered and report any downward trend. Monitor responses to therapy. Assess the patient's fatigue level and ability to ambulate safely and perform activities of daily living (ADLs). Monitor degree of dyspnea. Assess for pallor in the skin and conjunctivae.

Box 28.3

Gerontological Issues

Anemia of chronic disease is often diagnosed in an older patient who has an underlying medical condition that causes altered iron metabolism, deficiency of erythropoietin, or shortened life span of red blood cells. Unfortunately, anemia of chronic disease is often mistaken for iron deficiency anemia. Nutritional deficiencies and blood loss are common causes of iron deficiency anemia.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Possible nursing diagnoses are listed below with outcomes and interventions.

Activity intolerance related to tissue hypoxia and dyspnea

EXPECTED OUTCOME: The patient will be able to complete ADLs with minimal assistance.

EXPECTED OUTCOME: The patient will have knowledge about conserving energy.

- Monitor vital signs to evaluate tolerance to activity. *The patient experiencing activity intolerance may have tachycardia, increased respiratory rate, and decreased blood pressure with activity.*
- If the pulse or respiratory rate increases more than 20 percent from baseline during activity, reduce the activity level. *This is evidence that the activity is too strenuous and will result in increased hypoxia and dyspnea.*
- Plan care to conserve energy after periods of activ-

ity. *Balancing activities and rest periods assists the patient to conserve energy.*

- Assist the patient with self-care activities as needed. *Assisting with ADLs helps to decrease the amount of energy expended by the patient.*
- Place articles within easy reach of the patient to reduce physiological demands on the body.
- Encourage the patient to limit visitors, telephone calls, and unnecessary interruptions to conserve energy.
- Administer oxygen as ordered to relieve dyspnea. *The anemic patient does not have enough hemoglobin to carry oxygen to vital organs.*
- Assist with blood transfusion as ordered if hemoglobin levels are very low or symptoms are severe. *A blood transfusion is a quick way to raise hemoglobin levels and to correct severe symptoms.*

Imbalanced nutrition: less than body requirements related to disease, treatment, or lack of knowledge of adequate nutrition

EXPECTED OUTCOME: The patient will be able to appropriately select foods that will meet nutritional requirements.

- Consult a dietitian to provide diet instruction if the anemia is caused by a dietary deficiency.
- Teach the patient with folic acid deficiency that daily requirements can be met by including foods from each food group at every meal. *A balanced diet includes adequate amounts of folic acid.*
- Include foods high in iron for the patient with iron deficiency and to consume iron-rich foods with vitamin C to enhance absorption (see Box 28.2 Nutrition Notes).
- Administer supplements as ordered when dietary intake alone is not sufficient.

TABLE 28.1 CLINICAL MANIFESTATIONS OF ANEMIA

Body System	Mild (Hgb = 10–14 g/dL)	Moderate (Hgb = 6–10 g/dL)	Severe (Hgb <6 g/dL)
Skin	None	None	Pallor, jaundice, pruritus
Eyes	None	None	Jaundiced conjunctivae and sclerae, retinal hemorrhages, blurred vision
Mouth	None	None	Glossitis, smooth tongue
Cardiovascular	Palpitations	Increased palpitations	Tachycardia, increased pulse pressure, systolic murmurs, angina, congestive heart failure, myocardial infarction
Lungs	Exertional dyspnea	Frank dyspnea	Tachypnea, orthopnea, dyspnea at rest
Neurological	None	None	Headache, vertigo, irritability, depression, impaired thought processes
Gastrointestinal	None	None	Anorexia, hepatomegaly, splenomegaly
Musculoskeletal	None	None	Bone pain
General	None	Fatigue	Sensitivity to cold, weight loss, lethargy

- Instruct the patient to take the supplements as ordered by the physician. *The patient should not stop taking the medication until the physician advises him or her to do so.*
- Instruct the patient that vitamin B₁₂ injections are given for lifetime with pernicious anemia *since it is a chronic disease.*
- Instruct the patient with iron deficiency on the correct use of an iron supplement. *An iron supplement should be taken with vitamin C to enhance absorption.*
- Instruct the patient to notify the physician of any side effects related to iron supplements *such as nausea, diarrhea, constipation, and dark stools.*
- Administer intramuscular iron injections by the Z-track method *to avoid staining the injection site.*
- Administer liquid supplements with a drinking straw *to avoid staining the teeth.*

Risk for injury: falls related to weakness and dizziness

EXPECTED OUTCOME: The patient will be safe from injury related to fall.

- Assess the patient at risk for falls using a fall risk assessment tool *to determine risks.*
- Assist the patient to change positions slowly *to decrease dizziness and risk of falls.*
- Assist the patient with ambulation *to prevent a fall.*
- Protect the patient with pernicious anemia from injuries resulting from decreased sensation; i.e., take special care with heating pads and turning and positioning *since the ability to sense pain may be impaired.*

Impaired oral mucous membranes related to altered dietary status

EXPECTED OUTCOME: The patient will have intact oral mucous membranes.

- Provide good oral hygiene *to keep the oral cavity clean and prevent infection.*
- Encourage soft, bland foods, *which are more tolerable until healing can occur.*
- Instruct the patient to use a soft toothbrush for oral care *because it is more gentle until the healing can occur.*

EVALUATION. When successfully treated, the patient will tolerate a normal level of activity without shortness of breath or excess fatigue. The patient should be able to explain the correct treatment plan and therapeutic measures for long-term prevention including dietary choices and supplements as well as self-care measures. The patient will remain free from injury, and oral mucosa will be intact.

Aplastic Anemia

PATHOPHYSIOLOGY. Aplastic anemia differs from other types of anemia in that the bone marrow becomes fatty and incapable of production of the necessary numbers of RBCs. Also known as hypoplastic anemia, the cells that are

produced are normal in size and shape, but there are not enough of them to sustain life. The resulting **pancytopenia** (reduced numbers of all the formed elements from the bone marrow—RBCs, platelets, and WBCs) is the indicator that something is wrong with the bone marrow. Left untreated, aplastic anemia is almost always fatal.

CAUSES. Aplastic anemia may be congenital—that is, the person is born with bone marrow incapable of producing the correct number of cells. Or it may be due to exposure to toxic substances such as industrial chemicals (e.g., benzenes and insecticides), chemotherapy medications, or use of cardiopulmonary bypass during surgery. Other causes include certain bacterial and viral infections, such as tuberculosis and hepatitis.

SIGNS AND SYMPTOMS. The clinical features of aplastic anemia vary with the severity of the bone marrow failure. As with other anemias, early symptoms include progressive weakness, fatigue, pallor, shortness of breath, and headaches. As the disease progresses and the anemia and pancytopenia worsen, other symptoms, such as tachycardia and heart failure, may appear. Ecchymoses and petechiae appear on the skin surface because of the reduced platelet count (Fig. 28.1; also see Fig. 28.5). Blood may ooze from mucous membranes. Puncture sites may progress from oozing to frank bleeding. Often there is overt bleeding into vital organs. Infection occurs owing to reduced WBCs. When aplastic anemia is left untreated, most patients die from infection or bleeding.

DIAGNOSTIC TESTS. The diagnosis of aplastic anemia begins with a CBC. Usually all values are reported as being very low, with the occasional exception of the red blood cell count, in part because of the longer life span of RBCs.

FIGURE 28.1 Petechiae on the skin from thrombocytopenia. (From Goldsmith, LA, et al: *Adult and Pediatric Dermatology*. FA Davis, Philadelphia, 1997, p 61, with permission.)

pancytopenia: pan—all + cyto—cell + penia—poverty

Eventually the RBCs are also depleted. If the patient is having gross bleeding internally or externally, the RBC level can drop rapidly and dramatically. The most definitive test is the bone marrow biopsy. Because the bone marrow is essentially dead, the result is often described as a “dry tap,” in which pale, fatty, yellow, fibrous bone marrow is extracted instead of the red, gelatinous bone marrow normally seen. Not surprising, the more fatty and pale the marrow is, the more dysfunctional it is. Other diagnostic tests include total iron-binding capacity (TIBC) and serum iron level. It is common to find both these levels elevated because the RBCs are not being produced to use up the stores of iron in the production of hemoglobin.

TREATMENT. Early identification of the cause of the anemia and correction of the underlying problem are important to survival. Unfortunately, it is often difficult to determine the cause, and there is no way to reverse the damage already done. Aggressive supportive measures may be the only treatment. Most of these measures are aimed at prevention of infection and bleeding.

Today the most effective treatment for aplastic anemia is bone marrow transplantation (Box 28.4 Patient Perspective). Another common therapy is the administration of steroids to stimulate production of cells in the weakened bone marrow. Occasionally the administration of hormones may work to increase the viability of the marrow. Steroid and other hormone treatments may be tried before attempting a bone marrow transplant.

A new line of therapy is also available. In many treatment institutions, limited success is being obtained with the use of colony-stimulating factors, natural elements now being produced synthetically (Table 28.2). For example, erythropoietin (Epogen) stimulates the production of RBCs and filgrastim (granulocyte colony stimulator [Neupogen]) stimulates the production of WBCs. The major drawback to this type of therapy is the high cost. Many of the pharmaceutical manufacturers have patient access programs that help with the costs of these medications.

NURSING INTERVENTIONS. Nursing care of patients with symptoms related to reduced RBCs was presented earlier under Nursing Process for the Patient with Anemia. If the patient’s platelet count is low (usually less than 20,000), the patient is placed on bleeding precautions (Box 28.5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia). If the white count is low, the patient must be protected from infection (Box 28.6 Interventions for the Patient at Risk for Infection).

Sickle Cell Anemia

PATHOPHYSIOLOGY. Sickle cell anemia is an inherited anemia in which the RBCs have a specific mutation that makes the hemoglobin in the red cells very sensitive to oxygen changes. Any time a decrease in the oxygen tension is sensed, the cells begin an observable physical change process from their usual spherical shape to a sickle or crescent shape (Fig. 28.2). Sickled cells are very rigid and

Box 28.4

Patient Perspective

Bone Marrow Transplant

In June 2002, I took my daughter to the doctor for her sports physical. Later that day, I received a call telling me to take her to the university hospital immediately because she had a serious life-threatening illness. I kept telling myself and my husband that our small-town hospital must have made some sort of error. As it turned out, they had not. My daughter was diagnosed with aplastic anemia and needed a bone marrow transplant. I became obsessed with the illness, poring over every tidbit of medical information I could find. Sometimes I found myself out in the car unable to remember where I was going; sometimes I had to pull over because my eyes were filled with tears and I could no longer see.

My daughter was 16 at the time of her illness, yet it is the parents who sign consent forms and make the choices in care. When the chemotherapy was started and running through the IV tubing, I felt like grabbing the tubing and pinching it off, yelling, “I need more time to think about this decision,” but time was running out. Without a bone marrow transplant, she had about 8 months to live.

After transplantation, my daughter was in an isolation room for a month. I stayed with her every day, and at night I stayed at the inn that was attached to the hospital. If I was needed, I wanted to be no more than a minute away. I was one of the luckier parents because I had the financial means to manage this process. I thought about how horrible it would be if I had other children at home. Sometimes I would have such an urge to run away and escape from it all. I attended support groups that were held on the hospital unit. I got to know a lot of other parents with sick kids, and it became very upsetting to me at times. One day parents told me how well their child was doing; the next day I saw the child’s room empty and thought he must have gone home, only to find out later that he had died during the night. I wondered if my daughter would be next.

I look at my daughter now, 4 years later, alive and perfectly healthy, and I tell myself that I made the right choices for her. But she tells me that, if it happens again, she will not go through chemotherapy. I wonder, is chemo worse than death?

easily cracked and broken. The abnormal shape also causes the cells to become tangled in the blood vessels and organs. The result is congestion, clumping, and clotting.

As red cells are broken, the cellular contents spill out into the general circulation. The resulting increase in the bilirubin level causes jaundice. Gallstones (cholelithiasis) may develop because of the increased amounts of bile pig-

TABLE 28.2 HEMATOPOIETIC GROWTH FACTORS FOR CANCER THERAPY SUPPORT

Medication Class/Action	Example	Route	Side Effects	Nursing Implications
Colony-Stimulating Factors are hormones that stimulate the bone marrow to produce blood cells. They are synthetically produced for specific functions such as proliferation of white blood cells, red blood cells, and platelets.	Filgrastim (Neupogen) Pegfilgrastim (Neulasta) Target production of neutrophils so the patient has a better chance of recovery prior to the next cycle of chemotherapy	IV, subcutaneous Subcutaneous	Bone pain, leukocytosis	The patient may use acetaminophen for the bone pain. Monitor WBC counts until the desired level is achieved. The drug is discontinued once the absolute neutrophil count reaches 10,000/mm ³ .
	Epoetin alfa (Epoen, Procrit) Targets production of red blood cells	IV, Subcutaneous	Hypertension	Monitor the hematocrit and hemoglobin levels. Monitor blood chemistry. It may take up to 8 weeks to see a response to the medication. After 8 weeks, the dose may be increased. Given three times a week.
	Oprelvekin (Neumega) Targets production of platelets. Given for chemotherapy-induced thrombocytopenia to reduce the need for platelet transfusions.	Subcutaneous	Fluid retention, tachycardia, atrial fibrillation, atrial flutter	Monitor complete blood counts including platelet count; fluid and electrolyte status.

ments. The spleen and liver may enlarge because of the increase in retained cells and cellular materials.

Because the cells are fragile, there is a significant decrease in the life span of the RBCs in patients with sickle cell anemia. Normal red cells live about 120 days. Sickled cells survive only about 15 to 20 days, an 80 to 90 percent decrease in cell survival.

ETIOLOGY. Sickle cell disease is an autosomal recessive hereditary disorder. This means that if both parents pass on the abnormal hemoglobin, the child will have the disease. If only one parent passes on the abnormal hemoglobin, the child will have the sickle cell trait and will be able to pass the trait (or the disease if the other parent is also affected) on to his or her child.

In the United States, sickle cell anemia is most often found in those of African or Eastern Mediterranean heritage. Worldwide, many persons residing in Asia, the Caribbean, the Middle East, and Central America are affected. Nearly 10 percent of African Americans have the sickle cell trait; 1 of every 400 African American infants born has inherited the two sets of abnormal genes necessary to have the disease. Symptoms do not appear in infants until after the age of 6 months because up to that age the infant is using hemoglobin manufactured during fetal life, which is not affected by the sickling process.

SIGNS AND SYMPTOMS. The sickling changes just described are a daily occurrence. The rapid return of the oxygen level to normal usually returns the cells to their normal shape.

Occasionally, the sickling process cannot be reversed and the problem continues unabated. This sudden and severe sickling is called a *sickle cell crisis*. As more and more sickling occurs, the blood becomes sluggish and does not flow easily. It tends to collect in the capillaries and veins of the organs of the chest and abdomen, as well as joints and bones, and can cause infarction (tissue necrosis resulting from lack of blood supply). Tissue necrosis results in pain, fever, and swelling.

Factors that contribute to the development of a sickle cell crisis include those related to decreased oxygenation. Some examples include pneumonia with hypoxia, exposure to cold, diabetic acidosis, and severe infection. Sickle cell anemia presents problems for the patient who needs surgery. Anesthesia and blood loss during surgery and postoperative dehydration can trigger a crisis.

Common symptoms produced during sickle cell crises include severe pain and swelling in the joints, especially of the elbows and knees, as the sickled cells impede circulation. Abdominal pain is common with swelling of the spleen and engorgement of the vital organs. Hypoxia occurs as fever and pain increase, causing the patient to breathe rap-

Box 28.5**Interventions to Prevent Bleeding in the Patient with Thrombocytopenia**

- Use an electric razor instead of a safety razor for shaving.
- Use a soft toothbrush or gauze to clean the teeth. Avoid flossing.
- Avoid invasive procedures as much as possible, including enemas, douches, suppositories, and rectal temperatures.
- Avoid intramuscular injections.
- To avoid injury when checking blood pressure, pump cuff up only until pulse is obliterated.
- Avoid blood draws whenever possible. Use established access sites or group draws into once daily.
- Maintain pressure on intravenous (IV), blood draw, and other puncture sites for 5 minutes.
- Encourage use of shoes or slippers when out of bed.
- Keep area clutter free to prevent bumps and bruises.
- Avoid use of drugs that interfere with platelet function, such as aspirin products and nonsteroidal anti-inflammatory drugs.
- Administer stool softeners as ordered to prevent straining to have a bowel movement.
- Move and turn patient gently to avoid bruising.
- Instruct patient to avoid blowing the nose.

idly. The male patient may have a continuous, painful erection (priapism) from impaired blood flow through the penis. Symptoms of renal failure are common as circulation is slowed and the kidneys become clogged with cellular debris.

Repeated crises and infarctions lead to chronic manifestations such as hand-foot syndrome, an unequal growth of fingers and toes from infarction of the small bones in the hands and feet (Fig. 28.3). Additional manifestations of sickle cell disease are shown in Figure 28.4.

The patient with sickle cell anemia has impaired quality of life. Often, strenuous exercise or more exotic activities, such as scuba diving, are impossible because of the risk of crisis. Dehydration exacerbates the symptoms of sickle cell disease. Crises may occur without any apparent cause. In general, crises last from 4 to 6 days. They may occur in cycles close together for a time and then may become dormant for months to years. The cause of death in patients with sickle cell anemia is usually infection, stroke, or organ involvement.

DIAGNOSTIC TESTS. The most telling feature of sickle cell disease is a blood smear that shows sickle-shaped RBCs in circulation. The Sickledex test is a screening test that shows sickling of RBCs when oxygen tension is low.

Box 28.6**Interventions for the Patient at Risk for Infection**

- Place the patient in a private room.
- Assure that all personnel and visitors wash hands before entering the room.
- Teach the patient to wash hands before and after using the toilet and before and after eating.
- Teach the patient and family to wash hands before touching.
- Prevent staff or visitors with known infections from entering the patient's room.
- Teach the patient to not handle flowers or plants brought into the room.
- Teach the patient to avoid raw fruits, vegetables, and milk products.
- Avoid use of Foley catheters and other invasive devices.
- Use strict aseptic technique if invasive procedures are necessary.
- Use acetaminophen if an antipyretic is necessary; aspirin may induce bleeding.

Hemoglobin electrophoresis is a test used to determine the presence of hemoglobin (Hgb) S, the abnormal form of hemoglobin. Also, there is a decreased amount of hemoglobin, a lowered RBC count, an elevated WBC count, and a decreased erythrocyte sedimentation rate.

TREATMENT. No cure is available for sickle cell anemia. Treatment is aimed at patient education to prevent crises and supportive care when crises occur. Some patients may be placed on low-dose oral penicillin to help prevent infections, decreasing the risk of crises.

During acute crises, the patient is admitted to the hospital for 5 to 7 days. The nurse can anticipate that the patient will require sedation and analgesia for severe pain and blood transfusions to replace the sickled red cells lost by their being caught, crushed, and destroyed. Oxygen therapy decreases the dyspnea caused by the anemia, and large

FIGURE 28.2 Sickled cells in sickle cell disease.

FIGURE 28.3 Hand-foot syndrome. Note different lengths of fingers and toes. (Courtesy Sandoz Pharmaceutical Corp., East Hanover, NJ)

amounts of oral and intravenous fluids are given to flush the kidneys of the by-products of the many broken cells' debris. Antibiotics are used to treat infection that may have triggered the crisis.

New treatments are being developed to treat sickle cell disease. Frequent blood transfusions, often monthly, are one of the newest treatment recommendations. Hydroxyurea (Droxia) is a drug that has been shown to decrease crises, but it can cause life-threatening side effects; it should also be used with caution in female patients of

childbearing years because of the risk of birth defects. Corticosteroids may reduce the need for analgesics and oxygen. Bone marrow transplantation is also being investigated as a potential cure.

NURSING PROCESS: SICKLE CELL ANEMIA. Assessment/Data Collection. In the patient in crisis, assess circulation in the extremities every 2 hours, including pulse oximetry, capillary refill, peripheral pulses, and temperature. Frequent pain assessment is also necessary.

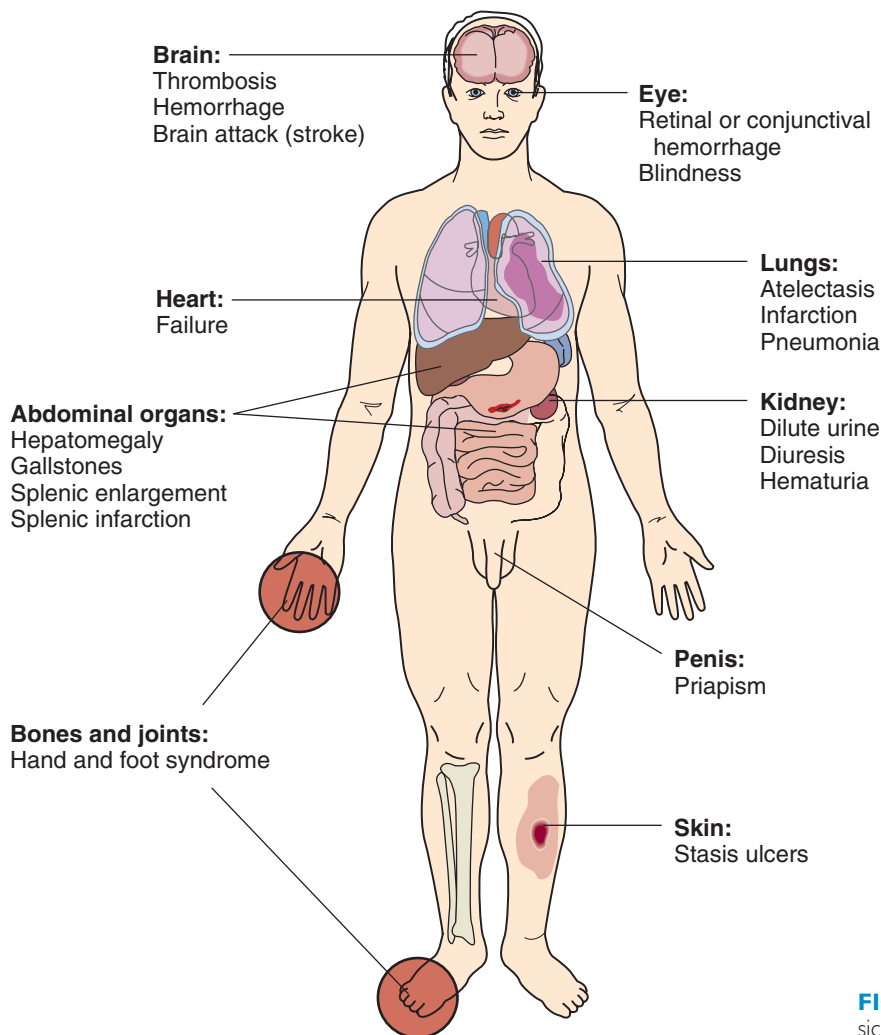

FIGURE 28.4 Clinical manifestations of sickle cell anemia.

Nursing Diagnosis, Planning, and Implementation

Risk for ineffective tissue perfusion related to sickled cells and infarction

EXPECTED OUTCOME: Patient will have adequate tissue perfusion as evidenced by presence of peripheral pulses, warm extremities, urine output within normal limits, and capillary refill less than 3 seconds.

- Encourage oral fluids, and assist the registered nurse (RN) to monitor intravenous (IV) fluids to dilute and aid in elimination of cell debris.
- Apply warm compresses as ordered to the painful areas, cover the patient with a blanket, and keep the room temperature above 72°F (~22°C) to reduce the vasoconstricting effects of cold.
- Avoid cold compresses because they decrease circulation and increase the number of sickled cells caught in a painful area.
- Avoid restrictive clothing and raising the knee gatch of the bed. These can restrict circulation.

Acute pain related to tissue infarction

EXPECTED OUTCOME: Patient will state pain is controlled at acceptable level.

- Administer opioid analgesics such as morphine as ordered for acute pain. (Analgesics may be given intravenously by the RN or by use of patient-controlled analgesia.)
- Administer acetaminophen (Tylenol) to control fever.
- Avoid giving aspirin because it may increase acidosis, which can worsen the crisis.
- Encourage bedrest during the acute phase of the crisis to reduce oxygen demand.

Evaluation. If nursing care has been effective, the patient will state that he or she is comfortable, and will not exhibit signs of poor circulation.

PATIENT TEACHING. During remission, teach the patient how to prevent acute episodes. Advise the patient to avoid tight-fitting clothing that restricts circulation. Also encourage the patient to avoid strenuous exercise, which increases oxygen demand, and cold temperatures and smoking, which cause vasoconstriction. Alcoholic beverages can also trigger a crisis and should be avoided. Patients should never fly in unpressurized aircraft or undertake mountain climbing or other sports that can cause hypoxia. Encourage patients to get a pneumococcal vaccine and

yearly flu vaccine. Encourage fluids to maintain hydration and reduce blood viscosity. Genetic counseling is important to prevent passing on the trait or disease to children. For more information, visit www.sicklecelldisease.org.

Polycythemia

Pathophysiology and Etiology

Polycythemia is really two separate disorders that are easily recognizable by similar characteristic changes in the RBC count. In both forms of polycythemia, the blood becomes so thick with an overabundance of RBCs that it closely resembles sludge. This thickness does not allow the blood to circulate easily. Laboratory tests show a hemoglobin level greater than 18 mg/dL, the RBC mass greater than 6 million, and a hematocrit more than 55 percent.

Polycythemia vera (PV) is known as primary polycythemia. Its cause is unknown. In PV, the RBCs, platelets, and WBCs are all overproduced, and the bone marrow becomes packed with too many cells. As this overabundance of cells spills out into the general circulation, the organs become congested with cells and the tissues become packed with blood. The skin takes on a plethoric (dark, flushed) appearance from the build-up of red cells. The thick blood and excess platelets can cause thrombosis and occlusion of vessels. PV is usually found in patients over age 50.

In contrast, secondary polycythemia is the result of long-term hypoxia. Common coexisting conditions that may predispose a patient to develop secondary polycythemia include pulmonary diseases such as chronic obstructive pulmonary disease (COPD), cardiovascular problems such as chronic heart failure, living in high altitudes, and smoking. The body makes more red cells in response to the low oxygenation associated with these conditions. Secondary polycythemia is a compensatory mechanism rather than an actual disorder.

Signs and Symptoms

The patient with PV commonly presents with hypertension, visual changes, headache, vertigo, dizziness, and ringing in the ears (tinnitus). Laboratory results show an increased level of all the bone marrow components (RBCs, WBCs, platelets), which is called **panmyelosis**. The patient may exhibit nosebleeds and bleeding gums, retinal hemorrhages, exertional dyspnea, and chest pains because of the increased pressure exerted by the excess cells. The patient with PV usually has a dark, flushed complexion. Intense itching is related to excess mast cells (and, therefore, histamine) in the skin. Abdominal pain with an early feeling of fullness with meals occurs because of the enlarged liver and spleen. Nearly all the symptoms in PV are due to the major problems of hypervolemia, hyperviscosity, and engorgement of capillary beds. Without treatment, patients with PV die of thrombosis or hemorrhage.

Treatment

Treatment of PV takes place in two stages. The first stage is to decrease the hyperviscosity problem. The most common

SAFETY TIP

Develop and implement a protocol for administration and documentation of the flu and pneumococcal vaccines (2006 National Patient Safety Goals from www.jcaho.org).

first-line treatment is therapeutic **phlebotomy**. Phlebotomy involves withdrawal of blood, which is then discarded. From 350 to 500 mL of blood are removed each time on an every-other-day basis, with the goal being a hematocrit of about 45 percent. This reduces the RBC levels, and the patient usually feels more comfortable quickly. Repeated phlebotomies eventually cause iron deficiency anemia, which in turn stabilizes RBC production; phlebotomies can then be reduced to every 2 to 3 months.

The problem that remains is the increased white blood cell and platelet counts because phlebotomy does very little to correct these overloads. Chemotherapeutic agents or radiation therapy, including radioactive phosphorus, may be used to suppress production of blood cells in some patients. **Leukemia** is a side effect of this therapy, so it is used only if the benefits outweigh the risks.

Nursing Care

Explain the phlebotomy procedure and reassure the patient that the treatment will relieve the most distressing symptoms. The procedure is the same as that used for donating blood. The patient should be active and ambulatory to help prevent thrombus formation. When bedrest is necessary, passive and active range-of-motion exercises should be implemented. Monitor the patient for complications such as hypovolemia and bleeding. Advise the patient to report any signs or symptoms of bleeding immediately.

If the patient has more advanced manifestations, such as an enlarged liver or spleen, offer several small meals each day so that the patient will be more comfortable while still receiving adequate nutrition. A dietitian can be consulted to discuss ways to maintain good nutrition. If the patient is on drug therapy, monitor CBC and platelet counts.

Patient Education

Instruct the patient to drink at least 3 L of water daily to reduce blood viscosity. Encourage avoidance of tight or restrictive clothing and elevation of feet when resting to prevent impairment of circulation. Use of support hose when active also promotes circulation. If anticoagulants or antiplatelet agents are ordered, instruct the patient about side effects to watch for and the importance of routine laboratory tests. Routine bleeding precautions are implemented (see Box 28.5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia). Warn the patient to stop activities at the first sign of chest pains. Instruct the patient to report chest pain, increased joint pain, decreased activity tolerance, or fever, as well as signs of iron deficiency anemia, such as pallor, weight loss, and dyspnea.

HEMORRHAGIC DISORDERS

Disseminated Intravascular Coagulation

Pathophysiology

Disseminated intravascular coagulation (DIC) involves a series of events that result in hemorrhage.

As its name implies, this syndrome is a catastrophic, overwhelming state of accelerated clotting throughout the peripheral blood vessels. In a short period, all the clotting factors and platelet supplies are exhausted and clots can no longer be formed. This results in bleeding from nearly every bodily route possible. DIC is not a disease but is a syndrome that develops secondary to some other severe physical problem. Once this deadly syndrome develops, the progression of symptoms is rapid.

Massive clotting in blood vessels leads to organ and limb necrosis. Organs most often affected include the kidneys and the brain, but other blood-engorged organs, such as the lungs, the pituitary and adrenal glands, and the gastrointestinal mucosa, are commonly involved. DIC is usually acute in onset, although in some patients it becomes a chronic condition. The prognosis depends on early diagnosis and intervention and the severity of the hemorrhaging. DIC has a very high mortality rate.

Etiology

DIC can develop after any condition in which the body has sustained major trauma. The sources of trauma are varied and can include an overwhelming infection; obstetric complications such as abruptio placentae, amniotic fluid embolism, or a retained dead fetus; or cancer-related causes such as acute leukemia or lung cancer. Massive tissue necrosis found in severe crush or burn injuries may increase the risk for development of DIC. Tissue necrosis secondary to extensive abdominal surgery with leakage of the intestinal contents can be related to DIC onset. Rarer causes of this condition have included heat stroke, shock, and poisonous snakebites, as well as fat embolism secondary to broken long bones.

Signs and Symptoms

Abnormal bleeding without a history of a serious hemorrhagic disorder is a cardinal sign of DIC. Early signs of bleeding include petechiae, ecchymoses (Fig. 28.5), and bleeding from venipuncture sites. Bleeding may progress to IV sites, skin tears, surgical sites, incisions, and the gastrointestinal tract and oral mucosa. Pain and enlargement of joints develop if bleeding into the joints occurs. All these signs and symptoms may occur at the same time. Massive bleeding may also be accompanied by nausea, vomiting, dyspnea, oliguria, convulsions, coma, shock, major organ system failure, and severe muscle, back, and abdominal pain.

Diagnostic Tests

Initial laboratory findings in DIC include a prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased platelet count, and increased evidence of fibrin degradation products. A decrease in hemoglobin is the result of spilled hemoglobin from the increased numbers of broken red cells. Blood urea nitrogen (BUN) and serum creatinine levels may also be increased. See Table 28.3 for laboratory findings specific for DIC.

Therapeutic Interventions

Effective treatment of DIC depends on early recognition of the condition. Treatment is first aimed at correcting the

FIGURE 28.5 Extensive hemorrhage into the skin in DIC. Note how the area is outlined in pen so the nurse can assess if the area is spreading. (From Harmening, DM: *Clinical Hematology and Fundamentals of Hemostasis*, ed 3. FA Davis, Philadelphia, 1997, p 520, with permission.)

underlying cause. Additional treatment consists of supportive interventions, including administration of blood, fresh frozen plasma, and platelets and the infusion of cryoprecipitate (containing clotting factors) to support hemostasis. Some health-care organizations include the use of intravenous heparin to help prevent the initial microembolization, but this practice is controversial. Additional therapies are being investigated.

Nursing Care

Care of the patient with DIC is a nursing challenge. Early intervention requires early recognition and reporting of signs of bleeding. In addition to supportive care, focus on the prevention of further bleeding episodes. Care should be taken to avoid any trauma that might cause bleeding. Be careful not to dislodge clots from any site because another clot may not form and the patient will hemorrhage. See Box

TABLE 28.3 LABORATORY ABNORMALITIES IN DISSEMINATED INTRAVASCULAR COAGULATION

Screening Test	Finding
Prothrombin time (PT)	Prolonged
Partial thromboplastin time (PTT)	Prolonged
Activated partial thromboplastin time (APTT)	Prolonged
Thrombin time (TT)	Prolonged
Fibrinogen	Reduced
Platelets	Reduced
Fibrin split products (FSP; also known as fibrin degradation products [FDP])	Elevated
Protamine sulfate	Strongly positive
Dimers (cross-linked fibrin fragments)	Elevated
Antithrombin III	Reduced
Factor assays (for factors V, VII, VIII, X, and XIII)	Reduced

28.5 (Interventions to Prevent Bleeding in the Patient with Thrombocytopenia) for bleeding precautions.

SAFETY TIP

Measure, assess and, if appropriate, take action to improve the timeliness of reporting, and the timeliness of receipt by the responsible licensed caregiver, of critical test results and values (2006 National Patient Safety Goals from www.jcaho.org).

Patient Teaching

Because a patient with DIC is often cared for in the intensive care unit, there are many chances for patient and family teaching. Explain all diagnostic tests to the patient if he or she is alert. If not, keep the family informed. A large part of family education is preparing the family for what the patient may look like in terms of bleeding and bruising, as well as specific equipment that may be in place, such as IV lines, a nasogastric (NG) tube, and a Foley catheter. It may be helpful to enlist the aid of social workers, chaplains, and other members of the health-care team to help support the family.

CRITICAL THINKING

Mrs. Johns

■ Mrs. Johns is admitted to your unit with DIC following the difficult delivery of her new baby.

1. What will you assess as you care for Mrs. Johns?
2. What treatment do you anticipate?
3. What concerns is Mrs. Johns likely to have?
4. Mrs. Johns is to receive IV fresh frozen plasma 300 mL over 30 minutes. How many milliliters per hour should be set on the IV controller?

Suggested answers at end of chapter.

Idiopathic Thrombocytopenic Purpura

Pathophysiology and Etiology

Acute **idiopathic thrombocytopenic purpura** (ITP) results from increased platelet destruction by the immune system. Any time platelet numbers are reduced, the risk for bleeding increases. Acute ITP usually affects children between the ages of 2 and 6, whereas chronic ITP mainly affects adults younger than age 50. The population most affected is women between ages 20 and 40.

Acute ITP usually occurs after an acute viral illness such as rubella or chickenpox. It may also be drug induced

idiopathic thrombocytopenic purpura: idio—unknown + pathic—disease + thrombo—clot + cyto—cell + penic—lack + purpura—hemorrhage in the skin

or associated with pregnancy. ITP is generally thought to be related to an immune system dysfunction. Antibodies responsible for platelet destruction have been found in nearly all diagnosed patients.

Signs and Symptoms

ITP produces clinical changes that are common to all forms of **thrombocytopenia**: petechiae, ecchymoses, and bleeding from the mouth, nose, or gastrointestinal (GI) tract. Bleeding may occur in vital organs, such as the brain, which may prove fatal. In the acute type, onset may be sudden and without warning, causing easy bruising, nosebleeds, and bleeding gums. Onset of chronic ITP is usually insidious.

Diagnostic Tests

A platelet count of less than 20,000/mm³ and a prolonged bleeding time suggest ITP. The greatly decreased platelet level places the patient at serious risk for hemorrhage. Examination of the platelets under the microscope shows them to be small and immature. Anemia may be present if there has been a bleeding episode. If a bone marrow aspiration is performed, the results show an adequate amount of the precursor cells for platelets, the megakaryocytes. However, instead of the 7- to 10-day life span that platelets usually have, these immature platelets have a life span of just a few hours.

Treatment

Most cases of acute ITP resolve spontaneously without treatment. Initial treatment, if necessary, is often the administration of steroids. The purpose of the steroids is to prolong the life of the platelets and strengthen the capillaries, making them less likely to break and cause bleeding. Some physicians order the use of chemotherapeutic drugs. The spleen may be removed because it is the primary site involved in platelet destruction. Often the patient undergoing splenectomy has tried all other courses of treatment unsuccessfully and may be experiencing bleeding episodes. Acute bleeding episodes are treated with transfusions of blood, platelets, and vitamin K.

Nursing Interventions

Care for the patient with ITP is the same as any patient with a bleeding disorder. See Box 28.5 (Interventions to Prevent Bleeding in the Patient with Thrombocytopenia) for bleeding precautions. Teach the patient to watch for and report signs and symptoms of bruising and bleeding (Box 28.7 Patient Teaching: Signs and Symptoms of Bleeding). The patient should avoid trauma and restrict activity during severe episodes.

Hemophilia

Hemophilia is a group of hereditary bleeding disorders that result from a severe lack of specific clotting factors. The two most common are hemophilia A (classic hemophilia) and

thrombocytopenia: thrombocyte—platelet + penia—lack

hemophilia: hemo—blood + philia—to love

Box 28.7

Patient Teaching: Signs and Symptoms of Bleeding

Notify your health care provider if the following occur:

- Easy bruising of skin
- Petechiae (small red spots on skin)
- Blood in urine
- Black tarry stools
- Bleeding from nose or gums
- New onset of painful joints

hemophilia B (Christmas disease). Von Willebrand's disease is another related bleeding disorder, but it represents a minority of cases and is not discussed in this chapter.

Pathophysiology

Recall that many different clotting factors make up the clotting mechanism. Hemophilia A accounts for 80 percent of all types of hemophilia and results from a deficiency of factor VIII. Hemophilia B is a factor IX deficiency; approximately 15 percent of persons with hemophilia have this type. The severity and prognosis of hemophilia depend on the degree of deficiency of the specific clotting factors. Mild hemophilia has the best prognosis because it does not cause spontaneous bleeding and joint deformities as severe hemophilia can.

After an injury, the person with hemophilia forms a platelet plug (which differs from a clot) at the site of an injury as would normally be expected, but the clotting factor deficiency keeps the patient from forming a stable fibrin clot. Continued bleeding washes away the platelet plug that initially formed. Contrary to popular myths, people with hemophilia do not bleed “faster” and are not at risk from small scratches.

Etiology

Hemophilia A and B are inherited as X-linked recessive traits. This means that the female carrier (daughter of an affected father) has a 50 percent chance of transmitting the gene to each son or daughter. Daughters who receive the gene are carriers, and sons who receive the gene are born with hemophilia. It is technically possible for daughters to be affected with hemophilia, although it is very rare.

Signs and Symptoms

Bleeding occurs as a result of injury or, in severe cases, spontaneously (unprovoked by injury). Bleeding into the muscles and joints (**hemarthrosis**) is common. Severe and repeated episodes of joint hemorrhage cause joint deformities, especially in the elbows, knees, and ankles, which decrease the patient's range of motion and ability to walk.

In mild hemophilia, excessive bleeding is usually associated only with surgery or significant trauma. However,

hemarthrosis: hem—bleeding + arthr—joint + osis—condition

once a person with mild hemophilia begins to bleed, the bleeding can be just as serious as that of the patient with a more severe form.

The patient with moderate hemophilia has an occasional bout of spontaneous bleeding. In severe hemophilia, spontaneous bleeding occurs more frequently. It would be possible for the patient to develop hemarthrosis or bleeding into the brain without any precipitating trauma. Severe episodes can produce large subcutaneous and deep intramuscular hematomas. Major trauma can cause bleeding so severe that it becomes life threatening.

Another unfortunate problem related to hemophilia treatment is the frequent need to replace clotting factors and other blood products. Before 1986, blood banks and other centers did not routinely test for human immunodeficiency virus (HIV) antibodies. Depending on the patient's age and frequency of treatment, many patients may have been exposed to HIV or hepatitis. Blood banks and pharmacies have checked their blood supplies for the presence of HIV since 1986. Today, the plasma proteins are artificially created or thoroughly cleansed to prevent transmission of disease.

Diagnostic Tests

Laboratory data reveal a prolonged PTT. The various factor levels are measured to determine which is missing. Once the missing factor is identified, the type of hemophilia is determined and necessary treatments can be implemented.

Therapeutic Interventions

Hemophilia is not curable. However, treatment advances have improved outcomes and many patients can now live a normal life span. Treatment is aimed at the prevention of crippling deformities and at increasing life expectancy. Treatment involves stopping bleeding episodes by administering the missing clotting factors. Hemophilia A is treated with factor VIII; hemophilia B is treated with factor IX. Each is available in a freeze-dried powder that is reconstituted with water and administered intravenously. The newest treatment employs factors made using recombinant DNA technology without the use of any human blood products. Blood transfusions are uncommon but may be necessary after severe trauma or surgery.

Complications related to therapy usually occur when therapy is started too late. Minor trauma generally needs to be treated with at least 72 hours of added clotting factors; major traumas and surgeries may require up to 14 days of added factors to prevent sudden bleeding. Health-care workers should pay careful attention to the patient who says that bleeding is starting even when no outward signs are evident. The patient usually knows from experience if bleeding is starting. If treatment is delayed at this time, the results can be disastrous. Some patients with severe disease are treated prophylactically to prevent bleeding.

Nursing Process: Hemophilia

ASSESSMENT/DATA COLLECTION. Because one goal is prevention of bleeding episodes, assess the patient and family for knowledge of the disease and its treatment and

understanding of preventive measures. Most patients care for themselves at home, starting their own IVs and administering treatment independently. Hospitalization is necessary only for surgery or major trauma. During an acute episode of bleeding, the hemoglobin and hematocrit are carefully monitored. Factor VIII or IX levels are monitored to determine if factor replacement has reached adequate levels. Vital signs are monitored for falling blood pressure and rising pulse rate, which are signs of hypovolemic shock. All body systems are assessed for signs of bleeding (see Box 28.7 Patient Teaching: Signs and Symptoms of Bleeding). A pain assessment is done using the WHAT'S UP? format.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Pain related to bleeding into tissues

EXPECTED OUTCOMES: The patient will verbalize that pain is relieved to a satisfactory level..

- Have the patient report the location, intensity, and quality of the pain. *Assessment of the pain provides the caregiver with data for treatment plan.*
- Administer opioids as prescribed including patient-controlled analgesia. *Analgesics are the primary way to manage moderate to severe pain.*
- Avoid the administration of intramuscular injections because of the risk of bleeding into the muscle, which would cause more pain.
- Reassess the level of pain within 1 hour after administration of analgesia to determine the effectiveness of the treatment ordered.
- Monitor sedation and respiratory status of the patient receiving opioids for pain. *Opioids depress the respiratory center of the brain.*

Ineffective protection: Risk for bleeding related to factor deficiencies

EXPECTED OUTCOMES: The patient will not have evidence of bleeding. The patient will verbalize understanding of bleeding precautions.

- Instruct the patient on bleeding precautions noted in Box 28.5 (Interventions to Prevent Bleeding in the Patient with Thrombocytopenia). *Identification of signs of bleeding will promote early intervention to prevent injury.*
- Assist with administration of factor concentrates, fresh frozen plasma, cryoprecipitate, blood, or a combination of these as ordered to treat acute episodes of bleeding. *See Chapter 27 for transfusion of blood products.*
- Apply ice or pressure on bleeding sites to help slow bleeding.
- Avoid intramuscular, subcutaneous, or rectal medications. *These routes can cause bleeding into tissues.*
- Instruct the patient that preventive care will be needed if surgery or dental procedures are needed. *These invasive procedures can be life-threatening events for the patient with hemophilia.*

Risk for ineffective management of therapeutic regimen related to knowledge deficit

EXPECTED OUTCOME: The patient will be able to discuss hemophilia and the treatment regimen required.

- Assess knowledge base and determine readiness to learn and incorporate new information. *Each patient is unique in the way that they learn new information.*
- Instruct the patient on ways to prevent bleeding and recognition of signs and symptoms of bleeding (Boxes 28.5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia and 28.7 Patient Teaching: Signs and Symptoms of Bleeding). *Identification of signs of bleeding will promote early intervention to prevent injury.*
- Instruct the patient to obtain emergency care in the event that bleeding occurs. *Intervention is critical for survival for acute bleeding.*
- Instruct the patient to administer factor treatments at home. *Treatment can often be administered at home and can be given more promptly if a trip to the emergency department is not necessary.*
- Instruct patients and families on the community services and hemophilia treatment centers available to the patient. *These centers are nationwide and coordinate care for patients with hemophilia.*
- Instruct the patient that the approach to care is multidisciplinary in nature and includes social services, dental, rehabilitation, nursing, financial, and medical needs. *These are all areas that impact the care of the patient with hemophilia.*

EVALUATION. If interventions have been effective, the patient will be comfortable and bleeding will be prevented or complications minimized. The patient and family will be able to state appropriate measures to prevent and treat bleeding episodes. The patient will be knowledgeable about the resources available to cope with the diagnosis of hemophilia.

SAFETY TIP

Encourage the active involvement of patients and their families in the patient's care as a patient safety strategy (2006 National Patient Safety Goals www.jcaho.org).

DISORDERS OF WHITE BLOOD CELLS

Leukemia

The term *leukemia* literally means “white blood.” It was first identified in 1845 when the blood of victims was examined and found to have an excess of “colorless” cells.

Pathophysiology

Leukemia is a malignant disease of the WBCs that affects all age groups. The immature WBCs (blast cells) generate in an explosive fashion in the bone marrow, lymph tissue, and spleen. The cells are abnormal and unable to effectively fight infection. There are so many abnormal cells developed and dumped into the peripheral circulation that they tend to collect in the body tissues and organs, especially where circulation is sluggish. Areas especially prone to infiltration with immature WBCs are the oral mucosa, anus, sinuses, and lungs. At the time of diagnosis, these areas are often inflamed, painful, and infected. It is common for patients to be diagnosed only after suffering with an infection that does not clear up easily.

As the disease progresses, the bone marrow continues to produce large numbers of the useless cells, the peripheral circulation is filled with them, and the bone marrow is packed with blast cells. Because so many of the blood stem cells are being used to make defective white cells, production of most other normal cells is impossible. The patient becomes anemic because of the lack of RBC production, and bleeding becomes a problem as fewer and fewer platelets are manufactured. But most importantly, even though the WBC count is very high, there are very few normal, mature, and active white cells with which to fight infection. Thus, the patient often begins to have raging infections that do not respond to antibiotics. Without treatment, leukemia leaves the patient unable to fight infection, unable to control bleeding, and in a downward spiral of fatigue and anorexia. Untreated leukemia is almost always fatal.

Classifications

Leukemias are classified as either acute or chronic and either lymphoid or myeloid. Symptoms of the acute leukemias begin very suddenly and the patient is very sick, whereas chronic leukemias develop very slowly and patients can be surprised by the diagnosis because they feel well. Lymphoid leukemias affect the lymphocytes. Myeloid leukemias originate in the stem cells of the bone marrow that develop into monocytes, granulocytes, erythrocytes, and platelets. The most common leukemias are discussed next.

ACUTE LEUKEMIAS. Acute lymphocytic leukemia (ALL) commonly affects children younger than age 15 and involves abnormal growth of the lymphocyte precursors (lymphoblasts). Acute myelogenous (myeloblastic) leukemia (AML) usually affects persons older than age 20 and has a poor prognosis. The patient with acute leukemia may present with sudden onset of high fever, abnormal bleeding from the mucous membranes, petechiae, ecchymoses, and easy bruising after minor trauma. Death usually results from infection.

CHRONIC LEUKEMIAS. Chronic lymphocytic leukemia (CLL) predominantly affects the B and T lymphocytes and usually occurs in adults older than age 40. Chronic myelogenous leukemia (CML) is characterized by the Philadelphia chromosome and occurs most often between the ages of 40 and 45.

Chronic leukemia usually develops in a three-stage process. First is the insidious phase, characterized by anemia and mild bleeding abnormalities. During this stage, the patient often feels well and is not even aware that he or she is sick. After a time, generally years, the disease progresses to the accelerated and acute phases, in which the scenarios are similar to the events seen in acute leukemias. Chronic leukemia is almost always fatal; the average survival time is 3 to 4 years after onset of the chronic phase and 3 to 6 months after onset of the acute phase. With advances in treatments, it is not uncommon to encounter patients who have been living with chronic leukemia for 10 years or more.

Etiology

The cause of leukemia is unknown. Risk factors are thought to include certain viruses because remnants of viruses have been found in leukemic cells. Often there are genetic and immunological factors involved. For example, persons with Down syndrome are more likely to develop leukemia. Other authorities point to exposure to radiation, in part because radiologists have been found to have a higher than average development of leukemia. Some patients have developed leukemia after being treated for another unrelated malignancy using radiation or chemotherapy. Researchers have noted the higher occurrence rate in persons who lived through the Hiroshima and Nagasaki atomic bombings during World War II. Water polluted with benzenes and other chemicals may be a factor. There is no single clear-cut cause for the development of leukemia.

Signs and Symptoms

Symptoms are similar for all types of leukemia and include low-grade fever caused by infection and pallor, weakness, lassitude, shortness of breath, and malaise caused by anemia. These symptoms may be present weeks or months before the appearance of other symptoms. The patient may also have fatigue, tachycardia, palpitations, and abdominal pain. Sternal pain and rib tenderness may result from crowding of bone marrow. If the leukemia has invaded the central nervous system, the patient may experience confusion, headaches, and personality changes. During the acute phase the patient may exhibit high fevers from infection. Ecchymosis or petechiae may result from thrombocytopenia.

Diagnostic Tests

Although a simple CBC often points toward the diagnosis, only bone marrow aspiration can show the degree of proliferation of the malignant WBCs and confirm the diagnosis of leukemia. The complete blood cell count may also show a decrease in the numbers of platelets, RBCs, and mature WBCs. A lumbar puncture helps determine if the central nervous system is involved. Genetic analysis of the peripheral blood and bone marrow components may show the presence of the Philadelphia chromosome in patients with CML.

Therapeutic Interventions

CHEMOTHERAPY. Systemic chemotherapy aims to eradicate the leukemic cells and induce a remission. Remission

means that the bone marrow is free to produce normally occurring cells in normal proportions without production of the immature WBCs. Chemotherapy types vary with the types of leukemia and the level of involvement. Radiation therapy is also sometimes used for initial treatment of leukemia.

The overall goal of the first treatments is to get the patient to a state of remission. Occasionally, partial remission is achieved when everything looks good except for an occasional leukemic cell seen in the bone marrow. Remission is not the same as cure.

There are four phases to the treatment of leukemia: induction, intensification, consolidation, and maintenance. Induction is the period in which an attempt to get the patient into remission is made. This first phase is difficult because chemotherapy is given in extremely high doses and on an aggressive timetable. Often the patient becomes quite ill from complications of the treatment. The patient may become depressed because the treatment seems worse than the disease at this stage. The nurse must help the patient deal with the side effects of anemia, thrombocytopenia, and leukopenia (See Box 28.8 Leukemia Summary, Box 28.6 Interventions for the Patient at Risk for Infection, and Chapter 10 Nursing Care of Patients with Cancer.)

If the first remission is accomplished, the other phases of treatment are begun. Intensification is similar to the initial induction phase, using the same drugs at even higher doses. The next phase, consolidation, is used to ensure that all leukemic cells have been eradicated from the body. Finally, the patient graduates to maintenance therapy in which the patient is kept free of leukemic cells (and in remission) for a period of years (and hopefully a lifetime). This requires years of continued chemotherapy treatments, often on a monthly basis. Radiation therapy may be used throughout this course of treatment to decrease the size of the liver or spleen or to decrease the numbers of leukemic cells in the central nervous system.

BONE MARROW TRANSPLANT. Bone marrow transplant (BMT) is sometimes used to treat leukemia. Preparation for BMT includes high-dose chemotherapy and/or total body irradiation. The goal is to destroy all the patient's malignant bone marrow and then, at the last possible moment, replace it with a donor's clean and healthy bone marrow (allogenic transplant). Another type of bone marrow transplant, known as an autologous transplant, uses the patient's own diseased bone marrow, which is harvested, chemically treated and cleaned, stored, and later reinfused. Transplanted bone marrow is given to the patient like a blood transfusion; generally through a central line placed in the chest. Once infused into the bloodstream, the new marrow travels to the bones, where, ideally, it will begin to grow and function normally. Bone marrow transplants are being performed at more and more centers across the United States.

A new and promising treatment for leukemia is peripheral blood stem cell transplantation. Hematopoietic stem cells can be collected from the patient during remission and

Box 28.8**Leukemia Summary**

<i>Signs and symptoms</i>	Fever (related to infection) Pallor Weakness, malaise Tachycardia Dyspnea Bone pain Headaches, confusion
<i>Diagnostic tests</i>	CBC Bone marrow aspiration Lumbar puncture
<i>Therapeutic interventions</i>	Chemotherapy Radiation therapy Bone marrow transplant
<i>Priority nursing diagnoses</i>	Risk for bleeding related to thrombocytopenia (see Boxes 28.5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia and 28.7 Patient Teaching: Signs and Symptoms of Bleeding) Risk for infection related to altered immune response (see Chapter 10 and Box 28.6 Interventions for The Patient At Risk For Infection) Fatigue related to decreased tissue oxygenation (see Chapter 10)

then reinfused at a later time. Donor stem cells are also sometimes used if a good match can be found.

Nursing Process

The patient with leukemia is at risk for many problems, including fatigue, bleeding, infection, and other complications of the disease and its treatment. The patient must understand the disease process and treatment regimen in order to participate in self-care. See Box 28–9 (Nursing Care Plan for the Patient with Leukemia) for interventions to deal with these problems. Additional diagnoses include knowledge deficit and anxiety. The following Web sites provide resources for patients and families with leukemia. See also Chapter 10 for general care of the patient with cancer.

MULTIPLE MYELOMA

Multiple myeloma is a deadly cancer of the plasma cells in the bone marrow. When the disease is caught in its early

CRITICAL THINKING**Mr. Washington**

■ Mr. Washington is on your unit undergoing initial treatment for leukemia. You enter his room and find it full of visitors.

1. What concerns do you have?
2. What do you do?

Suggested answers at end of chapter.

stages, treatment can prolong life by 3 to 5 years. More important, early detection can decrease the amount of pain and disability due to bony destruction and **pathological fractures**. Unfortunately, almost half the patients die within the first 3 months after diagnosis because of the silent and deadly nature of the disease. Another 40 percent of patients die within 2 years after diagnosis. Because early diagnosis is not often made, only 10 percent of patients can expect to live to the 5-year mark. Multiple myeloma most often affects men ages 50 to 70.

Pathophysiology

In this disorder, cancerous plasma cells in the bone marrow begin reproducing uncontrollably. These cells infiltrate bone tissue all over the body and produce hundreds of tumors that begin to devour the bone tissue. X-ray examination may show holes in the bones forming a Swiss cheese pattern (Fig. 28.6). As more and more of these holes are formed, the bone integrity becomes compromised and weak. Multiple myeloma usually affects the bones of the skull, pelvis, ribs, and vertebrae.

As the disease continues, the plasma cells infiltrate the major organs, including the liver, spleen, lymph nodes, lungs, adrenal glands, kidneys, skin, and GI tract. Because the diagnosis is usually made only after widespread invasion of the bones is well underway, the prognosis for patients with this disease is poor. Although the overall result of the disease is the devastating destruction of the bone and widespread osteoporosis, death is often from sepsis.

Etiology

The cause of multiple myeloma is unknown, although it is being researched. Some authorities believe this disease to be related to chronic allergies and hypersensitivity reactions. This line of thought stems from the fact that plasma cells are the first line of defense and are the producers of the immunoglobulins that help fight foreign bodies. For some reason, these defenders get out of control and begin to attack the host as well as foreign invaders. People who work in rubber, leather, farming, and petroleum industries are more likely to develop multiple myeloma. Radiation and chemical exposure may also be factors.

Box 28.9 NURSING CARE PLAN for the Patient with Leukemia

Nursing Diagnosis: Risk for injury from infection or bleeding related to pancytopenia

Expected Outcomes The patient is free from infection and bleeding. Signs and symptoms of infection or bleeding are reported promptly.

Evaluation of Outcomes Is the patient free from infection and bleeding, or are problems reported so that quick intervention can prevent further complications?

Interventions	Rationale	Evaluation
Monitor vital signs every 4 hours and as needed.	Elevated temperature is a sign of infection.	Are vital signs stable?
Monitor for swelling, redness, purulent drainage.	Falling blood pressure and elevated pulse rate may indicate sepsis or blood loss.	Are signs of infection present?
Protect patient from sources of infection (see Box 28.6 Interventions for the Patient at Risk for Infection).	These are signs of infection and should be reported promptly.	Are precautions being observed to prevent infection?
Observe for tarry stools, petechiae, ecchymosis (see Box 28.7 Patient Teaching: Signs and Symptoms of Bleeding).	Patient is at risk for infection because of ineffective WBCs.	Are signs of bleeding present?
Protect patient from injury that could cause bleeding (see Box 28.5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia).	These are signs of bleeding and should be reported promptly.	Are signs of bleeding present?
	Patient is at risk for bleeding because of reduced platelet count.	Are precautions being observed to prevent injury and bleeding?

Nursing Diagnosis: Fatigue related to decreased red cell count and oxygenation and effects of treatments

Expected Outcomes Patient is able to participate in activities that are important to him or her.

Evaluation of Outcomes Is patient able to identify and participate in activities that are important to him or her?

Interventions	Rationale	Evaluation
Assess fatigue using the WHAT'S UP? format.	A good assessment establishes a baseline and aids in planning.	Is fatigue present? To what degree?
Assist patient to identify activities that are important to him or her (e.g., activities of daily living [ADLs], attending a child's wedding, taking a trip). Assist in setting goals to work toward the desired activity.	If the patient cannot do everything he or she wishes, it may help to focus on the most important things.	Can patient identify important activities? What are they? How can the nurse assist the patient to reach activity goals?
Encourage a balanced diet. Contact dietitian as needed.	Poor nutrition contributes to fatigue.	Is patient eating a balanced diet? Is weight stable?
Allow periods of rest between activities.	Any activity (ADL, x-rays, even talking) can increase fatigue.	Is patient able to rest?
Ensure adequate sleep. Obtain order for sleeping aid if indicated.	Lack of sleep worsens fatigue.	Does patient state feeling rested on awakening? Is medication needed?
Provide for ADLs when patient is unable to do so independently.	Extreme fatigue may prevent the patient from participating in self-care.	Does patient need total assistance?

(Continued on following page)

Box 28.9 NURSING CARE PLAN for the Patient with Leukemia (*Cont'd*)

Nursing Diagnosis: Impaired oral mucous membranes related to chemotherapy and pancytopenia

Expected Outcomes The patient's oral mucous membranes will remain intact.

Evaluation of Outcomes Are oral mucous membranes intact, without lesions?

Interventions

Assess mouth daily for redness, edema, and lesions.

Encourage adequate nutrition and fluids.

Encourage patient to brush teeth after meals with a soft toothbrush. If irritation is severe or if the patient is at risk for bleeding, use swabs or sponge Toothettes instead of a toothbrush.

Avoid use of lemon-glycerin swabs for mouth care.

Obtain an order for a mouthwash containing diphenhydramine (Benadryl). Obtain an order for a topical anesthetic if mouth is very inflamed and painful.

Encourage the patient to avoid smoking, alcohol, acidic food or drinks, extremely hot or cold foods and drinks, and commercial mouthwash.

Advise patient to remove dentures for cleaning and at bedtime.

Rationale

Routine assessment helps identify problems early so treatment can be implemented.

Poor nutrition and dehydration increase the risk of oral lesions.

Brushing the teeth controls tooth and gum disease; a toothbrush may be too harsh if the patient is at risk for bleeding.

Lemon-glycerin swabs are drying to oral mucosa.

Diphenhydramine reduces inflammation; anesthetics reduce pain.

These things can be irritating to the mucosa.

Dentures left in for long periods can impair circulation and increase risk of lesions.

Evaluation

Are mucous membranes intact?

Is patient eating and drinking?

Is mouth care being provided after meals?

Is mouth care irritating? Are alternative methods needed?

Are products used appropriate?

Does mouthwash soothe pain?

Does patient state understanding of things to avoid?

Geriatric

Advise patient to remove dentures for cleaning and at bedtime.

Dentures left in for long periods can impair circulation and increase risk of lesions.

Are oral mucous membranes intact?

Signs and Symptoms

Skeletal pain is the most common complaint. The patient may describe the pain as constant severe back pain that increases with exercise or movement. The patient may complain about pain in the ribs. Other signs and symptoms include achiness of the long bones, joint swelling and tenderness, low-grade fever, and general malaise. Sometimes there is evidence of early peripheral neuropathy secondary to vertebral collapse and mild spinal cord compression. The patient may be unable to feel the true temperature of bath water and be burned or may be unable to feel wounds and infections on the feet. In more severe cases of cord compression, the patient may lose control of bladder and bowels. This is a true oncological emergency. Prompt emergency treatment is necessary to keep the patient from becoming paralyzed.

Occasionally, the patient will have pathological fractures of the long bones. These are fractures that occur with no trauma, such as the person who breaks a leg just turning over in bed or breaks a rib while sneezing. In advanced disease there is anemia, weight loss, thoracic spinal deformities from multiple rib destruction, and a loss of height because of pathological fractures and compacting of the vertebrae.

Because calcium is mobilized from the bones and into the blood, the patient is at risk for hypercalcemia. Signs and symptoms of hypercalcemia include anorexia, nausea, vomiting, mental changes (especially confusion), seizures, and weakness and fatigue. Kidney stones may result as the excess calcium passes through the kidneys.

Patients are susceptible to infection because of compromised immune function. Pneumonia is a common finding in patients with multiple myeloma. They may develop

FIGURE 28.6 X-ray of bone destruction in multiple myeloma. (From Huether, SE, and McCance, KL: *Understanding Pathophysiology*. Mosby, St Louis, 1996, p 548, with permission.)

anemia because of bone marrow dysfunction and reduced erythropoietin formation by diseased kidneys.

Patients often develop kidney failure as the filtering capacity of the kidney is blocked with calcium. Other factors include recurrent infections and deposits of myeloma cells in the kidneys.

Diagnostic Tests

A CBC shows moderate to severe anemia. Examination of the WBC count may show an increase in the number of white cells secondary to infection. X-ray examinations may show changes in the lungs and diffuse osteoporosis in the bones not already riddled with holes. Urine studies are positive for M-type globulins (Bence-Jones proteins) in 40 percent of patients. Bone marrow biopsy is done to confirm the diagnosis and determine the disease's stage.

Blood chemistries often show an increased amount of calcium in the blood. Hypercalciuria results as the calcium released out of the bones is flushed out in the urine. An intravenous pyelogram may be done to see how much calcium is collecting in the kidneys. A 24-hour urine collection is done to evaluate protein excretion.

Therapeutic Interventions

Long-term treatment of multiple myeloma consists of a two-pronged approach: (1) managing the disease and (2) managing the symptoms. To manage the disease, high-dose steroids (prednisone) and oral or intravenous chemotherapy agents are given. Another drug that is showing encouraging results for slowing progression of the disease is thalidomide. The goal of drug therapy is to suppress the plasma cell proliferation, which then helps decrease the amount and speed of bone destruction.

The second approach is control of symptoms. The nurse monitors the patient for signs and symptoms of hypercalcemia, hyperuricemia, dehydration, respiratory infection, renal problems, and pain. The physician may order the administration of intravenous bisphosphonate agents such as pamidronate (Aredia). This class of drugs inhibits bone resorption and is used to help keep serum calcium levels controlled. Oral compounds are also available to help keep the calcium within normal limits. The goal is to get the serum calcium level below 10 mg/dL. If hypercalcemia occurs, the physician will order an IV of normal saline to infuse at a high rate followed by regular administration of diuretics.

External beam irradiation may be given to especially painful areas of bone involvement. Fortunately, this treatment is quite effective, usually decreasing pain intensity in just a few days. The patient can expect to have a daily (or perhaps a twice-daily) therapy treatment over a course of 10 to 14 days that is delivered directly to the painful bony areas. Vigorous attention to administering pain medications during the early course of treatment greatly reduces the patient's pain levels.

The patient may need a laminectomy if vertebral collapse occurs. Because of demineralization of the bone, with resulting large amounts of calcium in the blood and urine, surgery for kidney stones and eventual dialysis for acute or chronic kidney failure may be necessary.

A newer treatment involves high-dose chemotherapy combined with stem cell transplantation. The patient's own peripheral stem cells can be removed and reinfused. These stem cells can then differentiate into new, healthy cells. Methods of cleaning the cells to prevent contamination with malignant cells are being researched.

Nursing Process: Multiple Myeloma

Assessment/Data Collection

Assess for fever or malaise that can signal the onset of infection. Other conditions to be alert for include anemia, hypercalcemia, fractures, and renal complications. Monitor intake and output, and strain urine for stones. Elevated BUN and creatinine levels will alert you to possible renal failure. Report back pain, leg weakness, sensory loss, or loss of bowel or bladder function because these can indicate spinal cord compression.

Nursing Diagnosis, Planning, and Implementation

Risk for infection related to compromised immune function

EXPECTED OUTCOME: Patient will remain free from infection as evidenced by temperature within normal limits, lungs clear

- See Box 24.6 Interventions for the Patient at Risk for Infection
- Encourage deep breathing, and keep patient active to decrease the risk of respiratory complications.

Risk for injury: fracture related to weakened bones; complications of immobility; complications due to hypercalcemia

EXPECTED OUTCOME: Patient will remain free from injury as evidenced by no fracture, and no complications related to immobility or hypercalcemia.

- Keep the patient mobile. Consult physical and occupational therapy as needed. *Bones in use are strongest, so the patient should remain up and moving as much as possible to help stimulate calcium resorption and decrease demineralization.*
- Assist the patient with walking to reduce the risk of pathological fractures of the long bones.
- If the patient is unsteady, use a walker or a support belt to reduce the risk of falls.
- If the patient is bedridden, reposition him or her every 2 hours to prevent complications related to immobility.
- Use a lift sheet to move the patient gently in bed to decrease the risk of skin damage and pathological fractures.
- Provide passive range-of-motion exercises to maintain mobility if the patient is unable to be independently mobile.
- Administer fluids so that daily output is never less than 1500 mL to flush kidneys and reduce the risk of kidney stones.
- Teach the patient the importance of good hydration at all times to minimize complications of hypercalcemia. Depending on time of year and the type and level of patient activities, the patient may need to have an intake of more than 4 L daily.

Evaluation

If nursing care has been effective, the patient will be free of infection or infection will be recognized and treated promptly. The patient will avoid injury, with no fracture, skin breakdown, or complications related to hypercalcemia. See Home Health Hints at the end of this chapter for additional suggestions for patients being cared for at home.

LYMPHATIC DISORDERS

Lymphatic disorders include Hodgkin's disease and the non-Hodgkin's **lymphomas**. Because the spleen is part of the lymph system, this section also discusses **splenectomy**.

Hodgkin's Disease

Despite its name, Hodgkin's disease (HD) is a lymphoma, which is a cancer of the lymph system. Its distinguishing feature is the presence of Reed-Sternberg cells, which make it different from all the other forms of lymphoma. HD is more prevalent in men than in women and occurs most often in young adults ages 15 to 40. After a decrease in incidence

in persons ages 40 to 55, the incidence peaks again in adults older than age 55. Of all the lymphomas, HD is the most curable type even when the disease is widely spread at the time of diagnosis.

Pathophysiology

Lymph nodes are made of tightly bound fibers and cells that serve as filtering devices for the body's immune system. Most often, HD begins as a single changed lymph node, usually in the cervical lymph nodes of the neck. As the disease progresses, the cancer invades the lymph node chains node by node. The path of cancer infiltration is usually the same as the path for lymph fluid flow. Left untreated, other lymphoid tissues such as the spleen become infiltrated with HD. The major organs eventually become involved with Hodgkin's disease. Common complaints of patients with organ involvement may include shortness of breath, feelings of fullness, weakness, and malaise. These organ-related symptoms usually motivate the patient to seek medical help.

A tentative diagnosis of HD is based on one or more painlessly enlarged nodes in the cervical, axillary, or inguinal areas. A biopsy of several of the enlarged nodes is performed to search for the presence of Reed-Sternberg cells, which confirms the diagnosis.

Etiology

The exact cause of HD is unknown. A possible viral origin has been proposed; it is more common in people who have had mononucleosis. Sometimes it occurs in families, suggesting a genetic link. Patients with impaired immune function, such as those with acquired immunodeficiency syndrome (AIDS) or those taking immunosuppressive drugs after organ transplant are also at higher risk.

Signs and Symptoms

Painless swelling in one or more of the common lymph node chains is a usual presentation (Fig. 28.7). Swelling can range from barely perceptible to the size of a softball, occasionally even larger. The patient may complain of generalized pruritus. One other curious event, alcohol-induced pain, is occasionally present. With just a few sips of any type of alcohol-containing beverage (beer, wine, or liquor), the patient may complain of intense pain at the site of disease. Because the lymph nodes in the upper chest and neck are often involved, the patient may have symptoms of obstruction, such as cough, dysphagia, or stridor.

Other common symptoms may include persistent low-grade fever, night sweats, fatigue, weight loss, and malaise. When these additional symptoms are present, the prognosis is worse. In older adults, there may be no enlarged lymph nodes visible, and these secondary symptoms may be the only presenting symptoms. Other symptoms associated with late-stage disease include edema of the neck and face, possible jaundice, nerve pain, enlargement of the retroperitoneal nodes, and infiltration of the spleen; liver and bones may also be involved.

Diagnostic Tests and Staging

Diagnosis usually begins with a lymph node biopsy of the easiest lymph node to access. Lymph node biopsies are done

lymphoma: lymph—fluid found in lymphatic vessels + oma—tumor

FIGURE 28.7 Cervical Hodgkin's disease. (A) Young boy with extensive cervical Hodgkin's disease. (B) Appearance several years later, when axillary manifestation developed. (C) Appearance 23 years after initial treatment with radiation. (From del Regato, JA, Spjut, HJ, and Cox, JD: *Cancer: Diagnosis, Treatment, and Prognosis*, ed 6. Mosby, St Louis, 1985, with permission.)

to check for abnormal histiocyte proliferation, nodular fibrosis, and necrosis. Other tests include bone marrow biopsy and aspiration, liver and spleen biopsies, routine chest x-ray examination, abdominal computed tomography (CT) scan to check for the presence of disease in the liver and spleen, lung scan, and bone scan. In some larger cancer centers, lymphangiography may be performed to view the flow of lymph in the lymph network. This test is accomplished by a skilled physician injecting dye into the lymph tracts located between the toes. The dye is observed as it migrates up the lymph chains, signaling blockages where present.

Hematological tests (e.g., complete blood cell count [CBC]) may show wide variability of red blood cells, indicating mild to severe anemia. The white blood cell (WBC) count is often abnormal and extreme (either very high or very low) because of bone marrow infiltration by disease.

These same tests are used for staging. HD is staged based on the Ann Arbor Clinical Staging Classification and is as follows:

- Stage I disease is limited to a single lymph node or site.
- Stage II disease occurs when two or more nodes are involved on the same side of the diaphragm. Limited organ involvement may or may not be present.
- Stage III disease is characterized by nodes on both sides of the diaphragm with or without organ involvement.
- Stage IV, the most serious form of the disease and the least curable, includes widely disseminated disease in several organs or tissues with or without associated lymph node involvement.

Therapeutic Interventions

Appropriate therapy includes the use of radiation and chemotherapy and depends on the stage of the disease. Radiation therapy, administered on an outpatient basis over a 4- to 6-week period, can cure most patients with stage I or stage II disease. Combinations of chemotherapy and radiation therapy are used for patients with stage III and stage IV disease. Results vary depending on the location and the stage of disease.

Nursing Care

Most nursing interventions are aimed at symptom management. If the patient is experiencing pruritus or night sweats,

nursing interventions are aimed at alleviation of discomfort. These may include changing the gown and bed linens several times a night and helping the patient remain clean and dry. Keeping the patient and family involved in the plan of care may relieve anxiety.

Later, nursing interventions are tailored to alleviate problems that arise secondary to chemotherapy and radiation therapy. See Chapter 10 for nursing interventions for these problems. Also see Box 28.9 Nursing Care Plan for the Patient with Leukemia.

Patient Teaching

In addition to the teaching needs outlined above, make sure that the patient and the family know about local chapters of the American Cancer Society and the Leukemia and Lymphoma Society. Both of these organizations have information, financial assistance, and counseling referral sources, which most patients find valuable. Another source for chemotherapy and radiation therapy information is the National Cancer Institute (NCI). The NCI can send as much information as the patient requests regarding all aspects of treatment at no charge. For more information about Hodgkin's lymphoma, visit www.cancer.org. Or visit the Leukemia and Lymphoma Society at www.leukemia.org or the National Cancer Institute at www.nci.nih.gov.

CRITICAL THINKING

Jeanine

■ Jeanine is a 60-year-old nurse diagnosed with stage II Hodgkin's disease. She wishes to continue working at her job on a respiratory unit at the local hospital while she undergoes treatment. What concerns do you have about this?

Suggested answers at end of chapter.

Non-Hodgkin's Lymphomas

All of the other types of lymphomas are clumped into a diverse classification known as the non-Hodgkin's lymphomas (NHLs). It is possible to sort these other types of

TABLE 28.4 HODGKIN'S DISEASE VERSUS NON-HODGKIN'S LYMPHOMA

	Hodgkin's Disease	Non-Hodgkin's Lymphomas
Age	Younger	Older
Degree of debilitation (overall)	Less	More
Presence of fever, night sweats (indicating more advanced disease)	More likely	Less likely
Spread to other areas at time of diagnosis	Local to regional area of spread	Advanced cancer—may have spread to many different areas
Types	Just one	Many different types

lymphomas into different categories based on the degree of malignancy. Non-Hodgkin's lymphomas arise in the lymphoid tissues of the body, just as Hodgkin's disease does, but they differ in several ways (Table 28.4).

Pathophysiology

The most distinguishing difference is the absence of the Reed-Sternberg cells in non-Hodgkin's lymphomas. Instead, many of these lymphomas arise from the B cells and T cells. The B cells are involved in recognizing and destroying specific antigens. Cells specifically involved include the memory B cells and the plasma cells. The T cells also are involved in registering antigens, but there are many more kinds of T cells. These include the amplifier T cells, helper T cells, suppressor T cells, memory T cells, cytotoxic T cells, and delayed hypersensitivity T cells. An abnormality in any of these cells can result in a type of NHL. Most cases of NHL are of B-cell origin.

Etiology

The cause of non-Hodgkin's lymphomas is unclear, but some viruses, such as the Epstein-Barr virus and herpesvirus, are thought to play a role in their development. Genetics also plays a role. Immune problems such as AIDS increase risk. Exposure to nuclear waste and some toxic chemicals may also increase risk.

Signs and Symptoms

Clinical features of malignant lymphomas include enlarged, painless, rubbery nodes in the cervical and supraclavicular areas, enlarged tonsils and adenoids, and occasional symptoms of dyspnea and cough. As the disease progresses, the patient may report fatigue, malaise, weight loss, and night sweats similar to Hodgkin's disease. NHL usually progresses more rapidly than HD.

Diagnostic Tests

Diagnosis is confirmed by histological evaluation of biopsied lymph nodes, tonsils, bone marrow, liver, bowel, skin, or other affected tissues. Other relevant tests include bone

Box 28.10

Lymphoma Summary

<i>Signs and Symptoms</i>	Swollen lymph nodes Fatigue Low-grade fever Night sweats
<i>Diagnostic tests</i>	CBC Lymph node biopsy Lymphangiography CT Scan
<i>Therapeutic Interventions</i>	Chemotherapy Radiation Bone marrow or stem cell transplant
<i>Priority Nursing Diagnoses</i>	Activity Intolerance Risk for Infection Risk for Ineffective Coping

scans, chest x-ray examination, lymphangiography, liver and spleen scans, CT of the abdomen, and intravenous pyelogram to determine the extent of the disease. Laboratory tests include a CBC, which often indicates anemia, serum uric acid level, and liver function studies. Serum calcium level may be elevated if bone lesions are present.

Therapeutic Interventions

Treatment usually involves multimodal therapy, including the use of chemotherapy and radiation therapy given in combination. Chemotherapy treatments are given on a set schedule of approximately once every month for about 6 months. These treatments may be performed on an inpatient or an outpatient basis. Radiation therapy is given to affected areas in advanced stages of NHL. Stem cell transplant may be tried in patients with advanced disease.

Nursing Care

You can provide emotional support by keeping the patient and family informed during the testing phase. Symptoms such as night sweats can be managed with frequent linen and gown changes. Help the patient maintain nutrition with attractively prepared meals. Spend time listening to the patient's concerns; involve the hospital chaplain in the patient's care if the patient desires. Refer the patient and family to the resources listed earlier for more information. See Box 28.10 Lymphoma Summary and Box 28.11 Nursing Care Plan for the Patient with Lymphoma for more information.

SPLENIC DISORDERS

The spleen is involved in a number of disorders, including cancers of the blood, lymph, and bone marrow; hereditary conditions such as sickle cell disease; and acquired problems such as idiopathic thrombocytopenia. Under normal

Box 28.11 NURSING CARE PLAN for the Patient with Lymphoma

Nursing Diagnosis: Activity intolerance related to fatigue and anemia

Expected Outcomes Patient will have activities of daily living (ADLs) needs met by self or caregiver.

Evaluation of Outcomes Is patient able to carry out ADLs or are ADL needs met by a caregiver?

Interventions

Assess amount of activity that causes fatigue.
Assist patient with activities as necessary.
Provide oxygen therapy as ordered.
Instruct patient to space rest with activities.

Rationale

Assessment helps guide plan of care.
The patient may need assistance with ADLs if fatigue is extreme.
Oxygen therapy can increase oxygen levels and activity tolerance.
Rest periods decrease oxygen needs and allow patient to conserve energy for next activity.

Evaluation

How much can patient do before becoming fatigued?
Does the patient need assistance?
Can family members assist?
Does patient tolerate activity better with oxygen therapy?
Is patient able to tolerate activity better after a rest period?

Nursing Diagnosis: Risk for infection related to bone marrow involvement and side effects of treatment

Expected Outcomes Patient will have no signs or symptoms of infection.

Evaluation of Outcomes Are signs and symptoms of infection absent? Is temperature within normal limits?

Interventions

Assess patient for risk factors for infection.
Monitor patient for signs and symptoms of infection, such as cough, fever, malaise, erythema, pain, or drainage and report immediately.
Teach patient and significant other signs and symptoms of infection to watch for and report.
Teach the patient to avoid exposure to others with influenza or other infections.
Teach patient proper hand washing and good oral and personal hygiene.

Rationale

The WBC count may be very high or very low, placing the patient at risk for infection.
Early detection and treatment of infection provides the best results.
The patient must be involved in monitoring for infection when at home.
Exposure increases risk for infection, especially with compromised immune function.
These activities reduce risk of infection.

Evaluation

Is the patient at risk? Are additional interventions indicated?
Are signs and symptoms of infection present?
Does patient verbalize understanding of signs and symptoms of infection and importance of reporting?
Does patient verbalize understanding of sources of infection to avoid?
Does patient demonstrate proper hand washing and hygiene?

Nursing Diagnosis: Risk for ineffective coping related to new diagnosis and potential lifestyle changes to accommodate treatments

Expected Outcomes The patient states ability to manage lifestyle changes and medical management of condition.

Evaluation of Outcomes Does patient carry out self-care necessary to manage treatment?

Interventions

Assess patient's level of distress related to uncertainty of the future, bothersome symptoms, changes in self-concept, and past coping mechanisms.

Rationale

Obtaining information regarding past experiences helps the nurse identify and correct misconceptions. The nurse can support effective coping mechanisms that worked in the past.

Evaluation

Is patient able to identify sources of anxiety?

(Continued on following page)

Box 28.11 NURSING CARE PLAN for the Patient with Lymphoma (Cont'd)

Interventions	Rationale	Evaluation
Assess for signs of maladaptive behaviors that interfere with responsible health practices, such as missed appointments or failure to attend to symptoms.	Long-term survival depends on keeping therapy schedule. The ability to manage and report symptoms early keeps the patient out of the hospital and in control of his or her own life.	Are past coping mechanisms effective? Does the patient keep appointments? Does the patient participate in self-care activities and report symptoms promptly?
Assist the patient to identify support systems and resources. Refer to social worker or other community resources as needed.	Resources can assist with participation in treatment plan, home care, or financial assistance.	Are resources identified and helpful?
Refer patient and family to a cancer survivors' support group.	Others who have been through treatment themselves can be a good support for patients with cancer.	Does the patient state that the support group is helpful?

circumstances, the spleen is not paid much attention; it generally performs its functions without much fanfare.

If the spleen enlarges markedly, the condition is referred to as **splenomegaly**. Other times, the spleen may or may not be enlarged, but the function is out of control so that too many red blood cells and platelets are removed from the peripheral circulation. Sometimes the spleen is not able to perform its job because of bleeding into the pulp of the organ, which renders it useless. Bleeding into the spleen can occur from various illnesses or from trauma. Regardless of the nature of the malfunction, one treatment option may be splenectomy.

Splenectomy

Splenectomy is the surgical removal of the spleen. This is sometimes used to treat selective hematological disorders and is also used, under different circumstances, to stage (or determine spread in) lymphomas. Splenectomy is performed fairly often in the United States, but, like any surgery, it is not without risk.

Patient Teaching

Explain to patients that this surgery removes the spleen, usually under general anesthesia. Inform patients that they can live a normal life after the surgery but that they may be more prone to infection, and that they should receive the influenza vaccine each year, preferably in the early fall.

Preoperative Care

Before the surgery, ensure that the CBC and coagulation profile are completed and reported to the physician. Blood transfusion may be ordered to correct the underlying anemia and to prepare for the loss of a great deal of blood stored in the spleen. Vitamin K is often ordered to correct clotting factor deficiencies.

Take the patient's vital signs and perform a baseline respiratory assessment. Note especially any signs of respira-

tory infections such as fever, chills, crackles, wheezes, or cough. If any of these are noted, make sure that the physician is aware of them because surgery may need to be delayed. Teach the patient routine coughing and deep breathing techniques to help prevent postoperative respiratory complications.

Postoperative Care

During the early postoperative period, watch carefully for bleeding, either external or internal. Be prepared to administer narcotics for pain, usually on an around-the-clock schedule so the patient is comfortable enough to deep breathe, cough, and ambulate. After narcotic administration, be sure to observe for side effects, which may include incomplete pain relief or hypoventilation. Monitor for fever every 4 hours, and expect a mild, low-grade, transient fever postoperatively. A persistent fever may indicate abscess or hematoma formation.

If the surgery was performed to decrease the numbers of cells being removed from the peripheral circulation, monitor the platelet count. Often the count begins to rise in just a few days, but it may take up to 2 weeks for the platelets to normalize.

Complications

A splenectomy can cause complications such as bleeding, pneumonia, and atelectasis. Respiratory problems occur because of the spleen's position close to the diaphragm. This placement requires the need for a high surgical incision that is very painful. Often the patient tries to restrict lung expansion after surgery to keep from hurting, but this splinting behavior may leave the patient at risk for pneumonia and respiratory problems. In addition, splenectomy patients are usually more vulnerable to infection, especially influenza, because the spleen's role in the immune response is no longer filled.

Other possible complications from splenectomy include

the development of pancreatitis and fistula formation. This is due to the fact that the tail of the pancreas is very close to the spleen, and irritation may have occurred.

Another serious complication is that of overwhelming postsplenectomy infection (OPSI). The causative agents in OPSI include streptococci, *Neisseria* spp., and influenza bacteria (as opposed to a flu virus). Patients at greatest risk of OPSI may include patients who had a splenectomy secondary to a cancer condition or during childhood.

Early symptoms of OPSI include fever and malaise that seem unremarkable. However, the infection may progress within a few hours to sepsis and death. Unfortunately, OPSI has a mortality rate as high as 70 percent. Be sure to include the signs and symptoms of OPSI in presplenectomy patient education. Also, stress the need to promptly obtain medical attention for the patient at the first signs and symptoms of OPSI. The patient should be directed to continue to receive lifetime vaccinations against these bacteria.

Home Health Hints

- Patients who are at risk for infection can place a sign on the front door of their homes to limit visitors or ask persons with colds to come back when they are well. The patient may appreciate the home nurse giving permission to be assertive in such circumstances.
- To prevent bruising, have the patient cut the feet off of white sport socks and wear them on the arms. They can be hidden under long-sleeve shirts and blouses and provide a cushion when doing housework.
- Patients with sickle cell anemia usually have lower blood pressures. It is important to report even mild hypertension in these patients.

REVIEW QUESTIONS

- Which assessment finding would you expect to find in the patient who has anemia?
 - Pain
 - Dyspnea
 - Vision changes
 - Skin rash
- Which of the following activities is contraindicated for the patient with sickle cell anemia?
 - Riding in an elevator
 - Taking a long car trip
 - Running in a marathon
 - Listening to a concert
- Which explanation for bleeding should you give to the family member of a patient with DIC?
 - “He is bleeding because he does not have enough RBCs.”
 - “He is bleeding because his white cells are depleted.”
 - “He is bleeding because his blood pressure is so high that it forces blood from mucous membranes.”
 - “He is bleeding because his body’s clotting factors have all been used up.”
- Which instruction will help the mother of a child with hemophilia prevent bleeding episodes?
 - “Your son should avoid contact sports.”
 - “Your son will have to avoid all potentially irritating foods.”
 - “Your son must never shave.”
 - “Your son should always live near a major hospital system.”
- Which family member should not be permitted to visit a patient with newly diagnosed leukemia?
 - The one who has a new baby at home.
 - The one who has a history of asthma.
 - The one who has received recent radiation treatment for cancer.
 - The one who has a runny nose.
- Which assessment finding is most frequently encountered in patients with multiple myeloma?
 - Pathological fractures
 - Mental status changes
 - Raging infections
 - Bleeding tendencies
- Which of the following nursing interventions are appropriate for a patient with thrombocytopenia? Choose all correct answers.
 - Avoid intramuscular injections.
 - Keep visitors who are ill away from the patient.
 - Encourage 4 L of fluid daily.
 - Avoid use of aspirin and NSAIDs.
 - Allow rest between activities.
 - Encourage use of shoes or slippers.
- A patient with hypercalcemia needs to drink at least 3 L of fluid per day. Today, he has had 1 measuring cup of coffee, 1 L of water, a can of soda that says it has 355 mL, and a half cup of juice. How many milliliters has he had so far today?
_____ mL
- Stage III Hodgkin’s disease is defined as which of the following?
 - Lymphatic involvement on both sides of the diaphragm

- b. Localized involvement of more than two adjacent or nonadjacent regions on one side of the diaphragm
 - c. Diffuse involvement of one or more extralymphatic organs or tissues such as the bone marrow or liver
 - d. Localized involvement of a single lymph node site, usually located in the cervical or supraclavicular area
10. Which circumstance places the patient at most risk for respiratory complications following a splenectomy?
 - a. Disturbance of clotting factors
 - b. Nothing by mouth (NPO) status
 - c. Need for frequent dressing changes
 - d. Location of surgical incision

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Johns

1. Monitor Mrs. Johns's vital signs and report falling blood pressure and rising pulse immediately. Inspect her skin for petechiae and ecchymoses. Outline ecchymotic areas with an ink pen in order to see if the area is increasing in size. Monitor urine for signs of blood. Test stools for occult blood. Monitor vaginal discharge for increasing bleeding. Report any changes promptly.
2. Anticipate assisting the RN with administration of blood or blood products. Instruct Mrs. Johns in the importance of preventing injury that could cause further bleeding. Other care will be supportive.
3. Mrs. Johns will be concerned for her new baby, who is most likely on another unit or already discharged home. Allow Mrs. Johns to talk about her concerns. Arrange visits with her family and baby if permitted by her condition and her physician.

$$4. \begin{array}{|l|l|} \hline 300 \text{ mL} & 60 \text{ min} \\ \hline 30 \text{ min} & 1 \text{ hour} \\ \hline \end{array} = 600 \text{ mL per hour}$$

■ Mr. Washington

1. Because of his leukemia and his treatment, Mr. Washington is at risk for infection. If he develops

an infection, he will have great difficulty getting over it. With so many visitors in the room, it is likely that one or more has a cold or virus. They may not be aware of the risk this poses to Mr. Washington. Mr. Washington is probably also fatigued because of his disease and treatment, and visiting requires energy.

2. You should kindly explain that while family visits are very important, Mr. Washington is very susceptible to catching colds or other illnesses and that it would be best to limit visitors to one or two at a time. Point out that persons with symptoms of colds or flu should not enter the room at all. Visits should also be brief to prevent overtiring the patient.

■ Jeanine

Jeanine will probably be fatigued from her disease, and fatigue may increase further from side effects of treatment. Staff nursing jobs can be tiring even for healthy nurses. In addition, she will be around patients with respiratory diseases, many of whom are contagious. Because of risk for infection secondary to the disease process and the treatment regimen, Jeanine might want to take a leave of absence during treatment or ask to be reassigned to a different area that is less demanding and away from direct patient care until her treatments have been completed.

QUESTIONS TO GUIDE YOUR READING

1. What are the structures of the respiratory system, and what is the function of each?
2. How does aging affect the respiratory system?
3. What questions should you ask when you take a history from a patient with a respiratory problem?
4. What findings do you expect when you inspect, palpate, percuss, and auscultate the chest?
5. What are the common diagnostic tests performed to diagnose disorders of the respiratory system?
6. What nursing care should you provide for patients undergoing each of these diagnostic tests?
7. What are common therapeutic measures used for patients with respiratory disorders?

NORMAL ANATOMY AND PHYSIOLOGY

The respiratory system consists of the nose, nasal cavities, pharynx, larynx, trachea, bronchial tree, lungs, and respiratory muscles. The parts superior to the chest cavity are collectively called the upper respiratory system, and those within the chest cavity make up the lower respiratory system (Fig. 29.1). The alveoli of the lungs are the site of gas exchange between the air and the blood; the rest of the system moves air into and out of the lungs.

Nose and Nasal Cavities

The nose is made predominantly of bone and cartilage covered with muscle and epithelium. Hairs inside the nostrils block the entry of dust and other particles. The two nasal cavities are inside the skull and are separated by the nasal septum, which is made of the vomer, ethmoid, and septal cartilage. The nasal mucosa is ciliated epithelium that is highly vascular; it warms and moistens inhaled air. Dust and microorganisms become trapped on mucus produced by goblet cells and are swept backward and down into the pharynx by the cilia. See Table 29.1 for a summary of protective mechanisms in the respiratory system.

The paranasal sinuses are air cavities in the maxillae and the frontal, sphenoid, and ethmoid bones that open into the nasal cavities. They too are lined with ciliated epithelium.

TABLE 29.1 PROTECTIVE MECHANISMS IN THE RESPIRATORY SYSTEM

Nasal hairs and turbinates	Trap dust and microorganisms
Mucous membranes	Warm and moisten inhaled air; trap inhaled particles
Cilia	Move particles toward pharynx to be swallowed or coughed out
Irritant receptors in nose and airways	Trigger sneeze and cough to remove foreign debris
Alveolar macrophages	Phagocytize foreign particles and bacteria

The mucus produced usually drains into the nasal cavities. The sinuses lessen the weight of the skull and provide resonance for the voice.

Pharynx

The pharynx is posterior to the nasal and oral cavities. It has three parts: nasopharynx, oropharynx, and laryngopharynx. The nasopharynx is an air passage above the level of the soft palate. The soft palate and uvula rise to block the nasopharynx during swallowing. The eustachian tubes from the middle ear cavities open into the nasopharynx; the adenoid (pharyngeal tonsil) is a lymph nodule on its posterior wall. The oropharynx is posterior to the oral cavity and is both an air and a food passage. The palatine tonsils are on the lateral

FIGURE 29.1 Respiratory system, anterior view, with microscopic view of alveoli and pulmonary capillaries. (Modified from Scanlon, VC, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA. Davis, Philadelphia, 2007.)

walls. Together with the lingual tonsils on the base of the tongue and the adenoid, the palatine tonsils form a ring of lymphatic tissue around the pharynx and destroy pathogens that penetrate the mucosa. The laryngopharynx is both an air and a food passage; it opens anteriorly into the larynx and posteriorly into the esophagus.

Larynx

The larynx is the voice box and the airway between the pharynx and trachea. It is made of nine pieces of cartilage, yielding a firm yet flexible tissue that keeps the airway open. It is lined with ciliated epithelium. The thyroid cartilage, commonly called the Adam's apple, is the largest of these cartilage pieces and is palpable on the front of the neck. The epiglottis is the uppermost cartilage and covers the larynx like a flap when the larynx is elevated during swallowing. The vocal cords are on either side of the rima glottidis (the airway opening). When pulled together across the rima glottidis and vibrated by exhaled air, the vocal cords produce sounds that may be turned into speech. The vagus and accessory cranial nerves are the motor nerves to the larynx.

Trachea and Bronchial Tree

The trachea is a tube, 4 to 5 inches in length, that extends from the larynx to the primary bronchi. C-shaped pieces of cartilage in the wall keep the trachea open. The mucosa is ciliated epithelium; mucus with trapped dust and microorganisms is swept upward toward the pharynx and is usually swallowed.

The bronchial tree is the series of air passages within the lungs, a succession of progressively smaller tubes that terminate in the alveoli. The right and left primary bronchi are branches of the trachea. Each gives rise to secondary bronchi: their structure is like that of the trachea. The bronchioles, however, have no cartilage in the walls to maintain patency, and they may be closed completely by contraction of their smooth muscle.

Lungs and Pleural Membranes

The lungs occupy the chest cavity on either side of the heart, extending from the clavicles to the diaphragm. On the medial (mediastinal) surface of each lung is an indentation called the hilus, where the primary bronchus and the pulmonary artery and veins enter the lung.

The pleural membranes are the serous membranes of the thoracic cavity. The visceral pleura is the membrane that covers the lungs; the parietal pleura lines the chest cavity. A small amount of serous fluid between these membranes prevents friction and keeps the membranes adhered together during breathing.

The functional units of the lung are the millions of alveoli, the air sacs that are the site of gas exchange. Both the alveoli and the surrounding alveolar capillaries are made of simple squamous epithelium; that is, their walls are only one cell in thickness to permit diffusion of gases (see Fig. 29.1).

Each alveolus is lined with a thin layer of tissue fluid that is essential for the diffusion of gases, but the surface

tension of the fluid tends to make the walls of an alveolus stick together internally. Certain alveolar cells secrete pulmonary surfactant, a lipoprotein that mixes with the tissue fluid and decreases surface tension to permit inflation. Also in the alveoli are the alveolar macrophages, which phagocytize pathogens or fine dust particles and debris that have not been trapped and swept out by the cilia.

Between clusters of alveoli is elastic connective tissue; it is capable of recoil when stretched (during inhalation) and contributes significantly to normal exhalation. The recoil of this tissue ensures that normal exhalation during quiet breathing is a passive process that does not require the expenditure of energy.

Mechanism of Breathing

Ventilation is the term for the movement of air into and out of the alveoli. Air moves from high-pressure to low-pressure areas, some of which are created by the respiratory muscles that are controlled by the nervous system. The respiratory centers are in the medulla oblongata and pons. The main respiratory muscles are the diaphragm inferior to the lungs and the external and internal intercostal muscles between the ribs. Accessory muscles of respiration are used during exercise and times of respiratory distress; these include the sternocleidomastoid, scalene muscles, and abdominal musculature.

Pressures important to breathing include atmospheric pressure, intrapleural pressure, and intrapulmonic (alveolar) pressure. Atmospheric pressure is the pressure of the air around us, which at sea level is 760 mm Hg; atmospheric pressure decreases as altitude increases. Intrapleural pressure is in the potential pleural space between the pleural membranes. Serous fluid causes the two membranes to adhere to each other, and because the elastic lungs are always tending to collapse and pull the visceral pleura away from the parietal pleura, the pressure in this potential space is always below atmospheric pressure (about 756 mm Hg). This is called a negative pressure. Intrapulmonic (alveolar) pressure is the pressure inside the alveoli and bronchial tree. This pressure fluctuates below and above atmospheric pressure during each cycle of breathing.

Inhalation

Inhalation, also called inspiration, occurs when motor impulses from the medulla cause contraction of the respiratory muscles. Impulses along the phrenic nerves cause the dome-shaped diaphragm to contract and flatten downward. Impulses along the intercostal nerves cause the external intercostal muscles to pull the ribcage upward and outward, expanding the chest cavity in the anteroposterior dimension. This then expands the pleural membranes. Intrapleural pressure becomes even more negative, but the serous fluid keeps the membranes together and the lungs expand as well. As the lungs expand, alveolar pressure falls below atmospheric pressure and air enters the nose and respiratory passages. Entry of air continues until alveolar pressure equals atmospheric pressure; this is a normal inhalation. A deeper inhala-

tion requires a more forceful contraction of the respiratory muscles (including accessory inspiratory muscles) to expand the chest cavity and lungs even further and permit the entry of more air.

Exhalation

Normal exhalation is a passive process that begins when motor impulses from the medulla decrease and the diaphragm and external intercostal muscles relax. The lungs are compressed as the chest cavity becomes smaller and the recoil of the elastic lung tissue compresses the alveoli. Alveolar pressure rises above atmospheric pressure, and air is forced out of the lungs until the two pressures are again equal. Under normal circumstances, energy is not required for exhalation (as it is for inhalation) because the elasticity of the lungs causes recoil and forces air out. A forced exhalation beyond the normal amount is an active process that requires contraction of the internal intercostal muscles to pull the rib cage downward and inward and contraction of the abdominal muscles to force the dome of the diaphragm upward, increasing compression of the lungs.

Transport of Gases in the Blood

Oxygen is carried in the blood by iron in the hemoglobin (Hgb) of red blood cells (RBCs). The iron-oxygen bond is formed in the lungs, where the partial pressure of oxygen (PO_2) is high. In tissues where the PO_2 is low, hemoglobin releases much of its oxygen.

Most carbon dioxide is carried in the blood in the form of bicarbonate ions in the plasma. These ions are formed when carbon dioxide enters RBCs and is converted to carbonic acid (H_2CO_3), which ionizes to bicarbonate ions (HCO_3^-) and hydrogen ions (H^+). The bicarbonate ions leave the RBCs for the plasma, and the remaining hydrogen ions are buffered by the hemoglobin in the RBCs. When the blood reaches the lungs, an area of lower partial pressure of carbon dioxide (PCO_2), these reactions are reversed—carbon dioxide is re-formed and diffuses into the alveoli to be exhaled.

Regulation of Respiration

Respiration is regulated by both nervous and chemical mechanisms. The medulla oblongata contains an inspiratory center and an expiratory center. The inspiratory center generates impulses that bring about contraction of the respiratory muscles, resulting in inhalation. When the impulses stop, exhalation occurs. If the lungs are overinflated, bronchi and bronchiole baroreceptors are stretched. The stretching inhibits the inspiratory center (and apneustic center) and exhalation follows. This protective mechanism is called the Hering-Breuer inflation reflex. In the pons, the apneustic center prolongs inhalation and the pneumotaxic center helps bring about exhalation. These centers provide a normal breathing rhythm, 12 to 20 breaths per minute with exhalation slightly longer than inhalation. When there is a need for more forceful exhalations, the inspiratory center activates the expiratory center, which brings about contraction of the internal intercostal muscles.

Normal breathing is essentially a reflex, but because the respiratory muscles are skeletal (or voluntary) muscles, it is possible to make changes. The cerebral cortex may override the medulla to permit voluntary changes in breathing, such as faster or slower breathing, holding one's breath, or singing. Eventually, the medulla resumes control and breathing is again a reflex.

Chemical regulation of respiration involves the blood levels of oxygen and carbon dioxide. Decreased blood oxygen is detected by chemoreceptors in the carotid body and aortic body; the response by the medulla is to increase respiration to take more air into the lungs. Increased blood carbon dioxide or a decrease in pH is detected by central chemoreceptors in the medulla and peripheral chemoreceptors; the response is increased respiration to exhale more carbon dioxide, which raises the pH back toward normal.

Carbon dioxide is usually the major regulator of respiration because even small changes in its blood level change the pH. Fluctuations in the oxygen level have no effect on pH, and an adequate oxygen level in the blood can be maintained even if breathing ceases for a few minutes. Residual air in the lungs is a contributing factor, as is the fact that air contains much more oxygen than we typically use (exhaled air is 16 percent oxygen). Oxygen becomes the major regulator only when its blood level is very low, as may occur with severe, chronic pulmonary disease.

Respiration and Acid-Base Balance

Because of its role in regulating the amount of carbon dioxide in body fluids, the respiratory system is important in the maintenance of acid-base balance, measured by blood pH. Any decrease in the rate or efficiency of respiration permits excess carbon dioxide to accumulate in the blood. The resultant accumulation of excess hydrogen ions lowers pH. This is called respiratory acidosis and can occur as a consequence of pulmonary disease or any impairment of gas exchange in the lungs.

Respiratory alkalosis occurs when the rate of respiration increases, eliminating exhaled carbon dioxide very rapidly. Less carbon dioxide in the blood means that fewer hydrogen ions are formed and the pH rises. Although not a common condition, respiratory alkalosis may occur during states of anxiety accompanied by hyperventilation or when accommodating to a high altitude, before RBC production increases to provide sufficient oxygenation of tissues.

The respiratory system may also help compensate for pH changes that are said to be metabolic; that is, of any cause other than respiratory. Metabolic acidosis occurs when the concentration of hydrogen ions in body fluids is above normal due to lowered HCO_3^- buffer. Common causes include kidney disease, uncontrolled diabetes mellitus, and severe diarrhea. Respiratory compensation involves an increase in the rate and depth of respiration to exhale more carbon dioxide, which decreases hydrogen ion formation and raises the pH toward normal. Metabolic alkalosis may be caused by overingestion of antacid medications or by vomiting of gastric contents high in hydrochloric acid. Respiratory com-

compensation involves a decrease in the breathing rate to retain carbon dioxide in the body, increasing the formation of hydrogen ions, which lowers the pH toward normal.

Respiratory compensation for an ongoing metabolic pH imbalance (such as kidney failure) cannot be complete because the amount of carbon dioxide that may be exhaled or retained is limited. At most, respiratory compensation is only about 75 percent effective.

Acid-base balance is discussed further in Chapter 5.

Effects of Aging on the Respiratory System

See Figure 29.2 for the effects of aging on respiration.

NURSING ASSESSMENT

Health History

Many factors in a patient's personal and family history affect respiratory function. Questions to ask while assessing the patient with a history of respiratory dysfunction are presented in Table 29.2. If at any time while you are taking the history the patient relates a specific symptom, redirect the line of questioning to further assess that symptom. One such line of questioning, as presented in Chapter 1, is the WHAT'S UP? format. For example, if the patient admits to shortness of breath (SOB), respond with the following questions (*Where is it?* doesn't apply to shortness of breath, so it may be skipped.):

- **How does it feel?** Does breathing feel tight, gasping, suffocating?
- **Aggravating and alleviating factors?** How much activity causes the SOB? Does anything else aggravate it? What do you do to lessen your SOB?
- **Timing?** When did you first experience SOB? Does it happen more at any particular time of day or year?
- **Severity?** Rate your SOB on a scale of 0 to 10, with 0 being easy breathing and 10 being the worst shortness of breath you can imagine.
- **Useful other data?** Do you have any other symptoms that occur along with the shortness of breath?
- **Patient's perception?** What do you think is causing your shortness of breath?

Because smoking is such a major risk factor for many types of lung disease, it is essential to ask about smoking history and encourage cessation (see Therapeutic Measures). Document smoking history in terms of *pack-years*. For example, if a patient has smoked two packs of cigarettes per day for 20 years, he has a 40 pack-year smoking history ($2 \times 20 = 40$ pack-years). It is also important to be aware of cultural influences on the patient's respiratory health (Box 29.1 Cultural Considerations).

Physical Assessment

Inspection

Inspection begins during the nursing history and continues during the physical assessment. Start with the nose, observing for symmetry, swelling, or other abnormalities. Note

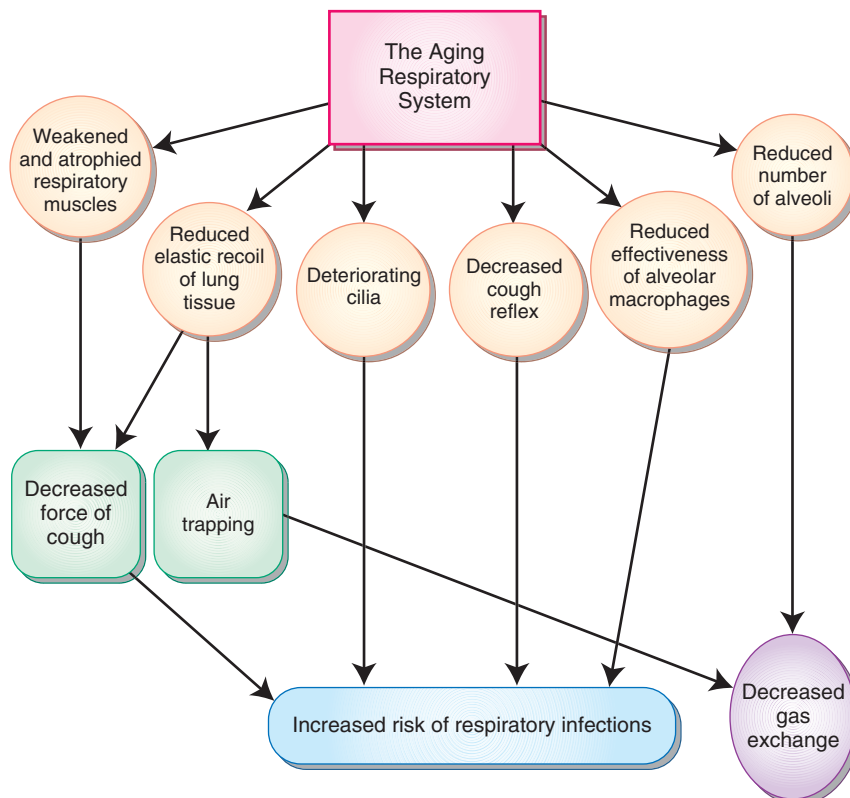

FIGURE 29.2 Effects of aging on respiration.

TABLE 29.2 QUESTIONS ASKED DURING NURSING ASSESSMENT OF THE RESPIRATORY SYSTEM

Category	Questions to ask	Rationale/Significance
Upper respiratory tract	Do you often have headaches or sinus tenderness?	These may indicate sinusitis.
	Do you often experience nosebleeds?	A history of nosebleeds may indicate an abnormality that can predispose to future nosebleeds.
	Has your voice changed?	A voice change may indicate a variety of disorders of the nose or throat, including cancer. Further investigation is necessary.
Lower respiratory tract	Do you ever feel short of breath, like you can't get enough air?	Many respiratory and cardiac problems result in shortness of breath.
	Do you have a cough? Is it productive?	A cough indicates respiratory irritation or excessive secretions.
	What does the sputum look like?	Yellow or green sputum may accompany an infection. Blood in the sputum may occur with tuberculosis, pulmonary embolism, or cancer.
	Have you recently experienced night sweats, chills, fever?	These are symptoms of tuberculosis.
	Do you ever feel confused, light-headed, or restless?	These symptoms might indicate a low PO_2 , reducing oxygen to the brain.
	Have you had any chest surgeries?	This may reveal problem areas the patient has not yet mentioned.
Exposures	Do you have any allergies that cause respiratory symptoms? How do you treat them?	The patient may take over-the-counter medications for allergies that affect respiratory function or interact with prescribed medications.
	Do you smoke? How many packs per day? For how many years? Are you exposed to secondhand smoke?	Many respiratory disorders are caused or aggravated by exposure to tobacco smoke.
	Are you or have you been exposed to airborne pollutants at work?	Pollutants such as asbestos, coal dust, or chemicals can cause lung disease.
Treatments	Do you take any medications or use inhalers (prescribed or over-the-counter) for your respiratory problems?	Information about medications gives further information about disorders, severity, and treatment. You should also consider drug interactions and side effects.
	Do you use home oxygen or other home respiratory treatments?	This helps determine the severity of disease and the severity of disease and the treatment.
Family history	Do any of your blood relatives have emphysema, asthma, or tuberculosis?	Some respiratory disorders have a hereditary tendency. Tuberculosis is contagious.

whether the patient is short of breath (dyspneic) while speaking or moving. If the patient is very dyspneic, he or she may speak in short sentences.

Observe the patient for use of accessory muscles of breathing (Figure 29.3). Use of the sternocleidomastoid muscles causes the shoulders to rise during labored inspiration. During forced expiration, the abdominal and intercostal muscles contract. The use of accessory muscles for breathing indicates respiratory distress. Retraction of the chest wall between the ribs can indicate serious distress.

Note the color of the skin, lips, mucous membranes, and nailbeds. A bluish color is called **cyanosis** and is a late sign of oxygen deprivation. Observe the trachea and chest for symmetry. Count the number of respirations per minute, noting depth and rhythm. Irregular respirations, or periods of **apnea** (absence of respirations), can indicate a patholog-

ical condition and are described in Figure 29.4. Observe the shape of the chest. Normally the chest is about twice as wide (side to side) as it is deep (front to back). If it is more rounded, it is called a barrel chest, which is associated with air trapping. See Table 29.3 for a summary of objective assessment data.

Palpation

Palpate the frontal and maxillary sinuses if sinus inflammation is suspected (Fig. 29.5). Use your thumbs to palpate gently below the eyebrows and below each cheekbone. Tenderness may indicate sinus inflammation or infection.

Respiratory excursion can also be palpated. This is a rough measurement of chest expansion on inspiration. It is not necessary to palpate expansion on every patient, but it may be helpful if hypoventilation or asymmetry is suspected. See Figure 29.6 for how to palpate respiratory excursion. You can palpate for **crepitus** (also called subcutaneous emphysema) if indicated. Crepitus feels like Rice Krispies under the

cyanosis: cyan—dark blue + osis—condition

apnea: a—not + pnea—breath

**Box 29.1****Cultural Considerations**

Pulmonary diseases associated with Japanese people include asthma related to dust mites in the straw mats that cover floors in Japanese homes and air pollution from living in urban areas. The nurse should encourage patients who have straw mats and who wish to keep them to have them sterilized.

Patients from Poland, Ireland, or other countries where mining is a primary occupation may have an increased incidence of respiratory disease. It is essential that health-care providers carefully screen Polish and Irish immigrants for respiratory conditions.

Health care practitioners should be aware of the variations among ethnic peoples of color when assessing for cyanosis. Cyanosis and decreased blood hemoglobin levels in darker skinned individuals gives the skin an ashen color instead of a bluish color. Thus, the nurse must examine the sclerae, conjunctivae, buccal mucosa, tongue, lips, nailbeds, and palms and soles of the feet to assess for lowered oxygen levels.

Smoking is deeply ingrained in the Arab American culture. Offering cigarettes is a rite of Arab hospitality. Arabs may have difficulty stopping smoking because of these cultural rituals.

Populations living in inner cities are at increased risk for respiratory diseases related to pollution. Strategies to increase the effectiveness of smoking cessation in African Americans include working with community and church groups in African American communities.

skin when felt with the fingers. It occurs when air leaks into subcutaneous tissues because of pneumothorax or a leaking chest tube site. Palpation for crepitus is not done routinely, but rather when the possibility of an air leak exists.

FIGURE 29.3 Accessory muscles of breathing. Note the prominent sternocleidomastoid muscles.

FIGURE 29.4 Abnormal respiratory patterns.

Percussion

Percussion is done by the experienced nurse. It involves tapping on the anterior and posterior chest, in each intercostal space, and comparing sounds from side to side. A normal chest sounds resonant and is the same on both the right and left sides except over the heart. If other percussion notes are heard, they may indicate a pathological condition and should be reported.

Auscultation

Auscultation provides valuable information about respiratory status. Use the diaphragm of your stethoscope to listen to the anterior and posterior chest during an entire inspiration and expiration at each interspace (Fig. 29.7). Auscultation of the posterior chest is easiest if the patient is sitting,

TABLE 29.3 OBJECTIVE ASSESSMENT OF THE RESPIRATORY SYSTEM

Category	Abnormal Findings	Possible Causes
Respiratory	Respiratory Rate <12 Respiratory Rate >24 Use of accessory muscles Barrel chest Adventitious sounds Cough Sputum	Respiratory depression, possibly from opioid or sedative use Respiratory distress from underlying disorder Restrictive or obstructive disorders Air trapping from obstructive disorder (COPD) See Table 29.4 Airway irritation or secretions Green, yellow, or tan sputum may indicate infection. Blood in sputum can indicate tuberculosis, cancer, or pulmonary embolism.
Integumentary	Cyanosis Nail clubbing	Tissue hypoxia Chronic tissue hypoxia
Neurological	Confusion	Lack of oxygen to the brain
Gastrointestinal	Weight loss	Dyspnea interfering with eating; use of calories for breathing

but if necessary, it may be done with the patient in a side-lying position. Asking the patient to breathe deeply through the mouth can help enhance the sounds. Allow the patient to rest at intervals to prevent hyperventilation. Regular and frequent practice helps you learn to distinguish normal from abnormal breath sounds. Abnormal extra sounds (another term is **adventitious**) indicate a pathological condition and are described in Table 29.4.

LEARNING TIP

Listen to breath sounds on all your friends and family members. Assuming they are normal, this will give you a good baseline so when you hear an abnormal or adventitious sound on a patient, you will recognize it as “not normal”!

FIGURE 29.5 Paranasal sinuses.

CRITICAL THINKING

Timothy

■ Timothy is a 16 year old brought into the emergency room by his mother because of an asthma attack. He says he feels short of breath, but when you listen to his lungs you hear no wheezing.

1. Does Timothy really need to be in the emergency room?
2. What should you do?
3. What do you think could be happening?

Suggested answers at end of chapter.

DIAGNOSTIC TESTS

Laboratory Tests

Blood Tests

COMPLETE BLOOD COUNT. Measurement of red blood cells and hemoglobin can give information about the oxygen-carrying capacity of the blood. **Dyspnea** can be

dyspnea: dys—bad + pnea—breathing

FIGURE 29.6 Palpation of respiratory excursion.

FIGURE 29.7 Auscultation of the chest. Use a systematic approach to auscultate the chest, comparing sounds from side to side.

caused by a reduction in RBCs or Hgb. See Table 29.5 for normal values.

ARTERIAL BLOOD GAS ANALYSIS. Arterial blood gases (ABGs) are measured to determine the effectiveness of gas exchange. The “Pa” portion of the ABG results refer to the partial pressure of the gas in arterial blood. See Table 29.6 for a basic interpretation of ABGs. The blood sample is usually taken from the radial artery in the wrist by a physician or laboratory technician specially trained to do this. This can be painful for the patient. Place pressure on the site for 5 minutes after the test to prevent bleeding.

D-DIMER. This blood test measures fibrin degradation products, which are present if there is a blood clot in the body. It helps diagnose the presence of a pulmonary embolism.

LEARNING TIP

If you remember that a normal blood pH is 7.35 to 7.45, then it is easy to remember a normal $Paco_2$ is 35 to 45 mm Hg.

LEARNING TIP

Remember 50. If the Pao_2 falls below 50 and the $Paco_2$ is above 50, the patient is in trouble and the physician should be notified. This is a crude analysis, but it is helpful when a quick assessment is needed.

Sputum Culture and Sensitivity

A sputum culture identifies pathogens present in the sputum. The sensitivity test determines which antibiotics will be effective against those pathogens. To obtain a sputum specimen, first obtain a sterile container. Some institutions have special containers for sputum that help prevent transmission of infection to the health-care worker (Fig. 29.8). Instruct the patient to take several deep breaths and then cough sputum into the sputum container. It is important that the patient not simply spit saliva or sinus drainage into the cup. The specimen must come from the lungs. It may be easiest to obtain a specimen first thing in the morning (after mouth care) because secretions build up during the night. Send the

TABLE 29.4 ABNORMAL LUNG SOUNDS

Abnormal (Adventitious) Sound	Cause of Sound	Description	Associated Disorders
Coarse crackles (sometime called rales)	Fluid in airways	Moist bubbling sound, heard on inspiration or expiration	Pulmonary edema, bronchitis, pneumonia
Fine crackles (rales)	Alveoli popping open on inspiration	Velcro being torn apart, heard at end of inspiration	Heart failure, atelectasis
Wheezes	Narrowed airways	Fine high-pitched violins mostly on expiration	Asthma
Stridor	Airway obstruction	Loud crowing noise heard without stethoscope	Obstruction from tumor or foreign body
Pleural friction rub	Pleura rubbing together	Sound of leather rubbing together, grating	Pleurisy, lung cancer, pneumonia, pleural irritation
Diminished	Decreased air movement	Faint lung sounds	Emphysema, hypoventilation, obesity, muscular chest wall
Absent	No air movement	No sounds heard	Pneumothorax, pneumectomy

TABLE 29.5 COMMON LABORATORY TESTS

Test	Normal Values	Associated Conditions
Red blood cell count	Male: 4.5–6.2 million Female: 4.2–5.4 million cells/mm ³ venous blood	↑ in chronic lung disease, dehydration ↓ in anemia, hemorrhage, overhydration with intravenous fluids
Hemoglobin	Male: 13.5–18 g/dL Female: 12–16 g/dL	Same as RBC count
White blood cell count	5000–10,000 cells/mm ³ venous blood	↑ in infection

specimen to the laboratory immediately. If the patient is unable to cough up sputum, extra fluids or a bedside humidifier may help. A respiratory therapist (RT) may be able to help obtain a specimen with a nebulized mist treatment or with a special suction catheter with a sputum trap. A physician order may be needed for these procedures.

Throat Culture

A throat culture is done to determine the presence of viral or bacterial pathogens in the pharynx. Use a swab to reach into

PATIENT CARE TIP

If the physician orders a “sputum for AFB,” tuberculosis is suspected, which is caused by an acid-fast bacillus. Ask whether the patient should be isolated while waiting for test results.

TABLE 29.6 ARTERIAL BLOOD GAS ANALYSIS

Normal Values	Interpretation
PaO_2	75–100 mm Hg ↑ in hyperventilation ↓ in impaired respiratory function
$Paco_2$	35–45 mm Hg ↑ in impaired gas exchange ↓ in hyperventilation
pH	7.35–7.45 ↑ in respiratory alkalosis with low $PaCO_2$ ↓ in respiratory acidosis with high $PaCO_2$
Hco_3	22–26 ↑ to buffer $PaCO_2$ in acidosis ↓ to buffer $PaCO_2$ in alkalosis
Oxygen saturation	95%–100% ↑ in hyperventilation ↓ in impaired respiratory function

FIGURE 29.8 A special container that helps prevent transmission of infection is often used to collect sputum for culture.

the pharynx (without touching the patient’s mouth) and rub the red area or lesions. Use a tongue blade to help hold the tongue down while obtaining the culture. Warn the patient that a gag reflex may be triggered. Once the culture is obtained, place it in a sterile tube with culture medium, according to package instructions. Send it immediately to the laboratory for analysis.

Oxygen Saturation

The oxygen saturation test (also called pulse oximetry, O_2 sat, and SaO_2) is simple and noninvasive. A sensor is placed on the patient’s finger or ear that measures the percentage of hemoglobin that is saturated with oxygen. Oxygen saturation can be measured at rest or while the patient is walking to determine the patient’s exercise tolerance. It is also often done with and without supplemental oxygen to determine the patient’s need for oxygen supplementation at home. See Table 29.6 for normal values. An SaO_2 value below 95 percent should be reported to the RN or physician. If the SaO_2 is less than 75 percent, prepare for emergency intervention.

Other Tests

Chest X-ray Examination

A chest x-ray examination may be ordered to help diagnose a variety of pulmonary disorders. Usually, posterior-anterior (PA) and side views (lateral) are taken. If a hospitalized patient is too ill to go to the radiology department, a portable chest x-ray machine can be used at the bedside to obtain a PA view.

Ventilation-Perfusion Scan

During a ventilation-perfusion scan (also called a lung scan or VQ scan), a radioactive substance is injected intravenously and a scan is done to view blood flow to the lungs (perfusion). Another radioactive substance is inhaled, and scanning shows how well oxygen is distributed in the lungs

TABLE 29.7 PULMONARY FUNCTION VALUES

Test	Definition	Normal Values*
Tidal volume (TV)	Air inspired and expired in one breath	400–600 mL at rest
Residual volume (RV)	Air remaining in lungs after maximum exhalation	1000–1500 mL
Functional residual capacity (FRC)	Air remaining in lungs after normal expiration	2300 mL
Inspiratory reserve	Amount of air beyond tidal volume that can be taken in with the deepest possible inhalation	2000–3000 mL
Expiratory reserve	Amount of air beyond tidal volume in the most forceful exhalation	1000–1500 mL
Forced vital capacity (FVC)	Maximum amount of air expired forcefully after maximum inspiration	3000–5000 mL
Forced expiratory volume in one second (FEV ₁)	Amount of air expired in first second of forced exhalation, expressed as percent of FVC	65%–85% of the FVC
Peak expiratory flow rate (PEFR)	Maximum flow of air expired during FVC (this is a rate rather than a volume)	450 L/min

*Normal values are approximate—normal values are individualized based on patient's sex, height, and age.

(ventilation). If an area of the lungs is well ventilated but has no blood supply, a pulmonary embolism is suspected. Chronic lung disease may cause poor ventilation and perfusion.

Pulmonary Function Studies

Pulmonary function studies are a series of tests done to determine lung volume, capacity, and flow rates. These are commonly used to help diagnose and monitor restrictive or obstructive lung disease. The patient is asked to use a special mouthpiece to blow into a cylinder that is connected to a computer. A computer printout is generated to show the results. See Table 29.7 for normal values. Some patients use handheld peak expiratory flow rate (PEFR) meters at home to monitor asthma symptoms. They might notice changes in PEFR before symptoms occur, allowing them to begin treatment before the problem becomes more serious.

Pulmonary Angiography

Pulmonary angiography involves an x-ray examination of the pulmonary vessels after intravenous (IV) administration of a radiopaque dye. A catheter is inserted into the femoral, brachial, or jugular vein and threaded through the heart to the pulmonary artery, where the dye is injected. Pulmonary angiography is used to help diagnose pulmonary embolism or other pulmonary vessel disorders. Patients receive nothing by mouth (NPO) for 4 to 8 hours before the procedure. Question the patient about allergies to x-ray dyes before scheduling the test. As with any procedure involving dye, inform the patient that the dye may cause a warm feeling when injected. Make sure a signed consent form is obtained before any invasive procedure is performed. Medications may be administered before or during the test for patient comfort.

After angiography, place the patient flat in bed for 3 to 8 hours, as ordered by the physician. Monitor vital signs and observe the injection site for bleeding. A sandbag may be used to place pressure on the site. Encourage fluid intake to promote excretion of the dye.

Bronchoscopy

Bronchoscopy involves the use of a flexible endoscope to examine the larynx, trachea, and bronchial tree. Bronchoscopy can be used diagnostically for visualization or to obtain a biopsy specimen for examination. It can also be used therapeutically to remove an obstruction, foreign body, or thick secretions. Instruct the patient the he or she will be able to breathe through the nose and that oxygen can be administered through the tube if necessary. A signed consent form is necessary for this invasive procedure.

The patient is NPO for 6 to 8 hours before the procedure. Be prepared to administer a sedative, and commonly an injection of atropine to dry excess secretions, before the procedure. An anesthetic spray may be used to numb the throat. After the test, monitor vital signs and watch for signs of laryngeal edema. Sputum may be blood tinged. The patient is NPO until the gag reflex returns. Check for the gag reflex by touching the pharynx with a cotton swab. After the gag reflex returns, ask the patient to swallow a sip of water before offering foods or fluids. A sore throat may be relieved with lozenges once the patient is able to swallow.

THERAPEUTIC MEASURES

Smoking Cessation

Probably the most important intervention for preventing and treating respiratory disease is smoking cessation. Many respiratory disorders are caused or aggravated by smoking, and stopping can prevent disease from occurring or slow its progression significantly. See Table 29.8 for interventions used to help patients stop smoking. Remind patients that if they have tried quitting before and failed, that does not mean that they will never be able to quit. Many patients try several times before quitting successfully. Formal smoking cessation programs and support groups can be helpful.

Many internet sites have information to help people stop smoking. Among these are the American Lung

TABLE 29.8 INTERVENTIONS TO STOP SMOKING

Intervention	Rationale
Behavior modification	If the patient can identify situations that are associated with smoking, such as eating a meal or experiencing stress, he can substitute other healthier behaviors, such as going for a walk.
Counseling	Counseling by a health care worker alone can result in a 3%–5% quit rate.
Setting a quit date	The cold turkey method is more effective than slow tapering, although the patient may choose to taper before the quit date.
Nicotine replacement therapy	Nicotine gum, patches, nasal sprays, and inhalers can reduce withdrawal symptoms.
Drug therapy (bupropion [Zyban], bupropione [BuSpar])	Better success rates are achieved with a combination of nicotine and bupropion.
Hypnosis	Hypnosis can help reduce the stress and anxiety associated with smoking cessation.

Association site at www.lungusa.org and the National Lung Health Education Program at www.nlhep.org. Or simply type *smoking cessation* into any search engine. The American Lung Association has a free online smoking cessation program that can be accessed at <http://www.ffsonline.org>. Alternatively, individuals can call 1-800-QUIT NOW to speak with a representative who will assist with cessation strategies.

Deep Breathing and Coughing

Effective coughing can keep the airways clear of secretions. An ineffective cough is exhausting and fails to bring up secretions. Instruct the patient to take two or three deep breaths, using the diaphragm. This helps get the air behind the secretions. After the third deep inhalation, tell the patient to hold the breath and cough forcefully. This is repeated as necessary. Good hydration can facilitate this process.

Huff Coughing

Patients with chronic obstructive pulmonary disease (COPD) typically have a weak cough and airways that collapse easily. Huff coughing may work better for them. To do this, instruct the patient to exhale deeply to remove as much trapped air as possible, then take a deep breath in to get air behind the secretions. Instead of closing the glottis to generate a forceful cough, the patient should keep the glottis and mouth open, and use the abdominal muscles to create a series of forced expirations, moving air and mucus up the bronchial tree. This creates “huff” sounds. Finally, the patient should take one more controlled inhalation and a final huff cough to expel the mucus.

Breathing Exercises

Breathing exercises are essential for patients with chronic lung disease. Diaphragmatic and pursed-lip breathing increase the effectiveness of breathing and help reduce panic when dyspnea occurs.

Diaphragmatic Breathing

The diaphragm is the major muscle of breathing, but patients often use less efficient accessory muscles when they are short of breath. Conscious use of the diaphragm during breathing can be relaxing and conserves energy. With practice, the patient should be able to use diaphragmatic breathing all the time without thinking about it. Teach the patient to do the following:

1. Place one hand on the abdomen and the other on the chest.
2. Concentrate on pushing out the abdomen during inspiration and relaxing the abdomen on expiration. The chest should move very little.

Pursed-Lip Breathing

This technique can be used any time the patient feels short of breath. It helps keep airways open during exhalation, which promotes carbon dioxide excretion. It should be done with diaphragmatic breathing. Counting during breathing also distracts the patient, reducing panic. Teach the patient to do the following:

1. Inhale slowly through the nose to the count of two.
2. Exhale slowly through pursed lips to the count of four.

Positioning

The patient who is short of breath should be positioned to conserve energy while allowing for maximum lung expansion. The patient in bed can use a Fowler’s or semi-Fowler’s position to keep abdominal contents from crowding the lungs. Most respiratory patients do not tolerate lying flat. Some patients prefer to sit in a chair while leaning forward and placing their elbows on their knees or an over-bed table with a pillow on it.

Patients with unilateral (one-sided) lung disease can benefit from the “good lung down” lateral position. This is a side-lying position with the good lung in the dependent position. Gravity causes greater blood flow to the dependent, “good” lung, thereby increasing oxygen saturation.

Oxygen Therapy

Oxygen therapy is ordered by the physician when the patient is unable to maintain oxygenation. Many patients are placed on supplemental oxygen when their oxygen saturation is less than 90 percent on room air. The physician’s order should include the method of administration and the flow rate. A variety of delivery methods are described in the following sections. The role of the nurse in oxygen therapy includes monitoring the flow rate, ensuring that the cannula and tubing or other device remain properly placed, and mon-

itoring the patient's response to treatment. If the patient becomes short of breath while on oxygen therapy, an RT or a physician should be notified. Instruct the patient to avoid smoking, using electrical equipment, and performing other activities that can cause fire in the presence of oxygen. The RT is knowledgeable about oxygen therapy and is an excellent resource when questions arise.

PATIENT CARE TIP

If a patient suddenly becomes confused, check the oxygen delivery system. The patient may have taken off the cannula, or the tubing may be kinked or disconnected, resulting in hypoxia and confusion.

Low-Flow Devices

NASAL CANNULA. The nasal cannula is the most common method of oxygen administration. Oxygen is delivered through a flexible catheter that has two short nasal prongs (Fig. 29.9). For the nasal cannula to be most effective, the patient must breathe through his or her nose. The cannula allows the patient to eat and talk, and it is generally more comfortable than other methods of administration. If the nasal mucous membranes become dry, an RT can place a water source on the system to humidify the oxygen. Oxygen can be delivered at 1 to 6 L/minute via a nasal cannula, according to the physician's order.

MASKS. Masks are used when a higher oxygen concentration is needed (Fig. 29.10). A disadvantage to masks is that they make some patients feel claustrophobic. Also, a mask must be replaced by a cannula for eating.

SIMPLE FACE MASK. A rate of 5 to 10 L/minute can deliver oxygen concentrations from 40 to 60 percent with a simple face mask.

FIGURE 29.9 Nasal cannula for oxygen delivery.

FIGURE 29.10 Oxygen masks. (A) Simple mask. (B) Partial rebreather mask. (C) Nonrebreathing mask. (D) Venturi mask.

PARTIAL REBREATHER MASK. A partial rebreather mask uses a reservoir to capture some exhaled gas for rebreathing. Vents on the sides of the mask allow room air to mix with oxygen. It can deliver oxygen concentrations of 50 percent or greater.

NONREBREATHER MASK. A nonrebreather mask has one or both side vents closed to limit the mixing of room air with oxygen. The vents open to allow expiration but remain closed on inspiration. The reservoir bag has a valve to store oxygen for inspiration but does not allow entry of exhaled air. It is used to deliver oxygen concentrations of 70 to 100 percent.

When a patient is using a partial rebreather or nonrebreather mask, ensure that the reservoir is never allowed to collapse to less than half full.

High-Flow Devices

VENTURI MASK. A Venturi mask is used for the patient who requires precise percentages of oxygen, such as the patient with chronic lung disease with CO₂ retention. A combination of valves and specified flow rates determines oxygen concentration.

Transtracheal Catheter

A transtracheal catheter is a small tube that is surgically placed through the base of the neck directly into the trachea to deliver oxygen (Fig. 29.11). This is an attractive alternative for some patients who are on long-term oxygen therapy

FIGURE 29.11 Transtracheal oxygen catheter.

at home because it does not obstruct the nose or mouth and can be easily covered with a loose scarf or collar. The patient is taught to remove and clean the catheter two or three times a day to prevent mucus obstruction. Check institution policy and procedure and the respiratory care department for specific care instructions.

Risks of Oxygen Therapy

Patients with chronic obstructive pulmonary disease (COPD) have chronically high PaCO_2 levels. Therefore, they depend on low PaO_2 levels to stimulate breathing, and high supplemental oxygen flow rates can depress respirations. Patients with COPD should be maintained on no more than 1 to 2 L of oxygen per minute. Occasionally, hospitalized patients receive higher flow rates, but they must be carefully monitored.

In addition, any patient can suffer lung damage from high oxygen concentrations delivered for more than 24 hours. If a patient exhibits symptoms of dry cough, chest pain, numbness in the extremities, lethargy, or nausea, the physician should be contacted. A PaO_2 greater than 100 mm Hg should also be reported.

Nebulized Mist Treatments

Nebulized mist treatments (NMTs) use a nebulizer to deliver medication directly into the lungs (Fig. 29.12). Such topical use of medication reduces systemic side effects. Bronchodilators such as albuterol or metaproterenol, mixed with normal saline solution and sometimes with supplemental oxygen, are most commonly administered. Other medications, including corticosteroids, mucolytics, and antibiotics, may also be given. An RT or a specially trained nurse administers the NMT. The patient uses a hand-held reservoir with tubing and a mouthpiece to breathe in the medication. NMTs are commonly ordered every 4 to 6 hours and as needed. You may call for an NMT as needed (prn) when a patient with chronic pulmonary disease becomes acutely

FIGURE 29.12 Patient receiving nebulized mist treatment.

dyspneic. Some patients are taught to administer their own NMTs at home.

Inhalers

Inhalers are another way to administer topical medication directly into the lungs, minimizing systemic side effects. Medications that can be inhaled include corticosteroids, bronchodilators, and mast cell inhibitors (cromolyn sodium). Metered-dose inhalers (MDI) use propellants to deliver medication. Figure 29.13 shows one way to use an MDI. Use of a spacer can increase the amount of medication that gets to the lungs (Fig. 29.14). Many MDIs use a chlorofluorocarbon (CFC) as a propellant, but CFC damages the ozone, so new ways to deliver inhaled medications are being developed. Many new models of inhalers (especially dry powder inhalers that do not use any propellants) are now available. It is important to carefully read the instructions for use before assisting a patient with any inhaler.

The RT or nurse must carefully instruct the patient because improper use can reduce the effectiveness of the medication. It is also important to teach the patient to avoid overuse of adrenergic bronchodilator inhalers. Patients with chronic lung disease may tend to use extra puffs when they feel short of breath. Adrenergic bronchodilators, when used too often, can cause severe rebound bronchoconstriction and even death.

Incentive Spirometry

Incentive spirometers are devices used to encourage deep breathing in patients at risk for collapse of lung tissue, a condition called atelectasis (Fig. 29.15). These devices are commonly ordered for postoperative patients. Patients are instructed to use the spirometer 10 times each hour they are awake. Because a variety of spirometers are available, consult with an RT and read package inserts for specific directions for use.

Chest Physiotherapy

Chest physiotherapy (CPT), which includes postural drainage, percussion, and vibration, helps move secretions from deep inside the lungs (Fig. 29.16). It is indicated for the patient who has a weak or ineffective cough and is therefore at risk for retaining secretions. Patients with COPD,

1. Gently twist the canister into the inhaler unit. Shake the inhaler, and remove the cap.

2. Exhale.

3. Place the inhaler mouthpiece in your mouth.

4. Press the canister down to actuate a dose of medication. As you do so, breathe in slowly and deeply. Time the dose and breath so the medication goes into the lungs, and not onto the tongue.

5. Hold your breath for 5 – 10 seconds. Repeat steps 2 – 4 if two puffs are ordered.

FIGURE 29.13 Instructions for use of a metered dose inhaler: See package inserts for specific instructions, since there are many types of inhalers available.

cystic fibrosis, or bronchiectasis and patients on ventilators benefit from CPT.

CPT is performed by an RT or specially trained nurse. For postural drainage, the patient is placed in various positions (head down to help drain secretions) and turned periodically during the treatment so all lobes of the lungs are drained. The therapist uses cupped hands to strike the chest repeatedly (percussion), producing sound waves that are

FIGURE 29.14 Use of a spacer increases the amount of medication that gets to the lungs.

transmitted through the chest, loosening secretions. The therapist may also apply vibration to the patient's chest, using the hands or a vibrator, to loosen secretions. A nebulizer treatment should be given before CPT to humidify secretions. The patient is instructed to cough and deep breathe at intervals during and after the treatment.

Flutter Mucus Clearance Device

An alternative to chest physiotherapy is a small hand-held device called the Flutter mucus clearance device (Fig. 29.17). When the patient blows into the mouthpiece, it makes a heavy steel ball inside bounce around in its chamber, which then sends vibrations back into the airways. This helps to loosen mucus and open the airways.

Thoracentesis

Thoracentesis involves the insertion of a needle into the pleural space. It is commonly done to aspirate fluid in patients with pleural effusion (fluid trapped in the pleural space). The procedure may be diagnostic, to determine the source of fluid, or therapeutic, to remove fluid and reduce respiratory distress. It may also be performed to aspirate blood or air or to inject medication.

When assisting a physician with a thoracentesis, first verify that the patient understands the procedure and that written consent has been obtained if required by institution policy. Have the patient void before the procedure. The patient should be aware that a sensation of pressure may be felt, but that severe pain is rare. Administer an analgesic if ordered before the procedure. Obtain a special procedure tray that has the equipment needed by the physician. Place the patient in a sitting position, bending over a bedside table, or in a side-lying position if unable to sit. You can position yourself in front of the patient and encourage relaxation during the procedure. If you are asked to hand equipment to the physician, be sure to keep everything sterile. The physician uses a local anesthetic before inserting a needle into the

thoracentesis: thoraco—chest + centesis—puncture

FIGURE 29.15 Incentive spirometers. (A) Voldyne volumetric deep breathing exerciser. (B) Triflow II incentive breathing exerciser. (Modified from Barnes, TA: *Respiratory Care Principles*. F.A. Davis, Philadelphia, 1991, p 434.)

patient’s back through the desired interspace. Specimens are withdrawn through the needle, labeled, and sent to the laboratory. If the thoracentesis is being done for therapeutic reasons, a sterile container is used to collect the remaining fluid. As much as 2 L can be removed, sometimes more, and the patient will usually report immediate reduction of dyspnea.

After the procedure, the physician may apply a petroleum jelly dressing to prevent air leakage into the wound. Assess vital signs, breath sounds, and the puncture site according to the physician’s orders (e.g., every 15 minutes times two, every 30 minutes times two, then every 4 hours for 24 hours). The patient is usually maintained on bedrest for 1 hour after the procedure. Label and send specimens to the laboratory as ordered. The physician may order a post-procedure x-ray examination to ensure that the lung was not punctured, causing a pneumothorax.

SAFETY TIP

Label all medications, medication containers (e.g., syringes, medicine cups, basins), or other solutions on and off the sterile field in perioperative and other procedural settings (2006 National Patient Safety Goals from www.jcaho.org).

Chest Drainage

Continuous chest drainage involves insertion of one or two chest tubes by the physician into the pleural space to drain fluid or air. The tubes are connected to a chest drainage system that collects the fluid or allows escape of the air.

Indications

Chest tubes and a chest drainage system are used when fluid or air has collected in the pleural space. This can occur with a pneumothorax, pleural effusion, penetrating chest injury, or during chest surgery. These conditions are covered in Chapter 31.

FIGURE 29.16 Patient receiving chest physiotherapy.

FIGURE 29.17 Flutter® Mucous Clearance Device. When the patient blows into the mouthpiece, the stainless steel ball bounces up and down, causing airways to vibrate. This helps open airways and loosen mucus. Consult package instructions before use (Courtesy of Axcan Scandipharm).

Chest Tube Insertion

The physician inserts drainage tubes through the chest wall into the pleural space either in surgery or at the bedside. If removal of air is the goal, the tube is inserted into the upper anterior chest, in the second to fourth intercostal space. If removal of fluid is the goal, the tube is inserted in the lower lateral chest, in the eighth or ninth intercostal space. If a patient has both air and fluid to drain, two tubes are inserted and may be joined with a Y connector before connecting to the tubing that leads to a drainage system. You can assist the physician by obtaining a chest tube insertion tray and chest drainage system and preparing it according to the manufacturer's directions. Ensure that the patient understands the procedure and that written consent has been obtained according to institutional policy. Administer an analgesic if ordered. Chest tube insertion is sometimes an emergency intervention, which necessitates that the nurse help prepare the patient quickly.

Once the tube has been inserted and the system is in place, ensure that each connection is securely taped with adhesive tape to prevent a break in the system. Petroleum jelly gauze and a sterile occlusive dressing are applied over the insertion site to prevent air leakage. If the dressing becomes soiled, do not change it. Reinforce it with additional dressings, and notify the physician.

Obtain two padded clamps to keep at the bedside. These are used to clamp the chest tube if the chest drainage system becomes accidentally disconnected from the tubing, for changing the drainage system, or for a trial period before chest tube removal. The tubes are never clamped for more than a few seconds, however, because this prevents air escape and causes build-up of air in the pleural space. This can create a tension pneumothorax, which is a life-threatening emergency. (See Chapter 31.)

Chest Drainage System

The drainage system has evolved from a set of glass bottles to a one-piece molded plastic system with chambers that correspond to the bottles. Some newer one-piece systems use special valves to eliminate the need for water. Some physicians, however, continue to use the bottle system. Studying the bottle system helps to understand the one-piece system (Fig. 29.18). One, two, or three bottles can be used. Study the pictures as you read the following sections.

WATER SEAL BOTTLE OR CHAMBER. Each time the patient exhales, air trapped in the pleural space travels through the chest tube to the water seal bottle or chamber, under the water, then bubbles up and out of the bottle. The water acts as a seal, allowing air to escape from the pleural space but preventing air from getting back in during the negative pressure of inspiration. Water in the tube fluctuates up with each inspiration and down with each expiration, as much as 5 to 10 cm. This is called **tidaling**. When the lung is reinflated, tidaling stops. If tidaling stops before the lung is reinflated, the tubing should be checked for a kink or occlusion. If constant bubbling occurs in the water seal

FIGURE 29.18 Pleur-Evac chest drainage system. (Courtesy Deknatel Snowden Pencer, Inc., Tucker, GA.)

chamber, the system should be checked immediately for leaks.

SUCTION BOTTLE OR CHAMBER. Sometimes a suction source is used to speed lung reinflation. A separate bottle with tubing attached to suction is used. The amount of suction depends on the level of water in the bottle, not the amount of suction set on the machine. The suction level is ordered by the physician and is almost always negative 20 cm of water. The suction should be turned on far enough to cause gentle bubbling in the suction bottle or chamber. Vigorous bubbling causes water evaporation which alters the amount of suction. If water evaporates, more must be added to maintain the correct amount of suction.

DRAINAGE BOTTLE OR CHAMBER. Sometimes a third bottle is needed to catch fluid drained from the pleural space. Drainage may be from pleural effusion, chest trauma, or surgery. Sometimes a small amount of drainage occurs because of the insertion of the chest tube. The drainage chamber is not emptied to measure drainage. Rather the drainage level in the bottle or chamber is marked and timed each shift to monitor the amount. It is documented as output on the intake and output record. If drainage suddenly increases or becomes very bloody, notify the physician.

Nursing Care

Nursing care of a patient with a chest tube involves regular assessment of the patient and the drainage system. See Box 29.2 Care of the Patient with a Chest Drainage System for

Box 29.2**Care of the Patient with a Chest Drainage System**

Assess the patient according to institution policy. Start with the patient and move toward the drainage system.

1. Observe respiratory rate, effort, and symmetry.
2. Assess shortness of breath, pain, or other discomforts.
3. Auscultate lung sounds (lung sounds may initially be muffled or absent on the side of a collapsed lung but should gradually return to normal as the lung reinflates).
4. Confirm that dressing is intact; observe for drainage. If necessary, reinforce the dressing and notify the physician. Do *not* change the dressing.
5. Palpate around insertion sites for crepitus.
6. Check all tubing for kinks, breaks, or broken connections. Verify that all connections are securely taped.
7. Ensure that there are no dependent loops of tubing. Excess tubing should be coiled on the bed.
8. Verify that drainage system is below level of patient's chest at all times.
9. Check drainage system or bottles for cracks or leaks.
10. Check water seal chamber for correct water level and for tidaling (unless lung reinflated). Add water if evaporation has decreased level. If continuous bubbling is present, check entire system for leaks and notify physician.
11. Check suction control chamber for gentle bubbling (or open to air). Confirm correct amount of water if indicated. Add water if needed.
12. Check and mark amount of drainage in collection chamber every 8 hours and prn or as ordered. Report any marked increase in bloody drainage. Record drainage as output.
13. Document findings.

Notify RN or physician if

- The patient suddenly complains of increasing dyspnea.
- The drainage chamber is full and needs to be changed.

specific assessment and care. If permitted by the physician, patients can be free to move around with the chest tube and drainage system. The drainage system must always be kept upright and below the level of the chest. If the patient must be transported, the drainage system is transported with the patient. Ask the physician if the patient can be safely transported without suction. The suction control chamber is then left open to allow air to escape. Tubing is not clamped for transport.

If a chest tube is accidentally pulled out before the pneumothorax is resolved, air can reenter the pleural space. Some physicians want an occlusive dressing placed over the site to prevent air from reentering. However, an occlusive dressing increases the risk of trapped air building up and placing pressure on the heart. You should be aware of the preferences of the patient's physician.

Stripping and Milking

In the past, it was routine to strip and milk the tubing from the patient to the drainage system to dislodge clots and maintain patency. Stripping is done by holding the proximal end of the tubing and using the other hand to squeeze the tubing between two fingers while sliding the fingers toward the drainage system. This is repeated on small sections of tubing until all have been stripped. It is now known, however, that this process can create negative pressure at the openings in the tubing that are within the pleural space, which can suck lung tissue in and cause damage. Stripping should be done only if it is ordered by the physician.

Milking is done by gently squeezing portions of tubing from the patient to the system without any sliding motion. This is somewhat safer for the patient but is still not done routinely. If tubing appears to be occluded, consult with the physician for specific orders.

Removal of Chest Tube

When the reason for the chest tube is resolved, the physician removes it and places petroleum jelly gauze and a sterile occlusive dressing over the site. Continue to watch for development of crepitus and to monitor the dressing site and respiratory status.

CRITICAL THINKING**Miss Israel**

- Miss Israel has a chest tube in place for a spontaneous pneumothorax. You note that the water seal chamber is bubbling vigorously. (1) What could cause bubbling in the water seal chamber? What should you do? (2) You are totaling intake and output for your 8-hour shift. There is 240 mL of serous fluid in the drainage chamber of the drainage system at 10 p.m. At 2 p.m., there was 190 mL. How much output should you record?

Suggested answers at end of chapter.

Tracheostomy

A **tracheotomy** is a surgical opening through the base of the neck into the trachea. It is called a **tracheostomy** when it is more permanent and has a tube inserted into the opening to maintain patency (Fig. 29.19). The patient breathes

tracheotomy: trach—trachea + otomy—incision

tracheostomy: trache—trachea + ostomy—opening or mouth

FIGURE 29.19 Patient with tracheostomy.

through this opening, bypassing the upper airways. A tracheostomy is performed for a variety of reasons, such as in patients who have had a cancerous larynx removed, patients with airway obstruction caused by trauma or tumor, patients who have difficulty clearing secretions from the airway, and patients who need prolonged mechanical ventilation.

The tracheostomy tube consists of three parts: an outer cannula, an inner cannula, and an obturator (Fig. 29.20). The obturator is a guide that is used only during insertion of the tube. After insertion, the obturator is immediately removed and kept at the bedside (commonly taped to the wall above the bed) for emergency use if the tracheostomy tube is accidentally removed. The outer cannula remains in place at all times and is secured by ties to prevent dislodging. The inner cannula is removed at intervals; usually every 8 hours and as needed for cleaning. Some newer tracheostomy tubes eliminate the need for an inner cannula. The tube may be metal or plastic. Plastic tubes generally have disposable inner cannulas, which can be replaced rather than cleaned. Plastic tubes may also have balloonlike cuffs that are inflated to prevent air escape during mechanical ventilation and to prevent aspiration of food or secretions. Institution policy may dictate that cuffs be deflated routinely to prevent tissue damage. See Box 29.3 Tracheostomy Cleaning Procedure for routine tracheostomy cleaning.

Communication is problematic for the patient with a tracheostomy tube because air is diverted out the tube rather than past the vocal cords and out the mouth. Fenestrated tubes are tubes with openings (fenestra) in the cannula to allow air to flow up into the larynx for speaking (see Fig. 29.20). The patient can be taught to plug the opening of the tube while speaking to divert air through the fenestra. Another option is a valve such as the Passy-Muir Tracheostomy and Ventilator Swallowing and Speaking Valve (Fig.

FIGURE 29.20 Tracheostomy tube. (A) Metal tube. (B) Cuffed plastic tube. (C) Fenestrated tube.

29.21). This is a special valve that allows air into the tracheostomy during inspiration but closes and redirects air up through the vocal cords and out the nose and mouth on expiration, allowing the patient to speak. For the valve to work, the tracheostomy tube must be small enough for air to flow around it or it must be fenestrated to allow air to flow up through the vocal cords. If cuffed, the cuff must be completely deflated.

Some tracheostomies are permanent. However, some patients can be weaned from the tracheostomy tube when

Box 29.3**Tracheostomy Cleaning Procedure**

1. Assemble equipment: tracheostomy care kit, sterile water or saline, suction equipment, hydrogen peroxide.
2. Explain the procedure to the patient.
3. Suction inner cannula if necessary. See Box 29.6 Suctioning Procedure for the Patient with a Tracheostomy.
4. Open and prepare the kit, keeping all equipment sterile. Fill one side of basin with half peroxide and half saline and the other with saline.
5. Don clean gloves.
6. Remove old tracheostomy dressing.
7. Remove inner cannula from tracheostomy tube and place it in peroxide solution.
8. While inner cannula is removed, the patient may be suctioned if necessary.
9. Don sterile gloves.
10. Use brush and pipe cleaners to clean inner cannula. Place in water or saline to rinse. Dry inside of cannula with pipe cleaner. Reinsert into tracheostomy tube.
11. Use cotton swab and sterile gauze with sterile peroxide and saline to clean around tracheostomy site. Rinse with saline to prevent skin irritation.
12. Replace ties. Remove old ties after new ties are securely in place.
13. Apply sterile tracheostomy dressing (drain sponge or “trach pants”). Use precut or folded dressing. Cutting gauze creates fibers that can enter the tracheostomy.

NOTE: A procedure manual should be consulted for more detailed instruction.

their condition has improved enough to allow breathing without it. The physician may replace the tube with a smaller tube to prepare the patient for its removal. This allows a plug to be inserted into the tracheostomy tube at intervals to force the patient to breathe around the tube through the nose and mouth. When the tracheostomy tube has been removed, the opening may be taped shut and covered with gauze until it is healed. The gauze often becomes saturated with secretions and is changed as needed.

Nursing Process for the Patient with a Tracheostomy

See Box 29.4 Nursing Care Plan for the Patient with a Tracheostomy.

Suctioning

Suctioning involves the use of a flexible catheter to remove secretions from the respiratory tract of a patient who is unable to cough effectively. This may be a patient with over-

FIGURE 29.21 The Passy-Muir Tracheostomy Speaking Valve allows air into the tracheostomy during inspiration but closes and redirects air up through the vocal cords and out the nose and mouth on expiration, allowing the patient to speak (Courtesy of Passy-Muir, Inc., Irvine, CA).

CRITICAL THINKING

Mr. Smith

■ Mr. Smith had a plastic cuffed tracheostomy tube that was small enough to allow airflow around it for talking when the cuff was deflated. The cuff was inflated for lunch to prevent him from aspirating. A friend stopped by for a chat and assisted Mr. Smith to plug his tracheostomy so he could talk. Mr. Smith’s face turned dark red, and his expression showed extreme anxiety.

1. What happened?
2. How could you help prevent this in the future?
3. How would you document this occurrence?

Suggested answers at end of chapter.

whelming secretions or a patient with a tracheostomy or endotracheal tube.

The procedures for suctioning are presented in Boxes 29.5 and 29.6. A procedure manual should be consulted for more detailed instruction. Remember that suctioning is both frightening and uncomfortable for a patient. Patients sometimes feel as though oxygen is being “vacuumed” from their lungs. Suctioning can cause hypoxia, vagal stimulation with resulting bradycardia, and even cardiac arrest. It is done only when necessary rather than on a routine basis. Coughing is the most effective way to clear secretions and should be encouraged if the patient is capable. Signs that suctioning is needed include crackles or wheezes heard with or without a stethoscope or a dropping oxygen saturation.

(Text continued on page 570)

Box 29.4 NURSING CARE PLAN for the Patient with a Tracheostomy

Nursing Diagnosis: Risk for ineffective airway clearance related to increase in secretions

Expected Outcomes Airway is free of secretions as evidenced by no audible crackles or wheezes in airway, inner cannula clear.

Evaluation of Outcome Is airway free of secretions?

Intervention

Assess lung sounds every 4 hours and pm.
Encourage patient to deep breathe and cough as able.
Encourage fluids if not contraindicated.

Encourage ambulation as able, or turn every 2 hours.
Clean tracheostomy according to agency policy. (See Box 29.3 Tracheostomy Cleaning Procedure.)
Suction patient using sterile technique pm (Box 29.6 Suctioning Procedure for the Patient with a Tracheostomy).
Suction only when necessary.
Monitor and document amount, color, and character of secretions. Report increase in secretions accompanied by fever.

Rationale

Coarse crackles or wheezes may indicate secretions in airways.
Patients may be able to clear own secretions without suctioning.
Fluids help hydrate secretions, making them easier to cough up.
Movement helps mobilize secretions.
Cleaning helps remove excess mucus and keeps airway clear.

Suctioning clears secretions from airways. Unnecessary suctioning irritates airways.

Purulent sputum accompanied by fever may indicate pneumonia.

Evaluation

Are coarse crackles or wheezes present?
Is patient able to cough up secretions effectively?
Is patient taking adequate fluids? Are secretions thin?
Is patient mobilized as much as possible?
Does cleaning help maintain an open airway?

Is suction necessary? Is airway free of secretions after suctioning?

Is sputum clear or white, and scant in amount? Was purulent sputum reported?

Nursing Diagnosis: Risk for infection related to bypass of normal respiratory defense mechanisms

Expected Outcomes Patient is free of infection, as evidenced by vital signs within normal limits, clear secretions.

Evaluation of Outcome Is patient free from symptoms of infection?

Intervention

Use good hand-washing practice.

Monitor and report signs and symptoms of infection: fever, increased respiratory rate, purulent sputum, elevated white blood cell (WBC) count.
Protect tracheostomy opening from foreign material: food, sprays, powders.
Use meticulous sterile technique for all tracheostomy care and suctioning.

Encourage a well-balanced diet.
Consult dietitian prn.

Take measures to prevent aspiration of food or secretions.

Rationale

Hand-washing is important in preventing infection.
Early recognition and treatment of infection enhances outcome.

Foreign materials in the tracheostomy may cause pneumonia.
Use of nonsterile technique may introduce microorganisms into the respiratory tract.
A well-balanced diet enhances immune function.

Aspiration can cause pneumonia.

Evaluation

Do all caregivers use good hand-washing technique?
Are signs of infection present?

Is tracheostomy adequately protected?
Is sterile technique used by all caregivers?

Is patient eating a balanced diet or receiving adequate supplementation?

Is there evidence that the patient is aspirating?

Nursing Diagnosis: Impaired verbal communication related to presence of tracheostomy tube

Expected Outcomes Patient uses alternate methods of communication effectively. Patient expresses satisfaction with ability to communicate needs.

Evaluation of Outcome Is patient able to use alternative methods to express needs? Does patient express satisfaction with ability to do so?

Intervention

Take time to allow patient to communicate needs.

Watch for patient's nonverbal cues.

Offer pen and paper or magic slate (if patient is literate).

Use picture board (available from Speech Therapy Department).

Teach patient with fenestrated or small tracheostomy tube how to cover opening with a plug or clean finger in order to talk.

Consult with speech therapist.

Rationale

Communication takes time; patient may become frustrated if hurried.

Gestures and facial expression can provide valuable cues.

The patient may be able to write out his or her needs/concerns.

The patient can point to a picture (water, toileting) that indicates his or her need.

Covering opening diverts air into larynx and allows speech.

Speech therapist may have additional methods for communicating with patient.

Evaluation

Does patient feel he or she is given adequate time for communication of needs?

Is the patient attempting to communicate with nonverbal cues?

Is patient able to write out needs?

Is patient able to point appropriately to needs?

Is patient able to communicate in this manner?

Did speech therapist provide alternative communication techniques?

Nursing Diagnosis: Disturbed body image related to presence of tracheostomy

Expected Outcomes Patient verbalizes acceptance of tracheostomy. Patient is willing to participate in tracheostomy care.

Evaluation of Outcomes Does patient verbalize acceptance of tracheostomy? Does patient participate in learning to care for tracheostomy?

Intervention

Assess patient's feelings about tracheostomy.

Approach patient with an accepting attitude.

Allow patient opportunity to verbalize concerns about tracheostomy.

Refer patient to support group if available.

Assist patient in finding attractive ways to conceal tracheostomy if desired.

Rationale

Assessment provides basis for care.

The patient will be aware of the nurse's nonverbal body language.

Verbalizing concerns helps the patient to sort out feelings and problem solve.

The patient may benefit from talking with others with tracheostomies.

Loose scarves or collars can help conceal and protect the tracheostomy.

Evaluation

Are the patient's feelings within an expected range for such a change in body image?

Does the patient indicate a feeling of acceptance from the nurse?

Does the patient verbalize feelings as needed? (Note: Some patients do not wish to share feelings and should not be forced to do so.)

Is patient receptive to a support group referral?

Is patient satisfied with appearance of tracheostomy?

(Continued on following page)

Box 29.4 NURSING CARE PLAN for the Patient with a Tracheostomy (Continued)

Nursing Diagnosis: Deficient knowledge related to care of new tracheostomy

Expected Outcomes Patient and significant other will verbalize understanding of self-care, demonstrate tracheostomy self-care procedures, and state resources for help after discharge.

Evaluation of Outcomes Are patient and significant other able to verbalize self-care actions and rationale? Are patient and significant other able to correctly demonstrate care procedures? Is patient able to state how to obtain help after discharge?

Intervention

Assess patient's and significant other's baseline knowledge of self-care.

Instruct patient and significant other in the following (see text for specific instruction):

- Tracheostomy cleaning
- Deep breathing and coughing
- Suctioning
- Prevention of infection and symptoms to report to health care provider
- Protection of tracheostomy from pollutants, water (no swimming, careful showering)

Provide follow-up with home health nurse after discharge.

Rationale

Teaching should only be initiated if a knowledge deficit exists.

The patient will need to care for self after discharge.

A home health nurse can provide reinforcement of instruction at home.

Evaluation

Does patient exhibit knowledge of self-care?

Does patient verbalize understanding of self-care and demonstrate all procedures correctly?

Is patient receptive to having a home health nurse assist?

Each step should be explained to the patient during suctioning even if he or she is unresponsive.

Intubation

Some patients are unable to breathe effectively and maintain adequate oxygenation because of airway obstruction or respiratory failure. These patients are intubated with a special endotracheal (ET) tube through the nose or mouth and into the trachea (Fig. 29.22). Patients in cardiopulmonary arrest are intubated during advanced cardiac life support, and patients undergoing general anesthesia during surgery are intubated and mechanically ventilated. Most intubated patients are also mechanically ventilated. Some patients have advance directives that indicate that they do not wish to be intubated. You should be familiar with the patient's wishes and bring them to the attention of the physician if necessary.

Because intubation can damage the vocal cords and surrounding tissues, it is usually a short-term intervention. Patients who need long-term ventilatory support have a tracheostomy tube placed.

NURSING CARE. Nursing care of the intubated patient includes regular assessment of the patient's respiratory status and tube placement. Lung sounds are auscultated bilaterally to ensure that the tube has not been displaced into one bronchus. The tube is carefully secured with tape or a Velcro holder to avoid dislodging. Oral tubes are repositioned and resecured to the opposite side of the mouth every 24 hours or according to institution policy to prevent tissue damage. An adhesive skin barrier should be applied under the tape to protect the skin. If the patient is alert, he or she is instructed to be careful not to pull on the tube. You may need to obtain an order for soft wrist restraints if absolutely necessary for the confused patient. Restraints can be avoided if a family member is available to sit with the patient. Some nursing interventions for the patient with a tracheostomy are also appropriate for the intubated patient. (See Box 29.4 Nursing Care Plan for the Patient with a Tracheostomy.)

Endotracheal tubes have a cuff (a balloonlike area around the tube) to help maintain proper placement and to prevent leakage of air around the tube. An RT usually inflates

Box 29.5**Oropharyngeal or Nasopharyngeal Suction Procedure**

1. Gather equipment: sterile suction catheter, sterile gloves, sterile container (these items may be found in a single “cath and glove” kit); sterile water or saline, suction machine with tubing.
2. Explain procedure to patient.
3. Connect catheter to suction tubing, keeping catheter inside sterile sleeve. Turn on suction to level specified by institution policy (usually 80–120 mm Hg for wall suction).
4. Pour saline into sterile container.
5. Put on sterile gloves. Keep dominant hand sterile at all times.
6. Suction small amount of saline into catheter to rinse catheter and test suction.
7. Have patient take several deep breaths.
8. With thumb control uncovered to stop suction, insert suction catheter through mouth or nose into the trachea until resistance is met or patient coughs.
9. Slowly withdraw catheter, suctioning intermittently while rotating it. The entire procedure should take no more than 10 to 15 seconds.
10. After allowing patient to rest, repeat steps 6 through 9 two more times if needed.

NOTE: A procedure manual should be consulted for more detailed instruction.

the cuff and maintains a specific cuff pressure and should be consulted for assistance with this activity.

Patients with ET tubes may need suctioning if they are unable to cough effectively. Visible secretions in the tube, crackles or wheezes heard with or without the stethoscope, or a drop in SaO_2 without another obvious cause are signs that suctioning is necessary. The ET tube suctioning procedure is sterile and is the same as suctioning a tracheostomy tube. Some institutions have in-line suctioning devices, which are connected to the ET tube within a sterile sleeve. This maintains sterility, protects the nurse, and simplifies the suctioning procedure. Oral suction keeps the mouth free of secretions.

The intubated patient is often extremely anxious, especially if she or he is alert. Explain the purpose of all care activities. Suctioning is particularly anxiety-producing and should be explained carefully even if the patient is unresponsive.

Intubated patients are at risk of developing ventilator-associated pneumonia (VAP) because normal respiratory defense mechanisms are bypassed. Good hand washing and

Box 29.6**Suctioning Procedure for the Patient with a Tracheostomy**

1. Gather equipment: sterile suction catheter, sterile gloves, sterile container (these items may be found in a single “cath and glove” kit); sterile water or saline, suction machine with tubing, manual resuscitation bag.
 2. Explain procedure to patient.
 3. Connect catheter to suction tubing, keeping catheter inside sterile sleeve. Turn on suction to level specified by institution policy (usually 80 to 120 mm Hg for wall suction). Connect oxygen source to manual resuscitation bag.
 4. Pour saline into sterile container.
 5. Put on sterile gloves. Keep dominant hand sterile at all times.
 6. Suction small amount of saline into catheter.
 7. Oxygenate patient with three ventilations using a manual resuscitation bag connected to an oxygen source, using the nonsterile hand. If the patient is mechanically ventilated, use manual sigh.
 8. With thumb control uncovered to stop suction, insert suction catheter through tracheostomy tube until patient coughs or resistance is met.
 9. Slowly withdraw catheter, suctioning intermittently while rotating it. The entire procedure should take no more than 15 seconds.
 10. Allow patient to rest.
 11. Repeat steps 6 through 10 two more times if needed. Some older sources recommend instilling sterile saline into the tracheostomy to loosen secretions. *This should be avoided.* It is now known that this procedure is not effective and may actually cause a drop in the patient’s SaO_2 .
- NOTE: A procedure manual should be consulted for more detailed instruction.

frequent mouth care to reduce risk of aspirating oral microorganisms can help prevent VAP.

Because the ET tube passes between the vocal cords, the patient is unable to speak. Provide paper and pencil or a picture board for communication. Yes/no questions can be answered by a nod or shake of the head.

Monitor arterial blood gas and oxygen saturation values and notify the physician of changes. If oxygen values drop or the patient becomes confused or agitated, the patient should be immediately inspected for a disconnected oxygen source or excessive secretions.

If the physician determines that the patient can breathe effectively without the tube, the tube will be removed. The patient will be slowly weaned from the ventilator first. Prior

FIGURE 29.22 Endotracheal tube. (Modified from Barnes, TA: *Respiratory Care Principles*. FA. Davis, Philadelphia, 1991, p 425.)

to tube removal, the patient's mouth and tube are suctioned and the cuff is deflated. After removal, the patient is observed closely for laryngeal edema or respiratory distress. The patient is maintained in high Fowler's position to maximize chest expansion.

Mechanical Ventilation

Ventilators are devices that provide ventilation (respirations) for patients who are unable to breathe effectively on their own (Fig. 29.23). Ventilators use positive pressure to push oxygenated air via a cuffed ET or tracheostomy tube into the lungs at preset intervals. Patients may need mechanical ventilation after some surgeries, after cardiac or respiratory arrest, for declining arterial blood gases related to worsening respiratory disease, or for neuromuscular disease or injury that affects the muscles of respiration.

Ventilator Modes

Ventilators can control ventilation or assist the patient's own respirations. See Table 29.9 for terms that aid understanding of ventilator function. There are many types and models of ventilators. Consult with the respiratory care department for an explanation of a patient's ventilator and how to troubleshoot alarms that may sound.

Ventilator Alarms

Several types of alarms are found on ventilators. Low-pressure alarms sound if the ventilator senses reduced pressure

FIGURE 29.23 Patient on ventilator.

in the system. This can be caused by disconnected tubing, leaks in tubing or around the ET tube, or an underinflated cuff. A low-pressure alarm may also sound if the patient has attempted to remove the tube.

High-pressure alarms sound for higher than normal resistance to airflow. This might occur if the patient needs to be suctioned; if the patient is biting on the tube, coughing, or trying to talk; if tubing is kinked or otherwise obstructed; or if worsening respiratory disease causes decreased lung

TABLE 29.9 VENTILATOR TERMINOLOGY

$F_{I_{O_2}}$	Fraction of inspired oxygen.
Tidal volume	Amount of air delivered with each breath.
Rate	Frequency of breaths delivered.
Assist control mode (AC; also called continuous mechanical ventilation, or CMV)	Ventilator delivers a breath each time patient begins to inspire. If patient does not breathe, the machine continues to deliver a preset number of breaths per minute.
Synchronized intermittent mandatory ventilation (SIMV)	Allows patient to breathe independently but delivers a minimum number of ventilations per minute as necessary. Synchronized to patient's own respiratory pattern.
Pressure support (PS)	Provides positive pressure on inspiration to decrease the work of breathing.
Continuous positive airway pressure (CPAP)	Provides positive pressure on inspiration and expiration to keep alveoli open in a spontaneously breathing patient.
Positive end-expiratory pressure (PEEP)	Provides positive pressure on expiration to help keep small airways open.

compliance. In addition, the high-pressure alarm may be triggered if the patient is anxious and is unable to time his or her breaths with those of the ventilator. Water in the tubing might also cause a high-pressure alarm. Consult with the respiratory care department for guidance in draining the tubing.

A loss of power alarm may signal a power failure or a disconnected plug. Be aware of emergency power sources and be prepared to manually ventilate if necessary. Volume and frequency alarms sound when tidal volume or number of breaths per minute fall outside preset parameters.

When an alarm sounds, always check the patient first. If the patient is stable, the machine may then be checked. Determine why the alarm is sounding and correct the problem quickly. If no cause can be found, disconnect the patient from the ventilator and call for help. Use a manual resuscitation bag until an RT arrives.

NURSING RESPONSIBILITIES. Before initiating mechanical ventilation, it is important that the health-care team be aware of advance directives and consult with the patient and family because many patients do not wish to be intubated and mechanically ventilated. Some patients accept mechanical ventilation if it is a temporary measure but not if it might be a permanent intervention.

Until recently, ventilators were used only in intensive care units. Now ventilators are seen on medical-surgical units, in nursing homes, and even in patients' homes. It is important that a team approach be used when caring for a mechanically ventilated patient. The social worker; RT; physical, occupational, and speech therapists; dietitian; nurse; and physician all work together to provide the comprehensive care needed by the patient. Respiratory therapists usually take responsibility for routine monitoring and equipment maintenance. The nurse is responsible for monitoring the patient, ensuring that ventilator settings are maintained as prescribed, providing initial response to alarms, keeping tubing free from water accumulation, and keeping the patient's airway free from secretions. In addition, the nurse keeps a manual resuscitation bag at the bedside for emergencies.

Good nursing care is essential for preventing ventilator-associated complications, especially pneumonia. Keep the head of the bed at a 45-degree angle to reduce the risk of aspiration. Oral care including toothbrushing every 12 hours and sponge Toothettes every 2 to 4 hours helps keep oral bacteria under control. Regular suctioning helps keep the airway clear.¹ Good nutrition is also essential, and has been shown to be related to eventual successful weaning.

Patients who are mechanically ventilated are unable to talk and can become very uncomfortable and anxious with no easy way to communicate. See Box 29.7 Tips for Caring for Mechanically Ventilated Patients for one nurse's tips for making ventilated patients feel more secure. These tips were developed after the author interviewed 12 patients who had been intubated. They shared their fears, anxieties, and physical discomforts.

Box 29.7

Tips for Caring for Mechanically Ventilated Patients

- Introduce yourself to the patient each time you enter the room. Make sure he or she can see you.
- Explain everything you are about to do.
- Check ventilator settings regularly.
- Give sedatives or anti-anxiety drugs as ordered. Request an order if necessary. Find out cause of unexplained anxiety (patient may be hypoxemic).
- Reassure the patient that anxiety is normal and that relaxing will help the ventilator to work with him or her.
- Assess for comfort and reposition at regular intervals. Be careful not to pull on the ventilator tubing. (Pulling hurts.)
- Suction quickly and smoothly, without jabbing. Avoid the use of saline with suctioning.
- Provide good oral care, moistening the lips with a cool washcloth and water-based lubricant. (Patients get thirsty.)
- Use restraints only as a last resort.
- Take the time to communicate with the patient. Talk to him or her, and provide a magic slate or pen and paper for the patient to talk to you. Make sure the call light is within reach at all times.
- Answer patient's call light and ventilator alarms promptly.

Source: Modified from Jablonski, RAS: If ventilator patients could talk. RN, 58:2:32, 1995.

Noninvasive Positive-Pressure Ventilation

Noninvasive positive-pressure ventilation (NIPPV) is an alternative to intubation and mechanical ventilation for patients who are able to breathe on their own but are unable to maintain normal blood gases. Patients with severe respiratory disease, sleep apnea, or neuromuscular diseases such as amyotrophic lateral sclerosis (ALS) that weaken respiratory muscles can benefit from this treatment. Instead of the invasive endotracheal or tracheostomy tube, NIPPV uses an external masklike device that fits over the nose or mouth and nose (Fig. 29.24). It can be successful in patients who are alert, able to cooperate, do not have excessive secretions, and are able to breathe on their own for periods of time. It can be used with or without supplemental oxygen. In an acutely ill patient, oxygen saturations are monitored.

Two basic types of NIPPV are available: continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP, Respironics, Inc. Murrysville, PA). In CPAP, the same amount of positive pressure is maintained throughout inspiration and expiration to prevent airway col-

FIGURE 29.24 Noninvasive positive-pressure ventilation. Note round face from steroid use.

lapse. In BiPAP, a different level of positive pressure is used on inspiration and expiration.

Problems to be alert for in patients receiving NIPPV include skin irritation from the mask and gastric distention from swallowing air. Apply an adhesive skin barrier to the

areas that come in contact with the mask to prevent irritation. To prevent gastric distention, place the patient in semi-Fowler's position and consult with the RT to adjust air delivery pressure if necessary. Topical saline or a special humidifier on the machine can reduce nose and mouth dryness. An air leak around the mask can cause air to blow in the patient's eyes, which can be irritating. If this happens, remove the mask and reposition it. Another problem is patient acceptance of NIPPV. Many patients do not like the tight mask covering their nose or mouth. Be patient in explaining the reason for this treatment and check the patient frequently to help control anxiety. Be sure to assess the patient's goals for therapy. Some patients may choose not to use NIPPV, but they must be fully aware of possible consequences.

Patients can use NIPPV nearly continuously, removing it to eat or use the bathroom. Other patients use it only when they are sleeping and are able to breathe effectively on their own during the day. Some use it for a few days until an acute exacerbation of disease is resolved, and others continue its use indefinitely at home.

REVIEW QUESTIONS

- During inhalation, which of the following muscle contractions takes place to enlarge the chest cavity from top to bottom?
 - Diaphragm moves down.
 - External intercostal muscles move down.
 - Diaphragm moves up.
 - Internal intercostal muscles move up.
- Deteriorating cilia in the respiratory tract predispose the elderly to which of the following?
 - Chronic hypoxia
 - Pulmonary hypertension
 - Respiratory infection
 - Decreased ventilation
- How should the nurse record smoking history on a patient who has smoked 2.5 packs of cigarettes per day for 10 years?
 - Patient has smoked cigarettes for 10 years.
 - Patient smokes 2.5 packs of cigarettes per day.
 - Patient has a 12.5 pack-year smoking history.
 - Patient has a 25 pack-year smoking history.
- Which of the following terms is used to describe violin-like sounds heard on chest auscultation?
 - Crackles
 - Wheezes
 - Friction rub
 - Stridor
- Which of the following is a normal value for oxygen saturation?
 - Less than 60 percent
 - 61 to 85 percent
 - 86 to 95 percent
 - More than 95 percent
- Place the following steps in the correct sequential order for obtaining a sputum specimen for culture.
 - Have the patient cough deeply from the lungs.
 - Teach the patient to inhale deeply several times.
 - Check the order for the test.
 - Send the specimen immediately to the laboratory.
 - Obtain the appropriate container.
- Which instruction is correct when teaching a patient how to use a metered-dose inhaler?
 - "Inhale deeply, place canister in mouth, depress top of canister, exhale."
 - "Exhale, place canister in mouth, depress canister and inhale at the same time."
 - "Cough, place canister in mouth, inhale deeply, cough again."
 - "Exhale, depress canister, place in mouth, inhale deeply."

SUGGESTED ANSWERS TO**CRITICAL THINKING****■ Timothy**

1. There is no way to know whether Timothy needs to be in the emergency room without further assessment. Remember that shortness of breath is very subjective and must be evaluated before discharge.
2. Collect further data. Have Timothy rate his shortness of breath. Look at his color and use of accessory muscles. Check his vital signs, peak expiratory flow rate, and oxygen saturation.
3. If Timothy is having an asthma attack, one explanation for the absence of wheezing on auscultation is that he is not moving enough air to generate the wheezing sound. If his airways are extremely tight, breath sounds may be so diminished that wheezing is not heard. This is a bad sign rather than a good one. If you suspect that this is happening, call for help. The physician may want to begin treatment quickly before further evaluation is done.

■ Miss Israel

(1) Bubbling in the water seal chamber indicates a leak in the system. Vigorous bubbling may indicate a large leak, and the physician should be contacted immedi-

ately. After you check the patient, check the entire system for cracks or leaks and correct any problems discovered. (2) 50 mL.

■ Mr. Smith

1. Mr. Smith plugged his tracheostomy while the cuff was still inflated, so no air could get to his lungs. If the plug is not removed immediately, he will be totally unable to breathe. Whenever the plug is in place, air must be able to travel around the tracheostomy tube or through the opening of a fenestrated tube for the patient to breathe.
2. To prevent this from happening in the future, Mr. Smith should be taught how his tracheostomy tube works and how to care for it.
3. "Trach tube cuff inflated for lunch as ordered. Answered call for help at 1230, found patient dark red in color, unable to breathe, trach plugged. Trach unplugged, respirations restored, vital signs stable. Patient stated he plugged trach so he could talk to his friend. Function of trach cuff explained to patient and friend. Both verbalize understanding to only plug trach when cuff is deflated or to call for nurse if unsure."

QUESTIONS TO GUIDE YOUR READING

1. What are the pathophysiologies of the disorders of the upper respiratory tract?
2. What are the etiologies, signs, and symptoms of disorders of the upper respiratory tract?
3. What are current therapeutic interventions for disorders of the upper respiratory tract?
4. What nursing care should you be prepared to provide for the patient with an upper respiratory disorder?
5. How will you know if your care has been effective?
6. What are the special needs of the patient who has undergone a laryngectomy?

Disorders of the upper respiratory tract include problems occurring in the nose, sinuses, pharynx, larynx, and trachea. Many of these problems are minor illnesses that can be cared for at home. Others can become serious if they are not recognized and treated in a timely manner.

DISORDERS OF THE NOSE AND SINUSES

Epistaxis

Pathophysiology

Epistaxis is more commonly known as a nosebleed. The nose can bleed either from the anterior or posterior region. Anterior bleeds are much more common and originate from a group of vessels called the Kiesselbach plexus. Anterior bleeds are easier to locate and treat than posterior bleeds because the blood vessels of the posterior nose are larger and bleeding can be severe and difficult to control.

Etiology

The most common cause of epistaxis is dry, cracked mucous membranes. Trauma, forceful nose blowing, nose picking, and increased pressure on fragile capillaries from hypertension are also factors. Anything that reduces the blood's ability to clot, such as hemophilia or leukemia, regular aspirin use, anticoagulant therapy, or chemotherapy, can also predispose a patient to nosebleeds. Cocaine use can also cause epistaxis.

Therapeutic Interventions

Instruct the patient with a nosebleed to sit in a chair and lean forward slightly to avoid aspirating or swallowing blood. If the patient swallows blood, it will be difficult to assess the extent of bleeding, and it might cause nausea and vomiting. Be sure to wear gloves and follow standard precautions. Place pressure on the nares for 5 to 10 minutes to stop bleeding. However, avoid placing pressure on the nose if a fracture is suspected to avoid further trauma. Ice packs to the nose and eye area may be used to constrict the bleeding vessels.

If first aid measures are ineffective in stopping bleeding, a physician may attempt more invasive treatment. Local application of a vasoconstrictive agent might be used to constrict the bleeding vessels. If the bleeding vessel can be located, the physician may cauterize it by use of an electrical cauterizing device, or by application of silver nitrate.

Gauze may be used to pack the anterior or posterior nasal cavity. The anterior cavity is packed firmly but gently, usually with half-inch petroleum gauze. To pack the posterior cavity, the physician must use a catheter and string via the nose to draw the packing through the mouth and into the posterior nasal cavity (Fig. 30.1). The strings are then brought out the mouth and taped to the patient's face so they can be used 2 to 4 days later to remove the packing. Placement and removal of packing can be very uncomfortable for the patient. If there is time, administration of an analgesic before the procedure is helpful. Petroleum jelly on the packing helps prevent gauze from adhering to the nasal

FIGURE 30.1 Nasal packing. (A) Catheters are used to pull packing into place. (B) Nasal packing in place.

mucosa. If the packing is to remain in place for a prolonged period, it is coated with an antibiotic ointment to reduce the risk of infection.

Additional products such as compressed sponges and nasal tampons are also available to pack the nose. A nasal balloon catheter employs a catheter with a balloon on the end (a specially made catheter, or a Foley catheter) that is inflated after placing it near the bleeding vessels in the nasal cavity. The inflated balloon places pressure on the bleeding vessels to stop the bleeding.

If the patient has lost a significant amount of blood, a transfusion may be necessary. Nosebleeds rarely cause death because blood loss lowers blood pressure, which in turn slows the bleeding. Ultimately the cause of the epistaxis is determined and corrected if possible.

Nursing Care

Monitor bleeding, noting the amount and color of drainage. Monitor vital signs and hemoglobin level for signs of excessive blood loss. If the patient swallows repeatedly, inspect

the back of the throat for bleeding. If bleeding does not stop within 10 to 15 minutes, or if it worsens, notify a registered nurse (RN) or physician immediately.

If posterior packing has been used, monitor the patient for airway obstruction from slipped packing. Know how to remove the packing in case of emergency. Institute comfort measures, and maintain the placement of the strings that will be used to remove the packing. The packing will be removed by the physician. Once bleeding is controlled, caution the patient not to blow the nose for up to 48 hours and to avoid nose picking. The patient should also avoid bending over, which can increase pressure in the nose. If the cause of the bleeding is dryness, teach the patient to use nasal saline spray or a room humidifier.

CRITICAL THINKING

Mr. Jondahl

■ Mr. Jondahl is brought to the emergency room with a nosebleed. His vital signs are BP 140/90, pulse 92, respirations 20. He states that he has never had a nosebleed before. He denies any history of coagulation disorders. His current medications include captopril (Capoten), furosemide (Lasix), and ibuprofen (Motrin). What are two areas you should assess further in trying to determine a cause? (Hint: If you are not familiar with Mr. Jondahl's medications, look them up.)

Suggested answers at end of chapter.

Nasal Polyps

Pathophysiology and Etiology

Polyps are grapelike clusters of mucosa in the nasal passages. They are usually benign, but they can obstruct the nasal passages. Although the exact cause is unknown, they are related to chronic inflammation, and people with allergies are prone to developing them. Some patients with nasal polyps also have asthma and are allergic to aspirin. This is called aspirin triad disease because the three components often occur together.

Therapeutic Interventions

Control of allergy symptoms may help control polyp development. Oral antihistamines or nasal corticosteroid sprays can help control inflammation. If polyps obstruct breathing, they can be removed. This is done as an outpatient procedure under local anesthesia, using laser or endoscopic surgery. Patients are taught to avoid aspirin products following surgery because they increase the risk of postoperative bleeding and recurrence of the polyps.

Deviated Septum

Pathophysiology and Etiology

The septum dividing the nasal passages is slightly deviated in most adults. This may result from nasal trauma but often

has no cause. Some septa may be so deviated that they block sinus drainage or interfere with breathing.

Signs and Symptoms

The patient may complain of a chronically stuffy nose or discomfort from blocked sinus drainage. Some patients experience headaches and nosebleeds.

Therapeutic Interventions

If the deviated septum is causing chronic discomfort, a submucous resection (SMR), or **nasoseptoplasty**, can be done. This surgery involves making an incision through the mucous membrane covering the septum and revising or removing the deviated portion. Nasal packing is then placed to reduce bleeding. This is generally done as an outpatient surgical procedure, under local anesthetic.

Nursing Care

Monitor vital signs and bleeding until the patient is stable following surgery. Excessive swallowing should alert you to check for blood running down the back of the throat. The patient will have nasal packing and a “mustache dressing” of folded gauze under the nose to catch drainage.

Most patients are discharged home once they are stable, so teaching is important. The patient should maintain a semi-Fowler's position as much as possible and avoid anything that might increase pressure and cause bleeding, such as sneezing, coughing, or straining to move the bowels. Stool softeners and cough suppressants may be ordered by the physician if necessary. Aspirin and related medications are avoided because they increase the risk of bleeding. Antibiotics may be ordered if packing is in place because of the risk of infection from nasal bacteria. The physician should be contacted for specific orders if the patient is on anticoagulant therapy at home. Ice can be used to reduce swelling and bruising. Instruct the patient to contact the physician if fever, excessive pain, swelling, or bleeding occurs and to return in 24 to 48 hours for removal of nasal packing. See Box 30.1 Patient Teaching After Nasal Surgery.

Rhinoplasty

Rhinoplasty is the surgical reconstruction of the nose, usually for cosmetic purposes. It may also be done to correct deformity caused by trauma. Nursing care is similar to that for the patient after nasoseptoplasty, described previously and in Box 30.1 Patient Teaching After Nasal Surgery.

Sinusitis

Pathophysiology and Etiology

Sinusitis is inflammation of the mucosa of one or more sinuses. It can be either acute or chronic. Chronic sinusitis is diagnosed if symptoms are present for more than 2 months and are unresponsive to treatment. The maxillary and eth-

nasoseptoplasty: naso—nose + septo—septum + plasty—plastic surgery

rhinoplasty: rhin—nose + plasty—to mold

sinusitis: sinu—sinus + itis—inflammation

Box 30.1**Patient Teaching After Nasal Surgery**

1. Your nose will feel stuffy and may drain. Change the moustache dressing as often as needed. Do *not* blow your nose. If you must sneeze, do so with your mouth open.
2. Drink plenty of fluids unless your physician advises otherwise.
3. Use a cool mist vaporizer to humidify air and prevent nasal drying.
4. Keep your head elevated on two pillows or sleep in a recliner chair.
5. An ice pack on your face may help reduce swelling.
6. Take pain medication as prescribed.
7. Call your physician if you have a fever higher than 101°F.
8. Return to see your physician in ____ days.

moid sinuses are the most commonly affected. The inflammation is often the result of a bacterial infection and may follow a viral upper respiratory illness. Because the mucous lining of the nose and sinuses is continuous, nasal organisms easily travel to the sinuses. When the infected mucous lining of the sinuses swells, drainage is blocked. Bacteria that normally reside in the sinuses multiply in the retained secretions. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Other causes of sinusitis include swelling caused by allergies, fungal infection, or intubation with a nasotracheal or nasogastric tube.

Signs and Symptoms

The patient usually has pain over the region of the affected sinuses and purulent nasal discharge. If a maxillary sinus is affected, the patient experiences pain over the cheek and upper teeth. In ethmoid sinusitis, pain occurs between and behind the eyes. Pain in the forehead typically indicates frontal sinusitis. Fever may be present in acute infection, with or without generalized fatigue and foul breath.

Complications

The patient who has received inadequate treatment, or who has not complied with treatment, is at risk for complications. Uncontrolled sinusitis may spread to surrounding areas, causing osteomyelitis, cellulitis of the orbit (infection of the soft tissues around the eye), abscess, or meningitis.

Diagnostic Tests

Uncomplicated sinusitis may be diagnosed based on symptoms alone. If repeated episodes occur, x-ray examination, a computed tomographic (CT) scan, or magnetic resonance imaging (MRI) may be done to confirm the diagnosis and determine the cause. Nasal discharge may be cultured to determine appropriate antibiotic therapy.

Therapeutic Interventions

Treatment is aimed at relieving pain and promoting sinus drainage. Adrenergic nasal sprays such as oxymetazoline (Afrin, Dristan) constrict blood vessels and therefore reduce swelling, but they should be used cautiously by patients with heart disease or hypertension because vasoconstriction increases blood pressure. Sprays may be used for up to 3 days; longer use may cause rebound congestion. Hot moist packs over the affected sinus for 1 to 2 hours twice a day may help decrease inflammation. Nasal irrigation with normal saline solution and a bulb syringe has helped some sufferers of chronic sinusitis. Acetaminophen or ibuprofen is given for pain and fever. Codeine or meperidine may be used if pain is severe. Expectorants such as guaifenesin (Robitussin), fluids, and a room humidifier can help liquefy secretions. Antihistamines dry and thicken secretions and are generally avoided. Antibiotics are used only if bacterial infection is suspected, as in the patient with purulent drainage and fever. If conservative treatment does not relieve symptoms, the physician may surgically drain the affected sinus and irrigate it with normal saline or an antibiotic solution.

One drainage procedure is the Caldwell-Luc procedure. The surgeon enters the maxillary sinus above the upper teeth, under the upper lip. The infected mucosa and bone are removed, and a new, larger opening is made to drain the sinus. Newer procedures use endoscopy to open and drain a chronically infected sinus.

Nursing Care

Patients with uncomplicated sinusitis are cared for at home. Instruct the patient to increase water intake to 8 to 10 glasses per day unless contraindicated. Excess water might be contraindicated in patients with fluid overload, such as those with cardiovascular compromise or kidney disease. Pressure may be relieved if the patient maintains a semi-Fowler's position, as in a reclining chair. Explain use of hot moist packs, analgesics, and prescribed medications. Instruct the patient to finish the antibiotic prescription even if he or she is feeling better before it is completed and to call the physician if pain becomes severe or if signs of complications such as a change in level of consciousness occur.

INFECTIOUS DISORDERS
Rhinitis/Common Cold**Pathophysiology and Etiology**

Rhinitis (also called coryza) is inflammation of the nasal mucous membranes. The release of histamine and other substances causes vasodilation and edema, which result in symptoms. It may occur as a reaction to allergens (sometimes called hay fever) such as pollen, dust, molds, or some foods, or it may be caused by viral or bacterial infection. Viral rhinitis is another name for the common cold.

rhinitis: rhin—nose + itis—inflammation

TABLE 30.1 DIFFERENTIATING RESPIRATORY TRACT INFECTIONS

Signs and Symptoms	Cold	Influenza	Bacterial Infection
Onset	Slow	Sudden	Usually slow
Fever	None or low grade	Common, may be $>101^{\circ}\text{F}$ (38.3°C)	Common, may be $>101^{\circ}\text{F}$ (38.3°C)
Headache	Rare	Common	Less common
Muscle aches	Less common	Common, may be severe	Less common
Cough	Present	Present, usually dry	Present, may be dry or productive
Chest pain	Absent	Common	Common
Fatigue	Slight	Common, prolonged, may be severe	Common
Runny nose	Common	Less common	Less common
Sore throat	Common	Less common	Less common
Complications	Rare	Pneumonia	Pneumonia
Treatment	Rest and fluids	Rest and fluids, antiviral agents in some cases	Antibiotics

Signs and Symptoms

Common symptoms include nasal congestion, localized itching, sneezing, and nasal discharge. Viral or bacterial rhinitis may also be accompanied by fever and malaise. Sometimes it is difficult to differentiate between a cold and the flu. See Table 30.1 for signs and symptoms of each.

Diagnostic Tests

If allergic rhinitis is suspected, skin testing may be done to determine the offending allergens. A blood test for IgE antibodies may also be done to determine if allergies are the cause.

Therapeutic Interventions

Treatment of viral rhinitis is symptomatic. Because most colds are caused by viruses, antibiotics are not effective. In one study, however, researchers found that 60% of patients who visited their physician for cold symptoms received a prescription for an antibiotic.¹ This practice is not only expensive, it also increases the risk of developing strains of bacteria that are resistant to antibiotics. Explain to the patient that requesting antibiotics for a viral infection is not only ineffective but potentially dangerous. Teach the patient that rest and fluids are the most effective treatment (Box 30.2 Nursing Care Plan for the Patient with an Upper Respiratory Infection).

Box 30.2 NURSING CARE PLAN for the Patient with an Upper Respiratory Infection

Nursing Diagnosis: Acute pain related to infectious process

Expected Outcomes Patient will be comfortable as evidenced by (1) statement of increased comfort and (2) ability to sleep at night.

Evaluation of Outcomes (1) Does patient express comfort? (2) Is patient able to sleep?

Interventions

- Assess for cause of discomfort: malaise, muscle aches, fever.
- Offer acetaminophen or other analgesic/antipyretics as ordered.
- Offer throat lozenges and salt-water gargles as ordered for irritated throat.
- Encourage rest.

Rationale

Knowing cause of discomfort helps guide intervention. Analgesics relieve pain. Antipyretics relieve fever, which may contribute to discomfort. Lozenges soothe irritated mucous membranes. Saltwater gargles may reduce swelling. Physical stress increases need for sleep. Rest boosts immune function.

Evaluation

Can interventions be directed toward specific symptoms? Do analgesics/antipyretics relieve discomfort? Do measures relieve throat irritation? Is patient resting comfortably?

Nursing Diagnosis: Hyperthermia related to infectious process

Expected Outcomes (1) Temperature lower than 103°F (39.4°C). (2) No signs/symptoms of dehydration.

Evaluation of Outcomes (1) Is fever controlled at safe level? (2) Is patient well hydrated?

Interventions

- Monitor temperature daily; every 4 hours if fever present.
- If patient begins chilling, recheck temperature when chilling subsides.
- Monitor for signs of dehydration: dry skin and mucous membranes, thirst, weakness, hypotension.
- Encourage oral fluids if not contraindicated.
- Administer antipyretic such as acetaminophen if fever is higher than 102.5°F (39°C) or for discomfort.

Rationale

Screening helps detect temperature changes early.
Chilling indicates rising temperature.
Fever causes loss of body fluids.
Fluids prevent or treat dehydration.
Antipyretics reduce fever. Fever enhances immune function, so should only be treated if very high, if patient has a history of febrile seizures, or if patient is uncomfortable.

Evaluation

Is patient febrile?
Is chilling present? Should temperature be checked more often?
Are signs of dehydration present?
Is patient taking fluids well?
Is fever higher than 102.5°F (39°C)? Are antipyretics indicated? Are they effective?

Nursing Diagnosis: Risk for infection: transmission to others related to presence of infectious disease

Expected Outcomes Risk for infection of others is reduced, as evidenced by the following:
(1) Patient states measures to prevent transmission. (2) Patient takes precautions against spread.

Evaluation of Outcomes Is transmission to others prevented?

Interventions

- Assess patient's understanding of infection transmission.
- Based on patient's previous knowledge, teach patient and all caregivers the importance of good handwashing after contact with patient or patient's belongings, covering nose and mouth when coughing or sneezing, and not sharing eating or drinking utensils.

Rationale

Understanding of mode of transmission is essential to prevention.
The nurse should build on patient's previous understanding and not repeat information.
Hand washing prevents spread of infection.
Covering nose and mouth prevents spread of infectious droplets. Many infections are transmitted via contaminated objects.

Evaluation

Does patient understand how infection is transmitted?
Does patient take precautions to prevent spread of infection?

Acetaminophen can be used for generalized discomfort. Antihistamines may help control symptoms by inhibiting the histamine response. Decongestants cause vasoconstriction, which reduces swelling and congestion. Any drugs that cause vasoconstriction should be used cautiously in patients with heart disease or hypertension. Severe allergies may be treated with desensitization (“allergy shots”).

Pharyngitis

Pathophysiology and Etiology

Pharyngitis, or inflammation of the pharynx, is usually related to bacterial or viral infection. It may also occur as a result of trauma to the tissues. The most common bacterial infection is caused by beta-hemolytic streptococci, commonly referred to as strep throat. If strep throat is not treated with antibiotics, it can lead to rheumatic fever, glomerulonephritis, or other serious complications.

Signs and Symptoms

The most common symptom of pharyngitis is a sore throat. Some patients may also experience **dysphagia** (difficulty swallowing). The throat appears red and swollen, and **exudate** (drainage or pus) may be present. Exudate usually signifies bacterial infection and may be accompanied by fever, chills, headache, and generalized malaise.

Diagnostic Tests

A physician may order a throat culture and sensitivity test (explained in Chapter 29) to identify the causative organism and determine which antibiotic will be effective.

Therapeutic Interventions

If the pharyngitis is bacterial, antibiotics are ordered. Acetaminophen or throat lozenges may be used to relieve discomfort. Saltwater gargles help reduce swelling, and increased fluids (if not contraindicated) and rest are encouraged. (See Box 30.2 Nursing Care Plan for the Patient with an Upper Respiratory Infection.)

Laryngitis

Pathophysiology and Etiology

Laryngitis is an inflammation of the mucous membrane lining the larynx (voice box). It can be caused by irritation from smoking, alcohol, or chemical exposure or a viral, fungal, or bacterial infection. It often follows an upper respiratory infection.

Signs and Symptoms

The most common symptom is hoarseness. Cough, dysphagia, or fever may also be present.

Diagnostic Tests

A physician may use a laryngeal mirror to view the larynx. If hoarseness persists for more than 2 weeks, a laryngoscopy may be done to rule out cancer of the larynx.

pharyngitis: pharyng—pharynx + itis—inflammation

dysphagia: dys—bad + phagia—to swallow

exudate: to sweat out

laryngitis: laryng—larynx + itis—inflammation

Therapeutic Interventions

Treatment includes rest, fluids, humidified air, and aspirin (in adults) or acetaminophen. Antibiotics are used if bacterial infection is present. Encourage the patient to avoid speaking to rest the voice. Obtain a “magic slate” (from the speech therapy department) or paper and pen to help the patient communicate. Throat lozenges may help increase comfort. Help the patient to identify and avoid causative factors. (See Box 30.2 Nursing Care Plan for the Patient with an Upper Respiratory Infection.)

Tonsillitis/Adenoiditis

Pathophysiology and Etiology

The tonsils are masses of lymphoid tissue that lie on each side of the oropharynx. They filter microorganisms to protect the lungs from infection. Tonsillitis occurs when the filtering function becomes overwhelmed with a virus or bacteria and infection results. The adenoids, a mass of lymphoid tissue located at the back of the nasopharynx, can also become involved. Tonsillitis is more common in children, but it is more serious when it occurs in adults. The most common organisms causing tonsillitis are *Streptococcus* species, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pneumococcus* species.

Signs and Symptoms

Tonsillitis usually begins suddenly with a sore throat, fever, chills, and pain on swallowing. Generalized symptoms include headache, malaise, and **myalgia**. On examination, the tonsils appear red and swollen and may have yellow or white exudate on them. The patient’s voice may sound like the patient has a hot potato in his or her mouth. If the adenoids are involved, the patient may have complaints of snoring, nasal obstruction, and a nasal tone to the voice.

Diagnostic Tests

A throat culture is done to discover the causative organism and determine effective treatment. A white blood cell count helps identify whether the infection is viral or bacterial. A chest x-ray examination may be done if respiratory symptoms are present.

Therapeutic Interventions

Antibiotics are prescribed for bacterial infection. Acetaminophen, lozenges, and saline gargles help promote comfort. For care of the patient who is not having a tonsillectomy, see Box 30.2 Nursing Care Plan for the Patient with an Upper Respiratory Infection.

TONSILLECTOMY. If tonsillitis becomes chronic, or if breathing or swallowing is affected, a tonsillectomy may be considered, although this is not a common procedure in an adult. An adenoidectomy may be performed at the same time. After the tonsillectomy, the patient is maintained in a semi-Fowler’s position to reduce swelling and promote drainage. Monitor the patient for bleeding and airway

myalgia: myo—muscle + algia—pain

patency, and provide comfort measures. Encourage fluids for hydration; cold fluids may help reduce pain and bleeding. Red-colored drinks are avoided because they interfere with observation for bleeding. A room humidifier helps prevent drying. Keep suction equipment available for emergencies.

CRITICAL THINKING

Mrs. Hiler

■ You are assessing Mrs. Hiler after a tonsillectomy. She is sleeping, but you notice that she swallows every few seconds. She has an intravenous (IV) line of normal saline solution running at 100 mL per hour. How do you respond? How many drops per minute do you set on her IV if the tubing has a drop factor of 15?

Suggested answers at end of chapter.

Influenza

Pathophysiology and Etiology

Influenza, commonly referred to as the flu, is a viral infection of the respiratory tract. Many different flu viruses have been identified, and new strains appear each year. Influenza is the cause of millions of lost work days each year. The elderly are at particular risk for complications and even death from influenza because of preexisting chronic disease and compromised immune function.

Influenza is easily transmitted via droplets from coughs and sneezes of infected individuals, or it may be transmitted by physical contact with a person or object that harbors the virus. The incubation period from time of exposure to onset of symptoms is 1 to 3 days.

Prevention

Yearly immunization is recommended for prevention of influenza. The Centers for Disease Control and Prevention (CDC) updates specific recommendations yearly based on research and availability of vaccine. For the 2005 to 2006 flu season, the CDC recommended priority influenza vaccination for the following high-risk groups:

- Persons aged ≥ 65 years with comorbid conditions
- Residents of long-term care facilities
- Persons aged 2 to 64 years with comorbid conditions
- Persons aged ≥ 65 years without comorbid conditions
- Children aged 6 to 23 months
- Pregnant women
- Health-care personnel who provide direct patient care
- Household contacts and out-of-home caregivers of children aged < 6 months²

Although Medicare covers the cost of a flu shot, many elders do not get one. Stress that they will not get the flu from the shot because it does not contain any live virus. Once the shot has been administered, it takes about 2 weeks

for antibodies to develop; it is then effective for about 4 months. Other preventive measures include hand washing and avoidance of individuals with influenza.

SAFETY TIP

In assisted living and long-term care facilities, develop and implement a protocol for administration and documentation of the flu and pneumococcus vaccines. Develop and implement a protocol to identify new cases of influenza and to manage an outbreak (2000 National Patient Safety Goals from www.jcaho.org).

Signs and Symptoms

Symptoms of flu include abrupt onset of fever, chills, myalgia, sore throat, cough, general malaise, and headache. It can last for 2 to 5 days, with malaise lasting up to several weeks.

Complications

The most common complication of influenza is pneumonia, which may be caused by the same virus as the flu or by a secondary bacterial infection. This should be considered if the patient experiences persistent fever and shortness of breath or if the lungs develop crackles or wheezes.

Diagnostic Tests

Viral cultures of throat or nasal swabbings can be done to identify influenza, but results may take 5 to 10 days. Rapid tests can identify the presence of flu virus in less than 30 minutes in an office setting, but are less reliable than cultures. Cultures may also be done to rule out bacterial infection. Once influenza has been identified in a geographical area, practitioners will test less often, and treat based on symptoms.

Therapeutic Interventions

Treatment is primarily symptomatic. Acetaminophen is given for fever, headache, and myalgia. Aspirin is avoided in children because it increases the risk for Reye's syndrome. Rest and fluids are essential. Antibiotics are used only if a secondary bacterial infection is present.

Antiviral drugs such as zanamivir (Relenza) and oseltamivir (Tamiflu) may be helpful for high-risk patients if given within 48 hours of exposure. These drugs may reduce the severity and duration of symptoms. Amantadine (Symmetrel) may also be given prophylactically to high-risk people who have not been immunized, and is recommended for use in nursing home residents where an outbreak of flu has occurred.

Nursing Care

Elderly or other high-risk patients may be hospitalized for treatment of influenza. These patients are closely monitored for signs of complications. Assess lung sounds and vital signs every 4 hours, and monitor for dehydration. Report

changes to an RN or physician. Encourage rest and fluids (if not contraindicated), and provide comfort measures. Educate patients about avoiding aspirin to treat influenza symptoms in children under 18 to prevent Reye's syndrome (see Box 30.2 Nursing Care Plan for the Patient with an Upper Respiratory Infection).

CRITICAL THINKING

Murdie

■ Murdie is a 97-year-old nursing home resident who develops flu symptoms. She is lethargic, confused, and feverish. Because of her mental status changes, you want to send her to the hospital, but her son asks you to please keep her where she is. She has a history of chronic obstructive pulmonary disease (COPD) and diabetes.

1. How could Murdie have caught the flu?
2. How could it have been prevented?
3. What can be done now to prevent her from developing complications that could lead to pneumonia or even death?
4. What other concerns do you have?

Suggested answers at end of chapter.

Other Viral Infections

In recent years, new viruses have become a worldwide concern. Three of these are described below. Continuous research is being conducted to learn more about the spread, prevention, and treatment of new viral infections.

Bird Flu

Avian influenza, more commonly known as bird flu, has been identified in Asia, Canada, and the Netherlands, and is a growing concern. Humans can contract it from contact with infected birds (often poultry) or their secretions or excrement. Transmission from human to human is rare, but is also a potential concern. Symptoms of bird flu are similar to influenza symptoms described above, but complications can be more severe and deadly. Conventional vaccines are not effective in preventing bird flu. Oseltamivir (Tamiflu) may be useful in treatment, along with supportive measures.

SARS

Severe acute respiratory syndrome (SARS) is another new virus that has influenzalike symptoms. It first appeared in China in 2002. SARS is a concern because it also can progress to deadly pneumonia and respiratory failure, even in previously healthy individuals. Transmission of SARS is believed to occur from contact with a contaminated person or object, or through the air. Antiviral medications used to treat HIV infection are currently being researched for treatment of SARS.

West Nile Virus

A third new virus, West Nile virus, is less deadly than bird flu or SARS, but can still cause serious complications. West Nile virus is transmitted from birds to humans by mosquitoes, and causes either no symptoms or flulike symptoms. However, in a few people, especially the elderly, it can progress to encephalitis (inflammation of the brain) and meningitis (inflammation of the covering of the brain and spinal cord). There is no specific treatment for West Nile virus. If patients develop complications, they are hospitalized for supportive care.

MALIGNANT DISORDERS

Cancer of the Larynx

Pathophysiology

Cancer of the larynx (the voice box) usually develops in the mucosal epithelium. It is evaluated based on the tumor-node-metastasis (TNM) staging system described in Chapter 10. It is usually a primary cancer and can spread to the lungs, liver, or lymph nodes. The prognosis for a patient with laryngeal cancer is often poor because metastasis (spread) may occur before the patient seeks help.

Etiology

Risk factors for cancer of the larynx include a history of alcohol and tobacco use. Exposure to industrial chemicals, hardwood dust, and chronic overuse of the voice are also factors. Men are five times as likely to be affected as women.

Prevention

Prevention begins with education; you can help educate patients about the relationship between cancer of the larynx and use of alcohol and tobacco. It is also important to teach patients to seek help when symptoms first occur because a delayed diagnosis may mean metastasis of the cancer and a poor prognosis. Teach that any hoarseness that lasts longer than 2 weeks should be investigated by a physician.

Signs and Symptoms

The most common symptom is persistent hoarseness because the vocal cords are located in the larynx (Box 30.3 Laryngeal Cancer Summary). The patient may also have throat or ear pain, shortness of breath, a chronic cough, and difficulty swallowing. Stridor may indicate a tumor obstructing the airway. Late signs include weight loss and halitosis (foul breath).

Diagnostic Tests

The larynx can be examined with a laryngeal mirror. Laryngoscopic examination and biopsy are used to diagnose and determine the stage of laryngeal cancer. A CT scan, magnetic resonance imaging (MRI), or other diagnostic tests may be done to determine the presence or extent of metastasis.

Box 30.3**Laryngeal Cancer Summary****Signs and Symptoms**

Hoarse voice
Pain
Cough
Shortness of breath
Difficulty swallowing
Weight loss
Foul breath

Diagnostic Tests

Examination with laryngeal mirror
Laryngoscopy with biopsy
Additional blood and radiographic studies to detect metastasis

Therapeutic Interventions

Radiation therapy
Chemotherapy (adjunct to radiation or surgery)
Endoscopic laser surgery to destroy tumor
Partial laryngectomy (preserves some voice)
Radical neck dissection with total laryngectomy (loss of voice)

Nursing Diagnoses

Risk for ineffective airway clearance
Acute pain
Impaired verbal communication
Risk for imbalanced nutrition

Therapeutic Interventions

If laryngeal cancer is diagnosed early in the disease, it may be treatable with radiation therapy; this treatment can preserve the patient's voice. Chemotherapy may be used with radiation or surgery, but it is not usually used alone. In more advanced cases, surgical intervention is necessary. The larynx will be either partially or completely removed (Fig. 30.2). If cancer has spread beyond the larynx, a radical neck dissection, which removes adjacent muscle, lymph nodes, and tissue, may be done. Surgery can be done using laser technology, endoscopy, or traditional methods.

After a partial laryngectomy, the patient may have a permanently hoarse voice. If a total laryngectomy is done, the patient will have a permanent tracheostomy (in this case called a laryngectomy) tube in place and no voice. Alternative methods of communication must be employed. A person who has had a total laryngectomy is sometimes referred to as a **laryngectomee**.

laryngectomee: larng—larynx + ectome—excision (person who has undergone laryngectomy)

Several alternatives for long-term speech exist:

- Esophageal speech involves swallowing air and forming words as the air is regurgitated back up the esophagus.
- Electronic devices are also available, which the patient places next to the neck or mouth. These devices use sound vibrations to help the patient form words. UltraVoice (Ultravoice Ltd) is a new electronic device that is placed inside an upper denture or retainer, and the patient speaks into a small microphone (Fig. 30.3A).
- Another alternative is a tracheoesophageal puncture (TEP), such as the Blom-Singer Voice Prosthesis (InHealth Technologies), which uses a surgically implanted voice prosthesis that creates a valve between the trachea and esophagus. If the patient holds a finger over the laryngectomy, air is diverted into the esophagus and the patient forms words as the air exits via the mouth (Fig. 30.3B).

All these devices take time to adjust to, and the patient will need support after discharge to continue to develop communication skills.

**LEARNING TIP**

Did you or your child ever “burp the ABCs”? If not, ask most any child to demonstrate! This is the same idea as esophageal speech.

Nursing Process: The Patient Undergoing Total Laryngectomy

PREOPERATIVE CARE. In addition to routine preoperative teaching, the patient undergoing laryngectomy surgery must be prepared for the loss of ability to breathe through the mouth and nose and the loss of the ability to speak. Initial instruction in communication techniques should take place before surgery to prevent the patient from feeling panicky after surgery when he or she is unable to communicate needs. A variety of techniques and devices are available. Consult the speech therapist before surgery to provide a picture board, magic slate, or paper and pencil. (See Chapter 49.) The patient is instructed to point to the picture that corresponds with the need or to write out his or her concern. A dietary consult is also important before surgery if the patient has been undernourished.

POSTOPERATIVE CARE. Assessment/Data Collection. Assessment of physical and psychosocial status, comfort, nutritional status, and ability to swallow is important both before and after surgery. After surgery, assessment of airway patency and respiratory function takes priority. Monitor lung sounds, oxygen saturation, and arterial blood gases. In addition, be sure to assess the patient's understanding of the disease process and self-care needs after surgery. It is important to evaluate the patient's support systems and

FIGURE 30.2 Laryngectomy. (A) Before laryngectomy. (B) After laryngectomy.

ability to cope with the partial or total loss of voice after surgery. Continued alcohol and tobacco use will increase the patient’s risk of recurrence.

Nursing Diagnosis, Planning, and Implementation Risk for ineffective airway clearance related to excessive secretions and new tracheostomy

EXPECTED OUTCOME: The patient will maintain a clear airway as evidenced by clear lung sounds and ability to cough up secretions.

- Monitor and record amount, color, and consistency of secretions; vital signs; oxygen saturation; lung sounds; and signs of respiratory distress. *Visible secretions, a drop in SaO₂, or an increase in crackles may indicate a need for suctioning.*

A change in amount or color of secretions, an increased temperature, or presence of adventitious sounds can indicate infection and should be reported to the physician immediately.

- Provide tracheostomy care and suctioning according to agency policy (see Chapter 29). *This keeps the airway clear.*
- Maintain strict sterile technique. *Prevention of infection is essential, since the airway no longer has the protection of normal upper airway defense mechanisms.*

A

B

FIGURE 30.3 Devices to aid speech in the laryngectomy patient. (A) UltraVoice is an electronic device that is placed inside a denture or retainer; the patient speaks into a small microphone. (Courtesy of UltraVoice Ltd.) (B) The Blom-Singer-Voice Prosthesis diverts air into the esophagus and out the mouth to form tracheoesophageal speech. (Courtesy of InHealth Technologies.)

- Place the patient in semi-Fowler's position *to allow for lung expansion and more effective coughing.*
- Encourage the patient to deep breathe and cough every hour *to keep airway free of secretions.*
- Administer oxygen as ordered. A special tracheostomy collar may be used to provide oxygen and humidification. *Humidification can help keep secretions mobile.*
- Avoid use of powders, sprays, or other airborne materials near the patient. *These can cause irritation or infection if they enter the laryngectomy.*

Acute pain related to surgical procedure

EXPECTED OUTCOME: The patient will state his pain level is acceptable.

- Assess pain level every 4 hours and prn. *A good assessment must guide treatment.*
- Assess sedation and respiratory status frequently. *Opioids are given carefully because they may reduce respiratory rate and cough reflex, which is vital to clearing the airway.*
- Include nonpharmacological pain control interventions (see Chapter 9). *Interventions such as distraction and relaxation may help with pain control and reduce (not eliminate) the need for opioids.*
- Administer analgesics as ordered, on an around-the-clock basis or via a patient-controlled pump, for the first few days after surgery. If the liver has been damaged from alcohol abuse, dosages are adjusted by the physician. *The patient who is pain free will be better able to participate in care and take measures to prevent complications, such as coughing and ambulating.*

Impaired verbal communication related to loss of vocal cords

EXPECTED OUTCOME: The patient will be able to communicate his or her needs.

- Use a picture board or paper and pencil *so the patient can communicate without speaking.*
- Make sure the patient has a call light or bell nearby at all times. *Patients can become panicky if they have a need and no way to summon a nurse.*
- Work with the speech therapist and physician to provide the patient with a method of communication that best fits his or her needs (Fig. 30.3). *Different patients prefer different long-term communication methods.*

Risk for imbalanced nutrition, less than body requirements related to absence of oral feeding

EXPECTED OUTCOME: The patient's weight and serum albumin levels will be within normal limits for height and age.

- Monitor weight and albumin levels. *Weight loss or low albumin levels reflect inadequate nutrition.*
- Monitor parenteral nutrition or tube feedings after

surgery until the neck has begun to heal and swallowing can be evaluated. *Nutrition must be maintained to support healing.*

- Consult a dietitian for nutrition guidance. *If the patient has a history of alcohol abuse, he or she may have been undernourished before surgery. You may need to advocate for the patient and ensure that he or she is receiving adequate calories for healing. A dietitian can assist with specific recommendations.*

Impaired swallowing related to edema or laryngectomy tube

EXPECTED OUTCOME: The patient will be able to swallow effectively.

- Consult a speech therapist to assist with a swallowing assessment and recommendations. *Speech therapists are trained to assess and treat swallowing disorders.*
- Assure the patient that aspiration will not occur *because there is no longer a connection between the mouth and the lungs.*
- Place the patient in high-Fowler's position *to make swallowing easier.*
- Stay with the patient during the first attempts to eat *to help alleviate anxiety.*

Grieving related to loss of voice

EXPECTED OUTCOME: Patient will express feelings of loss, and begin to plan for the future.

- Assess patient's feelings of loss. *Inability to speak is a loss that cannot be overemphasized. The patient may also be facing a career change if job-related exposure contributed to the disease or if loss of voice prevents returning to a previously held job.*
- Actively listen to the patient *to show your support and validate his feelings.*
- Assess and involve support systems. *Family support is important to the patient's long-term adjustment to his laryngectomy.*
- Contact the patient's clergy if he or she wishes. *A religious counselor can help with grief and spiritual distress.*

Disturbed body image related to change in body structure and function

EXPECTED OUTCOME: The patient will verbalize acceptance of new laryngectomy, and participate in self-care.

- Portray an accepting attitude. *Patients are very aware of nurses' nonverbal behavior, and looks of distaste can be very disturbing.*
- Allow the patient to share his or her feelings if he indicates a need to do so. *This may help the patient to work through feelings about the changes to his body image.*
- With the patient's permission, contact a local support group that may have names of people who have had similar experiences who are willing to visit

with the patient. *Visitors can provide firsthand information and support.*

- Assist the patient to find ways to camouflage the change, such as scarves or necklines that conceal but do not obstruct the airway. *Camouflage can help the patient feel less conspicuous, and also protect the airway.*

Evaluation. When evaluating the patient's progress toward goals, ask the following questions:

- Is the airway clear, without signs of infection?
- Does the patient verbalize an acceptable level of comfort?
- Do the patient and significant others demonstrate understanding of self-care at home or have referrals to continue learning self-care at home?
- Does the patient indicate satisfaction with the level and quality of communication?
- Are nutritional needs met, as evidenced by albumin levels greater than 3.0 and stable weight?
- Is the patient able to swallow if taking oral nutrition? Is the patient able to grieve appropriately?
- Does the patient have someone to talk to if he or she wishes?
- Does the patient show acceptance of the laryngectomy by learning to look at it and care for it?

It should be noted that many of these evaluative criteria are long term and may not be seen while the patient is hospitalized, so follow-up by a home care nurse is essential.

Patient Education. After assessing the patient's readiness to learn, the patient is taught self-care measures for his or her laryngectomy, including how to perform cleaning and suctioning. (See Chapter 29.) Involve the significant other or family whenever possible.

The patient must also be instructed to perform gentle range-of-motion exercises of the neck. Some patients may avoid extending the neck because of the location of the incision, causing muscle contracture and eventual inability to do so.

Referral to home nursing after discharge will provide assessment of the home environment, as well as follow-up instruction. A social service referral may be made for financial or psychosocial concerns if needed. Consult with the physician or check the local phone directory for laryngectomy support groups, and refer the patient to them if appropriate. The local branch of the American Cancer Society may also be able to provide information.

To find additional information for laryngectomees, visit the National Cancer Institute website www.cancer.gov. Many other websites can be found by using a search engine and searching the term "laryngectomy."

REVIEW QUESTIONS

- Which is the best explanation by a nurse for why a physician did not prescribe antibiotics for influenza?
 - "Most cases of influenza are caused by antibiotic-resistant bacteria."
 - "Influenza is caused by viruses."
 - "Antibiotics have too many serious side effects."
 - "Antibiotics can interact with other medications used for influenza."
- After a laryngectomy, which of the following assessments takes priority?
 - Airway patency
 - Nutritional status
 - Lung sounds
 - Patient acceptance of surgery
- Which of the following responses is correct when a patient asks why her physician didn't order a new antiviral drug for her flu?
 - "Antiviral drugs are for AIDS, not the flu."
 - "The side effects of the antiviral drugs are worse than having the flu."
 - "Antiviral drugs are only for children."
 - "These drugs work only if you start them within 48 hours after flu symptoms start."
- Which of the following positions is recommended for a patient experiencing a nosebleed?
 - Lying down with feet elevated
 - Sitting up with neck fully extended
 - Lying down with a small pillow under the head
 - Sitting up leaning slightly forward
- The nurse knows that the patient understands teaching related to prevention of influenza transmission when the patient demonstrates which behaviors? Choose all responses that are correct.
 - Washing hands frequently
 - Covering the nose and mouth during coughing or sneezing
 - Taking acetaminophen as ordered
 - Drinking extra fluids
 - Avoiding sharing eating utensils with others
- Which of the following communication methods will not work for the patient with a laryngectomy?
 - Placing a finger over the stoma
 - Providing a special valve that diverts air into the esophagus
 - Obtaining a picture board
 - Teaching the patient esophageal speech

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. Jondahl*

Consider the possibility of hypertension as a contributing factor. Mr. Jondahl's blood pressure is currently 140/90, which may be lower than normal for him because he has been bleeding. He is also on an antihypertensive drug and a diuretic. Explore the amount of ibuprofen being taken daily, because nonsteroidal anti-inflammatory drugs can interfere with platelet aggregation.

■ *Mrs. Hiler*

Mrs. Hiler may be swallowing blood. Examine the back of her throat with a flashlight. Check vital signs for evidence of impending shock. Notify a physician if bleeding is confirmed.

Use this formula to determine drops per minute:

100 mL	1 hour	15 gtt	=	25 gtt
1 hour	60 minutes	mL		mL

■ *Murdie*

1. Murdie may have contracted the flu from a visitor or a staff person at the nursing home. She is susceptible because of her age and comorbid conditions (COPD, diabetes).
2. Murdie's flu could probably have been prevented with a flu vaccination, but her son refused it because he believed it could cause her to get the flu.
3. If it is within 48 hours of symptom onset, a physician can prescribe an antiviral agent to help reduce her symptoms and shorten the course of her illness. In addition, you can provide fluids, acetaminophen, and comfort measures. You should also monitor her closely for evidence of bacterial infection or pneumonia, and report signs or symptoms immediately to a physician.
4. A major concern is that Murdie could transmit the flu to other residents or staff. Hopefully, they have all been vaccinated. In addition, you must decide whether or not to send Murdie to the hospital. Check her advance directives, and talk to her son about goals for her care. If necessary, educate him about differences in nursing home and hospital care.

QUESTIONS TO GUIDE YOUR READING

1. What is the pathophysiology of each of the disorders of the lower respiratory tract?
2. What are the etiologies, signs, and symptoms of each of the disorders?
3. What tests are useful for diagnosis of each of the disorders?
4. What are therapeutic interventions for disorders of the lower respiratory tract?
5. What data should you collect when caring for patients with disorders of the lower respiratory tract?
6. What nursing care will you provide for patients with disorders of the lower respiratory tract?
7. What specific nursing care can you provide for patients experiencing impaired gas exchange, ineffective airway clearance, or ineffective breathing pattern?
8. How will you know if your nursing interventions have been effective?

Disorders of the lower respiratory tract include problems of the lower portion of the trachea, bronchi, bronchioles, and alveoli. These disorders may be related to infection, noninfectious alterations in function, neoplasm (cancer), or trauma. Any pathological condition of the lower respiratory tract can seriously impair carbon dioxide and oxygen exchange.

INFECTIOUS DISORDERS

Acute Bronchitis

Bronchitis is an inflammation of the bronchial tree, which includes the right and left bronchi, secondary bronchi, and bronchioles. When the mucous membranes lining the bronchial tree become irritated and inflamed, excessive mucus is produced. The result is congested airways. Acute bronchitis is usually an isolated episode. If it occurs more than 3 months out of the year for 2 consecutive years, chronic bronchitis is diagnosed. See discussion of chronic bronchitis later in this chapter for more information that applies to both the acute and chronic forms.

Bronchiectasis

Pathophysiology

Bronchiectasis is a dilation of the bronchial airways (Fig. 31.1). The dilated areas form sacs that can remain localized or spread throughout the lungs. Secretions pool in these sacs and frequently become infected.

FIGURE 31.1 Bronchiectasis. Note dilated airway.

bronchitis: bronch—airway + itis—inflammation

bronchiectasis: bronch—airway + ectasis—dilation or expansion

Etiology

Bronchiectasis usually occurs secondary to another chronic respiratory disorder, such as cystic fibrosis, asthma, tuberculosis, bronchitis, or exposure to a toxin. Airway obstruction from a tumor or foreign body can also be a predisposing factor. Infection and inflammation of the airways weakens the bronchial walls and reduces ciliary function. Airway obstruction from excessive secretions then predisposes the patient to development of bronchiectasis.

Signs and Symptoms

The patient with bronchiectasis has recurrent lower respiratory infections. Sputum is copious and purulent and pools in the dilated airways. The accompanying cough can produce as much as 200 mL of thick, foul-smelling sputum in a single episode of coughing. Extreme airway inflammation may cause sputum to be bloody. If bronchiectasis is widespread throughout the lungs, the patient may experience dyspnea even with minimal exertion. Wheezes and crackles may be auscultated. Fever is present during active infection. Cor pulmonale (right-sided heart failure; covered in Chapter 26) and clubbing of the fingers may develop with chronic disease.

Diagnostic Tests

A chest x-ray examination may be done, but it may not show early disease. A computed tomographic (CT) scan provides a better view of the dilated airways. Sputum cultures determine infecting organisms and guide antibiotic therapy. Additional testing is done to determine the cause of bronchiectasis.

Therapeutic Interventions

Treatment is aimed at keeping the airways clear of secretions, controlling infection, and correcting the underlying problem. Antibiotics may be used intermittently or for prolonged periods. Measures to prevent infection, including vaccinations for flu and pneumonia, should be taken. **Bronchodilators** improve airway obstruction. **Mucolytic** agents help thin secretions, and chest physiotherapy helps mobilize secretions so they can be more effectively expectorated. Oxygen is used if hypoxemia is present. If the affected area of the lung is localized and symptoms are severe, surgery may be considered to remove the diseased area. Lung transplant may be considered in severe cases.

Pneumonia

Pneumonia is the cause of more than 10% of hospital admissions each year and is the most common cause of death from infection.

Pathophysiology

Pneumonia is an acute infection of the lungs that occurs when an infectious agent enters and multiplies in the lungs of a susceptible person. Infectious particles can be transmitted by the cough of an infected individual, from contaminated respiratory therapy equipment, from infections in other parts of the body, or from aspiration of bacteria from

bronchodilator: broncho—airway + dilator—to expand

mucolytic: muco—mucus + lytic—break up

the mouth, pharynx, or stomach. Organisms from the mouth and pharynx may be related to poor oral hygiene or may be present because of a cold or influenza virus. When pathogens enter the body of a healthy person, normal respiratory defense mechanisms and the immune system prevent the development of infection. In a person who is **immuno-compromised**, however, even microorganisms that are normally present in the oropharynx can cause an infection. Persons at risk for pneumonia are the very young, the elderly, and those who are immunocompromised, such as people with acquired immunodeficiency syndrome (AIDS) or another chronic illness.

When the microorganisms multiply, they release toxins that induce inflammation in the lung tissue, causing damage to mucous and alveolar membranes. This leads to the development of edema and **exudate**, which fills the alveoli and reduces the surface area available for exchange of carbon dioxide and oxygen. Some bacteria also cause necrosis of lung tissue.

Pneumonia may be confined to one lobe, or it may be scattered throughout the lungs. If it affects only one lobe, it is called lobar pneumonia. Generalized pneumonia is much more serious and is called bronchopneumonia. Bronchopneumonia occurs more often as a nosocomial (hospital-acquired) infection in hospitalized patients, the very young, or the very old.

Etiology

Pneumonia has a variety of causes, which are listed next.

BACTERIAL PNEUMONIA. The most common cause of community-acquired bacterial pneumonia, is *Streptococcus pneumoniae*; also called pneumococcal pneumonia. This organism accounts for approximately 90% of all bacterial pneumonias. Other community-acquired infections are caused by *Staphylococcus aureus* and *Mycoplasma pneumoniae*. Hospital-acquired pneumonias are often more serious and may be caused by *Escherichia coli*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*, among others.

VIRAL PNEUMONIA. Influenza viruses are the most common cause of viral pneumonia. The presence of viral pneumonia increases the patient's susceptibility to a secondary bacterial pneumonia. Generally, patients are less

ill with viral pneumonia than with bacterial pneumonia, but they may be ill for a longer period because antibiotics are ineffective against viruses.

FUNGAL PNEUMONIA. *Candida* and *Aspergillus* are two types of fungi that can cause pneumonia. *Pneumocystis carinii* is a fungus that typically causes pneumonia in patients with AIDS.

ASPIRATION PNEUMONIA. Some pneumonias are caused by aspiration of foreign substances. This most often occurs in patients with decreased levels of consciousness or an impaired cough or gag reflex. These conditions can occur with alcohol ingestion, stroke, general anesthesia, seizures, or other serious illness. Aspiration pneumonia increases the risk for subsequent bacterial pneumonia.

VENTILATOR-ASSOCIATED PNEUMONIA. A type of aspiration pneumonia, ventilator-associated pneumonia (VAP), develops in patients who are intubated and mechanically ventilated. The endotracheal tube keeps the glottis open, so secretions can be aspirated in to the lungs.

HYPOSTATIC PNEUMONIA. Patients who hypoventilate because of bedrest, immobility, or shallow respirations are at risk for **hypostatic** pneumonia. Secretions pool in dependent areas of the lungs and can lead to inflammation and infection.

CHEMICAL PNEUMONIA. Inhalation of toxic chemicals can cause inflammation and tissue damage, which can lead to chemical pneumonia.

CRITICAL THINKING

Mr. Smith

■ Mr. Smith is an 86-year-old man who was watching television when he couldn't sleep one night. After seeing a commercial for toilet cleaner, he decided his own toilet could use some attention. He used bleach and ammonia "to get it really clean." The combination created toxic fumes, which caused a severe chemical pneumonia. He was brought to the emergency room in acute respiratory distress.

1. As his nurse, what questions might you ask as you further assess the cause of his pneumonia?
2. What will you teach Mr. Smith related to prevention of similar episodes in the future?

Suggested answers at end of chapter.

SAFETY TIP

In assisted living and long-term care facilities, develop and implement a protocol for administration and documentation of the flu and pneumococcus vaccines. Develop and implement a protocol to identify new cases of influenza and to manage an outbreak (2006 National Patient Safety Goals www.jcaho.org).

immunocompromised: immune—referring to immune system
+ compromised—lacks resistance

exudate: to sweat out

Prevention

A vaccine is available to help prevent *Streptococcus pneumoniae* pneumonias in high-risk patients and people older than age 65. It is effective about 80% to 90% of the time and requires only a one-time injection. Some individuals may require a repeat vaccination after 5 years. Yearly influenza vaccination is also recommended for high-risk individuals.

hypostatic: hypo—below + static—standing

Box 31.1

Gerontological Issues

Advanced age is a significant risk factor for serious complications from respiratory infections such as influenza and pneumococcal pneumonia. Therefore, it is recommended that people over the age of 65 and individuals with chronic disease have yearly influenza vaccines and a once-in-a-lifetime pneumococcal vaccine.

Nursing care plays an important role in the prevention of nosocomial pneumonia. Regular coughing, deep breathing, and position changes for patients on bedrest or after surgery, prevention of aspiration for patients at risk, and good hand washing practices by both patients and health-care personnel can help prevent many cases (Box 31.1 Gerontological Issues). Ventilator-associated pneumonia risk can be reduced with frequent mouth care and use of a special endotracheal tube that allows continuous suctioning of secretions.

SAFETY TIP

To reduce the risk of health care–associated infections, comply with current Centers for Disease Control and Prevention (CDC) hand hygiene guidelines, found at www.cdc.gov/handhygiene (2006 National Patient Safety Goals from www.jcaho.org).

Signs and Symptoms

Patients with pneumonia present with fever, shaking chills, chest pain, dyspnea, and a productive cough. Sputum is purulent or may be rust colored or blood tinged. Crackles and wheezes may be heard on lung auscultation because of the secretions in the alveoli and airways.

Some bacterial and many viral pneumonias cause **atypical** symptoms. The patient may experience fatigue, sore throat, dry cough, or nausea and vomiting.

Elderly patients may not exhibit expected symptoms of pneumonia. New-onset confusion or lethargy in an elderly patient can indicate reduced oxygenation and should alert you to look for other symptoms or request further testing. New onset of fever or dyspnea should also cause suspicion of possible pneumonia in the elderly.

Complications

Complications from pneumonia most commonly occur in patients with other underlying chronic diseases. Pleurisy and pleural effusion (discussed later in this chapter) are two of the most common complications and generally resolve within 1 to 2 weeks. **Atelectasis** (collapsed alveoli) can

occur as a result of trapped secretions and may be resolved with efforts to keep the airways clear. Other complications result from spread of infection to other parts of the body, causing septicemia, meningitis, septic arthritis, pericarditis, or endocarditis. Treatment for each of these is antibiotics. Although antibiotics have greatly reduced the incidence of death related to pneumonia, it is still a common cause of death in the elderly.

Diagnostic Tests

A chest x-ray examination is done to identify the presence of pulmonary infiltrate, which is fluid leakage into the alveoli from inflammation (Fig. 31.2). In addition, sputum and blood cultures are obtained to identify the organism causing the pneumonia and determine appropriate treatment. Cultures should be obtained before antibiotics are started to avoid altering culture results. If the patient is unable to produce a sputum specimen, a nebulized mist treatment may be ordered to promote sputum expectoration. If this is unsuccessful, a bronchoscopy may be done to obtain a specimen from a very ill patient.

Therapeutic Interventions

Broad-spectrum antibiotics are initiated before culture results are completed (be sure to obtain the specimen before starting the antibiotics). Once the culture and sensitivity report is available, specific antibiotics are ordered if the cause is bacterial. Many patients can be treated with oral antibiotics as outpatients, but hospitalization and intravenous (IV) therapy may be necessary in the elderly, chronically ill, or acutely ill individual. If the pneumonia is caused by a virus, rest and fluids are recommended. Occasionally, antiviral medications are used.

Expectorants, bronchodilators, and analgesics may be given for comfort and symptom relief. Nebulized mist treatments or metered-dose inhalers may be used to deliver bron-

chodilators. Supplemental oxygen via nasal cannula or mask is used as necessary.

See Box 31.2 Pneumonia Summary.

Tuberculosis**Pathophysiology**

Tuberculosis (TB) is an infectious disease caused by the bacterium *Mycobacterium tuberculosis*. TB primarily affects the lungs, although other areas, such as the kidneys, liver, brain, and bone, may be affected as well. *M. tuberculosis* is an acid-fast bacillus (AFB), which means that when it is stained in the laboratory and then washed with an acid, the stain remains, or stays “fast.” *M. tuberculosis* can live in dark places in dried sputum for months, but a few hours in direct sunlight kills it. It is spread by inhalation of the tuberculosis bacilli from respiratory droplets (droplet nuclei) of an infected person.

Once the bacilli enter the lungs, they multiply and begin to disseminate to the lymph nodes and then to other parts of the body. The patient is then infected but may or may not go on to develop clinical (active) disease. TB infection without disease is called latent TB infection, or LTBI. During this time the body develops immunity, which keeps the infection under control. If the lungs are involved, the immune system surrounds the infected lung area with neutrophils and alveolar macrophages. This process creates a lesion called a tubercle, which seals off the bacteria and prevents spread. Similar processes take place in other affected areas of the body. The bacteria within the tubercle die or become dormant, and the patient is no longer infectious. If the patient’s immune system becomes compromised, however, some of the dormant

**Box 31.3****Gerontological Issues**

The age-related decline in immune system function can decrease the effectiveness of the tuberculosis antibodies in someone who previously had latent infection. The tuberculosis bacilli can be activated, causing active disease. Because of the risk of false negative tuberculin test results, a two-step test is recommended, with the second test done 1 to 3 weeks after the first.

bacteria can become active, causing active disease. Only 5% to 10% of infected individuals in the United States actually develop the disease, and even then it may not occur for many years (Box 31.3 Gerontological Issues).

**NURSING CARE TIP**

If the physician orders “sputum culture for AFB,” tuberculosis is suspected. Ask whether isolation precautions should be taken while waiting for culture results.

Etiology

Crowded or poorly ventilated living conditions place people at risk for becoming infected with tuberculosis. Although tuberculosis can infect any age group, the elderly are especially at risk. Elders may have contracted the disease many years before, but it reactivates as the aging process diminishes immune function. Patients with AIDS and chronic alcohol abuse have a very high risk because of their compromised immune function. In the United States, tuberculosis is also prevalent among the urban poor and minority groups.

Before 1985 the incidence of TB was steadily decreasing. Now it is again on the rise, in part because of the prevalence of AIDS, the development of antibiotic-resistant strains of the TB bacillus, and ineffective treatment programs. TB kills 8000 people each day worldwide, and is the world’s biggest killer of young people and adults.¹

Prevention

Clean, well-ventilated living areas are essential to the health of all people. If a hospitalized patient is known or suspected to have tuberculosis, he or she is placed in respiratory isolation to prevent spread to staff or other patients. Special isolation rooms are ventilated to the outside. Staff should wear special high-efficiency filtration masks when in the patient’s room. A regular surgical mask is *not* effective against TB. Verify with the institution’s infection control department that the masks provided are effective for use with TB patients. If the patient must travel through the hallway for tests or other activities, the patient must wear a mask. Additional protective barriers, such as gowns, gloves, or goggles, are used when contact with sputum is likely.

A vaccine against tuberculosis is available and is used in areas where TB is prevalent. It is safe, but its effectiveness has been questioned. It is not used routinely in the United States. Individuals who have had the vaccine will have a positive skin test for TB, so alternative methods for screening must be used.

Ultimately prevention will come from adequate treatment of patients with TB. A current concern is the development of antibiotic-resistant strains of the tuberculosis bacillus, which can develop when patients are noncompliant with drug therapy. When antibiotics are taken intermittently or discontinued early, the more virulent (stronger) bacteria survive and multiply, and are resistant to the drugs being used. This multi-drug-resistant TB (MDR-TB) can then be passed on to someone else. It is therefore vital to teach all patients the importance of strict compliance with drug therapy. Patients who are at risk for noncompliance with drug therapy must have a visiting nurse or other health professional observe each dose of antibiotic taken. This is called directly observed therapy (DOT) or directly observed therapy–short course (DOTS). DOT transfers responsibility for making sure the drugs are taken from the patient to the health-care worker. The World Health Organization reports the highest treatment success rates with DOT(S).

Signs and Symptoms

Active tuberculosis is characterized by a chronic productive cough, blood-tinged sputum, and drenching night sweats. A low-grade fever may be present. If effective treatment is not initiated, a downhill course occurs, with pulmonary fibrosis, **hemoptysis**, and progressive weight loss.

Complications

Spread of the tuberculosis bacilli throughout the body can result in pleurisy, pericarditis, peritonitis, meningitis, bone and joint infections, genitourinary or gastrointestinal infection, or infection of many other organs.

Diagnostic Tests

Routine screening for tuberculosis infection is usually done with a purified protein derivative (PPD) skin test. The PPD is injected intradermally; the test is considered positive if a raised area of **induration** occurs within 48 to 72 hours. If there is a red area around the induration, this is not measured. The size of induration that indicates a positive test varies based on the individual's history (Table 31.1). A red area without induration is not considered a positive result. A positive result indicates that a person has been exposed; it does not mean that active TB disease is present.

In 2004, a new test was approved by the Food and Drug Administration (FDA) that may be more specific and reliable than the PPD test. The QuantiFERON-TB Gold (QFT-G) test is a blood test that detects the cell-mediated immune response to TB bacteria in blood. Unlike the PPD skin test, the QFT-G is valid in individuals who have been vaccinated against TB.

hemoptysis: hem—blood + ptysis—to spit

HIV = human immunodeficiency virus.

Source: Retrieved August 5, 2002, from Centers for Disease Control and Prevention: Diagnosis of tuberculosis infection and disease. www.phppo.cdc.gov.

NURSING CARE TIP

You have probably had a PPD skin test so you can do your clinical practice for school. When you have it checked, the clinician should touch your arm. Just looking at it is not adequate to judge whether there is a raised area of induration.

Some health care institutions use a two-step process for baseline testing of employees and residents. If an individual has a negative test, he or she is retested in 1 to 3 weeks. This is because someone who was exposed many years ago may not react to the first test. The first test acts as a “reminder” to the immune system to react. The second test will then be positive in the person with a past TB infection.

A chest x-ray examination is used as a screening tool in someone with a known positive test. Diagnosis is made based on sputum culture results.

Therapeutic Interventions

Treatment consists of specific antibiotic therapy. First-line drugs have the fewest adverse effects (Box 31.4). However, these drugs can be toxic to the liver and nervous system, as well as have other side effects. Second-line drugs are more toxic and are reserved for cases that do not respond to first-line drug therapy. Generally, two or three antibiotics are given simultaneously to allow lower doses of each individual drug, reduce the incidence of serious side effects, and reduce the risk of developing resistant bacteria. Drugs must be taken for 6 months, or up to 2 years for MDR-TB. Because of the

Box 31.4**Antibiotics Used to Treat Tuberculosis****First-Line Drugs**

Isoniazid
Rifampin
Ethambutol
Pyrazinamide

Second Line Drugs

Rifabutin
Rifapentine

**NURSING CARE TIP**

Some institutions use a *Candida* or mumps skin test along with a PPD skin test. This does not mean the patient is being tested for *Candida* or mumps because everyone generally reacts to these. Rather the patient is being tested for **anergy**, or the inability of the immune system to react to an antigen. If a *Candida* or mumps test produces positive results, the TB results are considered to be reliable.

The *Candida* or mumps test is administered in the same way as the PPD test. If more than one test is administered, use an indelible marker to identify which test is which, and clearly document (draw a picture) of where each test was placed. Check institution policy; it may direct where the tests are administered—PPD in the right arm and *Candida* in the left, for example.

length of therapy and the incidence of side effects, you must anticipate that compliance may be a problem.

Additional treatment is supportive. Rest and good nutrition are important for aiding the patient's own immune system to work. Patients must be isolated until their sputum no longer contains bacteria.

Patients with latent TB infection do not need to be treated, but some health departments recommend treatment to reduce the risk of progression to active disease and subsequent spread to others.

The Centers for Disease Control and Prevention has an excellent website with lots of information about tuberculosis at www.cdc.gov. Simply type "tuberculosis" into the search window.

Nursing Process

ASSESSMENT/DATA COLLECTION. Perform thorough respiratory and psychosocial assessments of the patient with TB. The severity of the disease determines the impact on the patient's lifestyle. It is also imperative to determine the patient's knowledge of the disease and treatment and his or her compliance with drug treatment.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. Nursing interventions for impaired gas exchange,

ineffective airway clearance, ineffective breathing pattern, and activity intolerance are found in Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder. Additional nursing diagnoses for the patient with TB follow.

Risk for ineffective management of therapeutic regimen related to knowledge deficit

EXPECTED OUTCOME: Patient will follow treatment regimen and infection will be cured.

- Assess patient's and family's ability and intent to follow treatment regimen. *It is essential that patients are diligent about taking their drugs in order to eradicate the infection and to prevent spread to others.*
- Teach patient and family that drugs must be taken as scheduled for the entire course (6 months or longer) or a drug-resistant form of disease may develop. *Patients may be more likely to comply if they understand the rationale for taking their medications.*
- Forwarn the patient that rifampin turns urine and other body fluids red. *This might frighten the patient from taking drugs if he or she is unprepared.*
- Teach patient to report side effects of medications. *If side effects can be managed, the patient is more likely to comply with therapy.*
- Request an order for a visiting nurse. *A visiting nurse can monitor compliance. Directly observed therapy (DOT) has been found to increase compliance with medications.*

Risk for infection transmission related to knowledge deficit about how infection is spread, or noncompliance with control measures

EXPECTED OUTCOME: Patient will verbalize understanding of and employ measures to prevent spreading infection.

- Assess patient's understanding of how TB is spread. *Teaching should build on patient's current knowledge.*
- Teach the patient how TB is spread and the importance of following measures to avoid spread. *The patient will be more likely to comply if he understands the rationale for his actions.*
- Teach the patient to use a tissue to cover the mouth and nose when coughing or sneezing. *TB is spread by droplet nuclei that can be contained with a tissue.*
- Teach patient to flush tissues down the toilet or dispose of carefully in the trash. *TB bacteria can live in dried sputum for months, so careful disposal is essential.*
- Teach all family members the importance of careful hand washing. *Hand washing is an important measure in preventing all kinds of infections.*
- Instruct the patient in the importance of compliance with follow-up sputum cultures. *Once sputum cultures are negative, the patient is no longer contagious.*

Box 31.5 NURSING CARE PLAN for the Patient with a Lower Respiratory Tract Disorder

Note: The most commonly used nursing diagnoses related to respiratory disorders are presented in the following care plan. This is not a care plan for any one respiratory disorder. Rather, use it as a reference for use when one of the nursing diagnoses applies to the patient, based on a thorough respiratory assessment.

Nursing Diagnosis: Impaired gas exchange related to decreased ventilation or perfusion

Expected Outcomes The patient will experience improved gas exchange, as evidenced by (1) improving arterial blood gases or pulse oximetry and (2) statement of acceptable level of dyspnea.

Evaluation of Outcomes (1) Are blood gases or SaO_2 improving? (2) Does patient state that dyspnea is gone or controlled at an acceptable level?

Interventions

- Assess lung sounds, respiratory rate and effort, use of accessory muscles.
- Observe skin and mucous membranes for cyanosis.
- Assess degree of dyspnea on a scale of 0 to 10, 0 = no dyspnea, 10 = worst dyspnea.
- Monitor for confusion or changes in mental status.
- Monitor arterial blood gas values and pulse oximetry as ordered.
- Elevate head of bed or help patient to lean on overbed table.
- Position with good lung dependent (“good lung down”).
- Administer supplemental oxygen at <2 L/min unless ordered otherwise.
- Place a fan in the patient’s room.
- Teach patient relaxation exercises.
- For chronic disease, teach patient diaphragmatic and pursed-lip breathing. (See Chapter 29.)
- Encourage patient to stop smoking if patient is a current smoker.
- For severe dyspnea, ask physician about an order for intravenous morphine sulfate.

Rationale

Respiratory rate less than 12 or more than 24 or use of accessory muscles indicates distress.

Diminished lung sounds indicate possible poor air movement and impaired gas exchange.

Cyanosis indicates poor oxygenation. Oral mucous membrane cyanosis indicates serious hypoxia.

The patient’s subjective report is the best measure of dyspnea.

Changes in mental status can signal impaired gas exchange.

$\text{PaO}_2 < 80$ mm Hg, $\text{Paco}_2 > 45$ mm Hg, or $\text{SaO}_2 < 90$ indicate impaired gas exchange.

Upright positioning promotes lung expansion.

This position allows the healthier lung to be better perfused and increases gas exchange.

Supplemental oxygen decreases hypoxia. Rates more than 2 L/min may depress hypoxic drive.

The feeling of a breeze on the patient’s face may make the patient feel he is getting more air.

Relaxation exercises decrease perceived dyspnea.

Breathing exercises promote relaxation and increase CO_2 excretion.

Smoking is damaging to lungs and respiratory function.

Low doses of IV morphine cause vasodilation, which helps relieve pulmonary edema and anxiety.

Evaluation

Are lung sounds clear and audible?
Is respiratory rate 12 to 20 per minute and unlabored?

Are skin and mucous membranes pink?

Is patient’s degree of dyspnea within parameters that are acceptable to patient?

Is patient alert and oriented? If not, could poor gas exchange be the reason?

Are values within patient’s baseline values?

Did change of position relieve some distress?

Is SaO_2 improved in this position?

Is oxygen placed properly on patient? Does it provide relief from dyspnea?

Is a fan available to the patient and does it help?

Does patient use relaxation effectively?

Does patient use breathing exercises correctly? Do they help?

Is patient receptive to smoking cessation? Are resources available?

Does morphine provide relief from dyspnea?

(Continued on following page)

Box 31.5 NURSING CARE PLAN for the Patient with a Lower Respiratory Tract Disorder (Continued)

Nursing Diagnosis: Ineffective airway clearance related to excessive secretions

Expected Outcomes The patient will have improved airway clearance as evidenced by (1) clear breath sounds and (2) ability to cough up secretions.

Evaluation of Outcomes (1) Are breath sounds clear? (2) Is patient able to effectively cough up and expectorate secretions?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> Assess lung sounds q4th and prn. 	Crackles and wheezes may indicate excess secretions in airways.	Do lung sounds indicate retained secretions?
<ul style="list-style-type: none"> Monitor amount, color, and consistency of sputum. 	Thick, purulent sputum indicates infection and should be reported to the physician.	Does sputum indicate infection?
<ul style="list-style-type: none"> Encourage oral fluids; use cool steam room humidifier. 	Hydration decreases viscosity of secretions and aids expectoration.	Is patient able to take oral fluids? Are secretions thin and easily expectorated?
<ul style="list-style-type: none"> Turn patient q2h or encourage to ambulate if able. 	Movement mobilizes secretions.	Is patient mobile?
<ul style="list-style-type: none"> Encourage patient to cough and deep breathe every hour and prn. 	Controlled coughing following deep breaths is more effective.	Does patient cough and deep breathe effectively?
<ul style="list-style-type: none"> Administer expectorants as ordered. 	Expectorants help liquefy secretions and trigger the cough reflex.	Are expectorants effective?
<ul style="list-style-type: none"> If patient is unable to cough up secretions, suction per institution policy. 	Suctioning is necessary to remove secretions when the patient is unable to cough effectively.	Is suctioning necessary? Does it help remove secretions?
<ul style="list-style-type: none"> Obtain order for chest physiotherapy or flutter valve if indicated. 	Percussion and postural drainage help mobilize secretions.	Is chest physiotherapy effective and well tolerated by the patient?

Nursing Diagnosis: Ineffective breathing pattern related to anxiety or pain

Expected Outcomes The patient will maintain an effective breathing pattern as evidenced by (1) respiratory rate between 12 and 20 per minute, even, and unlabored; and (2) arterial blood gas and oxygen saturation results within patient's normal range.

Evaluation of Outcomes (1) Is patient's respiratory rate within normal limits and unlabored? (2) Does breathing pattern support normal blood gas and SaO₂ values?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> Assess respiratory rate, depth, and effort q4h and prn. 	Respirations less than 12 or more than 20 may indicate an ineffective pattern.	Is respiratory pattern ineffective?
<ul style="list-style-type: none"> Monitor blood gas and oxygen saturation values. 	An ineffective breathing pattern will not maintain oxygenation.	Is breathing pattern adversely affecting oxygenation?
<ul style="list-style-type: none"> Determine and treat the cause of ineffective breathing pattern. 	Pain or anxiety can cause a patient to change the breathing pattern, and should be treated.	Is a contributing factor identifiable and correctable?
<ul style="list-style-type: none"> Place patient in Fowler's or semi-Fowler's position. 	This allows for maximum chest expansion.	Is the patient in a comfortable position that enables adequate expansion?
<ul style="list-style-type: none"> Teach patient to use diaphragmatic breathing, with a regular 2 second in, 4 second out pattern. 	Breathing exercises promote relaxation and increase CO ₂ excretion.	Is the patient able to demonstrate an effective breathing pattern?

Nursing Diagnosis: Activity intolerance related to imbalance between oxygen supply and demand

Expected Outcomes Patient will receive assistance with self-care until he or she is able to carry out own ADLs.

Patient will space rest and activity in order to provide as much self-care as possible.

Evaluation of Outcomes Are patient's care needs met by self or caregiver?

Interventions

- Assess amount of activity the patient can tolerate without becoming short of breath.
- Monitor vital signs and oxygen saturation with activities.
- Allow patient to rest between activities. Bedrest may be necessary during acute dyspnea.
- Obtain bedside commode, shower chair, handheld showerhead, if needed.
- Obtain portable oxygen if patient is able to ambulate.
- Allow uninterrupted rest at night as much as possible.
- Slowly increase activity as able.
- Refer patient with chronic lung disease to a pulmonary rehabilitation program.

Rationale

- Patients should be encouraged to do as much as they can for themselves, to avoid becoming deconditioned.
- Respiratory rate will rise and SaO_2 will drop if activity is not tolerated.
- Even talking or eating can be exhausting to a patient who is dyspneic.
- Assistive devices can help the patient conserve energy.
- Portable oxygen may enable the patient to ambulate and prevent deconditioning.
- Lack of sleep can contribute to activity intolerance.
- Increasing activity helps maintain muscle tone and endurance.
- Pulmonary rehabilitation programs can help patient increase exercise tolerance.

Evaluation

- What is patient able to do?
- Are vital signs and SaO_2 stable?
- Is patient able to catch his or her breath between activities?
- Do assistive devices allow patient more independence?
- Is patient able to ambulate and maintain SaO_2 WNL with portable oxygen?
- Is patient able to sleep uninterrupted? Can interferences be delayed till morning?
- Is patient able to increase a little each day? Is this a realistic goal for patient?
- Is patient willing to participate in a rehabilitation program?

EVALUATION. If nursing care has been effective, the patient will understand his or her disease and the importance of taking care of himself or herself. The patient will take medications and receive follow-up care as ordered. He or she will take measures to protect others from catching TB. Additional evaluation is found in Box 31.5 Nursing Care Plan for the Patient with Lower Respiratory Tract Disorder.

NURSING PROCESS FOR THE PATIENT WITH A LOWER RESPIRATORY INFECTION

Priority nursing diagnoses and interventions for patients with lower respiratory infections are presented in Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder.

CRITICAL THINKING

Mr. Woo

■ Mr. Woo is being tested for tuberculosis. You check his skin tests, and find that the PPD test in his left forearm is negative, with no redness or induration. You also find that the *Candida* test in his right forearm is negative, with no redness or induration. How do you document these results? How do you interpret them?

Suggested answers at end of chapter.

RESTRICTIVE DISORDERS

Restrictive disorders are those problems that limit the ability of the patient to expand his or her lungs. These are caused by a decrease in the **compliance** (or elasticity) of the lungs or chest wall.

Pleurisy (Pleuritis)

Pathophysiology

Recall that the visceral and parietal pleurae are the membranes that surround the lungs. Between these membranes is

CRITICAL THINKING

Jim

■ Jim is a 36-year-old accountant with bronchiectasis secondary to cystic fibrosis. You enter his room during an episode of uncontrollable coughing and offer him support. You observe his sputum as you dispose of it—a whole Styrofoam coffee cup full of thick, bright yellow sputum; the smell makes you nauseous. Even after coughing, his lungs sound congested from retained secretions. You offer him mouth care before you leave his room.

1. What questions can you ask Jim to assess his cough?
2. What nursing diagnosis is most appropriate for Jim?
3. What nursing care can you provide to enhance secretion removal?
4. You have an order for guaifenesin 300 mg q4h prn. It is supplied as 200 mg per 5 mL. How much will you administer?
5. How would you document this episode of coughing?

Suggested answers at end of chapter.

a small amount of serous fluid that prevents friction as the pleurae slide over each other during respiration. If the membranes become inflamed for any reason, they do not slide as easily. Instead of sliding, one membrane may “catch” on the other, causing it to stretch as the patient attempts to take a breath. This causes the characteristic sharp pain on inspiration. The irritation causes an increase in the formation of pleural fluid, which in turn reduces friction and decreases pain.

Etiology

Pleurisy is usually related to another underlying respiratory disorder, such as pneumonia, tuberculosis, tumor, or trauma. Nonrespiratory disorders such as pancreatitis or certain autoimmune disorders can also result in pleurisy.

Signs and Symptoms

Pleurisy causes a sharp pain in the chest on inspiration. Pain also occurs during coughing or sneezing. Breathing may be shallow and rapid because deep breathing increases pain. The patient may also exhibit fever, chills, and an elevated white blood cell count if the cause is infectious. A pleural friction rub is heard on auscultation.

Complications

As pleural membranes become more inflamed, serous fluid production increases, which may result in pleural effusion (see next section). If pleuritic pain is not controlled, patients have difficulty breathing deeply and coughing, which may lead to atelectasis. If infection goes untreated, **empyema** can result.

Diagnostic Tests

Diagnosis is based on signs and symptoms, including auscultation of a pleural friction rub. A chest x-ray examination

and complete blood cell count (CBC) may be done. FVC (forced vital capacity) is reduced more than FEV₁ (forced expiratory volume in one minute) since expansion is limited by the restrictive disorder; airways and FEV₁ may be normal. Additional testing is done to determine the underlying cause.

Therapeutic Interventions

Treatment is aimed at correcting the underlying cause. Nonsteroidal anti-inflammatory drugs (NSAIDs) or opioids are given to control pain and facilitate deep breathing and coughing. The physician may perform a nerve block by injecting anesthetic near the intercostal nerves to block pain transmission.

Pleural Effusion

Pathophysiology

When excess fluid collects in the pleural space, it is called a pleural effusion. Fluid normally enters the pleural space from surrounding capillaries and is reabsorbed by the lymphatic system. When a pathological condition causes an increase in fluid production or inadequate reabsorption of fluid, excess fluid collects. A normal amount of pleural fluid around each lung is 1 to 15 mL. More than 25 mL of fluid is considered abnormal; as much as several liters of fluid can collect at one time. The effusion can be either transudative, forming a watery fluid from the capillaries, or exudative, with fluid containing white blood cells and protein from an inflammatory process.

Etiology

Like pleurisy, pleural effusion is generally caused by another lung disorder. It is a symptom rather than a disease. Transudative effusions may result from heart failure, liver disorders, or kidney disorders. Exudative effusions more commonly occur with lung cancer, infection, or inflammation.

Signs and Symptoms

Symptoms depend on the amount of fluid in the pleural space. The patient may or may not experience pleuritic pain. Increasing shortness of breath occurs because of the decreasing space for lung expansion. Cough and **tachypnea** may be present. A dull sound is heard when the affected area is percussed. Lung sounds are decreased or absent over the effusion, and a friction rub may be auscultated.

Diagnostic Tests

A chest x-ray examination is done to determine whether pleural effusion is present. If a thoracentesis is done, fluid samples are sent to the laboratory for culture and sensitivity and cytological examination. Further tests may be done to determine the cause of the effusion.

Therapeutic Interventions

Bedrest is recommended to enhance spontaneous resolution of the effusion. If symptoms are severe, a therapeutic thoracentesis is done to remove the excess fluid from the pleural space and relieve the patient of dyspnea. See Chapter 29 for

tachypnea: tachy—rapid + pnea—breathing

how to assist with a thoracentesis. The physician will use x-ray examinations and percussion, or sometimes ultrasound, to determine where to insert the needle to obtain the fluid. If the fluid accumulation is large or recurring, a chest tube might be placed to continuously drain the pleural space. Occasionally talc or another irritating agent will be instilled via the chest tube to cause the pleural membranes to adhere to each other, eliminating the pleural space and preventing future episodes of pleural effusion. Treatment of the underlying cause of the effusion is necessary to prevent recurrence.

Empyema

Empyema is the collection of pus in the pleural space. It is a pleural effusion that is infected. Empyema is usually a complication of pneumonia, tuberculosis, or lung abscess.

Symptoms, diagnosis, therapeutic interventions, and nursing care are the same as the care of the patient with a pleural effusion, with an added emphasis on resolving the infection. A chest tube or surgery may be necessary to drain the area.

Pulmonary Fibrosis

Pathophysiology

Pulmonary fibrosis (PF), sometimes called interstitial lung disease, is a group of disorders that cause scarring and fibrosis of lung tissue. PF may evolve from injury to the alveoli, causing chronic inflammation; inflamed tissues are gradually replaced by fibrous connective tissue. Alveoli become thick and scarred, and gas exchange becomes difficult.

Etiology

A variety of factors are linked with pulmonary fibrosis, including heredity, exposure to certain viral illnesses, wood and metal dust exposure, medications, and smoking. It may also be associated with some autoimmune disorders such as lupus erythematosus or rheumatoid arthritis. Chronic GERD (gastroesophageal reflux disease) may play a role. Often PF is called idiopathic PF because no specific cause can be found.

Signs and Symptoms

Patients with PF experience progressive shortness of breath. Inspiratory crackles and chronic cough are present. Some experience flulike symptoms. Fatigue is common. Clubbing of fingers may be present. Patients usually follow a downhill course.

Diagnostic Tests

A chest x-ray may show lung infiltrates. A CT scan may be done. Spirometry is done to verify that the condition is restrictive. ABGs may show reduced PaO_2 . A bronchoscopy and lung biopsy can help rule out other causes of the patient's symptoms, and can show inflammation and fibrosis. A blood test (ANA titer) may show whether an autoimmune response is involved.

Therapeutic Interventions

Glucocorticoids (steroids) are used to reduce inflammation. Drugs to suppress the immune system may reduce autoim-

une activity. Patients should be encouraged to stop smoking. Oxygen is used if needed to maintain blood gasses. Patients should receive flu and pneumococcus vaccines. Younger patients may be considered for a lung transplant. Pulmonary rehabilitation helps patients maintain optimum activity tolerance.

Atelectasis

Atelectasis is the collapse of alveoli. It most commonly occurs in postsurgical patients who do not cough and deep breathe effectively, although it can be caused by anything that causes hypoventilation. Areas of the lungs that are not well aerated become plugged with mucus, which prevents inflation of alveoli. As a result, alveoli collapse. Compression of lung tissue from effusion or a tumor can also cause atelectasis. The focus of nursing care is on prevention. Patients should be taught the importance of coughing and deep breathing whenever there is the risk for hypoventilation. Frequent position changes and ambulation are also important.

NURSING PROCESS FOR THE PATIENT WITH A RESTRICTIVE DISORDER

Assessment/Data Collection

Perform a routine respiratory assessment. Monitor lung sounds for friction rub or decreasing breath sounds in any of the lobes. Assess pain level. Promptly report any increase in dyspnea, changes in vital signs or pulse oximetry, or increased white blood cell count or temperature.

Nursing Diagnosis, Planning, and Implementation

Priority nursing diagnoses are similar to other respiratory disorders, and are addressed in Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder. In addition, it is essential to address pain if present since pain can prevent the patient from breathing effectively.

Acute pain

EXPECTED OUTCOME: Patient will be comfortable enough to breathe deeply and cough; respiratory rate 12 to 20.

- Position patient for comfort. *Sometimes laying on the affected side for short periods will help reduce chest wall movement and pain.*
- Administer pain medication as ordered, preferably around-the-clock, to prevent pain from becoming severe. *Pain must be controlled so patient can breathe deeply and prevent further complications. NSAIDs or acetaminophen is usually tried first since they will not suppress cough and respirations.*
- If opioids are required to control pain, carefully monitor respirations and cough. *Opioids can suppress respirations and cough, which can further complicate the underlying disorder.*

- Teach patient the importance of deep breathing and coughing. *This can help prevent further complications, but may be difficult if associated with pain or suppressed by opioids.*

Evaluation

If interventions have been effective, the patient should report a decrease in dyspnea and anxiety. Pain will be controlled so that the patient is able to take deep breaths and cough effectively, and the patient will be free of signs and symptoms of infection.

OBSTRUCTIVE DISORDERS

Chronic Obstructive Pulmonary Disease/Chronic Airflow Limitation

Chronic obstructive pulmonary disease (COPD) is the fourth leading cause of death in the United States, and is expected to move to third place by 2020. Approximately 12.1 million adults have been diagnosed with COPD.² In the past, it was more common in men, but the incidence in women is rising due to more women smoking. The death rate from COPD in women nearly tripled between 1980 and 2000.

Pathophysiology

Chronic obstructive pulmonary disease is a group of pulmonary disorders characterized by difficulty exhaling because of airways that are narrowed or blocked by inflammation and mucus. More effort is required to push air out through obstructed airways (Fig. 31.3). **Emphysema**, chronic bronchitis, and asthma are disorders that limit airflow. A patient with COPD often has some degree of both emphysema and chronic bronchitis, although usually bronchitis is the dominant disorder. Asthma may also be present, but it differs somewhat because the airway constriction in asthma is usually reversible. A patient with asthma that is unremitting is treated as having COPD. Airflow limitation in emphysema and bronchitis is progressive and minimally reversible (Fig. 31.4).

COPD may also be referred to as chronic airflow limitation (CAL) or chronic obstructive lung disease (COLD). COPD develops over at least 30 years before symptoms become evident and may be advanced by the time the patient seeks treatment. It is characterized by periods of relative stability and **exacerbations** (acute worsening of symptoms), which may be triggered by respiratory infection or another stressor. See Box 31.6 COPD Summary.

LEARNING TIP

Restrictive disorders cause difficulty with inhalation and lung expansion. Obstructive disorders are associated with difficulty exhaling.

emphysema: to inflate

AIR TRAPPING IN CHRONIC AIRFLOW LIMITATION

A. Air trapping from excess mucous

Air movement during inspiration

Air trapping during expiration

B. Air trapping from decreased elastic recoil and narrowed airways

Normal inspiration

Impaired expiration

Air trapped due to decreased elastic recoil of alveolus and collapsed airway

FIGURE 31.3 Air trapping in COPD.

CHRONIC BRONCHITIS PATHOPHYSIOLOGY. Chronic bronchitis is similar to acute bronchitis, with symptoms occurring for at least 3 months of the year for 2 consecutive years. Patients may have multiple exacerbations, each lasting 2 weeks or more. The bronchial tree becomes inflamed from inhaled irritants, and impaired ciliary function reduces the ability to remove the irritants. The mucus-producing glands in the airways become hypertrophied, producing excessive thick, tenacious mucus, which obstructs airways and traps air (Fig. 31.5). These changes lead to chronic low-grade infection.

EMPHYSEMA PATHOPHYSIOLOGY. Emphysema affects the alveolar membranes, causing destruction of the alveolar walls and loss of elastic recoil. This also causes damage to adjacent pulmonary capillaries. Because of the loss of elastic recoil, passive expiration is impaired and air is trapped in the alveoli. Reduction in pulmonary capillaries reduces gas exchange. Emphysema can occur primarily in the respiratory bronchioles (centrilobular emphysema), with delayed alveolar damage, or in the respiratory bronchioles and alveoli (panlobular emphysema) (Fig. 31.6).

FIGURE 31.4 Chronic bronchitis and emphysema are the primary underlying disorders in COPD. Asthma may also play a role.

Etiology

Smoking is the single most important risk factor for COPD. Other factors include passive (secondhand) smoking, air pollution, and exposure to industrial chemicals. Some familial predisposition to chronic bronchitis has been demonstrated. A small number of individuals have an inherited deficiency of the enzyme alpha-antitrypsin (α_1 AT), which causes a predisposition to the development of emphysema. Patients with this inherited tendency who also smoke have a very high risk of developing the disease. Children of smoking parents are at higher risk because of secondhand smoke exposure.

Prevention

Prevention is important because no cure for COPD is currently available. Avoidance of smoking and other inhaled irritants is vital, especially in those individuals with parents or siblings with COPD. According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines, “smoking cessation is the single most effective- and cost-effective intervention to reduce the risk of developing COPD and slow its progression.”³

NURSING CARE TIP

This is a self-care tip. If you are a smoker, now is a good time to quit. COPD is deadly. Check Chapter 29 for ways to quit smoking. Good luck!

Signs and Symptoms

Classic symptoms of COPD are cough, sputum production, and dyspnea. Patients exhibit prolonged expiration because of obstructed air passages. Air trapping causes the lungs to become hyperinflated, which in turn leads to the classic barrel-shaped chest. The patient with chronic bronchitis has a chronic productive cough, shortness of breath, and activity

Box 31.6

COPD Summary

Signs and Symptoms

- Cough
- Chronic sputum production
- Dyspnea that occurs every day, worse with exercise
- Activity intolerance
- Crackles, wheezes, diminished breath sounds
- Barrel chest
- Use of accessory muscles

Diagnostic Tests

- Chest x-ray examination, CT scan
- Arterial blood gas analysis
- CBC
- Sputum analysis
- Spirometry
- α_1 AT level if hereditary deficiency suspected

Therapeutic Management

- Smoking cessation
- Bronchodilators (PO, NMT, MDI)
- Corticosteroids, expectorants
- Flu and pneumonia vaccinations
- Supplemental oxygen
- Breathing exercises
- Chest physiotherapy
- Pulmonary rehabilitation

Priority Nursing Diagnoses

- Impaired gas exchange
- Ineffective airway clearance
- Activity intolerance

MDI = metered-dose inhaler; NMT = nebulized mist treatment; PO = by mouth.

intolerance. Symptoms may initially be worse in the winter months. Crackles and wheezing are often noted on auscultation and may improve after coughing.

The most characteristic symptom of emphysema is progressive shortness of breath, accompanied by activity intolerance. Use of accessory muscles is evident. Auscultation reveals diminished breath sounds. Remember that many patients have symptoms of both chronic bronchitis and emphysema.

Arterial blood gases (ABGs) may be checked during an acute exacerbation of COPD and may show an increase in PaCO_2 and often a low PaO_2 . The patient develops **polycythemia** in response to reduced oxygenation, which results in a ruddy skin color. Cyanosis may also be present.

polycythemia: poly—many + cyt—cells = emia—in the blood

FIGURE 31.5 (A) Chronic bronchitis. Note inflamed airways and excessive mucus. (B) Asthma. Note narrowed bronchial tubes and swollen mucous membranes. (C) Emphysema. Note distended respiratory bronchioles and alveoli.

In late stages of COPD, patients may lose weight and become malnourished. They have difficulty eating because of severe dyspnea, and the increased work of breathing expends more calories. Chronic hypoxemia causes release of certain chemicals that may also lead to weight loss.

Complications

Some patients with emphysema develop large air spaces within the lung tissue (**bullae**) or adjacent to the pleurae (**blebs**). These are like blisters that can rupture and cause the lung to collapse. Right-sided heart failure may develop because the heart has to work harder to pump blood to the diseased lungs. (See the section on cor pulmonale in Chapter 26.) Death usually results from respiratory infection or respiratory failure.

Diagnostic Tests

Information from a chest x-ray examination, CT scan, blood gas analysis, CBC, and sputum analysis is correlated with the history and physical examination to diagnose COPD. Spirometry can help differentiate an obstructive versus a restrictive disorder: FEV_1 is reduced more than FVC in COPD; lung volume may be relatively normal, but forced expiration is reduced because of the obstruction. An α_1AT level is checked if deficiency is suspected, especially in patients with a family history of COPD.

COPD is classified according to spirometry results and symptoms (Box 31.7 COPD Stages).

Therapeutic Interventions

The goals of COPD treatment, according to the GOLD guidelines, are to:

- Prevent disease progression
- Relieve symptoms
- Improve exercise tolerance
- Improve health status
- Prevent and treat complications
- Prevent and treat exacerbations
- Reduce mortality
- Prevent or minimize side effects from treatment

In addition, cessation of cigarette smoking should be included as a goal throughout any management program.³

SMOKING CESSATION. Even late in the disease process, stopping smoking can slow disease progression and prolong life. Exposure to other respiratory contaminants should also be minimized. Hair spray, body powder, and other household aerosols should be avoided. Figure 31.7 shows the benefit of smoking cessation and impact on the length of time to disability and death. Box 31.8 Patient Perspective is a personal account from one woman who understood too late the importance of smoking cessation.

OXYGEN. Oxygen therapy is usually delayed until stage IV disease, and then is used to keep SaO_2 at or above 90%. It is generally ordered at a flow rate of 1 to 2 L/minute. Higher flow rates may suppress the hypoxic drive in patients who are chronic CO_2 retainers, although this is uncommon. Higher flow rates may be used during acute exacerbations in a monitored setting. Patients with chronic oxygen saturation levels of less than 88% should be placed on home oxygen.

FIGURE 31.6 Types of emphysema. (A) Normal lungs. (B) Centrilobular emphysema. (C) Panlobular emphysema.

MEDICATIONS. Medications commonly used include adrenergic and anticholinergic MDIs (inhalers) or NMTs (nebulized mist treatments) to open airways, corticosteroid inhalers to control inflammation, expectorants, and, intermittently when needed, antibiotics. Much focus is now placed on a combination of long-acting adrenergic agents and corticosteroids (Advair, Symbicort) and a new long-acting anticholinergic agent (tiotropium/Spiriva), all of which may reduce exacerbations and prolong survival.

Box 31.7

COPD Stages

Stage 0—At Risk. Patient has cough and sputum production, but lung function is normal.

Stage 1—Mild COPD. Mild airflow limitation, with cough and sputum. Patient may not realize his lung function is abnormal.

Stage 2—Moderate COPD. Airflow limitation worsening, patient begins to feel short of breath on exertion.

Stage 3—Severe COPD. Increasing airflow limitation and shortness of breath. Patient experiences decreased quality of life.

Stage 4—Very Severe COPD. Severe airflow limitation; exacerbations may be life-threatening.

Adapted from GOLD Guidelines, 2005.³

Antitussives should be avoided in patients with COPD because they need to be able to cough up secretions.

Oral theophylline bronchodilators are sometimes used, but have a lot of side effects so are avoided if possible. Oral corticosteroids may be used late in the disease to increase reduction in airway inflammation, but should ideally be reserved for acute exacerbations. A newer treatment is

Box 31.8

Patient Perspective

Sarah

At the age of 17, I started the habit which would change my life. I started to smoke.

At first it was just a few cigarettes, but as time passed I smoked more and more until I reached two packs a day. This habit continued for 42 years, disregarding all the warnings about what could happen. I was sure this would never happen to me.

Now at age 75, I must do three breathing treatments a day, and carry an inhaler with me at all times. I have a cough that cannot be controlled. I can no longer ride a bike with my grandchildren, play badminton, or even bowl. My lungs won't let me. Going shopping is no longer fun—it's a chore. I have to walk slowly or I can't breathe.

All the things I enjoyed most I've given up because for 42 years I was a slave to cigarettes. If any of you smoke, stop now. Smell the coffee and roses without coughing.

antitussive: anti—against + tussive—cough

(Fletcher C, Peto R: The natural history of chronic airflow obstruction. *BMJ* 1:1645–1648, 1977.)

replacement of α_1 AT in those patients who are deficient. See Table 31.2 for a more detailed list of medications used in the treatment of COPD.

Patients with COPD should also be assessed for depression. Depression is common with chronic illness, and often goes undiagnosed. Patients may not complain of feeling depressed, but may experience more physical symptoms. Antidepressant medications, if indicated, can increase quality of life for COPD patients.

SUPPORTIVE CARE. A pneumococcal vaccination and yearly influenza vaccinations are recommended to reduce the risk of respiratory infection. Avoidance of crowds and exposure to people with respiratory infections is advised.

Good hydration and a cool mist humidifier help keep secretions loose. Chest physiotherapy may be used to help the patient remove excessive secretions. A dietitian consultation is helpful for the patient who is unable to maintain a

TABLE 31.2 SELECTED MEDICATIONS USED FOR LOWER RESPIRATORY TRACT DISORDERS

Drug Class/Action	Examples	Route	Side Effects	Nursing Implications
Adrenergic bronchodilators Stimulate beta receptors to dilate bronchioles	Albuterol (Ventolin, Proventil) Metaproterenol (Alupent, Metaprel) Pirbuterol (Maxair) Salmeterol (Serevent) Formoterol (Foradil)	PO, Inhaled PO, Inhaled Inhaled Inhaled Inhaled	Increased heart rate, tremor, anxiety	Use with care in patients with cardiac disease. Overuse can cause rebound bronchospasm. Albuterol, metaproterenol, and pirbuterol are short acting; used as rescue inhalers. Serevent and Foradil are long acting, used bid to prevent symptoms.
Anticholinergic agents Block parasympathetic response, causing bronchodilation	Ipratropium (Atrovent) Tiotropium (Spiriva)	Inhaled Inhaled	Dry mouth	Caution in narrow-angle glaucoma and prostatic hypertrophy
Methylxanthines Relax bronchial smooth muscle to dilate airways	Theophylline (Theovent, Theolair, Uniphyll) Aminophylline	PO PO, IV	Tremor, anxiety, tachycardia, nausea, vomiting	Can become toxic. Therapeutic theophylline level 10–20 $\mu\text{g/mL}$.
Corticosteroids Reduce inflammation in airways	Methylprednisolone (Medrol, Solu-Medrol) Prednisone Triamcinolone acetonide (Azmacort) Beclomethasone (Beclivent) Fluticasone (Flovent) Budesonide (Pulmicort)	PO, IV PO Inhaled Inhaled Inhaled Inhaled	Cushingoid side effects with prolonged use: moon face, sodium and water retention, buffalo hump, osteoporosis, hyperglycemia. Fewer side effects with inhaled route.	Must be used regularly to prevent symptoms. Never discontinue abruptly. Monitor blood glucose while on high doses. Rinse mouth following use to prevent local infection. If using glucocorticoid and adrenergic MDIs together, use adrenergic inhaler first to open airways.

Drug Class/Action	Examples	Route	Side Effects	Nursing Implications
Combination Agents	Albuterol and ipratropium (Combivent)	Inhaled	See individual agents	See individual agents
	Fluticasone and salmeterol (Advair)	Inhaled		
	Budesonide and formoterol (Symbicort)	Inhaled		
Mast Cell Inhibitors				
Stabilize mast cells to reduce histamine release	Cromolyn sodium (Intal)	Inhaled	Few side effects.	Effective for allergic asthma. May be used prophylactically before exercise or allergen exposure.
	Nedocromyl (Tilade)	Inhaled		
Expectorants				
Liquefy secretions and stimulate cough	Guaifenesin (Robitussin, Mucinex)	PO	Few side effects.	Encourage fluids.
Antileukotrienes				
Inhibit leukotriene synthesis or activity, a mediator of inflammation in asthma	Zafirlukast (Accolate)	PO	Headache	Must be taken regularly to prevent symptoms. Monitor for elevation of liver enzymes.
	Montelukast (Singulair)	PO		
	Zileuron (Zyflo)	PO		
Antitussives				
Suppress cough reflex	Codeine	PO	Related to opioids; may be sedating at high doses.	Avoid giving to patient who has secretions that need to be expectorated.
	Dextromethorphan (DM suffix in cough preparations)	PO		

NOTE: This table is an overview. A drug guide should be consulted for complete administration guidelines.

PO = by mouth; IV = intravenous; MDI = metered-dose inhaler.

desirable weight. Breathing exercises help improve oxygenation and reduce anxiety. (See Chapter 29.)

REHABILITATION. Pulmonary rehabilitation programs can help patients increase exercise tolerance and maintain a sense of well-being (Fig. 31.8). Patients exercise in a monitored environment, and benefit from the support of other patients with similar problems. Some groups of pulmonary rehabilitation patients have even formed harmonica clubs! Playing their harmonicas mimics pursed lip breathing and may strengthen the diaphragm, the major muscle of breathing.

SURGERY. A newer treatment for emphysema is the surgical removal of some of the diseased lung tissue (called lung volume reduction surgery, or LVRS). This increases the space available for good lung tissue to expand, reducing dyspnea and increasing exercise tolerance. This is a high-risk procedure, but it has allowed some patients to return to a more normal activity level and increase quality of life. It does not lead to longer survival in most patients. Lung transplant may be an option in select patients.

MECHANICAL VENTILATION. If arterial blood gases worsen despite treatment, intubation and mechanical ventilation may be considered, depending on the patient's Advance Directive. Unfortunately, mechanical ventilation will not make a patient's disease better, and weaning may be

FIGURE 31.8 Patients build exercise tolerance in pulmonary rehabilitation programs. Note therapist monitoring oxygen saturation.

difficult or impossible once it is initiated. Use of noninvasive positive pressure ventilation (NIPPV; see Chapter 29) may be a good alternative for many patients.

END-OF-LIFE PLANNING. It is important to assess whether the patient has a Living Will or Durable Power of Attorney (DPOA) for Healthcare (see Chapter 16). COPD is a progressive disease, and patients can increase the quality of their life and death by making decisions in advance. Patients should make decisions about whether they would want to be intubated and mechanically ventilated, or have CPR in event of a cardiac arrest. CPR is rarely successful in a patient with end-stage COPD. Patients should be made aware of palliative care options, and assured they will be kept as comfortable as possible.

Research is ongoing to determine which treatments will alter long-term outcomes of the disease. Check the American Lung Association website for more information at www.lungusa.org.

Nursing Process

See Nursing Process for the Patient with an Obstructive Disorder, following the section on cystic fibrosis, and Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder. Priority nursing diagnoses for the patient with COPD include Impaired Gas Exchange, Ineffective Airway Clearance, and Activity Intolerance.

Asthma

The incidence of asthma is on the rise. Nearly 20 million people in the United States have asthma, and 5000 people die from asthma each year.⁴ It is more prevalent in African Americans than in whites. Asthma deaths are more prevalent in lower socioeconomic groups, presumably because of lack of compliance with treatment regimens. With careful monitoring and treatment, however, patients with asthma can control their symptoms and lead normal lives.

Pathophysiology and Etiology

Asthma is characterized by inflammation of the mucosal lining of the bronchial tree and spasm of the bronchial smooth muscles (**bronchospasm**). This causes narrowed airways and air trapping, which is why it is considered an obstructive disorder (see Fig. 31.5). Inflammation occurs in part because asthma triggers cause release of inflammatory substances such as histamine and leukotrienes. Symptoms are intermittent and generally reversible, with periods of normal airway function. About 50% of asthmatics develop the disorder in childhood, and many outgrow it. However, a significant number develop symptoms again later in life. Children with asthma should be counseled that smoking can increase the risk of recurrence in adulthood.

The tendency to develop asthma is inherited. Some sources classify asthma as either allergic or idiosyncratic (unusual). Allergic asthma is triggered by allergens such as

pollen, foods, medications, animal dander, air pollution, molds, or dust mites. It is commonly seasonal. Individuals who developed asthma as children tend to have allergic asthma. Idiosyncratic asthma is generally diagnosed in adults and is related to environmental or other nonallergic factors, such as environmental irritants, smoking, and respiratory or sinus infection.

Emotional upset and exercise can also trigger symptoms in some persons with asthma. Gastroesophageal reflux disease (GERD) can also trigger symptoms. It is believed that stomach acid may reflux into the esophagus and then be aspirated, triggering asthma. This occurs especially at night. GERD and its treatment are discussed in Chapter 33. Asthma frequently complicates chronic bronchitis or emphysema.

Prevention

Although asthma cannot be prevented at this time, research is ongoing to determine factors associated with its development. Exposures to allergens and respiratory syncytial virus (RVS) in infancy are believed to play a role. Smoking may be associated with recurrence of asthma that started in childhood. It is important that the patient identify triggers of asthma symptoms and avoid them whenever possible. Compliance with prophylactic and maintenance therapy is also important.

Signs and Symptoms

Asthma symptoms are intermittent and are often referred to as “attacks,” which may last from minutes to days. The patient complains of chest tightness, dyspnea, and difficulty moving air in and out of the lungs. Once initial symptoms are controlled, airways may remain hypersensitive and prone to asthma symptoms for many weeks.

On examination, you will note an increased respiratory rate as the patient attempts to compensate for narrowed airways. Inspiratory and expiratory wheezing is heard because of turbulent airflow through swollen airways with thick secretions and may sometimes be audible even without a stethoscope. Air is trapped in the lungs, and expiration is prolonged. A cough is common and may produce thick, clear sputum. Use of accessory muscles to breathe is a sign that the attack is severe and warrants immediate attention.

Be aware that an absence of audible wheezing may not signal improvement but rather may be an ominous sign that the patient is not moving enough air to make a sound. If wheezing is not heard, use of accessory muscles and peak expiratory flow rate values must be carefully evaluated. Once treatment begins to be effective and the patient is moving more air, wheezing may become audible.

Asthma is classified according to frequency of symptoms (Table 31.3).

Complications

Status asthmaticus occurs if bronchospasm is not controlled and symptoms are prolonged. As the patient increases the respiratory rate to compensate for narrowed airways, a lot of carbon dioxide is blown off and respiratory

bronchospasm: broncho—airway + spasm—convulsion, narrowing

TABLE 31.3 CLASSIFICATION OF ASTHMA

Mild Intermittent	Asthma symptoms twice a week or less, night symptoms twice a month or less.
Mild persistent	Asthma symptoms more than twice a week, but no more than once a day; symptoms at night more than twice a month. Asthma attacks affect activity.
Moderate persistent	Asthma symptoms every day; nighttime symptoms more than once a week. May affect activity.
Severe persistent	Symptoms throughout the day on most days; nighttime symptoms often. Physical activity likely limited.

From the National Heart, Blood, and Lung Institute, <http://www.nhlbi.nih.gov>, July 2005.

alkalosis occurs. If the attack is not resolved and the patient begins to tire, the patient will no longer be able to compensate and PaCO_2 will rise, resulting in respiratory acidosis. This can lead to respiratory failure and death if untreated.

Diagnostic Tests

Diagnosis is based on the patient’s report of symptoms, physical examination, and spirometry. Peak expiratory flow rate and forced expiratory volume in one second (FEV_1) are reduced during symptomatic periods. Asthma can be differentiated from COPD during spirometry testing by administering an adrenergic agonist (such as an albutrol inhaler) and then retesting. Asthma symptoms can generally be reversed with the medication, while COPD cannot. Allergy skin test-

FIGURE 31.9 Patient with asthma using a peak flowmeter to monitor peak expiratory flow rate.

ing and increased serum IgE and eosinophil levels indicate allergic involvement and may help determine treatment.

During a severe attack, arterial blood gases may initially show decreased PaCO_2 . Late in the course of an attack, PaO_2 decreases and PaCO_2 increases.

Therapeutic Interventions

Patients must learn to manage their asthma at home. The better they can monitor and manage their symptoms, the fewer acute episodes and hospitalizations will be required.

MONITORING. Some patients monitor their peak expiratory flow rate (PEFR) at home (Fig. 31.9). This is a measure of the amount of air the patient can blow into a peak flowmeter from fully inflated lungs and is measured in liters per minute. The patient determines his or her normal PEFR during symptom-free times. Readings can be charted to keep track of progress (Fig. 31.10). If the PEFR begins to

FIGURE 31.10 Peak flow chart. The green zone is 80% to 100% of the patient’s normal peak flow rate. The yellow zone is 50% to 80% of normal. The red zone is less than 50% of normal. The patient works with the physician to determine which actions to take when readings fall in the yellow or red zones.

Asthma Action Plan for _____ Doctor's Name _____ Date _____
 Doctor's Phone Number _____ Hospital/ Emergency Room Phone Number _____

GREEN ZONE: Doing Well

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,
Peak flow: more than _____
 (80% or more of my best peak flow)
 My best peak flow is: _____

Take These Long-Term-Control medicines Each Day (include an anti-inflammatory)

Medicine	How much to take	When to take it

Before exercise _____ 2 or 4 puffs 5 to 60 minutes before exercise

YELLOW ZONE: Asthma is Getting Worse

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-
Peak flow: _____ to _____
 (50% – 80% of my best peak flow)

First Add: Quick-Relief Medicine – and keep taking your GREEN ZONE medicine
 _____ (short-acting beta₂-antagonist) 2 or 4 puffs, every 20 minutes up to 1 hour
 Nebulizer, once

Second If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment
 Take the quick-relief medicine every 4 hours for 1 to 2 days
 Double the dose of your inhaled steroid for _____ (7-10) days

-Or-
 If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment
 Take: _____ (short-acting beta₂-antagonist) 2 or 4 puffs or Nebulizer
 Add: _____ (oral steroid) mg/day For _____ (3-10) days
 Call the doctor before/ within _____ hours after taking the oral steroid.

RED ZONE: Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-
Peak flow: less than _____
 (50% of my best peak flow)

Take this Medicine
 _____ (short-acting beta₂-antagonist) 4 or 6 puffs or Nebulizer
 _____ (oral steroid) mg

Then call your doctor NOW. Go to the hospital or call for an ambulance if:
 You are still in the red zone after 15 minutes AND
 You have not reached your doctor

DANGER SIGNS
 Trouble walking and talking due to shortness of breath
 Lips or fingernails are blue

FIGURE 31.11 Asthma action plan.

fall below the patient’s personal norm, treatment that has been predetermined with the health-care provider should be initiated (Fig. 31.11). PEFR results may indicate the onset of asthma before the patient experiences any symptoms.

AVOIDANCE OF TRIGGERS. The patient is instructed to identify and avoid asthma triggers. If triggers cannot be avoided, the patient can use bronchodilator or mast cell inhibitor inhalers as prescribed before exposure. Inhalers can be especially useful before exercise. Recent studies have shown that a high-salt diet may worsen exercise-induced airway inflammation. Animal dander and foods that cause symptoms are best avoided when possible. Eliminating carpets and curtains in bedrooms, using vinyl mattress and pillow covers, and installing a portable or central air filter can reduce dust mite exposure. Maintenance of indoor humidity between 40% and 50% can reduce mold growth. If cold air triggers symptoms, the patient should keep the nose and mouth covered when outside in cold weather. Smoking and exposure to secondary smoke are strongly discouraged.

Aspirin and nonsteroidal anti-inflammatory drugs can cause asthma symptoms in some individuals. Beta-blocking

medications (propranolol, metoprolol), used commonly for hypertension, block beta receptors in the lungs, preventing the sympathetic nervous system from promoting bronchodilation. These drugs should be avoided if they make symptoms worse.

MEDICATIONS. Medications for asthma treatment may be intermittent or continuous, depending on the chronicity of symptoms. See Table 31.2 for a summary of medications used in the treatment of lower respiratory disorders.

For patients with only occasional symptoms, adrenergic bronchodilators such as albuterol (Proventil, Ventolin) are used. They may be administered via MDI when symptoms occur, or before exercise or other events that trigger asthma. Long-acting bronchodilators (Serevent, Foradil) can help prevent symptoms.

If the patient needs to use an adrenergic MDI more than three times a week, an inhaled corticosteroid (Pulmicort, Flovent) may be added. Because they are used topically, side effects are minimal. Inhaled corticosteroids are important in maintenance therapy to prevent symptoms. Instruct the patient that corticosteroids must be used regularly to prevent

NURSING CARE TIP

If separate bronchodilator and corticosteroid inhalers are used at the same time, instruct the patient to use the bronchodilator first. This opens the airways and allows the corticosteroid to be better distributed in the lungs.

symptoms and they do not provide immediate symptom relief during an acute attack. Combined corticosteroids and long-acting adrenergic bronchodilators (Advair, Symbicort) in one inhaler have been shown to be very effective in controlling asthma symptoms.

Mast cell inhibitors (Intal, Tilade) may help prevent symptoms, but are often not useful. Some patients use mast cell inhibitors 10 to 15 minutes before exposure to allergens or exercise to reduce symptoms.

If inhaled medications do not control symptoms, or if the patient has nocturnal symptoms, oral antileukotrienes may be tried; theophylline bronchodilators are generally used as a last resort because of their many side effects. Immunotherapy (allergy shots) may be used for some patients with allergic asthma.

An acute asthma attack may be treated with an inhaled (MDI or NMT) or subcutaneous adrenergic bronchodilator or, rarely, intravenous aminophylline. Intravenous or oral corticosteroids (methylprednisolone, prednisone) are potent anti-inflammatory agents that are useful in an acute episode but are avoided for long-term therapy if possible because of their cushingoid side effects. (See the section on Cushing's syndrome in Chapter 39.) Corticosteroids must be tapered before discontinuing to prevent withdrawal symptoms. (See the section on Addisonian crisis in Chapter 39.)

Medications that are used routinely are called maintenance medications. Short-acting adrenergic inhalers such as albuterol are used for acute attacks and are called rescue medications. It is important that patients understand the difference between maintenance and rescue medications and use them appropriately.

Oxygen is generally not necessary because many patients hyperventilate during an acute attack. If the attack is prolonged and the patient becomes cyanotic or PaO_2 levels begin to fall, oxygen therapy will be used.

NURSING CARE TIP

Instruct the patient to contact the health-care provider if using more than two adrenergic MDI canisters per month. This has been associated with an increased risk of death.

Nursing Process

See Nursing Process for the Patient with an Obstructive Disorder, following cystic fibrosis section in this chapter.

Box 31.9

Asthma Summary

Signs and Symptoms	Chest tightness, dyspnea Wheezing
Diagnostic Tests	Spirometry ABGs in acute attack
Therapeutic Interventions	Identification and avoidance of triggers Inhaled corticosteroids Inhaled bronchodilators Oral bronchodilators and steroids if inhaled ineffective
Complications	Status asthmaticus
Priority Nursing Diagnoses	Impaired gas exchange Ineffective airway clearance Anxiety

Primary nursing diagnoses include Impaired Gas Exchange, Ineffective Airway Clearance, and Anxiety.

See Box 31.9 Asthma Summary.

Cystic Fibrosis

In the past, cystic fibrosis (CF) was thought to be just a childhood disease because most affected children did not survive past puberty. However, with new treatments, patients with CF are living longer and more productive lives. Some CF patients now marry, have careers, and live well into their 30s.

Pathophysiology

CF is a disorder of the exocrine glands that affects primarily the lungs, gastrointestinal (GI) tract, and sweat glands. The disease varies in severity; some patients have no GI involvement. Abnormal sodium and chloride transport across cell membranes, causing thick, tenacious secretions, is responsible for many of the characteristic symptoms. Thick, sticky respiratory secretions that are difficult to remove cause airway obstruction, resulting in air trapping and frequent respiratory infections.

Similar abnormalities in the pancreas cause blocked ducts and retained digestive enzymes. These retained enzymes digest and destroy the exocrine pancreas. The absence of digestive enzymes in the intestines causes malabsorption of essential nutrient, frequent foul-smelling, fatty stools, and excess flatus.

Patients with CF secrete sweat that is high in sodium and chloride because these electrolytes are not reabsorbed as they pass through the sweat ducts.

Etiology

CF is a genetic disorder. Both parents must be carriers of the defective gene for CF to be present in a child. Patients who marry are counseled on the risk of potential offspring having the disease.

Signs and Symptoms

Symptoms usually first appear in infancy or childhood, although a few individuals are not diagnosed until adulthood. Respiratory symptoms are often the first visible manifestation of the disease and range from chronic sinusitis to production of thick, tenacious sputum. Patients with CF are at risk for frequent respiratory infections, manifested by an increase in cough and purulent sputum. Finger clubbing is common. Late in the disease, hemoptysis may occur related to damaged blood vessels within the lungs. Over time, bouts of infection become more frequent, with eventual loss of lung function and respiratory failure. Antibiotic-resistant bacteria are a threat to life in these individuals.

Frequent foul-smelling stools result from the lack of enzymes in the small intestine. Inability to absorb fat-soluble vitamins and poor appetite due to respiratory disease result in malnutrition. Bowel obstruction, cirrhosis, cholecystitis, and cholelithiasis are associated findings.

Chronic disease causes delayed sexual maturation in both males and females, and infertility is common.

Complications

Patients with CF are at risk for a variety of complications, including bronchiectasis, pneumothorax, cor pulmonale, and respiratory failure. Bowel obstructions can occur as a result of thick mucus binding with poorly digested fecal matter. Diabetes from pancreatic islet cell involvement may be present late in the disease. Death is usually the result of pulmonary complications, especially antibiotic-resistant infection.

Diagnostic Tests

Because so many different gene mutations can occur in CF, genetic testing may be used to confirm a suspicion of CF but not for screening. The standard diagnostic test is the sweat chloride test. If respiratory symptoms are accompanied by excessive amounts of sodium chloride in sweat, CF is diagnosed. You may recall public health campaigns that advise parents to kiss their babies and report any salty taste to their physicians. Chest x-ray and spirometry may also be done.

Therapeutic Interventions

Because there is no cure for CF, treatment is aimed at controlling infection and relieving symptoms. Removal of thick sputum is promoted with hydration, use of the Flutter mucous clearance device, and chest physiotherapy up to four times a day. Regular exercise also helps mobilize secretions. A hot shower may be an easy occasional alternative to loosen secretions. Nebulized mist treatments using saline or mucolytic medications may be used before chest physiotherapy. Medications to decrease the viscosity of secretions have not yet been entirely successful, but new drugs are constantly being tested. Inhaled bronchodilators and corticosteroids are sometimes useful. High doses of ibuprofen (Motrin) may slow lung deterioration. Breathing exercises, incentive spirometry, and effective coughing techniques are also helpful. Lung transplant is a potentially promising treatment.

Prevention of infection is vital to slowing progression of lung damage. Patients should receive a yearly flu vacci-

nation. Antibiotics must be administered as soon as signs of infection occur. Prophylactic antibiotic therapy may be used. Some patients use home intravenous antibiotic therapy. Antibiotic-resistant infections are a deadly threat to the CF patient.

Pancreatic enzyme replacement (Pancrease, Viokase) helps reduce symptoms related to malabsorption and improve nutritional status. An increase in calorie requirements necessitates a high-calorie, nutrient-dense diet. For more information, visit the Cystic Fibrosis Foundation at www.cff.org.

Nursing Process

See Nursing Process: The Patient with an Obstructive Disorder below. Also, be sure to remember the special needs of the adolescent patient with this chronic, debilitating disease. Not only are normal physical growth and development delayed, but psychosocial development is also affected by repeated hospitalizations and the necessity of routine daily medication and treatments.

NURSING PROCESS FOR THE PATIENT WITH AN OBSTRUCTIVE DISORDER

Assessment/Data Collection

Perform a complete respiratory assessment as presented in Chapter 29. Frequency of assessment is dictated by the severity of the patient's condition. Note level of consciousness; poor gas exchange can cause confusion and lethargy. Assess respiratory rate and effort. Observe skin and mucous membranes for cyanosis. Auscultate lung sounds for adventitious sounds. Monitor cough and color and amount of sputum. Note exercise tolerance, and measure degree of dyspnea on a scale of 0 to 10. Monitor oxygen saturation or arterial blood gases. Careful documentation of findings allows you to monitor and report trends in the patient's progress.

Nursing Diagnosis, Planning, and Implementation

A number of nursing diagnoses are appropriate for the patient with an obstructive disorder. As always, choose diagnoses based on defining characteristics and the patient's individual assessment findings.

Impaired Gas Exchange, Ineffective Airway Clearance, Ineffective Breathing Pattern, and Activity Intolerance

These are priority problems for most chronic respiratory patients. Interventions for these diagnoses are presented in Box 31.5 Nursing Care for the Patient with a Lower Respiratory Tract Disorder.

Imbalanced nutrition related to poor appetite and increased calorie expenditure

EXPECTED OUTCOME: The patient's weight will be stable at desired weight for height.

- Monitor food intake and weekly weight. *Regular monitoring can help identify nutrition problems before they are severe.*
- If the patient is too dyspneic to eat, schedule rest periods and bronchodilator treatments before meals. *Eating takes a lot of energy, and resting can help conserve energy before a meal. Bronchodilators can reduce dyspnea while eating.*
- Create a pleasant eating environment. *Unpleasant views or odors can spoil an appetite.*
- Provide smaller, more frequent meals of the patient's favorite foods. *Eating a lot at one time can fill up the stomach and reduce room for lung expansion.*
- Encourage family members to bring favorite foods from home for the hospitalized patient. *A large tray of unappetizing food may be more than a patient can handle, and may spoil the appetite. Be sure to note sodium or other restrictions; although the patient with end-stage disease may be allowed a more lenient diet, excess sodium can cause fluid retention and increase dyspnea.*
- Consult a dietitian for liquid supplements recommendations. *A specialized supplement such as Pulmocare provides less carbon dioxide when metabolized and may be used for patients with respiratory disease*
- See also Box 31.10 Nutrition Notes.

Anxiety related to acute dyspnea

EXPECTED OUTCOME: The patient will state that anxiety is controlled; the patient will be able to use techniques to control dyspnea and anxiety when they occur.

- Remain with the patient who is acutely dyspneic and anxious. *Feeling alone during episodes of dyspnea can increase anxiety.*
- Calmly remind the patient to breathe slowly in through the nose and out through pursed lips. *During acute episodes of dyspnea, the patient may forget that breathing exercises can help.*
- Teach relaxation exercises during times when anxiety is minimal, and remind the patient to use them during acute anxiety. *Relaxation can help reduce muscle tension and distract the patient.*
- Administer antianxiety medications as ordered. *Medications can reduce anxiety but can also depress respirations, so should be used with caution.*
- Contact RN to administer intravenous morphine. *Morphine helps acute dyspnea and anxiety in patients with end-stage disease.*

Evaluation

If interventions have been effective, the patient will learn techniques to make breathing as comfortable as possible, and will be able to cough up secretions and maintain a clear airway. He or she will be able to manage anxiety symptoms and complete ADLs or other desired activity without dysp-

Box 31.10

Nutrition Notes

Optimizing Nutrition in Patients with Respiratory Disease

Many factors affect nutrition in a patient with respiratory disease. For example, patients commonly have an inadequate food intake because of anorexia, shortness of breath, gastrointestinal (GI) distress, or a combination of these problems.

Caloric requirements are frequently increased in patients with pulmonary disease. The caloric cost of breathing ranges from 36 to 72 calories each day in normal people, but it increases to 430 to 720 calories each day in patients with chronic obstructive pulmonary disease (COPD). Both decreased food intake and increased energy requirements may contribute to the weight loss often seen in these patients. When caloric intake is decreased, the body begins to break down muscle stores, including the respiratory muscles, which only exacerbates the problem.

The GI distress common in respiratory patients may be related to malnutrition of the GI tract. Malnutrition and the resulting decrease in antibody production lower the patient's resistance to infection. Also, the malnourished patient's lungs produce less pulmonary phospholipid, a fatlike substance that assists in lubricating lung tissue and helps to protect the lungs from inhaled pathogens.

To some extent, all the respiratory muscles atrophy from inactivity when a machine does the work for the patient. Nutrition support improves the likelihood of successful weaning in patients receiving mechanical ventilation.

Many patients with COPD have carbon dioxide retention and oxygen depletion. The medical goal for these patients is to decrease the level of carbon dioxide in their blood. Because fat calories produce less carbon dioxide when metabolized than carbohydrate calories, a diet with as much as 50% of the calories from fat may be prescribed. Several companies produce complete nutritional supplements with higher fat content formulated for patients with respiratory disease. Medical opinion is not unanimous on this issue because some evidence has related a high fat intake to immunosuppression in some patients.

Nursing Intervention

Many respiratory patients are breathless and lack the energy to eat. Offer small frequent feedings of nutrient-dense foods. Select foods that require little or no chewing. To lessen abdominal pressure on the diaphragm, discourage gaseous foods.

nea. The patient's intake should be adequate to maintain a stable weight. If any of the patient's goals have not been met, the plan of care should be revised.

Patient Education

The patient must be aware of the contributing factors to the disease and eliminate them if at all possible. The patient who is a smoker should not simply be told to quit smoking; he or she should be referred to a smoking cessation program and be provided with medication, nicotine patches, or other resources and support as necessary to quit. (See Chapter 29.) Techniques for effective breathing and anxiety control should also be taught.

PULMONARY VASCULAR DISORDERS

Pulmonary Embolism

Pathophysiology

An **embolism** is a foreign object that travels through the bloodstream. It may be a blood clot, air, or fat. A pulmonary embolism (PE), sometimes called pulmonary thromboembolism (PTE), is usually a blood clot that has traveled into a pulmonary artery (Fig. 31.12). Resulting obstruction of blood flow causes a ventilation-perfusion mismatch, which

CRITICAL THINKING

Mr. Franklin

■ Mr. Franklin is admitted to the respiratory unit with exacerbated COPD. He has a history of emphysema and now has an acute infection complicating his disease. His lung sounds are very diminished, and he is short of breath at rest, even on 2 L of oxygen per nasal cannula. You walk into his room when he puts on his call light and find him sitting on the bedside commode with a look of panic in his eyes. He is gasping for breath, his color is gray, and his respiratory rate is 36 per minute.

1. What do you do first?
2. What can you teach Mr. Franklin to prevent an acute dyspneic episode in the future?
3. How will you document this episode?

Suggested answers at end of chapter.

in this case means that an area of the lung is well ventilated with air but has no blood flow, or perfusion. Because reduced or no blood supply is available to pick up the oxygen in the affected portion of the lung, it becomes pulmonary “dead space,” causing seriously impaired gas exchange.

Pulmonary embolism

FIGURE 31.12 Pulmonary embolism.

Occasionally damage occurs to a portion of the lung because of lack of oxygen. This is called lung infarction, and it is not common because oxygen is delivered to lung tissue not only from the pulmonary arteries but also via the bronchial arteries and the airways.

Etiology

Most pulmonary emboli originate in the deep veins of the lower extremities (deep vein thrombosis, or DVT). Some risk factors of DVT, and therefore PE, include surgical procedures done under general anesthesia, heart failure, fractures of the lower extremities, immobility, obesity, oral contraceptive use, smoking, and a previous history of DVT or PE. Less common causes of PE include fat emboli from compound fractures, amniotic fluid embolism during labor and delivery, and air embolism from entry of air into the bloodstream.

Prevention

Prevention of thrombi in the deep veins of the legs is the most important factor in the prevention of a pulmonary embolism. Regular ambulation is advised if the patient is able. If a patient is at risk for DVT or PE, low-dose heparin, enoxaparin, warfarin (Coumadin), or intermittent compression stockings are used to prevent thrombus formation. If a DVT is diagnosed, prompt treatment is essential to prevent PE.

Signs and Symptoms

The most common symptom of PE is a sudden onset of dyspnea for no apparent reason. The patient may be gasping for breath and appear anxious. Tachycardia, tachypnea, and cough may be present. Auscultation may reveal crackles or a friction rub. If lung infarction has occurred, hemoptysis and pleuritic chest pain may also be present. Some patients have no symptoms at all. Be alert to the presence of risk factors and obtain immediate assistance if the cause of dyspnea might be PE. Death can occur if treatment is not quick and effective.

Complications

High blood pressure within the pulmonary circulation (pulmonary hypertension) may result from arterial occlusion and lead to right ventricular failure. This occurs because the right ventricle is unable to push blood into the occluded artery. As a result, the contraction becomes weak, cardiac output falls, and the patient becomes hypotensive.

Diagnostic Tests

A spiral CT scan is a new and fast type of CT scan that is noninvasive and can diagnose PE quickly. If this is not available, a lung scan (ventilation-perfusion scan) is done to assess the degree of ventilation of lung tissue and the areas of blood perfusion. If an area is well ventilated but poorly perfused (i.e., a mismatch), PE is suspected.

A pulmonary angiogram can outline the pulmonary vessels with a radiopaque dye injected via a cardiac catheter. This can show where blood flow is diminished or absent, suggesting an embolism.

Chest x-ray examination, electrocardiogram (ECG), arterial blood gas analysis, or magnetic resonance imaging

(MRI) may also be done. However, many of these show changes only in the presence of a very large embolism or infarction.

A blood test called D-dimer can be helpful to rule out PE. Results can be obtained in less than an hour. D-dimer is a fibrin fragment that is found in the blood after any thrombus formation. It can be present in a number of disorders, but if it is negative, PE can be eliminated as a possible cause of the patient's symptoms.

Therapeutic Interventions

The body naturally dissolves clots in 7 to 10 days. However, if the embolism is large, a thrombolytic agent might be used. These agents, such as streptokinase, urokinase, reteplase and tissue plasminogen activator (t-PA), dissolve clots and are very effective. However, they must be used within 4 to 6 hours of the clot's occurrence and are associated with a risk for hemorrhage.

If a thrombolytic agent is not used, treatment is aimed at preventing extension of the clot and the formation of additional clots. Heparin, a potent anticoagulant medication, is administered via continuous intravenous infusion. Sometimes an intermittent IV or subcutaneous route is used. Heparin is never given intramuscularly because of the risk of hematoma development. Clotting studies (partial thromboplastin time [PTT]) is monitored and maintained at 1.5 to 2 times the control value. Sometimes heparin therapy is initiated even before a diagnosis of PE is made. It is believed that it is safer to begin therapy and then stop if PE is not confirmed than to wait until all test results are available.

Oxygen is administered as ordered. Intubation and mechanical ventilation may be required in some cases.

Warfarin sodium (Coumadin), an oral anticoagulant, is used for at least 3 to 6 months following PE to prevent recurrence. It can also be used for long-term prevention of repeated clots in patients who have risk factors that cannot be resolved. Warfarin therapy can be initiated 2 to 3 days after the initiation of heparin therapy. Because it has a slow onset of action, it may require several days for the full anticoagulant effect to occur. The patient will be on both anticoagulants for a time. Warfarin therapy is monitored regularly with prothrombin time (PT) and international normalized ratio (INR). See Chapter 22 for nursing care of patients on anticoagulant therapy.

If clots are a recurring problem, a filter may be placed into the inferior vena cava via the jugular or femoral vein. One filter that is commonly used is the Greenfield filter, which filters out clots traveling from the lower extremities toward the heart and lungs.

In patients with life-threatening symptoms, a surgical embolectomy can be performed. This is a rare procedure that is reserved for emergency situations.

Nursing Process

ASSESSMENT/DATA COLLECTION. Assess the patient for respiratory distress, including respiratory rate and effort, cyanosis, confusion, and subjective feelings of dyspnea and

anxiety. Auscultate lung sounds. Note sputum color and amount, watching especially for hemoptysis. Monitor arterial blood gases and oxygen saturation. Monitor heart sounds and peripheral edema for signs of heart failure. Contributing factors, such as calf pain, should be noted. Remember, any sudden onset of dyspnea should be taken seriously and reported quickly.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. The priority nursing diagnosis for a patient with a pulmonary embolism is impaired gas exchange (see Box 31.5 Nursing Care Plan for the Patient with Lower Respiratory Tract Disorder for interventions for impaired gas exchange). Because of the impaired perfusion of the affected area of the lung, oxygen and carbon dioxide exchange are limited. Anxiety occurs related to dyspnea. Risk for injury related to anticoagulant therapy is a concern once treatment is initiated (see Chapter 22).

Risk for injury (bleeding) related to anticoagulant therapy

EXPECTED OUTCOME: The patient will have no evidence of bleeding related to anticoagulant therapy. The patient will verbalize understanding of self care measures.

- Monitor coagulation studies and report results to the physician. *Anticoagulant therapy may be adjusted as often as every 6 hours based on laboratory results.*
- Protect the patient from injury *so that excessive bleeding does not occur.*
- Encourage the patient to wear shoes or slippers when ambulating *to protect from injury.*
- Teach patient to use a soft toothbrush and an electric razor *to prevent injury.*
- Avoid use of IM injections. *IM injection can result in hematoma in an anticoagulated patient.*
- Instruct the patient to report any signs of bleeding, such as hematuria or easy bruising. *Bleeding may be associated with excessively prolonged clotting, and may require a change in anticoagulant dosing or administration of an antidote.*

EVALUATION. The patient should state that dyspnea and anxiety are controlled, and verbalize understanding of anticoagulant therapy and precautions.

See Box 31.11 Pulmonary Embolism Summary.

Pulmonary Arterial Hypertension

Pathophysiology and Etiology

Primary pulmonary arterial hypertension (PAH) occurs when the arteries that carry deoxygenated blood from the heart to the lungs become narrowed as a result of changes in the lining and smooth muscle of the vessels. The result is elevated pressure in the pulmonary arteries, causing the right ventricle to work harder to push blood into them. Eventually the right ventricle fails (cor pulmonale). The reason for these vascular changes is not known. Primary PAH is more common in women between ages 20 and 40 and has a hereditary tendency.

Box 31.11

Pulmonary Embolism Summary

Signs and Symptoms	Sudden-onset dyspnea, tachypnea Tachycardia Hemoptysis Crackles History of blood clot
Diagnostic Tests	D-dimer CT scan Ventilation perfusion lung scan Angiogram
Therapeutic Interventions	Thrombolytic therapy Anticoagulants Oxygen
Complications	Pulmonary hypertension
Priority Nursing Diagnoses	Impaired gas exchange Anxiety Risk for injury from anticoagulant therapy

Secondary PAH results from other disorders, such as coronary artery disease or mitral valve disease, both of which increase pressures in the left side of the heart. Liver disease, systemic lupus erythematosus, and scleroderma are also associated with PAH, as is capillary destruction related to alveolar damage in COPD. Right ventricular failure eventually occurs as the heart works to push blood against high pulmonary arterial pressures.

PAH has also been caused by use of the appetite suppressants fenfluramine (Fen-Phen) and dexfenfluramine. Both of these drugs have been removed from the U.S. market by the FDA.

Signs and Symptoms

The most common symptoms include dyspnea and fatigue, which worsen over time. Crackles and decreased breath sounds are heard on auscultation. Cyanosis and tachypnea are noted. If heart failure is present, peripheral edema and distended jugular veins are seen. Angina may result from right ventricular ischemia. Death used to occur within 2 to 3 years of diagnosis, but newer treatments can extend life for up to 15 or 20 years.

Diagnostic Tests

Arterial blood gases commonly show hypoxemia and hypocapnia. Cardiac catheterization can be done to determine high pulmonary arterial pressures. An ECG may show right ventricular hypertrophy. A chest x-ray examination, spirometry, lung scan, and pulmonary angiogram may be done to determine underlying causes in secondary PAH.

Therapeutic Interventions

No cure is available for pulmonary hypertension except for lung or heart-lung transplant. In secondary pulmonary hyper-

tension, the underlying disorder is treated. Supportive care includes a low-sodium diet and diuretics to reduce blood volume (and therefore pressure), oxygen, and cardiac monitoring. Vasodilators such as calcium channel blockers or angiotensin-converting enzyme (ACE) inhibitors may be used to reduce pulmonary artery pressure. Warfarin may be used to prevent clotting. Epoprostenol (Flolan) is a vasodilator that may reverse some of the vascular changes and prolong survival, but has many serious side effects, and must be continuously administered IV via an implanted pump. Bosentan (Tracleer) is a new oral drug that blocks endothelin, a substance that causes blood vessels to constrict. Silfenadil (Viagra) is being tested for possible use in PAH.

Nursing care is collaborative and focuses primarily on patient assessment. Fowler's or high-Fowler's position may help reduce dyspnea, and rest and comfort measures are helpful in treating fatigue and anxiety.

TRAUMA

Pneumothorax

The term **pneumothorax** literally means “air in the chest” and is used to describe conditions in which air has entered the pleural space outside the lungs. If the pneumothorax occurs without an associated injury, it is called a spontaneous pneumothorax. A secondary spontaneous pneumothorax may occur due to underlying lung disease. Traumatic pneumothorax results from a penetrating chest injury.

Pathophysiology and Etiology

Recall that the pleural cavity has visceral and parietal pleurae. These membranes normally are separated only by a thin layer of pleural fluid. Each time a breath is taken in, the diaphragm descends, creating negative pressure in the thorax. This negative pressure pulls air into the lungs via the nose and mouth. If either the visceral pleura or the chest wall and parietal pleura are perforated, air enters the pleural space, negative pressure is lost, and the lung on the affected side collapses (Fig. 31.13). Each time the patient takes a breath, the temporary increase in negative pressure draws air into the pleural space via the perforation. During expiration, air may or may not be able to escape through the perforation.

SPONTANEOUS PNEUMOTHORAX. If no injury is present, the pneumothorax is considered spontaneous. This occurs mostly in tall, thin individuals and in smokers. Patients who have had one spontaneous pneumothorax are at greater risk for a recurrence. Patients with underlying lung disease (especially emphysema) may have blisterlike defects in lung tissue, called bullae or blebs, that can rupture, allowing air into the pleural space. Weakened lung tissue from lung cancer can also lead to pneumothorax.

TRAUMATIC PNEUMOTHORAX. Penetrating trauma to the chest wall and parietal pleura allows air to enter the

FIGURE 31.13 Types of pneumothorax. (A) Spontaneous pneumothorax. (B) Traumatic pneumothorax. (C) Tension pneumothorax with mediastinal shift.

pleural space. This can occur as a result of a knife or gunshot wound or from protruding broken ribs.

OPEN PNEUMOTHORAX. If air can enter and escape through the opening in the pleural space, it is considered an open pneumothorax.

CLOSED PNEUMOTHORAX. If air collects in the space and is unable to escape, a closed pneumothorax exists.

TENSION PNEUMOTHORAX. If a pneumothorax is closed, air, and therefore tension, builds up in the pleural space. As tension increases, pressure is placed on the heart and great vessels, pushing them away from the affected side of the chest. This is called a mediastinal shift. When the heart and vessels are compressed, venous return to the heart is impaired, resulting in reduced cardiac output and

symptoms of shock. Tension pneumothorax is often related to the high pressures present with mechanical ventilation. It is a medical emergency.

HEMOTHORAX. The term **hemothorax** refers to the presence of blood in the pleural space. This can occur with or without accompanying pneumothorax (hemopneumothorax) and is often the result of traumatic injury. Other causes include lung cancer, pulmonary embolism, and anticoagulant use.

Signs and Symptoms

Sudden dyspnea, chest pain, tachypnea, tachycardia, restlessness, and anxiety occur with pneumothorax. On examination, asymmetrical chest expansion on inspiration may be noted. Breath sounds may be absent or diminished on the affected side. In a “sucking” chest wound, air can be heard as it enters and leaves the wound.

If tension pneumothorax develops, the patient becomes hypoxemic and hypotensive as well. The trachea may deviate to the unaffected side. Heart sounds may be muffled. Bradycardia and shock occur if emergency intervention is not provided.

Diagnostic Tests

History, physical examination, and chest x-ray examination are used to diagnose pneumothorax. Chest x-ray examinations are repeated to monitor the resolution of the pneumothorax with treatment. Arterial blood gases and oxygen saturation are monitored as needed throughout the course of treatment.

Therapeutic Interventions

A small pneumothorax may absorb with no treatment other than rest, or the trapped air may be removed with a small-bore needle inserted into the pleural space. Chest tubes connected to a water seal drainage system are used to remove larger amounts of air or blood from the pleural space. See Chapter 29 for complete information about chest drainage. Smaller devices that have special one-way valves to allow air to escape but not reenter the chest may be used for some patients who are treated at home. Some injuries require surgical repair before the pneumothorax can be resolved.

If the pneumothorax is recurrent, other treatments can be used to prevent additional episodes. Sterile talc or certain antibiotics (such as tetracycline) can be injected into the pleural space via thoracentesis, irritating the pleural membranes and making them stick together. This is called **pleurodesis**, or sclerosis, and prevents recurrent pneumothorax. Pleurodesis is painful; prepare the patient with an analgesic before the procedure.

Nursing Care

Nursing care of the patient with a pneumothorax involves close monitoring of the condition. A frequent and thorough assessment should be done, including level of consciousness, skin and mucous membrane color, vital signs, respiratory

rate and depth, and presence of dyspnea, chest pain, restlessness, or anxiety. Regular auscultation of lung sounds provides information about reinflation of the affected lung. Any signs of increasing or tension pneumothorax are reported to the physician immediately. See Chapter 29 for care of the patient with a chest tube and water seal drainage system.

See Box 31.12 Pneumothorax Summary.

Rib Fractures

Etiology and Signs and Symptoms

Chest trauma is often accompanied by fractured ribs. Uncontrolled coughing, especially in the presence of osteoporosis or cancer can also fracture ribs. The fourth through ninth ribs are the most commonly affected. Broken ribs can be very painful, and often prevent the patient from breathing deeply or coughing effectively, which can result in atelectasis or pneumonia. Displaced ribs can also damage abdominal organs or lung tissue, causing pneumothorax.

Treatment

In the past, elastic rib belts were used to stabilize the ribs while healing took place. These are no longer used because it further restricts deep breathing. Pain control is the most important treatment. Keeping the patient comfortable allows coughing and deep breathing, which in turn prevents complications such as pneumonia and atelectasis. If traditional pain control measures such as NSAIDs or opioids are ineffective, intercostal nerve blocks may be used. Ribs generally heal in about 6 weeks.

Flail Chest

Pathophysiology and Etiology

When multiple ribs are fractured, the structural support of the chest is impaired. As a result, the affected part of the

Box 31.12

Pneumothorax Summary

Signs and Symptoms	Sudden-onset dyspnea, chest pain, tachypnea Asymmetrical chest expansion Diminished or absent breath sounds on affected side
Diagnostic Tests	Chest x-ray ABGs
Therapeutic Interventions	Chest tube and water seal drainage Pleurodesis for recurrent pneumothorax
Complications	Tension pneumothorax Shock
Priority Nursing Diagnoses	Impaired gas exchange Acute pain Anxiety

hemothorax: hem—blood + thorax—chest

pleurodesis: pleur—pleural membrane + desis—binding

chest collapses with inspiration and bulges with expiration. This is called **paradoxical respiration**, which is ineffective in ventilating the lungs and results in hypoxia.

Signs and Symptoms

The patient with a flail chest exhibits chest movement that is opposite to that usually seen with respiration. The patient is dyspneic, anxious, tachypneic, and tachycardic.

Treatment

The patient is given supplemental oxygen. Intubation and mechanical ventilation may be necessary. If lung damage has occurred, chest tubes may be necessary for re-inflation.

NURSING PROCESS FOR THE PATIENT WITH CHEST TRAUMA

The following nursing process is based on the stabilized patient. For emergency care of the trauma patient, see Chapter 12.

Assessment/Data Collection

When caring for the patient following chest trauma, it is important to monitor respiratory status continuously. Any sign of worsening status should be reported to the physician immediately, such as a change in vital signs or lung sounds; change in respiratory rate; increase in dyspnea, chest pain, pallor, or cyanosis; development of tracheal deviation; or new onset of anxiety or restlessness. Pain is monitored. If a chest wound is present, it is cared for and closely monitored. Additional assessment may be necessary depending on the type of injury sustained.

Nursing Diagnosis, Planning, and Implementation

Priority nursing diagnoses for the patient with chest trauma include Impaired Gas Exchange, Ineffective Breathing Pattern, and Acute Pain. Additional diagnoses may be appropriate depending on the individual patient's assessment. See Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder for interventions for impaired gas exchange and ineffective breathing pattern.

Acute pain related to chest trauma

EXPECTED OUTCOME: Patient will state pain is controlled, and will be able to cough and deep breathe.

- Administer NSAIDs or opioids as ordered. *Pain must be controlled so the patient is able to breathe deeply and prevent atelectasis and pneumonia.*
- If opioids are used, monitor for depressed respirations and reduced cough reflex. *Depressed respirations and cough increase the risk of atelectasis and pneumonia.*
- Teach the patient to splint the chest for coughing. *This may help reduce chest movement and pain during coughing.*

Evaluation

Are pain, anxiety, and dyspnea controlled? Is the respiratory rate within normal limits? Are vital signs stable? Frequent evaluation is essential, so that failure to progress can be quickly reported.

RESPIRATORY FAILURE

Acute Respiratory Failure

Pathophysiology

Acute respiratory failure is diagnosed when the patient is unable to maintain adequate blood gas values. Hypoxemia may result from inadequate ventilation (air movement in and out of lungs) or poor oxygenation (adequate ventilation but inability to get the oxygen into the blood and therefore the cells) or both.

Etiology

An acute respiratory infection in a patient with chronic airway obstruction is often the precipitating factor in acute respiratory failure. Other causes include central nervous system disorders that affect breathing, such as a stroke or myasthenia gravis, inhalation of toxic substances, opioid overdose, and aspiration.

Prevention

Avoidance of respiratory infections in patients with chronic respiratory disease is important. Patients should be instructed to notify their physician immediately if sputum becomes purulent so treatment can be initiated.

Sedatives and narcotics should be used carefully or avoided in patients with chronic respiratory disease because these are respiratory depressants and can precipitate failure.

Signs and Symptoms

The patient with impending respiratory failure may become restless, confused, agitated, or sleepy. Arterial blood gases show decreasing PaO_2 and pH and increasing PaCO_2 , which lead to respiratory acidosis. The patient is cyanotic and dyspneic, and respiratory rate becomes rapid and deep in an effort to blow off excess CO_2 .

Diagnostic Tests

Respiratory failure is diagnosed when PaO_2 falls below 60 mm Hg or PaCO_2 is elevated above 50 mm Hg. Some patients with chronic respiratory disease have adapted to impaired gas exchange. In these patients a drop in PaO_2 of 10 to 15 mm Hg is considered acute failure. Sputum cultures or chest x-ray examinations may be used to determine the cause and guide treatment. Pulse oximetry is used to continuously monitor oxygen saturation.

Therapeutic Interventions

Carefully assess the patient and report significant findings to the physician immediately. It is easy to mistakenly treat symptoms of agitation or confusion with sedatives, which will speed the onset of respiratory failure. Oxygen therapy via nasal cannula or mask is provided. If the patient has a

chronically high PaCO_2 , oxygen is administered at a flow rate of 1 to 2 L to prevent interference with the hypoxic drive. Antibiotics or other treatments are ordered to correct the underlying cause of the failure. Bronchodilators promote ventilation and secretion removal. The patient is instructed to cough and deep breathe if able. Suctioning is indicated if the patient is unable to cough effectively. Mechanical ventilation via endotracheal tube or noninvasive positive pressure ventilation (NIPPV) may be required. Before invasive ventilation is initiated, it is important to check the patient's advance directives.

Acute Respiratory Distress Syndrome/Acute Lung Injury

Acute respiratory distress syndrome (ARDS), also called adult respiratory distress syndrome, is a group of disorders that has diverse causes but similar pathophysiology, symptoms, and treatment.

Pathophysiology and Etiology

ARDS occurs because of acute lung injury (ALI). The most common cause of injury is sepsis. Other causes include pneumonia, trauma, shock, narcotic overdose, inhalation of irritants, burns, pancreatitis, and aspiration, among others. Each of these causes begins a chain of events leading to alveolocapillary damage and noncardiac pulmonary edema (pulmonary edema that is not caused by heart failure). ARDS usually affects patients without a previous history of lung disease.

The alveolocapillary membranes become inflamed and damaged either by direct contact with an inhaled irritant or by chemical mediators that are released when systemic injury occurs. The membranes become leaky, so that proteins, blood cells, and fluid move from the capillaries into the interstitial space and then into the alveoli. Surfactant, a substance that reduces surface tension in the alveoli, is reduced. Alveoli collapse (atelectasis) and fibrotic changes take place. These changes cause the lungs to become stiff, or less compliant, making the patient work very hard to inspire. Blood supply to the alveoli may be adequate, but collapsed, wet alveoli are unable to oxygenate it. In other areas of the lungs, vasoconstriction reduces the ability of the vessels to pick up oxygen from functioning alveoli. Tired respiratory muscles, in combination with edema and atelectasis, reduce gas exchange and result in hypoxia. As the condition progresses, atelectasis and edema worsen and the lungs may hemorrhage. A chest x-ray examination appears white because of the excessive fluid in the lungs. These changes explain some of the older names for what is now known as ARDS: wet lung, white lung, shock lung, and stiff lung.

Prevention

Early recognition and treatment of underlying disorders is important in prevention of ARDS. Good nursing care can help reduce aspiration and some types of pneumonia.

Signs and Symptoms

Initially the patient may experience dyspnea and an increase in respiratory rate. Respiratory alkalosis results from hyper-

ventilation. Fine inspiratory crackles may be auscultated. As the condition worsens, breathing becomes more rapid and labored and the patient becomes cyanotic. The patient is no longer able to oxygenate the blood and get rid of carbon dioxide, and respiratory acidosis occurs. Oxygen therapy does not reverse the hypoxemia. If ARDS is not reversed, eventually hypoxemia leads to decreased cardiac output, shock, and death.

Complications

Complications that can result from ARDS include heart failure, pneumothorax related to mechanical ventilation, infection, and disseminated intravascular coagulation (DIC). The death rate for ARDS in the past was 100%. With newer treatments, it is now closer to 70%. Most patients who survive ARDS recover completely.

Diagnostic Tests

Diagnosis is made based on history of a causative injury, physical examination, chest x-ray examination, and blood gas analysis. An ECG is done to rule out a cardiac-related cause.

Therapeutic Interventions

The patient with ARDS is cared for in an intensive care unit. Treatment begins with oxygen therapy that is adjusted based on repeated ABG results. Intubation and mechanical ventilation are necessary in most cases, with the use of positive end-expiratory pressure (PEEP) to keep the airways open. Diuretics may be used to reduce pulmonary edema, but care must be taken to prevent fluid depletion. IV fluids are administered if blood pressure or urine output is low. A pulmonary artery catheter may be used to monitor hemodynamic status. If infection is the underlying cause, antibiotics are administered. Parenteral nutrition may be given to maintain nutritional status while the patient is acutely ill. Positioning the patient with the less involved lung in the dependent position ("good lung down") allows the better lung to be well perfused with blood and may increase PaO_2 . Prone positioning has also been shown to increase oxygenation in patients with ARDS.

NURSING PROCESS FOR THE PATIENT EXPERIENCING RESPIRATORY FAILURE

Assessment/Data Collection

Assess the patient's degree of dyspnea on a scale of 0 to 10 if the patient is able to participate. Respiratory rate, effort, and use of accessory muscles are noted. Arterial blood gases and oxygen saturation values are monitored as ordered. The presence of cyanosis is noted.

Mental status, including restlessness, confusion, and level of consciousness, is also assessed, because reduced oxygenation can produce central nervous system (CNS) symptoms. Symptoms of the underlying cause of respiratory failure are monitored. If the cause is infectious, sputum

amount and color, temperature, and white blood cell counts are monitored.

All assessment findings should be compared with earlier data. Even subtle changes in the assessment findings can be significant and should be reported.

Nursing Diagnosis, Planning, and Implementation

Priority nursing diagnoses include Impaired Gas Exchange, Ineffective Airway Clearance, and Ineffective Breathing Pattern (see Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder). Related diagnoses include Activity Intolerance, Anxiety, Disturbed Thought Processes, and Self-Care Deficit.

NURSING CARE TIP

The good lung down position can help increase oxygenation in patients with lung disease. Gravity results in more blood in the dependent lung, where it can receive oxygen from the healthier lung tissue. If both lungs are diseased, the right lung down position may be beneficial, because the right lung has a larger surface area.⁶

Evaluation

If interventions have been effective, the patient will state that dyspnea is controlled. Mental status will be normal for the patient. Airways will be kept clear at all times, and the patient's respiratory rate will be regular and within normal limits.

LUNG CANCER

Lung cancer is the leading cause of cancer death in the United States. More men and women die from lung cancer each year than any other type of cancer. An estimated 172,570 new cases and 163,510 deaths are predicted for the United States in 2005.⁶ The 5-year survival rate for lung cancer ranges from 1% to 47% depending on the type of lung cancer and on how early in the course of the disease it is diagnosed. The incidence of lung cancer among men is slowly decreasing. The incidence in women was steadily rising for years because of increasing numbers of women who smoke, but now appears to have leveled off.

Pathophysiology

Lung cancers originate in the respiratory tract epithelium; most originate in the lining of the bronchi (Fig. 31.14). The four major types of lung cancer are identified by the type of cells that are affected. These include small cell lung cancer (SCLC), large cell carcinoma, adenocarcinoma, and squamous cell carcinoma. The latter three types are classified as non-small cell lung cancer (NSCLC).

FIGURE 31.14 Lung cancer: The black arrow marks the tumor site. (Photograph courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

About 13% of lung cancers are SCLC (sometimes called oat cell carcinoma). SCLC grows rapidly and often has metastasized by the time of diagnosis. It is usually caused by smoking and is most often found centrally, near the bronchi. The patient with small cell carcinoma has a poor prognosis, with survival time averaging less than 1 year.

The remaining 87% of lung cancers are classified as non-small cell. Large cell carcinoma is a rapidly growing cancer that can occur anywhere in the lungs. It metastasizes early in the disease, so these patients also have a poor prognosis.

Adenocarcinoma occurs more often in women, and most often in the peripheral lung fields. It is slow growing but often is not diagnosed until metastasis has occurred. It is less closely linked with smoking. Prognosis may be better than other lung cancer types.

Squamous cell carcinomas usually originate near the bronchi and metastasize late in the disease. They are associated with a history of smoking. The prognosis for individuals with squamous cell carcinoma may also be better than for some other lung cancers.

Etiology

The most common cause of lung cancer is tobacco smoke. Cigarettes contain chemicals that cause DNA to mutate, creating changes in cells and development of tumors. Smokers have an approximately 13 times greater risk for developing lung cancer than nonsmokers. If a patient stops smoking, the risk of lung cancer decreases significantly. Unfortunately, even with all this information, 25.2% of men and 20.7% of women in the United States continue to smoke.⁷ Twenty-eight percent of high school teens smoke; 90% of adults who smoke started as teens.⁸

Environmental tobacco smoke (ETS) has also been shown to cause lung cancer. A study by the American Cancer Society showed that women who were married to smokers but who had never smoked themselves were 20% more likely to die of lung cancer.⁹ Other factors that contribute to increased lung cancer risk are exposure to

asbestos, radon, or arsenic; air pollution; diesel exhaust; and radiation. Genetic predisposition and a diet poor in fruits and vegetables may also be factors.

Prevention

The single most important way to prevent lung cancer is to reduce smoking. Many programs educate schoolchildren about the dangers of smoking. Smoking cessation programs are available for people who desire to quit. Contact your local American Cancer Society chapter for smoking cessation programs that can be recommended to patients. See Chapter 29 for more information on smoking cessation.

Signs and Symptoms

Manifestations of lung cancer depend on the location of the tumor. Commonly, patients exhibit a cough with sputum production. These symptoms may be ignored by the patient because they are also associated with smoking and other chronic respiratory disorders. Repeated respiratory infections may occur, producing thick, purulent sputum. Sputum may become bloody (hemoptysis). The patient may experience dyspnea. If the airway becomes obstructed by the tumor, wheezing or stridor may be heard. Late signs include chest pain, weight loss, anemia, and anorexia.

Complications

Pleural Effusion

Fifty percent of patients with lung cancer develop pleural effusion. Pleural fluid collects in the pleural space as a result of irritation or obstruction of lymphatic or venous drainage by the tumor.

Superior Vena Cava Syndrome

If the tumor obstructs the superior vena cava, blood flow is interrupted, causing distention of the jugular veins and swelling of the chest, face, and neck. Diuretics may help relieve the fluid build-up. Radiation may be used to shrink the obstruction.

Ectopic Hormone Production

Some lung cancers produce **ectopic** hormones that mimic the body's own hormones. Ectopic production of antidiuretic hormone (ADH) can produce syndrome of inappropriate ADH production (SAIDH), which is associated with fluid retention. Ectopic production of adrenocorticotropic hormone (ACTH) can cause Cushing's syndrome. These disorders are discussed in Chapter 39.

Atelectasis and Pneumonia

Atelectasis occurs when tumor growth prevents ventilation of areas of the lung. Patients with lung cancer also have a greater risk for pneumonia.

Metastasis

Common sites of lung cancer metastasis include the brain, bones, opposite lung, liver, adrenal gland, and lymph nodes.

ectopic: displaced

Diagnostic Tests

A complete medical history and physical examination are done to look for symptoms and risk factors for lung cancer. A chest x-ray examination is done to identify a mass. However, all tumors may not show up on a radiograph. A CT scan and lung scan may be done to provide more specific information about the size and location of a tumor. Sputum is analyzed for abnormal cells. Brain and bone scans are done to find metastatic lesions.

Diagnosis is confirmed with a biopsy of the lesion. A biopsy specimen may be obtained via bronchoscopy, percutaneous biopsy (a needle through the skin guided by radiograph), or mediastinoscopy (use of an endoscope into the mediastinum to look for changes in mediastinal lymph nodes).

Therapeutic Interventions

Tumors are staged based on the tumor-node-metastasis (TNM) staging system. (See Chapter 10.) Staging helps determine appropriate treatment (Table 31.4). If NSCLC is localized and in an early stage, it may be cured with surgical removal of the tumor. This can be accomplished with a segmental or wedge resection, which removes only the affected lung segment. A **lobectomy** (removal of a lobe) or removal of an entire lung may be done in more advanced cases (Fig. 31.15). Surgery is contraindicated if the cancer has spread to the other lung or has metastasized to distant areas.

Chemotherapy is the treatment of choice in SCLC, because usually it has metastasized by the time of diagnosis. New types of chemotherapy that target only cancer cells may be effective in some people. Radiation may be used in combination with chemotherapy. Surgery is not indicated in SCLC; the goal of treatment is not cure but rather palliation of symptoms.

TABLE 31.4 STAGES OF LUNG CANCER

Cancer Type	Stage	Characteristics
Non–small cell lung cancer	I	No metastasis to lymph nodes.
	II	Atelectasis or pneumonia may be present.
	III	Cancer has spread to local lymph nodes.
	IV	Cancer has invaded chest wall and usually has spread to lymph nodes.
Small cell lung cancer	Limited	Tumor has metastasized to distant organs and lymph nodes.
	Extensive	Cancer is limited to one side of the chest.
		Cancer cells are found outside one side of the chest or in pleural fluid.

lobectomy: lobe—lobe (of lung) + ectomy—excision

FIGURE 31.15 Types of surgeries for lung cancer: (A) Wedge resection. (B) Segmental resection. (C) Lobectomy. (D) Pneumonectomy.

Radiation may be used to shrink a tumor to reduce symptoms in patients who are unable to undergo surgery. Both radiation and chemotherapy may be used before or after surgery as **adjuvant** treatments. For more information about cancer treatments and nursing care, see Chapter 10. For more on lung cancer, visit the American Cancer Society website at www.cancer.org.

NURSING PROCESS FOR THE PATIENT WITH LUNG CANCER

Assessment/Data Collection

Perform a complete biopsychosocial assessment of the patient with lung cancer. Assess and document respiratory rate and depth, skin and mucous membrane color, lung sounds, cough, and sputum amount and character. Ask the patient to rate the degree of pain and dyspnea on appropriate scales. Ask about appetite and weight loss, as well as symptoms of other complications. Note activity tolerance and fatigue.

The patient will likely be grieving about his or her illness and its prognosis. Assessment of the patient's coping strategies and support systems will help you plan care for psychosocial needs. When you recall the prognosis for patients with some types of lung cancer, the need to consider

planning for terminal care becomes obvious (Box 31.13 Ethical Considerations). The presence of a Living Will or Durable Power of Attorney should be noted (see Chapter 16).

Nursing Diagnosis, Planning, and Implementation

Possible diagnoses that may be experienced by the patient with lung cancer include Impaired Gas Exchange, Ineffective Airway Clearance, Imbalanced Nutrition: Less Than Body Requirements, Pain, Constipation Related to Opioid Use, Anticipatory Grieving, and Activity Intolerance, among others. See Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder for care of patients with respiratory diagnoses. See Chapter 10 Nursing Care of Patients with Cancer for interventions related to cancer diagnoses.

Evaluation

Carefully consider the patient's individual goals when evaluating care. Is the patient comfortable and free from unnecessary dyspnea? Is the airway clear, and is nutrition maintained? Are medication side effects manageable? Have patients with terminal conditions come to terms with their impending death, and have they been able to do those things most important to them before their death?

See Box 31.14 Lung Cancer Summary.

Box 31.13

Ethical Considerations

Truth Telling

Mr. David Hammill, 88 years old, is admitted to a room on the surgical unit following a thoracotomy. He has been diagnosed with a metastatic tumor of the lung but does not yet know the diagnosis. His son has power of attorney, so Dr. Lester told the son and family the diagnosis. Dr. Lester decided not to tell Mr. Hammill the diagnosis because he believes that Mr. Hammill would become upset and depressed. Dr. Lester has written an order saying that the patient should not be told his diagnosis.

Mr. Hammill has been asking the nurses, staff, and his family what the physician found in surgery and what the results of the pathology reports were. Dr. Lester has visited Mr. Hammill several times but has avoided talking about the diagnosis by saying that not all the laboratory tests are back yet. The family has been avoiding visiting the patient so that he will not ask them about the diagnosis. The family often asks the nurse when Mr. Hammill will be told his diagnosis. They believe the physician should tell him. Some questions to consider are:

- If the patient is continually asking for information, should the nurse tell him?
- What degree of “truth” is required?
- What about partial truths and white lies?
- Can it ever be beneficial to withhold the truth?
- Would it be different if the patient and family were not asking for information?
- What does *paternalism* mean, and why might the physician be taking such a position with this patient?
- Does the hospital have an ethics committee? Could such a committee help?
- What options are available to the nurse or for the nurse to suggest to the family?

THORACIC SURGERY

A surgical incision made into the chest wall is called a **thoracotomy**. A thoracotomy may be performed for a number of reasons, including biopsy; removal of tumors, lesions, or foreign objects; to repair trauma following penetrating or crushing injuries; or to repair or revise structural problems.

Types

Pneumonectomy

A **pneumonectomy** is the surgical removal of a lung. This is usually done to treat lung cancer. It may also be used to treat severe cases of tuberculosis, bronchiectasis, or lung

pneumonectomy: pneum—lung + ectomy—excision

Box 31.14

Lung Cancer Summary

Signs and Symptoms	Cough, hemoptysis Dyspnea, wheezing Repeat respiratory infections
Diagnostic Tests	Chest x ray CT scan Biopsy
Therapeutic Interventions	Resection Chemotherapy Radiation
Complications	Pleural effusion, superior vena cava syndrome, ectopic hormone production, atelectasis, metastasis
Priority Nursing Diagnoses	Impaired gas exchange Ineffective airway clearance Activity intolerance

abscesses. Chest drainage is not usually used following a pneumonectomy because once the lung is removed, the air in the thoracic cavity is absorbed and the cavity fills with serosanguineous fluid. At about 6 months after surgery, the fluid is coagulated and the thoracic cavity is stabilized.

Lobectomy

Lobectomy is the surgical removal of one lobe. This also may be done for lung cancer, tuberculosis, or another localized problem.

Resection

Resection refers to removal of a smaller amount of lung tissue; that is, less than one lobe. A segmental resection is the removal of one segment of a lobe; a wedge resection is removal of a small wedge of lung tissue. See Figure 31.15.

Video-Assisted Thoroscopic Surgery

Video-assisted thoroscopic surgery (VATS) is a new technique that uses a specialized endoscope to perform surgery. It can be done with two or three small incisions, so is much less invasive than traditional thoracotomy that requires opening the chest. It can be used for staging and treatment of some tumors.

Lung Transplantation

Lung transplant can benefit patients with a variety of serious pulmonary disorders, including pulmonary hypertension, emphysema, cystic fibrosis, and bronchiectasis. Either a single lung, both lungs, or heart and lungs have been successfully transplanted. Better criteria for selecting patients and donors, as well as advancements in surgical techniques, have improved outcomes for these patients.

NURSING PROCESS FOR THE PATIENT UNDERGOING THORACIC SURGERY

Preoperative Nursing Care

Perform a thorough assessment before surgery, with a focus on the respiratory system. This gives a baseline against which to judge changes postoperatively. Routine preoperative teaching is done by the nurse in conjunction with the physician and health team. The patient should understand that he or she will wake up in an intensive care environment. If at all possible, it is helpful to have the patient and family tour the intensive care unit before the surgery to decrease anxiety postoperatively. Prepare the patient for waking up after surgery with an endotracheal tube connected to a ventilator, oxygen, chest tubes, intravenous fluids, cardiac monitor, Foley catheter, and possibly an epidural catheter for pain control. Let the patient know he or she will not be able to talk while the ET tube is in, and explain the use of the call light, picture board, or alternate communication techniques. Consult the surgeon for specific plans.

Advise the patient that position changes and early ambulation help prevent complications following surgery. Also instruct the patient in the use of an incentive spirometer and coughing and deep breathing techniques.

Postoperative Nursing Care

Assessment/Data Collection

Following thoracic surgery, patients initially are in an intensive care unit. Larger hospitals have special intensive care units specifically for surgical or thoracic patients. Here patients can be closely monitored for signs of complications. Frequent assessment of vital signs and hemodynamic stability; respiratory rate, depth, and effort; and lung sounds is performed. Remember that lung sounds are absent on the side of a pneumonectomy. An increase in pulse rate or a falling blood pressure may indicate internal bleeding and should be reported immediately. Oxygen saturation is monitored continuously. Often patients report an immediate improvement in breathing because the pulmonary blood supply is no longer being routed to diseased lung tissue.

Assessment for tracheal deviation alerts you to the possible complication of mediastinal shift. The trachea is normally positioned straight above the sternal notch. If the trachea deviates from the midline position, the surgeon should be notified immediately. Secretions are monitored and reported to the physician if they become thick, yellow or green, or foul smelling. Arterial blood gases are monitored closely. Chest tubes are usually present (except following pneumonectomy) and are monitored as explained in Chapter 29. Pain is assessed using a pain rating scale, and incision sites are monitored for redness, edema, or drainage. If the patient is mechanically ventilated, additional assessment of the endotracheal tube and ventilator settings will be necessary.

Nursing Diagnosis, Planning, and Implementation

See Box 31.5 Nursing Care Plan for the Patient with a Lower Respiratory Tract Disorder for basic interventions. Following are some additional interventions specific to the patient following thoracic surgery.

Ineffective airway clearance related to presence of ventilator, inability to cough, sedation

EXPECTED OUTCOME: Patient will have a clear airway as evidenced by clear lung sounds, and absence of airway noise and high pressure ventilator alarms.

- Suction according to agency policy. *The airway must remain free of secretions to prevent ventilator-associated pneumonia and dyspnea. Continuous suction may be possible with some ET tubes.*
- Once extubated, remind the patient to cough and deep breathe regularly. *This helps clear the airway.*
- Administer analgesics as ordered. *Postoperative pain must be controlled for the patient to be able to cough effectively.*

Impaired gas exchange related to surgical intervention, opioid use, and removal of lung tissue

EXPECTED OUTCOME: SpO_2 will be $\geq 90\%$.

- Monitor SpO_2 . *Interventions should maintain SpO_2 at or greater than 90%.*
- Reposition patient every 1 to 2 hours. Consult surgeon for specific positioning orders. *Some surgeons want patients positioned with the operative side up, others with the operative side down. Fowler's position allows room for lung expansion and helps prevent aspiration.*
- Encourage use of an incentive spirometer as ordered following extubation *to encourage the patient to deep breathe and maximize oxygenation.*
- Monitor chest tube and water seal drainage system, if used. *This helps reexpand the lung and must remain intact at all times.*
- Administer oxygen and bronchodilators as ordered *to maintain oxygenation.*

Acute pain related to surgical procedure

EXPECTED OUTCOME: Patient will state or indicate that pain is controlled. If unable to communicate, objective signs of acute pain (increase in vital signs, restlessness) are absent.

- Administer analgesics as ordered, around the clock. *Pain control is important for the patient to be able to ambulate and deep breathe and cough effectively.*
- Monitor respiratory rate and effort if not mechanically ventilated. *Opioids depress respirations.*
- Teach the patient to splint the incision while coughing. *This can stabilize the site and reduce pain, increasing the likelihood of effective coughing.*

Impaired physical mobility related to discomfort at surgical site

EXPECTED OUTCOME: Patient will maintain mobility.

- Perform range-of-motion exercises, passively at first, then actively when the patient is able. *This helps prevent contracture of the arm and shoulder on the affected side.*
- Assist the patient to ambulate as tolerated on first or second postoperative day as ordered. *Ambulation helps maintain mobility and prevent postoperative complications.*

Risk for infection related to surgical incision and stress of major surgery

EXPECTED OUTCOME: Patient will be free of signs of infection as evidenced by clean and dry incision, temperature and WBC count WNL, clear sputum, and clear urine.

- Monitor temperature, WBC count, incision, sputum, and urine for signs of infection *so infection can be identified and treated quickly.*
- Use meticulous sterile technique for all invasive procedures: suctioning, dressing changes, catheter insertion. *This prevents introduction of pathogens.*

- Use standard infection control precautions, including careful hand washing *because the patient is at increased risk for infection.*
- Monitor nutritional intake. Consult dietitian for recommendations. *Adequate nutrients are essential for wound healing and immune function.*
- Maintain head of bed at minimum 30 degrees elevation *to help prevent aspiration of gastric contents.*
- Provide frequent oral care *to reduce risk of aspiration of oral bacteria.*
- Assist with ventilator weaning and extubation as soon as possible. *Mechanical ventilation is associated with increased risk of pneumonia.*

Evaluation

The patient's airway should remain clear, and secretions should be easily coughed up. The patient should report an acceptable comfort level and be able to cough, deep breathe, and ambulate without excessive discomfort. The patient's breathing should be unlabored, with a respiratory rate of 12 to 20 per minute. The patient's affected arm and shoulder should maintain full range of motion. Signs of infection should be absent.

Home Health Hints

- When a patient is using oxygen by nasal cannula, the area around the ears can become irritated or excoriated. A small sponge-type hair roller can be placed around the tubing to protect the ears.
- When a home health patient has a metered-dose inhaler (MDI), the nurse should not assume he or she is using it correctly. The patient should be observed using it.
- When a patient requires more than one MDI, the canisters can be numbered in the order they are to be taken.
- Read inhaler package inserts to find how many puffs are in an inhaler; and help the patient devise a system for keeping track of how many puffs are used so he does not run out. Manufacturers no longer recommend seeing if canisters float or sink in water to determine if they are empty—this can be unreliable.
- To help the COPD patient conserve energy, he or she can be encouraged to sit on a stool when cooking at the stove or doing dishes. A shower stool can be obtained from a medical supply store. Personal care activities should be spaced throughout the day.
- Support bars, also obtained from a medical supply store, can be strategically placed in the shower area, on the walls along hallways, and in a passageway to the restroom. This can help the patient ambulate when fatigued and also help prevent falls.
- If the COPD patient is tempted to adjust his or her own oxygen flow rate, equipment suppliers can put on a locking flowmeter. Increasing flow rate can reduce hypoxic drive and cause hypoventilation.
- Nebulizer parts should be cleaned at least three times a week, using warm water and a common home disinfectant solution for 30 minutes.
- COPD patients often have a difficult time eating. Not only do these patients have intolerance to activities but they also experience changes in their taste due to secretions and medications. Instruct the patient to rinse out his or her mouth prior to eating to help improve taste. Softer foods are often more palatable and require less energy to eat.
- When in the home it is important to not only assess your patient but also the primary caregiver. Many times he or she is experiencing caregiver role strain. Discuss options available and consider having a social worker consulted to assist with counseling and community resources. Contact the physician to discuss your concerns and ideas.

ETHICAL CONSIDERATIONS DISCUSSION

This is a difficult situation. Some elderly patients may not believe that they have a right to question a physician or be fully informed and will simply agree to whatever is suggested. Most families will express their needs, but there are some geographical areas where traditional physician-patient relationships follow a very paternalistic model. This situation provides an opportunity to examine autonomy, paternalism, and veracity. You can see that most of these principles have been placed on the “back burner” if not dismissed altogether in this situation.

Consider the principle of autonomy. You can see that respect for autonomy has been ignored in this situation. The patient was not given the opportunity to participate in his diagnosis and treatment plan so he is no longer a participant in his own care. By disrespecting the patient’s right to participate in his care, the physician has placed the patient in a precarious position. The patient is indicating that he would like to know his diagnosis. Most patients at this point need time to resolve life issues and prepare for death. This is a natural function, and by denying the patient this opportunity, not

only is the team causing harm, they are not maximizing benefit.

So, what about telling partial truths? One possible response is that before partial truths are told to a patient, the health care professional should consider very carefully the impact of any information and the possible consequences of partial truths. If there is not full disclosure, there is danger for misinterpretation of facts.

To act as a patient advocate and pursue having the patient and family hear the full truth is potentially risky. In some areas, the perceived omnipotence of physicians is still upheld and to act in a way that directly goes against physician orders will likely have consequences. However, as a nurse you must uphold your professional code of ethics. First approach the physician with your concerns. If he or she fails to understand the need for disclosure, then discuss the situation with your supervisor or Ethics Committee.

Bad news is never welcome; however, in the case of terminal illness it provides the patient and family time to prepare for what is coming.

REVIEW QUESTIONS

- A patient asks the nurse why he doesn’t feel sick even though his TB test is positive. The nurse knows the patient has been diagnosed with LTBI. Which explanation is best to provide the patient?
 - “TB often does not make people feel sick, but it is contagious nevertheless.”
 - “You have latent disease, which just stays in your system but won’t ever make you sick.”
 - “You have TB infection, but not active disease. As long as your immune system stays strong, it can keep the infection from making you sick.”
 - “Even though you do not feel sick, the positive test shows that you have the disease and must be treated.”
- Which of the following assessment findings does the nurse expect in the patient with emphysema?
 - Purulent sputum
 - Diminished breath sounds
 - Generalized edema
 - Dull chest pain
- A patient with shortness of breath is being tested for lung cancer. Which diagnostic test will be most conclusive?
 - Chest x-ray
 - MRI
 - Sputum culture
 - Biopsy
- A patient with recurrent pneumothorax is scheduled to have pleurodesis done in one hour. Which nursing intervention should take priority at this time?
 - Encourage fluids.
 - Encourage coughing and deep breathing.
 - Administer a prn analgesic as ordered.
 - Administer a prn bronchodilator as ordered.
- Which of the following assessment findings in the patient with pneumonia most indicates a need to remind the patient to cough and deep breathe?
 - The patient complains of chest pain.
 - The patient has removed her oxygen.
 - The patient develops wheezes and crackles.
 - The patient has a fever of 101°F (38.3°C).
- A patient is admitted to the hospital with shortness of breath. The nurse notes increasing confusion and combativeness over the past hour. Which of the following actions is appropriate first?
 - Assess the patient; check to see if the oxygen is flowing correctly.
 - Page the physician stat.
 - Put up the patient’s side rails and apply soft restraints.
 - Administer an intramuscular sedative.

7. Which of the following interventions is most appropriate for the patient with an ineffective breathing pattern?
 - a. Encourage the patient to cough and deep breathe.
 - b. Teach the patient controlled diaphragmatic breathing.
 - c. Encourage oral fluids.
 - d. Allow the patient to rest between activities.
8. A patient with end-stage COPD has a nursing diagnosis of impaired gas exchange. Which assessment finding shows that interventions have been effective?
 - a. The patient's SaO_2 is 97% on 2 liters of oxygen.
 - b. The patient appears comfortable.
 - c. The patient is coughing up copious white sputum.
 - d. The patient is able to move in bed without difficulty.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mr. Smith

1. A complete respiratory history is taken as described in Chapter 29. An open-ended question such as "What happened to bring you to the hospital?" elicits information about the incident. In addition, questions to determine mental status and ability to make decisions and function safely on his own are appropriate. If any concerns arise, a social service consultation will be helpful for discharge planning.
2. Mr. Smith should be instructed to always read label warnings before using any cleaning products in the future and to never mix bleach and ammonia!

■ Mr. Woo

Document exactly what you see: "No redness or induration at either the PPD or *Candida* test sites." Date and time your entry, and sign. What does this mean? Everyone has been exposed to, and should react to *Candida* with some degree of redness and induration. The fact that Mr. Woo has no reaction at all may mean that his immune system is not working well, or he is "anergic." Therefore, the fact that his PPD test shows no redness and swelling could just be because of his anergy even though he may be infected with TB. So, this is an unreliable test for him. Mr. Woo will need a chest x-ray and a sputum culture to be sure he is not infected. At this time it is not known whether the QuantiFERON-TB Gold test is accurate in immune-compromised patients.

■ Jim

1. Ask questions based on the WHAT'S UP? format:

Where (not applicable)

How does it feel? Does the coughing cause chest pain? Are you short of breath?

Aggravating and alleviating factors. What makes the cough worse? What seems to help? Do you use any techniques at home that are helpful?

Timing. How often do you cough during a day? Is it interfering with sleep and rest?

Severity. How bad is it on a scale of 0 to 10? How much sputum are you coughing up? Is it usually this color?

Useful other data. Are you experiencing any other symptoms with your cough (such as shortness of breath, nausea, loss of appetite)?

Patient's perception. Is it better or worse than usual today? How can I help? (The patient with long-standing disease often knows what will help but is hesitant to ask.)

2. The most appropriate nursing diagnosis is ineffective airway clearance related to excessive secretions and ineffective cough.
3. Provide hydration with oral liquids and a room humidifier to liquefy secretions. Administer expectorants as ordered. Instruct the patient in coughing and deep breathing exercises to increase the effectiveness of his cough. Provide good oral care following expectoration of sputum to freshen the patient's mouth. Obtain an order for chest physiotherapy to help loosen and drain secretions.
- 4.

$$\frac{300 \text{ mg} \quad | \quad 5 \text{ mL}}{\quad \quad \quad | \quad 200 \text{ mg}} = 7.5 \text{ mL}$$

5. "Patient coughed up 200 mL of bright yellow, foul-smelling sputum. Lungs have scattered crackles and

wheezes throughout after coughing episode. Expectorant given; fluids encouraged. Mouth care provided."

■ Mr. Franklin

1. You need to do several things at once. You will begin by speaking in a calm voice and trying to help Mr. Franklin to calm himself by doing pursed lip breathing. Assure him that you will help him and won't leave. At the same time, check his oxygen to make sure it is on the ordered number of liters and that his tubing is not kinked or disconnected. Grab the bedside table for him to lean on. Call for someone to page a respiratory therapist to do an NMT if ordered. Have someone bring a pulse oximeter to check his oxygen saturation. Also call for the registered nurse (RN) to administer IV morphine if ordered. All this should take about 1 minute! Once Mr. Franklin is a bit calmer, you can find out what happened. Did the exertion of moving to the bedside commode cause his dyspnea? Check his vital signs and lung sounds, and work with the RN to determine if this represents a change in Mr. Franklin's condition that should be reported to the physician.
2. Teach Mr. Franklin that he should probably stay on bedrest until his acute exacerbation is resolved. Once he is able to start moving around, he should call for help to get up. Review his controlled breathing exercises, which he can use during movement, and encourage rest between activities.
3. "3:00: Patient up on BSC, RR 36 and labored, color gray, appeared very apprehensive. O₂ on at 2 L per min per NC, assisted to lean on overbed table. Encouraged pursed lip breathing. VS 146/64, 102, 36, Sao₂ 82%. RT paged; administered PRN NMT. LS diminished, no cough. At 3:15, patient appears much calmer, RR 24 and less labored, Sao₂ 90%."

QUESTIONS TO GUIDE YOUR READING

1. What are the structures of the gastrointestinal tract and of the accessory glands: liver, gallbladder, and pancreas?
2. What are the functions of each organ of the gastrointestinal tract and of the accessory glands: liver, gallbladder, and pancreas?
3. How does age affect the gastrointestinal tract and accessory glands?
4. Which data should you collect when caring for a patient with a disorder of the gastrointestinal system, liver, gallbladder, or pancreas? Differentiate normal and abnormal findings.
5. What are the techniques used in a physical examination of the abdomen conducted for a patient with possible gastrointestinal system, liver, gallbladder, or pancreas disease?
6. How would you prepare, teach, and provide follow-up care for patients having various diagnostic tests of the gastrointestinal tract?
7. What are types and uses of nasogastric and intestinal tubes?
8. What is nursing care for insertion and maintenance of nasogastric tubes?
9. What are therapeutic interventions for patients with gastrointestinal disease?

REVIEW OF NORMAL GASTROINTESTINAL, LIVER, GALLBLADDER, AND PANCREAS ANATOMY AND PHYSIOLOGY

The gastrointestinal (GI) tract (or alimentary tube) is part of the digestive system (Fig. 32.1). It extends from the mouth to the anus and consists of the oral cavity, pharynx, esophagus, stomach, small intestine, and large intestine (or colon). Digestion begins in the oral cavity and continues in the stomach and small intestine. Most absorption of nutrients takes place in the small intestine. The large intestine is where the majority of water is reabsorbed from digested food. Indigestible material, mainly cellulose, is then eliminated from the large intestine.

Oral Cavity and Pharynx

The boundaries of the oral cavity are the hard and soft palates superiorly, the cheeks laterally, and the floor of the mouth inferiorly. Within the oral cavity are the teeth and tongue and the openings of the ducts of the salivary glands.

The teeth begin mechanical digestion, the physical breakup of food into smaller pieces to create more surface

area for the chemical digestion brought about by enzymes. The roots of the teeth are in sockets in the jawbones (the mandible and maxillae). The gums, or gingiva, cover the jawbones and surround the bases of the crowns (tops) of the teeth. The tooth sockets are lined with a periodontal membrane (ligament) of dense fibrous connective tissue which cements the roots of the teeth.

The tongue is made of skeletal muscle innervated by the hypoglossal nerve (twelfth cranial nerve). The papillae on the upper surface of the tongue contain taste buds, innervated by the facial and glossopharyngeal nerves (seventh and ninth cranial). The tongue is important for chewing because it keeps food between the teeth. Elevation of the tongue is the first step in swallowing.

The three pairs of salivary glands are the parotid, submandibular, and sublingual glands. Their ducts carry saliva to the oral cavity. The presence of anything in the mouth increases the rate of secretion; this is a parasympathetic response mediated by the facial and glossopharyngeal nerves. Saliva is mostly water, which is used to dissolve food for tasting and moisten the food for swallowing. The only digestive enzyme in saliva that functions in the mouth is amylase, which digests starch to maltose. Usually, however, food does not remain in the mouth long enough for amylase to have any significant effect. There is also lingual lipase, however being activated by acidic pH, it begins its action in the stomach.

The pharynx is a muscular tube that is a passageway for food exiting the oral cavity and entering the esophagus. When a mass of food is pushed backward by the tongue, the constrictor muscles of the pharynx contract as part of the swallowing reflex. This reflex is regulated by the medulla and pons. The uvula closes off the nasopharynx while the epiglottis closes the opening to the larynx.

Esophagus

The esophagus is about 10 inches long and carries food from the pharynx to the stomach. No digestion takes place in the esophagus. **Peristalsis** (rhythmic contraction of muscles) of the muscle layer in the wall of the esophagus is one way; food reaches the stomach even if the body is upside down. At the junction with the stomach, the lumen of the esophagus is surrounded by the lower esophageal sphincter (LES; gastroesophageal sphincter, or cardiac sphincter), a circular smooth muscle. The LES relaxes to permit food to enter the stomach and then contracts to prevent the back-up of stomach contents. Incomplete closure of the LES may allow gastric juice to splash up into the esophagus.

Stomach

The stomach is in the upper left abdominal quadrant, to the left of the liver and in front of the spleen. It is a J-shaped, saclike organ that extends from the esophagus to the duodenum of the small intestine. Some digestion takes place in the stomach, and it also serves as a reservoir for food so that digestion may take place gradually.

The parts of the stomach are shown in Figure 32.2. The LES provides the opening from the esophagus to the stom-

FIGURE 32.1 Anterior view of the digestive system. (From Scanlon, VC, and Sanders, T: *Essentials of Anatomy and Physiology*, ed 4. F.A. Davis, Philadelphia, 2003, p 351, with permission.)

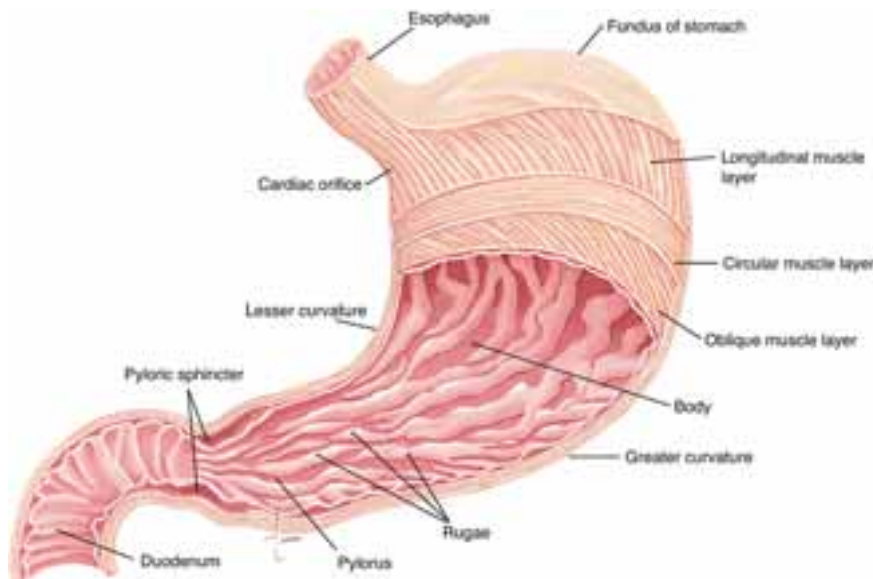

FIGURE 32.2 Stomach: anterior view and partial section. (From Scanlon, VC, and Sanders, T: *Essentials of Anatomy and Physiology*, ed 4. F.A. Davis, Philadelphia, 2003, p 357, with permission.)

ach. The fundus forms the upper curve of the stomach. The body of the stomach is the large, central portion, bounded laterally by the greater curvature and medially by the lesser curvature. The pylorus is adjacent to the duodenum, and the pyloric sphincter surrounds the junction of the two organs.

When the stomach is empty, the mucosa has folds called rugae. The rugae flatten out as the stomach fills and permit expansion of the lining. The mucosa contains gastric pits, the glands of the stomach that produce gastric juice. Gastric juice is mostly water and contains mucus, pepsinogen, hydrochloric acid, gastric lipase, and intrinsic factor. Mucus helps form a bolus and protects the mucosal lining. Pepsinogen is an inactive enzyme that is changed to active pepsin by hydrochloric acid; pepsin begins the digestion of proteins to polypeptides. Hydrochloric acid creates the pH of 1 to 2 that is necessary for pepsin to function and to kill most microorganisms that enter the stomach; it also denatures proteins. Gastric lipase helps digest triglycerides. Intrinsic factor aids in the absorption of vitamin B₁₂.

Gastric juice is secreted at the sight or smell of food; this is a parasympathetic response. The presence of food in the stomach stimulates the secretion of the hormone gastrin by the gastric mucosa. Gastrin increases the secretion of gastric juice.

The stomach wall has three layers of smooth muscle: circular, longitudinal, and oblique. These provide for very efficient mechanical digestion to change food to a thick liquid called chyme. The pyloric sphincter contracts when the stomach is churning food and relaxes at intervals to allow small amounts of chyme to pass into the duodenum, then contracts again to prevent the back-up of intestinal contents into the stomach. Carbohydrates are most readily digested by the stomach, followed by proteins and fats.

Small Intestine

The small intestine is about 1 inch in diameter and approximately 10 feet long. Within the abdominal cavity, the coils

of the small intestine are encircled by the colon. The small intestine extends from the stomach to the cecum of the colon. The duodenum is the first 10 inches and contains the hepatopancreatic ampulla (ampulla of Vater), the entrance of the common bile duct and the pancreatic duct. The jejunum is about 3 feet long, and the ileum is about 6 feet in length.

Digestion is completed in the small intestine, and the end products of digestion are absorbed into the blood and lymph. Bile from the liver and enzymes from the pancreas function in the small intestine (Table 32.1). When chyme enters the duodenum, the intestinal mucosa produces the enzymes sucrase, maltase, and lactase, which complete the digestion of disaccharides to monosaccharides; the peptidases, which complete the digestion of proteins to amino acids; and nucleosidases and phosphatases, completing nucleotide digestion.

The absorption of nutrients requires a large surface area, and the small intestine has extensive folds for this purpose. The circular folds (plicae circulares) are macroscopic folds of the mucosa and submucosa. Villi are folds of the mucosa, and microvilli are microscopic folds of the cell membranes on the free surface of the intestinal epithelial cells. Within each villus is a capillary network and a lymph capillary called a lacteal. Water-soluble nutrients (monosaccharides, amino acids, minerals, water-soluble vitamins) are absorbed into the blood in the capillary networks. Fat-soluble vitamins and fatty acids and glycerol are absorbed into the lymph in the lacteals.

Large Intestine

The large intestine extends from the ileum of the small intestine to the anus. It is about 5 feet long and 2.5 inches in diameter. The cecum is the first part, and at its junction with the ileum is the ileocecal valve, which prevents back-up of colon contents into the small intestine. Attached to the cecum is the small, dead-end appendix.

TABLE 32.1 DIGESTIVE SECRETIONS

Organ	Enzyme or Other Secretion	Function	Site of Action
<i>Salivary Glands</i>	Amylase	Converts starch to maltose	Oral cavity
	<i>Stomach</i>	Pepsin	Converts proteins to polypeptides
	Hydrochloric acid	Changes pepsinogen to pepsin; maintains pH 1–2; destroys pathogens	Stomach
<i>Liver</i>	Bile salts	Emulsifies fats	Small intestine
<i>Pancreas</i>	Amylase	Converts starch to maltose	Small intestine
	Lipase	Converts emulsified fats to fatty acids and glycerol	Small intestine
	Trypsin	Converts polypeptides to peptides	Small intestine
<i>Small Intestine</i>	Peptidases	Converts peptides to amino acids	Small intestine
	Sucrase, maltase, lactase	Converts disaccharides to monosaccharides	Small intestine

The other parts of the colon are the ascending, transverse, and descending colon, which encircle the small intestine; the sigmoid colon, which turns medially and downward; the rectum, which is about 8 inches long; and the anal canal, the last inch that surrounds the anus (clinically, the terminal end of the colon is usually referred to as the rectum).

Although no digestion takes place in the colon, its functions are important. The colon temporarily stores and then eliminates undigestible material. The mucosa absorbs significant amounts of water and minerals, as well as the vitamins produced by the normal bacterial flora.

Elimination of feces is accomplished by the defecation reflex, a spinal cord reflex over which voluntary control may be exerted. When peristalsis propels feces into the rectum, receptors in the smooth muscle layer detect the stretching and generate impulses to the spinal cord. The returning motor impulses cause contraction of the smooth muscle of the rectum and relaxation of the internal anal sphincter, which surrounds the anus. Surrounding the internal sphincter is the external anal sphincter, which is made of skeletal muscle and may be voluntarily contracted to prevent defecation.

The liver, gallbladder, and pancreas are called accessory organs of digestion because they produce or store digestive secretions but are not sites of the digestive process. Mechanical and chemical digestion of ingested foods take place throughout parts of the GI tract.

Liver

The liver fills the right and center of the upper abdominal cavity just below the diaphragm. It has a larger right lobe and a smaller left lobe.

The blood supply of the liver differs from that of other organs. The liver receives oxygenated blood by way of the hepatic artery. By way of the portal vein, blood from the abdominal digestive organs and the spleen is brought to the liver before being returned to the heart. This special pathway is called hepatic portal circulation and permits the liver to regulate blood levels of nutrients or to remove poten-

tially toxic substances such as alcohol from the blood before the blood circulates to the rest of the body.

The only digestive function of the liver is the production of bile by the hepatocytes (liver cells). Bile flows through small bile ducts, converges into larger ones, and leaves the liver by way of the common hepatic duct (Fig. 32.3). The common hepatic duct joins the cystic duct of the gallbladder to form the common bile duct, which carries bile to the duodenum.

Bile is mostly water and bile salts. Its excretory function is to carry bilirubin and excess cholesterol to the intestines for elimination in feces. The digestive function of bile is accomplished via bile salts, which emulsify fats in the small intestine. Emulsification is a type of mechanical digestion in which large fat globules are broken into smaller globules but are not chemically changed. Production of bile is stimulated by the hormone secretin, which is produced by the duodenum when acidic chyme enters the small intestine.

Functions of the Liver

The liver is involved in a great variety of metabolic functions, most of which involve the synthesis of specific enzymes. For the sake of simplicity, these functions may be grouped into categories.

CARBOHYDRATE METABOLISM. The liver regulates the blood glucose level by storing excess glucose as glycogen and changing glycogen back to glucose when the blood glucose level is low. The liver also changes other monosaccharides such as fructose and galactose to glucose, which is more readily used by cells for energy production.

AMINO ACID METABOLISM. The liver regulates the blood levels of amino acids based on tissue needs for protein synthesis. Of the 20 amino acids needed for the production of human proteins, the liver is able to synthesize 12, called the nonessential amino acids, by the process of transamination. The other eight amino acids, which the liver cannot synthesize, are called the essential amino acids. Essential amino acids are required in the diet.

FIGURE 32.3 The liver, gallbladder, pancreas, and duodenum.

Excess amino acids (those not needed for protein synthesis) undergo the process of deamination in the liver; the amino group is removed and the remaining carbon chain is converted to a simple carbohydrate that is used for energy production or converted to fat for energy storage. The amino groups are converted to urea, a nitrogenous waste product that is removed from the blood by the kidneys and excreted in urine.

LIPID METABOLISM. The liver forms lipoproteins for the transport of lipids in the blood to other tissues. The liver also synthesizes cholesterol and excretes excess cholesterol into bile to be eliminated in feces.

The liver is also the main site of the process called beta oxidation, in which fatty acid molecules are split into two-carbon acetyl groups. These acetyl groups may be used by the liver to produce energy, or they may be combined to form ketones to be transported to other cells for energy production.

SYNTHESIS OF PLASMA PROTEINS. The liver synthesizes albumin, clotting factors, and globulins. Albumin, the most abundant plasma protein, helps maintain blood volume by pulling tissue fluid into capillaries. Clotting factors produced by the liver include prothrombin and fibrinogen, which circulate in the blood until needed for chemical clotting. The globulins synthesized by the liver become part of lipoproteins or act as carriers for other molecules in the blood.

PHAGOCYTOSIS BY KUPFFER CELLS. The fixed macrophages of the liver are called Kupffer cells (or stellate reticuloendothelial cells). They phagocytize worn blood cells and pathogens that circulate through the liver. Many of the bacteria that enter the liver come from the colon, after

being absorbed along with water. Portal circulation brings this blood to the liver before entering circulation throughout the remainder of the body. These bacteria are normal flora of the colon but would be harmful elsewhere.

FORMATION OF BILIRUBIN. The fixed macrophages of the liver phagocytize worn red blood cells (RBCs) and form bilirubin from the heme portion of their hemoglobin. The liver also removes from the blood the bilirubin formed in the spleen and red bone marrow and excretes it into bile to be eliminated in feces.

STORAGE. The liver stores the minerals iron and copper; the fat-soluble vitamins A, D, E, and K; and the water-soluble vitamin B₁₂.

DETOXIFICATION. The liver synthesizes enzymes that alter harmful substances to less harmful ones. Alcohol and medications are examples of potentially toxic chemicals. The liver also converts ammonia from the colon bacteria to urea, a less toxic substance.

ACTIVATION OF VITAMIN D. The skin, kidneys, and liver each perform a different role in providing the body with activated vitamin D.

Gallbladder

The gallbladder is a muscular sac about 3 to 4 inches long located on the undersurface of the left lobe of the liver. Bile in the common hepatic duct from the liver flows through the cystic duct (see Fig. 32.3) into the gallbladder, which stores bile until it is needed in the small intestine. The gallbladder also concentrates bile by absorbing water.

When fatty foods or partially digested proteins enter the duodenum, the duodenal mucosa secretes the hormone

cholecystokinin. One function of cholecystokinin is to stimulate contraction of the smooth muscle of the wall of the gallbladder. Contraction of the gallbladder forces bile into the cystic duct, then into the common bile duct, which empties into the duodenum.

Pancreas

The pancreas is about 6 inches long, and is located posterior to the greater curvature of the stomach. (See Fig. 32.3.) The digestive secretions of the pancreas are produced by exocrine glands called acini. The small ducts of these glands unite to form larger ducts and finally converge into the pancreatic duct, which joins the common bile duct to enter the duodenum at the hepatopancreatic ampulla. The accessory duct has a direct line from the pancreas into the duodenum.

The pancreatic digestive enzymes are involved in the digestion of all four of the organic molecule categories. The enzyme pancreatic amylase digests starch to maltose. Pancreatic lipase converts emulsified fats to fatty acids and monoglycerides. Trypsinogen is an inactive enzyme that is changed to active trypsin in the duodenum. Trypsin digests

polypeptides to shorter chains of amino acids. Pancreatic juice also contains proteolytic enzymes: chymotrypsin, carboxypeptidase, and elastase. Ribonuclease and deoxyribonuclease, for the digestion of RNA and DNA, respectively, are contributed by the pancreas as well.

The pancreas also produces a bicarbonate juice, which is alkaline because of its high sodium bicarbonate content. The function of bicarbonate juice is to neutralize the hydrochloric acid in gastric juice as it enters the duodenum from the stomach. The pH of duodenal chyme is raised to about 7.5, which prevents corrosive damage to the mucosa and creates the optimal pH for intestinal enzyme action.

Secretion of pancreatic juice is stimulated by the hormones of the duodenal mucosa. Secretin stimulates the production of bicarbonate pancreatic juice, and cholecystokinin stimulates secretion of the pancreatic enzyme juice.

Aging and the Gastrointestinal System, Liver, Gallbladder, and Pancreas

Many changes occur in the aging gastrointestinal (GI) system (Fig. 32.4). The sense of taste becomes less acute, and

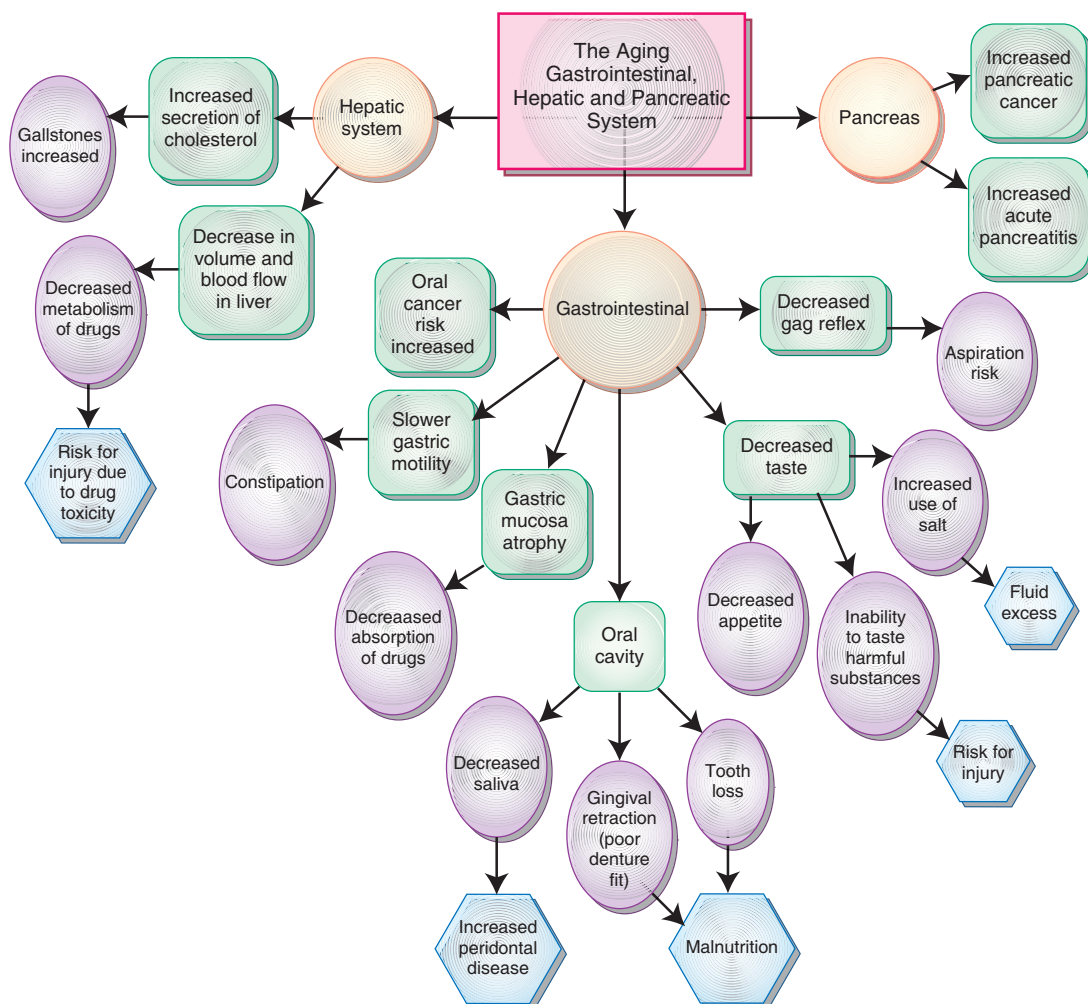

FIGURE 32.4 Aging and its effects on the gastrointestinal, hepatic, and pancreatic systems is shown on this concept map.

**Box 32.1****Gerontological Issues**

With increasing age, the liver decreases in volume, mass, and blood flow. These changes are significant because the liver acts to metabolize many drugs. If a patient has impaired liver function, there may be toxic levels of a drug present in the blood. It is important to assess liver function tests and perform a medication review to determine those that are metabolized by the liver. Older adults may require reduced doses of many drugs.

there is greater likelihood of periodontal disease and oral cancer. There may be difficulties with chewing if teeth have been lost. Secretions throughout the GI tract are reduced, and the effectiveness of peristalsis diminishes because of loss of muscle elasticity and slowed motility. Indigestion may become more common, especially if the LES loses its tone, and there is greater chance of peptic ulcer. In the colon, diverticula may form. Constipation may be a problem, as may hemorrhoids. The risk of colon cancer also increases with age.

The liver usually continues to function well into old age, unless damaged by pathogens such as the hepatitis viruses or by toxins such as alcohol (Box 32.1 Gerontological Issues). There is a greater tendency for gallstones to form, sometimes necessitating removal of the gallbladder.

In the absence of specific pathological conditions, the pancreas usually functions well, although acute pancreatitis of unknown cause is somewhat more common in the elderly.

**NURSING ASSESSMENT/
DATA COLLECTION**

Nursing assessment and data collection of the GI system, liver, gallbladder, and pancreas includes a patient history and physical examination (Tables 32.2, 32.3, and 32.4).

Subjective Data**Health History**

Demographic data is obtained, including travel history, which may help in diagnosing the cause of GI symptoms such as diarrhea. Assessment of current signs and symptoms includes asking the WHAT'S UP? questions: where it is, how it feels, aggravating and alleviating factors, timing, severity, useful data for associated symptoms, and perception by the patient of the problem. Also documented are the patient's normal bowel pattern; changes in bowel patterns or habits; a history of any gastrointestinal diseases, such as ulcers, cancer, Crohn's disease, or colitis; or an unexplained weight loss or gain. Information about previous GI surgeries is obtained. Signs or symptoms of disease, such as bloody or tarry stools, rectal bleeding, stomach pain, or abdominal pain, are also noted.

Ask the patient about any nausea, vomiting, or abdominal distention. Information about the timing or other com-

TABLE 32.2 SUBJECTIVE ASSESSMENT OF THE GASTROINTESTINAL SYSTEM

Category	Questions to Ask During History Assessment	Rationale/Significance
Health History	<ul style="list-style-type: none"> Assess current symptoms using the WHAT'S UP format. What are your bowel patterns? How often do you usually have a bowel movement? What is the color? What is the consistency? Any diarrhea or constipation? Have you had any blood in your stool or on the toilet tissue? Have you had any change in appetite? Nausea and/or vomiting? Bloating? Excess gas? Do you have any history or gastrointestinal illnesses or surgeries? 	<ul style="list-style-type: none"> This will help you adequately assess the patient's current problem. Changes in bowel habits could indicate new disease process. Blood in stool could indicate hemorrhoids, early sign of cancer, inflammatory diseases such as ulcerative colitis. Appetite changes can be common with gastrointestinal disorders. Can be associated with GI disorders. Patient may have a recurring problem.
Medications	<ul style="list-style-type: none"> What medications are you currently taking? How do the drugs relate to the GI system? Are they working? How do you know? Have you recently taken any NSAIDs, aspirin, anticoagulants or steroids? Do you routinely take laxatives? Fiber? 	<ul style="list-style-type: none"> Provides baseline information about patient. These medications can cause gastric upset and/or bleeding. Patient may have dependency on laxatives.

Nutrition		
<i>Nutritional Assessment</i>	<ul style="list-style-type: none"> • Are taking or have you recently taken antibiotics? • Describe your usual diet. Tell me what you ate yesterday for the entire day. • Do you have any food allergies? • Do you have indigestion, dysphagia, heartburn, nausea, vomiting, diarrhea, constipation, flatulence, or bowel incontinence? • Have you had a change in appetite? • Have you had a change in weight—gain or loss? • Are there any foods that you cannot eat? • Do you have a family history of any gastrointestinal disorders such as cancer? • Are there any cultural considerations I should be aware of regarding your food intake or care? 	<ul style="list-style-type: none"> • Diarrhea due to <i>C. difficile</i> can be caused by recent antibiotic use. • Provides information about your patient's nutritional status. Older adults may be on a fixed income and unable to afford adequate nutrition. • These may interfere with proper nutrition. If patient has any of these symptoms, use the WHAT'S UP format to gather more specific information.
<i>Family History</i>		<ul style="list-style-type: none"> • Some diseases are thought to be hereditary.
<i>Cultural Influences</i>		<ul style="list-style-type: none"> • Many societies use herbs, vitamins, or home remedies to care for disorders.

mon triggers of episodes of nausea or vomiting may help the practitioner identify their cause. Such information may also help determine appropriate treatment for any future nausea or vomiting. Abdominal distention in the presence of nausea and vomiting may indicate intestinal obstruction. Patients

with liver, gallbladder, or pancreatic disease may also complain of feeling bloated, of having gas or belching frequently, or of right upper quadrant (RUQ) tenderness.

Question the patient about any observed changes in bowel elimination. Diarrhea may be caused by irritation of

TABLE 32.3 SUBJECTIVE ASSESSMENT OF THE LIVER, GALLBLADDER, AND PANCREAS

Category	Questions to Ask During History Assessment	Rationale/Significance
Health History		
	<ul style="list-style-type: none"> • Do you have abdominal pain? (Use WHAT'S UP? to further assess.) Do any foods cause pain? • What do your stools look like? • Does your abdomen feel distended or full? • How much alcohol do you drink each day? • Do you bruise or bleed easily? • Have you had any recent blood transfusions or blood products, dental procedures, body piercing or tattooing, or intravenous injection with a potentially contaminated needle? • Have you experienced nausea and vomiting? 	<ul style="list-style-type: none"> • Pain can be associated with disease of the liver, gallbladder, or pancreas. Fatty foods can cause pain related to gallbladder disease. • Clay-colored stools indicate liver or gallbladder disease. Black stools may indicate bleeding, which can be related to liver disease. Fatty stools occur with pancreatic disease. • Fluid in the abdomen, or ascites, occurs with liver disease. • Excess alcohol intake is associated with liver disease and pancreatitis. • Bleeding is associated with liver disease, because clotting factors are made in the liver. • Breaks in skin may be the route of entry for hepatitis (type B or C) or other pathogens.
Nutrition	<ul style="list-style-type: none"> • Has your appetite or weight changed? 	<ul style="list-style-type: none"> • These are generalized symptoms that may be associated with disease of the liver, gallbladder, or pancreas. • Anorexia and weight loss accompany many liver, gallbladder, and pancreatic disorders. • These disorders tend to run in families.
Family History	<ul style="list-style-type: none"> • Does anyone in your family have liver, gallbladder, or pancreatic disease or alcoholism? 	
Medications	<ul style="list-style-type: none"> • Do you use any over-the-counter drugs or herbal remedies? 	<ul style="list-style-type: none"> • Many drugs and herbs are toxic to the liver.

TABLE 32.4 OBJECTIVE ASSESSMENT OF THE GASTROINTESTINAL SYSTEM, LIVER, GALLBLADDER, AND PANCREAS

Category	Physical Assessment Findings	Possible Abnormal Findings/Causes
<i>Height, Weight, and Body Mass Index (BMI)</i>	<ul style="list-style-type: none"> • Normal height, weight and normal body mass index 	<ul style="list-style-type: none"> • Decreases in height, weight, and BMI could indicate inadequate nutrition or malabsorption problems. • Current weight loss could indicate new onset of a disease such as cancer.
<i>Oral Cavity</i>	<ul style="list-style-type: none"> • Moist, pink oral mucosa, without lesions, inflammation, tenderness, or discolorations. • Pink, rough tongue. 	<ul style="list-style-type: none"> • Foul odor may indicate infection or poor oral hygiene. • Dry tongue with cracked furrows could indicate dehydration possibly due to vomiting or diarrhea.
<i>Abdomen Inspection</i>	<ul style="list-style-type: none"> • Teeth should be intact. Dentures should fit properly. • Abdomen contour should be flat, rounded, or convex. Shape should be symmetrical. • Skin color should be consistent with overall skin tone. No visible scars or discolorations. 	<ul style="list-style-type: none"> • Broken teeth or ill-fitting dentures can contribute to inadequate nutrition. • Irregularities in contour such as bulging or masses may be due to distention, tumors, hernia, or previous surgeries. Any scars, dressings, appliances such as an ostomy should be noted. Indicate what the stoma looks like. • Scars may be present if the patient has had previous surgeries or injuries. Striae are present if the skin has been stretched, i.e., with pregnancy or weight gain. Bruising could be related to injury or altered liver function. Note any caput medusae and spider angiomas. Jaundice color may indicate liver or gallbladder disease.
<i>Auscultation</i>	<ul style="list-style-type: none"> • Soft bowel sounds should be heard in all quadrants every 5-15 seconds. • Circulatory sounds should be absent. 	<ul style="list-style-type: none"> • Hyperactive sounds are heard with increased motility such as diarrhea. Hypoactive sounds are associated with decreased motility such as abdominal surgery, paralytic ileus, or bowel obstruction. • A humming sound may be heard over the liver in patients with chronic liver failure.
<i>Percussion</i>	<ul style="list-style-type: none"> • Completed by experienced practitioner such as physician or nurse practitioner. 	
<i>Palpation</i>	<ul style="list-style-type: none"> • No pain, muscle tension, rigidity, or masses should be felt on light palpation. The abdomen should feel soft. • Abdominal girth should be appropriate for patient without increasing. • Deep palpation is done by the advanced practitioner. 	<ul style="list-style-type: none"> • Muscle tension, rigidity, or pain may be experienced by many abdominal disorders. • Patients with ascities due to liver disease may have an increased girth that increases as the disease worsens.

the bowel. Constipation may indicate decreased water intake or excessive water loss. Observe the patient's stool for evidence of bacteria (a foul smell), fat (stool floats on the water surface and appears greasy), pus, blood, or mucus. Patients with liver or gallbladder disease may have pale or clay-colored stools.

Ask about the patient's usual work activities and work setting. Document exposure to chemicals such as paint fumes, industrial dyes, acids, farm pesticides, or other liver-toxic substances.

Determine if the patient has had any recent blood transfusions or blood products, dental procedures, body piercing or tattooing, or intravenous injection with a potentially contaminated needle. These procedures cause a break in the skin which can allow an entry point for hepatitis virus (type B or C) as well as other pathogens.

Investigate the patient's activities other than work. Document reports of fatigue along with information about when the fatigue occurs. Ask the patient about stressors such as financial concerns, problems dealing with the health-care environment, and any family or personal problems. Attempt to determine what coping mechanisms the patient usually employs to deal with stressors.

Medications

The patient is asked about medication use such as nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, vitamins, laxatives, enemas, or antacids. Heavy use of medications that can cause irritation and bleeding in the GI tract, such as NSAIDs or aspirin, should be carefully noted. Elderly patients with arthritis often use these types of medications for pain control. The patient's knowledge of the side effects

of these medications should be assessed to identify teaching needs. Elderly patients may use laxatives regularly and develop a dependence on them. Teaching may be needed on normal bowel patterns and laxative use. Also ask the patient what medications are being taken with or without a physician's prescription. Many people do not consider over-the-counter preparations and herbal or natural products that they purchase without a prescription important enough to report and must be asked specifically to do so.

CLOSTRIDIUM DIFFICILE. Question the patient about recent hospitalizations or antibiotic use. Hospitalization or recent antibiotic use is a risk factor for *C. difficile*. With antibiotic use, a decrease in normal flora can result, allowing an overgrowth of *C. difficile*. The toxins produced by *C. difficile* can cause diarrhea, colitis, toxic megacolon, dehydration, colonic perforation, and sometimes death. Nurses should monitor patients closely for signs of *C. difficile* infection such as diarrhea, nausea, anorexia, and abdominal tenderness or pain. These symptoms should be reported to the physician as this infection can be fatal.

LEARNING TIP

Consider *C. difficile* infection if the patient has diarrhea associated with recent antibiotic use or hospitalization. Educate patients to report its occurrence. Protect your patients with excellent hand hygiene and by following isolation procedures. *C. difficile* can be carried on your hands, nails, rings, or shoes.

CRITICAL THINKING

Mrs. Todd

■ Mrs. Todd, age 74, has arthritis and takes eight aspirin daily for pain control. She is scheduled for an **esophagogastroduodenoscopy** (EGD) for suspected GI bleeding caused by unexplained anemia.

1. What is a likely cause of the GI bleeding?
2. What could you do to help prevent future bleeding episodes for Mrs. Todd?

Suggested answers at end of chapter.

Nutritional Assessment

A diet history should include usual foods and fluids, allergies, appetite patterns, swallowing difficulty, and use of nutritional and herbal supplements. A patient food diary can be used to provide more detailed information. Elderly patients may be on fixed incomes, which may limit their food budget and result in meal skipping or purchasing of inexpensive foods. The elderly patient's daily food intake

Box 32.2

Gerontological Issues

A complete bowel history should be obtained for older adults before beginning a bowel program. A bowel history includes the following:

- Normal bowel evacuation pattern
- Characteristics of stool
- Presence of any bleeding or mucus with the stool
- Use of products and medications to stimulate or slow bowel function
- Report of usual diet
- Amount of fluids—number and size of beverages, glasses per day (beverages containing caffeine, such as coffee, tea, and sodas, do not count as fluids because of the diuretic effect of caffeine)
- Exercise and physical activity
- Rituals and practices related to bowel function

should be explored, especially if malnutrition, financial limitations, or living alone is noted.

Also explored during a nutritional assessment are patterns of gastric acid reflux, indigestion, heartburn, nausea, vomiting, diarrhea, constipation, flatulence, and bowel incontinence, all of which may interfere with proper nutrition (Box 32.2 Gerontological Issues). Acid reflux can be assessed by asking patients if they experience reflux with a bile taste or awaken with an unpleasant taste in their mouth.

Patients with disease of the liver, pancreas, or gallbladder commonly have changes in appetite such as anorexia or alterations in eating preferences. Ask the patient about any abnormal weight loss or unexpected weight gain and changes in food tolerance, including the type or amount of offending foods. For example, patients with gallbladder disease may report that they feel nauseated or bloated after eating fried or greasy foods. Determine whether the patient ingests alcohol or uses other recreational drugs. If the patient does acknowledge using alcohol or other drugs, record the type, frequency, and amount used.

Family History

Family history of close relatives with conditions that may influence the patient's GI status is assessed. Some GI problems such as colon cancer are thought to be hereditary. The patient's history should note whether there is a family history of liver, pancreas, or gallbladder diseases, such as diabetes mellitus, alcoholism, cancer, heart disease, or bleeding tendencies. These diseases have a high incidence within families.

Cultural Influences

Many cultures have special dietary practices and restrictions (Box 32.3 Cultural Considerations). See Box 32.4 for assessment questions. Understanding these cultural influ-

**Box 32.3****Cultural Considerations**

Most societies of the world use various foods and herbs for maintaining health. With increased attention to herbal therapies in the United States, the U.S. National Institutes of Health is studying 40 foods that are thought to fight disease. Among them are garlic, carrots, soy, cranberry juice, licorice, and green tea. Green tea has been used in Japan and China for centuries as a means of maintaining health and preventing disease.

African Americans

Obesity is seen as positive among many African Americans. They often view individuals who are thin as “not having enough meat on their bones.” One needs to have adequate meat on his or her bones so that when an illness occurs, one can afford to lose weight. Many African American diets are high in animal fat and fried foods and low in fiber, fruits, and vegetables.

Appalachians

The diet of some Appalachians is deficient in vitamin A, iron, and calcium. The nurse working with this population needs to do a dietary assessment and teach patients food selections that include adequate vitamin A, iron, and calcium.

Arabs

Many Arabs eat food only with their right hand because it is regarded as the clean hand. The left hand, commonly used for toileting, is considered unclean. Thus, the nurse should feed the Arab patient with the right hand regardless of the nurse’s dominant handedness. Additionally, some may not drink beverages with their meals because some individuals consider it unhealthy to eat and drink at the same meal. Likewise, mixing hot and cold foods may be seen as unhealthy.

Muslim Arabs may refuse to eat meat that is not *halal* (slaughtered and prepared in a ritual manner). Because Muslim Arabs are prohibited from ingesting alcohol or eating pork, they may refuse medication that includes alcohol, such as mouthwashes, toothpaste, alcohol-based syrups and elixirs, and products derived from pigs, such as insulin, gelatin-coated capsules, and skin grafts. However, if no substitute is available, Muslims are permitted to use these preparations.

The condition of the alimentary tract has priority over all other body parts in the Arab’s perception of health. Gastrointestinal complaints are the most common reason Arab Americans seek care.

Asian Indians

Among Asian Indians, nutritional deficiencies are patterned from their region of emigration. For example,

beriberi (thiamine deficiency) is found in people emigrating from rice-growing areas. Pellagra (niacin deficiency), causing skin and mental disorders and diarrhea, is found in people emigrating from maize-millet areas. Thiamine deficiency is common among people mostly dependent on rice. Thorough milling of rice, washing rice before cooking, and allowing the cooked rice to remain overnight before consumption the following day result in the loss of thiamine.

Asian Indians use chili, which may make it difficult for them to eat food that is tasteless or the use of chili may cause problems with UGI conditions.

Commitment to the sacred cow concept has an impact on Hindus by encouraging dairy and milk use. However, lactose intolerance affects more than 10% of adults. The adequacy or inadequacy to digest lactose may be due to genetic differences among Asian Indians.

Goiter is prevalent among some Asian Indian immigrants resulting from an iodine deficiency in food and water from their homeland. Fluorosis occurs in other parts of India resulting from drinking water high in fluoride. Osteomalacia is prevalent where diets are deficient in calcium and vitamin D. Endemic dropsy is prevalent among Asian Indians emigrating from West Bengal, resulting from using mustard oil for cooking. The nurse needs to be aware of these conditions and their causes when working with Hindus and Asian Indians and teach patients prevention.

Brazilians

There is an increase in gastrointestinal distress among Brazilians when they first come to the United States, partially because many have a lactose intolerance and partially because of different methods of milk pasteurization. The nurse can assist the patient in identifying alternative food sources for Brazilian patients to obtain needed calcium in their diet.

Jewish

Among Jews, the laws regarding food are commonly referred to as the laws of Kashrut, or the laws of what foods are permissible in accordance with the religious law. The term *kosher* means fit for eating; it is not a brand or form of cooking.

Foods are divided into those that are permitted (clean) and forbidden (unclean). The kosher slaughter of animals prevents undue cruelty to the animal and ensures the animal’s health for its consumer. Care must be taken that all blood is drained from the animal before eating it.

Among the more conservative and Orthodox Jews, dairy products and meat may not be mixed together, whether in cooking, serving, or eating. This involves

separating the utensils used to prepare foods and the plates used to serve them. To avoid mixing foods, religious Jews have two sets of dishes, pots, and utensils: one set for dairy products and one for meat.

Cheeseburgers, meat lasagna, and grated cheese on meatballs and spaghetti are not acceptable. Milk cannot be used in coffee if served with a meat meal. Nondairy creamers can be used as long as they do not contain sodium caseinate, which is derived from milk.

Fish, eggs, vegetables, and fruits are considered neutral and may be used with either dairy or meat dishes. A “U” with a circle around it or a “K” is used on food products to indicate kosher.

When working in a Jewish person’s home, the nurse should not bring food into the house without knowing whether the patient is kosher. If the patient is kosher, do not use any cooking items, dishes, or silverware without knowing which are used for meat and which are used for dairy. It is important for the nurse to understand the dietary laws so as not to offend the patient. The nurse should advocate for kosher meals if they are requested and plan medication times accordingly.

Although liberal Jews decide for themselves which dietary laws, if any, they follow, many still avoid pork and pork products out of a sense of tradition and symbolism. It would be insensitive to serve pork products to Jewish patients unless they specifically request it.

Kosher meals are available in hospitals and long-term care facilities. Even though the organization may not have a kosher kitchen, frozen kosher meals can be obtained from several organizations, most of which are located in large cities with large Jewish populations. The kosher kitchen closest to your organization can be obtained by calling the Jewish synagogue nearest the organization to obtain the address and telephone number.

Kosher meals arrive on paper plates with plastic utensils sealed in plastic. The nurse should not unwrap the utensils if the patient is able to do so or change the food-stuffs to another serving dish. Determining a patient’s dietary preferences and practices regarding dietary laws should be done during the admission assessment.

Mexican Americans

Good health to Mexican Americans, which is largely a part of “God’s will,” can be maintained by dietary practices that keep the body in balance. To provide culturally competent care, the nurse must be aware of the hot-and-cold theory of disease when offering health teaching. Many diseases are thought to be caused by a disruption in the hot-and-cold balance theory of the body. Thus, by eating foods of the opposite variety, one may either cure or prevent specific hot-and-cold illnesses and conditions.

Examples of hot disease conditions include infection, diarrhea, sore throats, stomach ulcers, liver conditions, kidney problems, gastrointestinal upsets, and febrile conditions. Foods that are considered “cold” are therefore viewed as remedies for hot illness conditions. Cold foods include fresh fruits and vegetables, dairy products, barley water, fish, chicken, goat meat, and dried fruits. However, there are significant differences in what are considered hot and cold foods and illnesses among Mexican American families depending on their native region in Mexico.

Examples of cold illness conditions include cancer, malaria, earaches, arthritis and related conditions, pneumonia and other pulmonary conditions, headaches, menstrual cramping, and musculoskeletal conditions. Hot substances used to treat these conditions typically include cheeses, liquor, beef, pork, spicy foods, eggs, grains other than barley, vitamins, tobacco, and onions.

ences, respecting them, and assisting the patient to maintain desired cultural practices are important for nutritional maintenance.

Objective Data

Height, Weight, and Body Mass Index

When the GI system is assessed, the patient’s height and weight are obtained for planning care. The patient’s ideal body weight according to height is obtained using current reference charts. Body mass index (BMI) is calculated to measure body fat and used with waist circumference measurements to determine patient’s health risk factors (Table 32.5). Excess waist circumferences (for women, more than 35 inches; for men, more than 40 inches) place people at greater risk for diabetes and cardiovascular disease.

Oral Cavity

Gastrointestinal assessment begins with the oral cavity. The lips are examined for lesions, abnormal color, and symmetry. With a penlight and tongue blade, the oral cavity is inspected

for inflammation, tenderness, ulcers, swelling, bleeding, and discolorations. Any odor of the patient’s breath is noted. A foul odor may indicate infection or poor oral care. The tongue should be pink with a rough texture and assessed for signs of dehydration such as dryness, cracks, or furrows. The patient’s gums should be pink without swelling, redness, or irregularities. The teeth or dentures are examined for loose, broken, or absent teeth and the fit of the dentures or dental work. Ill-fitting dentures can affect the patient’s nutritional intake and obstruct the airway. Loose teeth can become dislodged and aspirated into the airway. Broken teeth can be a source of pain and contribute to poor nutritional intake. The patient’s knowledge of dental and oral care is assessed. The ability of the patient to perform oral care is noted and included in the plan of care if there are deficits.

Abdomen

Be prepared to assist with a thorough physical assessment of the patient. Instead of following the usual inspect-palpate-percuss-auscultate (IPPA) format, assess the abdomen start-

Box 32.4

Cultural Considerations

Questions to ask when performing a cultural nutritional assessment:

1. What types of your cultural foods are available in your community?
2. What are your preferred foods over foods available and eaten?
3. Which foods do you most commonly consume?
4. How and where are your foods chosen and purchased?
5. Who prepares the food in your household?
6. Who purchases the food in your household?
7. How is your food stored for future use?
8. How is your food prepared before eaten?
9. How is any uneaten food discarded?
10. What foods do you eat to maintain your health?
11. What foods do you avoid to maintain your health?
12. What foods do you eat when you are ill?
13. What foods do you avoid when you are ill?

ing with inspection, then auscultation, percussion, and palpation. This is to prevent palpation from changing other assessment findings.

INSPECTION. To inspect the abdomen, patients are placed in a supine position with their arms at their sides. The abdomen is visually inspected to note the condition of the skin and the contour. The contour may be rounded, flat, concave, or distended, depending on the patient's body type. Abdominal pulsatile masses are noted, they may be visible in thin persons or they may indicate an abdominal aortic aneurysm. Irregularities in contour may be due to distention, tumors, hernia, or previous surgeries. Also note

TABLE 32.5 CALCULATING BODY MASS INDEX AND WAIST MEASUREMENT

To calculate body mass index:	Step 1. Multiply body weight (in pounds) by 703. Step 2. Multiply height (in inches) by height. Step 3. Divide answer in step 1 by answer in step 2.
To obtain waist measurement:	Step 1. Place measuring tape at the level of the top of the iliac crest. Step 2. Pull snugly around the waist. Step 3. Read measurement at end expiration.
Findings	Below 18.5 Underweight 18.5–24.9 Normal 25–29.9 Overweight 30 and over Obese

any wounds, tubes, and ostomy device including type and location.

Inspect the patient's skin for scars, **striae** (commonly called stretch marks; light silver-colored or thin red lines on the abdomen), bruising, **caput medusae** (bluish purple swollen vein pattern extending out from the navel), and **spider angiomas** (thin reddish purple vein lines close to the skin surface). Note any petechiae. The patient's abdomen is observed for any visible masses, visible movement or peristalsis, or **jaundice** (also called **icterus**, a yellowing of the skin and the sclerae of the eyes).

Jaundice is a cardinal symptom of liver or gallbladder disease and red blood cell disorders. Old red blood cells are cleared from the circulatory system by phagocytes in the spleen, liver, lymph nodes, and bone marrow. In the process, the compound heme (part of hemoglobin) is split into iron and another substance that is metabolized to bilirubin. The liver is then responsible for converting bilirubin to a water-soluble compound that can be excreted in bile. If the liver is unable to convert or conjugate bilirubin to a water-soluble compound, or if bile drainage is obstructed, serum bilirubin is elevated and pigments are deposited in body tissues.

When serum bilirubin levels elevate, the patient's skin color changes to yellow. The yellow color varies from pale yellow to a striking golden orange. The color intensity is directly related to the amount of elevation of the serum bilirubin. Jaundice can be seen in nearly every body tissue and fluid where there is any amount of albumin. Pigment may occasionally be seen in cerebrospinal fluid or joint fluid. Pigment is not seen in saliva or tears. Urine becomes dark, and if bile flow to the bowel is obstructed, stools will be a light clay color (Box 32.5 Cultural Considerations). Describe any abnormal finding completely in the patient's record, and report your findings promptly.

AUSCULTATION. When auscultating the patient's abdomen, the upper right quadrant is auscultated first (Fig. 32.5). Then a clockwise direction is followed to listen to the other quadrants. The stethoscope is pressed lightly on the abdomen to listen for bowel sounds, which are soft clicks and gurgles that may be heard every 5 to 15 seconds, occurring irregularly 5 to 30 times per minute. **Bowel sounds** at this rate are considered normal. Bowel sounds are produced when peristalsis moves air and fluid through the GI tract and are categorized as normal, hyperactive,

Box 32.5

Cultural Considerations

The nurse should be aware of the variations of assessing for jaundice among people of color. To assess for jaundice in a patient with dark skin, look at the sclerae, conjunctivae, palms of hands, soles of feet, and in the buccal mucosal for patches of bilirubin pigment.

hypoactive, or absent. Hyperactive bowel sounds are usually rapid, high pitched, and loud and may occur with hunger or gastroenteritis. Hypoactive bowel sounds are bowel sounds that are infrequent and can occur in patients with a paralytic ileus or following abdominal surgery. Bowel sounds are considered absent if no sounds are auscultated after listening to all four quadrants for 2 to 5 minutes in each quadrant. However, this timing is an area for further research as in practice auscultation for this amount of time is rarely done. With a bowel obstruction, a high-pitched tinkling sound that is proximal to the obstruction and absent distal to the obstruction may be heard. Abnormal or absent bowel sounds are important findings and should be documented and reported to the physician.

Note the presence of any vascular sounds or bruits (swooshing sounds) that are heard with the stethoscope over the aorta, which are normally not present. Patients with chronic liver failure may have a humming sound over their liver. This finding usually indicates overloaded venous circulation in the liver.

LEARNING TIP

In a complete bowel obstruction, air and fluid are propelled forward by peristalsis proximal to the obstruction. This produces proximal high-pitched bowel sounds when the air and fluid create turbulence as they hit the obstruction and are unable to pass. Absent bowel sounds are heard distal to the obstruction. If a patient has a nasogastric (NG) tube for suction, turn off the suction before listening for bowel sounds.

PERCUSSION. Percussion produces a sound that identifies the density of the organs beneath and is performed by the physician or advanced nurse practitioner. Percussion is used to detect fluid, air, and masses in the abdomen and to identify size and location of abdominal organs (especially the liver and spleen). Tympanic high-pitched sounds indicate the location of air, and dull thuds indicate fluid or solid organs.

PALPATION. Light palpation of the abdomen concludes the physical assessment. If the patient is having pain that area should be palpated last. Using the same quadrant approach as previously mentioned, lightly depress the abdomen not more than 0.5 to 1.0 inch during the palpation (see Fig. 32.5). Note any muscle tension, rigidity, masses, or expressions of pain. Deep palpation of the abdomen is done only by physicians and highly skilled nurses such as nurse practitioners.

Abdominal girth is measured by placing a tape measure around the patient's abdomen at the iliac crest. A mark can be made at the measurement site so that measurements

FIGURE 32.5 Abdominal quadrants are auscultated from the right upper quadrant in a clockwise manner.

obtained by others are made at the same location for comparison. Abdominal girth is increased in patients with distention or conditions such as ascites (accumulation of fluid in the peritoneal cavity). Daily measurements should be obtained and recorded to monitor changes when abdominal girth is abnormal.

The advanced nurse practitioner or physician performs all other types of palpation. The liver is not normally palpable, but if enlarged, it may be felt below the right lower rib cage. Rebound tenderness is determined by pressing down on the abdomen a few inches and quickly releasing the pressure. If the patient feels a sharp pain during this procedure, appendicitis may be indicated.

Diagnostic Studies

Use standard precautions when obtaining specimens of body fluids, substances, or blood. Hand hygiene before and after the procedure, wearing gloves, and using goggles if splashing may occur are important.

Laboratory Tests

The complete blood cell count (CBC) reveals if anemia or infection is present (Tables 32.6 and 32.7). Anemia may occur with GI bleeding or cancer. Electrolyte imbalances often occur with GI illness as a result of vomiting, diarrhea, malabsorption, or use of GI suction. **Carcinoembryonic antigen** (CEA) and carbohydrate antigen 19-9 are markers used to monitor GI cancer treatment effectiveness and detect recurrence. These markers are also found in patients with cirrhosis, hepatic disease, and alcoholic pancreatitis and in heavy smokers.

Bilirubin is an excellent measure of liver and gallbladder functioning. In addition, certain enzymes such as alanine aminotransferase (ALT; formerly called serum glutamic pyruvic transaminase [SGPT]), aspartate aminotransferase (AST; formerly called serum glutamic oxaloacetic transaminase [SGOT]), and lactic dehydrogenase (LDH) are

TABLE 32.6 COMMON LABORATORY TESTS USED TO ASSESS GASTROINTESTINAL FUNCTION

Test	Definition	Normal	Significance of Abnormal Findings
		Carcinoembryonic Antigen	
	Blood test to detect protein that is usually found in fetal gut tissue.	Less than 5 ng/mL (nonsmokers)	Increased values indicate possible colorectal cancer, other cancers and inflammatory bowel disease
		Complete Blood Cell Count	
Red Blood Cell Count	Blood test to determine size, shape, color and intracellular structure of red blood cells.	4.2–5.2 million/mm ³ (women) 4.5–6.2 million/mm ³ (men)	Decreased values indicate possible anemia or hemorrhage
Hemoglobin	Blood test to determine the amount of hemoglobin in circulation. Hemoglobin reflects the oxygen-carrying capacity of the blood.	12–16 g/dL (women) 14–18 g/dL (men)	Increased values indicate possible hemoconcentration, caused by dehydration. Decreased levels can indicate anemia, hemorrhage, or hemodilution such as with cirrhosis.
Hematocrit	Measures the percentage of the total blood volume that is made up of RBCs.	38%–46% (women) 42%–54% (men)	Same as hemoglobin.
		Electrolytes	
Calcium	Blood test used to determine serum calcium levels.	8.0–10.5 mg/dL	Decreased values indicate possible malabsorption.
Chloride	Blood test used to determine serum chloride levels.	98–107 mEq/L	Decreased values indicate possible malabsorption.
Potassium	Blood test used to determine serum potassium levels.	3.5–5.0 mEq/L	Decreased values indicate possible GI suction, diarrhea, vomiting, intestinal fistulas.
Sodium	Blood test used to determine serum sodium levels	135–145 mEq/L	Decreased values indicate possible malabsorption and diarrhea.
		Fecal Analysis	
Stool for Occult Blood	Normally minimal quantities of blood are passed into the GI tract. Stool sample is taken to determine if blood is present in the stool.	Negative	Presence indicates possible peptic ulcer, cancer of the colon, ulcerative colitis.
Stool for Ova and Parasites	Stool sample to determine if pathogenic bacteria, or parasites are present in the stool.	Negative	Presence indicates infection.
Stool Cultures	Same as above.	No unusual growth	Presence of pathogens may indicate <i>Shigella</i> , <i>Salmonella</i> , <i>Staphylococcus aureus</i> , or <i>Bacillus cereus</i> infections.
Stool for Lipids (Fecal Fat)	Test that measures the fat content in the stool. Used to confirm diagnosis of steatorrhea.	2–5 g per 24 hours (normal diet)	Increased values indicate possible malabsorption syndrome or Crohn's disease, increased in pancreatic disease.

released by damaged liver cells. Elevations in these blood values in the absence of known trauma or heart muscle damage such as a heart attack are excellent indicators of liver damage.

Stool Tests

Stool samples can be tested for **occult blood** (blood not seen by the naked eye). A series of three tests are usually done to increase the chances of detecting blood. False-positive

occult blood results can occur with bleeding gums following a dental procedure; ingestion of red meat within 3 days before testing; ingestion of fish, turnips, or horseradish; and use of drugs, including anticoagulants, aspirin, colchicine, iron preparations in large doses, NSAIDs, and steroids.

Stool for ova (eggs) and parasites is collected to detect intestinal infections caused by parasites and their ova. The test usually requires a series of three stool specimens collected every second or third day. The stool specimen is col-

TABLE 32.7 COMMON LABORATORY TESTS FOR LIVER, GALLBLADDER, AND PANCREAS DISORDERS

Test	Definition	Normal Range	Significance
Blood			
Alanine aminotransferase (ALT)	Blood test to determine serum ALT levels. ALT is found mainly in the liver. With injury or disease of the liver, ALT is released into the bloodstream.	5–35 IU/dL	↑ in chronic liver failure and hepatitis
Albumin	Blood test which measures serum protein levels.	3.1–4.3 g/dL	↓ in liver disease
Amylase	Blood test to determine serum levels to detect and monitor pancreatitis.	53–123 U/L	↑ in pancreatitis, gallstones
Ammonia	Blood test to determine serum levels. Ammonia is a by-product of protein catabolism.	12–55 mol/L	↑ in chronic liver failure, hepatitis
Aspartate aminotransferase (AST)	Enzyme found in highly metabolic tissues such as the liver. AST is released into blood stream when cells lyse.	8–20 units/L	↑ in chronic liver failure, viral hepatitis, acute pancreatitis
Bilirubin			
Total serum	Sum of the conjugated and unconjugated bilirubin.	0.1–1.0 mg/dL	↑ in liver and gallbladder disease with red blood cell destruction
Conjugated (direct)	Bilirubin which is conjugated in the liver (joined with glucuronide).	0.0–0.4 mg/dL	↑ with gallstones, gallbladder obstruction, extensive liver metastasis
Unconjugated (indirect)	Bilirubin in the blood stream which has not yet passed through the liver.	0.1–1.0 mg/dL	↑ with red blood cell destruction or liver disease such as hepatitis or cirrhosis
Calcium	Blood test to determine serum levels.	9–10.5 mg/dL	↓ with acute pancreatitis, liver disease, or malabsorption
Cholesterol	Blood test to determine serum levels.	150–200 mg/dL	↑ in pancreatitis, gallbladder disease; ↓ may indicate severe liver disease. Patient should fast 12–14 hours prior to test.
Lactic dehydrogenase (LDH)	Blood test to determine levels of this intracellular enzyme which is released with injury or disease.	110–250 IU/L	↑ in liver disease
Potassium	Blood test to determine serum levels. Major cation within the cell.	3.5–5.0 mEq/L	↓ with diarrhea, intestinal fistulas, vomiting, suctioning
Prothrombin time	Blood test used to determine adequacy of clotting mechanism. Used to monitor anticoagulation therapy with warfarin (Coumadin).	11–12.5 s	↑ in liver disease, vitamin K deficiency
Urine			
Urine amylase	Urinalysis examination used to assist in making the diagnosis of pancreatitis.	Depends on test	↑ in acute pancreatitis
Urine bilirubin	Urinalysis exam used to measure predominantly conjugated bilirubin.	Negative	↑ in chronic liver failure, hepatitis, biliary obstruction. Used primarily for screening purposes.
Urobilinogen	Included in a routine urinalysis to support the diagnosis of hemolysis.	0.3–1.0 Ehrlich unit in 2 hr	↑ with destruction of red blood cells, hepatitis, chronic liver failure, obstructive jaundice

lected using a tongue blade, placed in a container with a preservative, and sent immediately to the laboratory. The stool must be examined within 30 minutes of collection. False-negative results can occur as a result of urine in the specimen or if the specimen is not fresh.

Stool cultures (sterile collection technique) are done to determine the presence of pathogenic organisms in the GI

tract. Stool can also be examined for lipids (fat). Excessive secretion of fecal fats (**steatorrhea**) may occur in various digestive and absorptive disorders. The stools are collected for 72 hours and stored on ice if necessary before being sent to the laboratory.

(Text continued on page 650)

TABLE 32.8 DIAGNOSTIC PROCEDURES FOR GASTROINTESTINAL SYSTEM

Procedure	Definition/Normal Finding	Significance of Abnormal Findings	Nursing Management
Noninvasive			
<i>Radiologic Flat Plate of Abdomen</i>	X-ray of the abdomen showing an anterior to posterior view.	Stool or gas may be detected as with constipation or bowel obstruction.	No preparation is necessary.
<i>Upper GI Series</i>	X-ray examination of the esophagus, stomach, duodenum, and jejunum using an oral liquid radiopaque contrast medium. A fluoroscope outlines the contours of the organs. Normal finding should show normal anatomic structures.	Used to detect such things as strictures, ulcers, tumors, polyps, hiatal hernias, and motility problems.	Clear liquid diet night before procedure. NPO for 6–8 hours prior to test. No smoking morning of procedure. Provide increased fluids and laxative after procedure.
<i>Lower GI Series (Barium Enema)</i>	Colon is filled with barium and x-rays are performed to visualize the position, movements, and filling of the colon. Normal finding would be no polyps, inflammation, diverticula, stenosis, or tumors.	Tumors, diverticula, stenosis, obstructions, inflammation, ulcerative colitis, and polyps can be detected.	Patient is placed on a low-residue or clear liquid diet for 2 days before the test. Laxatives, bowel cleansing solutions (such as GoLYTELY), and enemas may be administered the evening before the test. The bowel needs to be adequately cleaned out for adequate visualization during the test. Encourage fluids and possibly laxatives to clear barium from colon.
<i>Computed tomography (CT)</i>	Uses a beam of radiation to allow three-dimensional visualization of abdominal structures. Diluted oral barium or other contrast media may be used to distinguish normal bowel from abnormal masses. Normal finding is no masses.	May show abnormal masses.	Clear liquid diet the morning of the test. If a contrast medium is to be used note allergies to contrast media. Consent form is signed. NPO for 2 to 4 hours before the procedure.
<i>Ultrasonography</i>	High-frequency sound waves are passed through the abdomen to view soft-tissue structures.	Abnormal soft tissue structures.	NPO after midnight.
Invasive			
<i>Nuclear Scanning (cholescintigraphy, ^{99m}Tc Di-isopropyl Iminodiacetic Acid Scintigraphy [DISIDA], Hepatobiliary Imidodiacetic Acid [HIDA] scan, or imidodiacetic Acid [IDA] Angiography)</i>	Involves injecting a patient with a small amount of intravenous radioactive isotope. Serial images of the gallbladder, bile duct and duodenum are recorded. Normal finding is no evidence of biliary disease, obstruction or ejection problems. A contrast medium is injected and identifies abnormalities of vascular structure and function, observes masses, and notes bleeding sites. A normal finding is no evidence of abnormal vasculature or masses.	Confirms any biliary disease, ejection problem or obstruction. Neoplasms of liver, gallbladder or pancreas. May indicate abnormal vasculature.	Fasts for 2–6 hours prior to procedure. May be given cholecystokinin. Ask if allergies to contrast media or iodine. NPO for 2–8 hours prior to test. Stop medications that interfere with clotting about 1 week prior to exam. Assess for bleeding and hematoma formation after the exam.
<i>Endoscopy</i>	Uses a tube and a fiberoptic system (endoscope) for observing the inside of a hollow organ or cavity. The physician can also remove polyps, take biopsy specimens, or coagulate bleeding sites that are identified.	Strictures, polyps, tumors, bleeding.	Consent form is signed for any endoscopic procedure.

Procedure	Definition/Normal Finding	Significance of Abnormal Findings	Nursing Management
		Invasive	
<i>Esophagogastroduodenoscopy (EGD)</i>	Endoscopy which visualizes the esophagus, the stomach, and the duodenum. Biopsy or cytology specimens can be obtained. Normal findings would indicate all normal structures without inflammation, bleeding or cancer.	Abnormalities such as inflammation, cancer, bleeding, injury, and infection can be detected.	See endoscopy. May use a preoperative checklist. NPO for 8–12 hours. May need to premedicate to relax patient. Monitor vital signs and prevent aspiration after procedure. Monitor for pain, bleeding, fever and dysphagia after the procedure.
<i>Endoscopic retrograde cholangiopancreatography (ERCP)</i>	Endoscopy which permits the physician to visualize the liver, gallbladder, and pancreas. May use contrast medium. An endoscope is passed through the esophagus to the duodenum, where dye is injected that outlines the pancreatic and bile ducts. Normal findings would indicate all normal structures without inflammation, bleeding, or cancer.	Liver, gallbladder, or pancreas disease.	See endoscopy and EGD. NPO after 8 PM the night before exam. Check prothrombin time prior to procedure. Monitor for pain, fever, chills which could indicate infection. Monitor for onset of pancreatitis.
<i>Proctosigmoidoscopy</i>	Examination of the distal sigmoid colon, the rectum, and the anal canal using a rigid or flexible endoscope (sigmoidoscope). Normal finding would be no ulcerations, punctures, laceration, tumors, hemorrhoids, polyps, fissures or fistulas.	Ulcerations, punctures, lacerations, tumors, hemorrhoids, polyps, fissures, fistulas, early malignancies and abscesses can be detected.	Clear liquid diet for 24 hours prior to exam. Laxative the night before exam. Enemas the morning of the exam.
<i>Colonoscopy</i>	Visualization of the lining of the large intestine to identify abnormalities through a flexible endoscope, which is inserted rectally. A biopsy specimen may be obtained or polyps be removed during the colonoscopy. A normal finding would show a normal colon without signs of inflammation, ulcers, polyps, or cancer.	Colon cancer, polyps, inflammation.	Clear liquid diet for 24 hours prior to exam. Bowel preparation (GoLYTELY) the night before exam. Possibly enemas the evening prior to examination and the morning of the examination. Patient will receive conscious sedation during examination. Monitor for complications such as hemorrhage and severe pain. Instruct patient that cramping will last for several hours after test, and blood may be present in stool if specimen was taken.
<i>Gastric Analysis</i> Basal cell secretion test Gastric acid stimulation test	Gastric analysis measures the secretions in the stomach. For the basal cell secretion test, a nasogastric (NG) tube is inserted and the contents of the stomach are suctioned out through the tube using a syringe. Stomach contents are collected at intervals. The gastric acid stimulation test measures the amount of gastric acid for 1 hour after subcutaneous injection of a histamine drug.	Diagnosis of duodenal ulcer, gastric carcinoma, pyloric or duodenal obstruction, and pernicious anemia are made.	Before the basal cell secretion test, the patient should avoid taking any drugs that could interfere with gastric acid secretion, such as cholinergics and antacids. The patient is NPO after midnight the night before the test.
Endoscopic ultrasonography	Endoscopic ultrasonography is performed through the endoscope using sound waves.	Tumors in various GI structures and organs.	Similar to endoscopy.
Percutaneous liver biopsy	The physician generally inserts a needle through the skin and into the liver to withdraw a small sample for examination. Normal finding would be negative for cancer, cirrhosis, hepatitis or other liver diseases.	May identify cancer, cirrhosis, hepatitis, or other causes of liver disease.	Signed consent. Ensure laboratory tests such as CBC, coagulation studies have been ordered and reviewed. NPO for 6–8 hours prior to procedure. Rest several hours after procedure; restricted activity 1 day. Monitor biopsy site pressure dressing for bleeding. Monitor vital signs after procedure. Coughing and straining avoided after the procedure. Medicate for pain.

Radiographic Tests

Flat Plate of the Abdomen

A flat plate of the abdomen is an x-ray examination giving an anterior-to-posterior view (see Table 32.8). Radiographs visualize abdominal organs and can detect such abnormalities as tumors, obstructions, and strictures. For an x-ray examination, the patient should be dressed in a hospital gown without any metal such as zippers, belts, or jewelry. Pregnant patients or those thought to be pregnant should avoid x-ray examinations.

Upper Gastrointestinal Series (Barium Swallow)

An **upper gastrointestinal series** (UGI series) is an x-ray examination of the esophagus, stomach, duodenum, and jejunum using an oral liquid radiopaque contrast medium (barium) and a **fluoroscope** to outline the contours of the organs. An upper gastrointestinal (UGI) series is used to detect such things as strictures, ulcers, tumors, polyps, hiatal hernias, and motility problems.

The patient receives nothing by mouth (*non per os* in Latin, abbreviated NPO) for 6 to 8 hours before the procedure. Usually the patient has a clear liquid supper the night before the procedure and is then NPO until the procedure is done. Because smoking can stimulate gastric motility, the patient is discouraged from smoking the morning of the procedure. Patient teaching includes information about the patient's diet before and after the procedure, the barium ingestion, and the appearance of stools afterward.

During the procedure, the patient drinks the thick, chalky barium while standing in front of a fluoroscopic tube. X-ray films are taken in various positions and at specific intervals to visualize the outline of the organs and to note the passage of the barium through the GI tract. The patient should understand that the procedure may take several hours depending on the rate at which the barium moves through the patient's gastrointestinal tract.

A laxative is usually ordered after the procedure to expel the barium and prevent constipation or a **barium impaction**. The patient is instructed to drink 12 8-oz glasses of water per day for several days to prevent dehydration, which can lead to constipation. The abdomen is assessed for distention and bowel sounds. The stool is monitored to determine whether the barium has been completely eliminated. Initially, the barium causes the patient's stool to be white, but it should return to its normal color within 3 days. Constipation with distention indicates a barium impaction.

Lower Gastrointestinal Series

The **lower GI series** (barium enema) is performed to visualize the position, movements, and filling of the colon. Tumors, diverticula, stenosis, obstructions, inflammation, ulcerative colitis, and polyps can be detected. The patient is placed on a low-residue or clear liquid diet for 2 days before the test to empty the bowel. Laxatives, bowel-cleansing solutions (such as GoLYTELY), and enemas may be administered the evening before the test. GoLYTELY is chilled and drunk full strength with no ice, 8 oz every 10 minutes for a total of 4 L. Inform the patient that a watery diarrhea will begin in about 1 hour and continue up to 5 hours as the bowel is cleared. This is necessary for adequate visualization during the procedure. Inadequate bowel preparation may result in poor test results or test cancellation (Fig. 32.6). The patient either receives a clear liquid diet the morning of the test or is NPO after midnight the night before. The area around the rectum should be clean before the patient is sent for the procedure. If the patient has active inflammatory disease of the colon or suspected perforation or obstruction, a barium enema is contraindicated. Active GI bleeding may also prohibit the use of laxatives and enemas.

During the procedure, barium is instilled rectally and x-ray films are taken with or without fluoroscopy. The patient may experience some abdominal cramping and an urge to have a bowel movement during the procedure. The patient is

FIGURE 32.6 (A) An image of a patient who was poorly prepared for a barium enema. (B) An image of a patient who was adequately prepared for a barium enema. (Courtesy Dr. Russell Tobe.)

told to take slow, deep breaths and to tighten the anal sphincter. The rate of flow of the barium is slowed until the cramping diminishes. The procedure takes about 15 minutes, and the patient is allowed to use the bathroom immediately after the procedure.

The patient's stools are monitored after the procedure to note if all the barium is passed, as with the UGI series. Constipation development is monitored. The patient is encouraged to drink at least one 8-oz glass of liquid per hour for the next 24 waking hours to help remove the barium. Laxatives may be ordered to help clear the barium from the colon. The patient is told to report any abdominal pain, bloating, or absence of stool, all of which could indicate constipation or bowel obstruction, as well as any rectal bleeding.

CRITICAL THINKING

Mrs. Pearl

■ Mrs. Pearl is a 95-year-old woman undergoing a lower GI series for complaints of abdominal pain. As her nurse, what concerns might you have for Mrs. Pearl as she undergoes this test? How can you address them?

Suggested answers at end of chapter.

Computed Tomography

Computed tomography (CT) uses a beam of radiation to allow three-dimensional visualization of abdominal structures. Diluted oral barium or other contrast media may be used to distinguish normal bowel from abnormal masses. The patient may have a clear liquid diet the morning of the test. If a contrast medium is to be used, any allergies to iodine or contrast media are noted, a consent form is signed, and the patient is NPO for 2 to 4 hours before the procedure.

Nuclear Scanning

Nuclear scanning involves injecting a patient with a small amount of radioactive isotope. The scan may be called a cholescintigraphic, DISIDA, HIDA, or IDA scan, depending on the radioactive isotope and exact procedure that is used. Prior to the procedure, the patient fasts and does not chew gum for at least 2 to 6 hours. After the injection, the isotope is secreted into the bile and goes anywhere the bile goes. Visualization of these areas occurs about 60 minutes after the IV injection. The scanning camera (like a Geiger counter) traces the path of the isotope as it travels through the bile ducts, gallbladder, and intestines. Serial images are recorded. A patient may be given a fatty meal or cholecystokinin to stimulate emptying of the gallbladder. Any biliary disease, ejection problem, or obstruction can be confirmed with this examination. The test takes about 2 hours.

Angiography

Angiography may be ordered for patients with symptoms of arterial occlusive disease of the hepatic, biliary, and pan-

creatic arterial vessels. It is used to evaluate suspected neoplasms in these organs. Medications that might cause bleeding, such as aspirin, NSAIDs, or anticoagulants, are stopped about 1 week prior to the procedure. A contrast medium is injected and identifies abnormalities of vascular structure and function, masses, and show bleeding sites. Prior to the procedure, the patient usually is NPO for 2 to 8 hours. The injection of contrast medium is done about 1 hour before the examination. Radiographs are taken about every 20 minutes for 1 hour or until the structures are readily viewed. The radiopaque material is iodine based, so ask the patient about any allergies to iodine. Following the procedure, observe for bleeding at the puncture site. Patients with liver disease may have clotting disorders and should be assessed for bleeding or hematomas at the site. Monitor pulses distal to the insertion site.

Liver Scan

A liver scan involves injecting a slightly radioactive medium that is taken up by the liver. An instrument is passed over the liver that records the amount of material taken up by the liver and forms a composite "picture" of the liver. The physician may be able to determine tumors, masses, and abnormal size and patterns of blood vessel. The procedure takes a short time.

Endoscopy

Endoscopy uses a tube and a fiberoptic system (endoscope) for observing the inside of a hollow organ or cavity. In addition to viewing the structures, the physician can also remove polyps, take biopsy specimens, or coagulate bleeding sites that are identified.

A consent form must be signed for any endoscopic procedure.

Esophagogastroduodenoscopy

Esophagogastroduodenoscopy (EGD) visualizes the esophagus (**esophagoscopy**), the stomach (**gastroscopy**), and the duodenum. Abnormalities such as inflammation, cancer, bleeding, injury, and infection can be seen.

The procedure is explained to the patient. Because this is an invasive procedure, patients may be asked to sign an operative consent form, and a preoperative checklist may be necessary, depending on institution policy. To prevent aspiration of stomach contents into the lungs if vomiting occurs, the patient is NPO for 8 to 12 hours before the procedure. Sedatives such as diazepam (Valium) or midazolam (Versed) may be given before the procedure to help relax the patient. The patient may be given atropine sulfate to dry secretions in the mouth. A local anesthetic in spray or gargle form is administered just before the scope is inserted to inhibit the gag reflex.

The patient is placed on the left side, and the flexible fiberoptic endoscope tube is passed orally down the GI tract (Fig. 32.7). Photographs or videotapes of the procedure can be made. Biopsy or cytology specimens can be obtained.

FIGURE 32.7 Gastroscopy.

After the procedure, vital signs are checked as ordered. Patients are placed on one side to prevent aspiration while sedation and the local anesthetic wear off. Patients are NPO until the gag reflex returns (usually within 4 hours). Patients are assessed for signs of perforation, which include bleeding, fever, and dysphagia. Midesophageal perforation can cause referred substernal or epigastric pain. Blood loss secondary to perforation can lead to hematoma formation, which in turn can result in cyanosis and referred back pain. Distal esophageal perforation may result in shoulder pain, dyspnea, or symptoms similar to those of a perforated ulcer. The patient may have a sore throat for a few days.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) permits the physician to visualize the liver, gallbladder, and pancreas (Fig. 32.8). The procedure allows both direct viewing and use of contrast medium. An endoscope is passed through the esophagus to the duodenum, where dye is injected that outlines the pancreatic and bile ducts.

FIGURE 32.8 Endoscopic retrograde cholangiopancreatography. (Modified from Watson, J, and Jaffe, S: *Nurse's Manual of Laboratory and Diagnostic Tests*, ed 2. FA. Davis, Philadelphia, 1995, p 525, with permission.)

The patient is prepared for an ERCP in the same manner as for an EGD, with nothing by mouth after 8 p.m. the night before the examination. In addition, the patient is asked about allergies to iodine. Ensure that any ordered laboratory studies, such as a prothrombin time, have been done before the procedure and that the patient has removed dentures. Follow-up care is similar to an EGD. In addition, the nurse is alert to patient complaints such as increased right upper quadrant pain, fever, or chills, which may indicate infection. Hypotension, tachycardia or rapid heart rate, increasing RUQ pain, nausea, or vomiting may indicate perforation or the onset of pancreatitis. Report such findings immediately.

Lower Gastrointestinal Endoscopy

PROCTOSIGMOIDOSCOPY. Proctosigmoidoscopy is the examination of the distal sigmoid colon, the rectum, and the anal canal using a rigid or flexible endoscope (sigmoidoscope). Ulcerations, punctures, lacerations, tumors, hemorrhoids, polyps, fissures, fistulas, and abscesses can be detected. Malignancies at an early stage can be detected, so an annual examination for patients 40 years old and older is recommended.

Proctosigmoidoscopy requires the lower bowel to be cleaned out. The patient usually receives a clear liquid diet 24 hours before the test and a laxative the night before the test. The morning of the procedure a warm tap-water enema or sodium biphosphate (Fleet) enema is given. Bowel preparation may not be ordered for patients with bleeding or severe diarrhea.

The patient is positioned in a left lateral knee-to-chest position, which allows the sigmoid colon to straighten by gravity. A rigid proctoscope is used to visualize the rectum. A flexible scope is then used to permit visualization above the rectosigmoid junction. Patients are told they may feel pressure as though they are going to have a bowel movement. During the procedure, one or more small pieces of intestinal tissue may be removed (biopsy specimens). Rectal or sigmoid polyps are removed with a snare. An electrocoagulating current is used to cauterize sites to prevent or stop bleeding. Specimens are labeled and sent to the pathology laboratory immediately for examination.

After the procedure, the patient is allowed to rest for a few minutes in the supine position to avoid orthostatic hypotension when standing. Pain and flatus may occur from instilled air. The patient is observed for signs of perforation such as bleeding, pain, and fever.

COLONOSCOPY. Colonoscopy provides visualization of the lining of the large intestine to identify abnormalities through a flexible endoscope, which is inserted rectally. A biopsy specimen may be obtained or polyps be removed during the colonoscopy.

The patient receives a liquid diet 24 hours before the test and is NPO after midnight before the procedure. A bowel preparation solution such as GoLYTELY is given the night before the procedure. Drinking this solution can be

SAFETY TIP

Older patients may experience fatigue and weakness during bowel preparation and may be unable to complete it. Monitor the patient for distress. Consult the physician if you note any patient distress during bowel preparation. Observe the patient often because defecation urgency, especially in unfamiliar surroundings, may create a fall risk.

unpleasant for the patient. In addition, a laxative, suppository (bisacodyl [Dulcolax]), or enema may be needed.

Conscious sedation, for example, midazolam (Versed) is used to relax and ease pain during the procedure. The patient is positioned on the left side with the knees bent. A small amount of air is instilled into the colon to help the physician visualize the bowel. The air causes pressure and may be uncomfortable for the patient. The patient is encouraged to relax and take slow deep breaths through the nose and out the mouth. Vital signs are monitored throughout the procedure to watch for a vasovagal response, which can lead to hypotension and bradycardia.

After the procedure, the patient is monitored until stable. Complications such as hemorrhage or severe pain are reported. When giving the patient discharge instructions, explain that flatus and cramping will occur for several hours after the test, that blood may be present in the stool if a biopsy specimen was taken, and to report problems to the physician.

Gastric Analysis

Gastric analysis measures the secretions in the stomach. Diagnoses of duodenal ulcer, gastric carcinoma, pyloric or duodenal obstruction, and pernicious anemia are made. A diagnosis of pernicious anemia is ruled out by the finding of acid. A diagnosis of gastric carcinoma may be made by the presence of cancer cells in the gastric secretions. There are two tests performed in gastric analysis: the **basal cell secretion test** and the **gastric acid stimulation test**.

Before the basal cell secretion test, the patient should avoid taking any drugs that could interfere with gastric acid secretion, such as cholinergics and antacids. The patient is NPO after midnight the night before the test. For the procedure, a nasogastric (NG) tube is inserted and the contents of the stomach are suctioned out through the tube using a syringe. The NG tube is connected to wall suction, and stomach contents are collected every 15 minutes for 1 hour. The specimens are labeled according to the time they were collected and the order in which they were obtained. The gastric acid is tested for pH using indicator paper or a pH meter. The amount of gastric acid is also measured. Too much hydrochloric acid may indicate a peptic ulcer; too little could be a sign of cancer or pernicious anemia.

The gastric acid stimulation test measures the amount of gastric acid for 1 hour after subcutaneous injection of a histamine drug. If abnormal results occur, radiographic tests or endoscopy can be done to determine the cause.

Ultrasonography

The use of high-frequency sound waves through the abdomen allows the physician to view soft-tissue structures. The sound waves reflect varying images based on the density of the soft tissues in the abdomen. The patient is asked not to take anything by mouth after midnight on the day of the examination. A clear gel is applied to the abdomen and to the transducer on the sonograph. The gel improves the conduction of sound waves and thus improves the images obtained. The transducer is placed on the skin and moved over the abdomen while the technician views the sonograph screen and takes periodic pictures. The procedure takes about half an hour and requires no follow-up care.

Endoscopic Ultrasonography

Endoscopic ultrasonography is performed through the endoscope using sound waves. Tumors can be detected in various GI structures and organs. Preprocedure and postprocedure care are similar to those for endoscopic care. During the test the patient must lie still while a transducer with gel is moved back and forth over the abdomen to produce images.

Percutaneous Liver Biopsy

If less invasive tests do not aid in diagnosis of liver disease, a liver biopsy may be done. This may be done to identify cancer, cirrhosis, hepatitis, or other causes of liver disease. The physician generally inserts a needle through the skin and into the liver to withdraw a small sample for examination. This procedure places the patient at risk for bleeding because the liver is highly vascular and because many patients with liver disease have reduced clotting ability.

Before the biopsy, ensure that the patient understands the procedure and that a consent has been signed if required by institution policy. You should also ensure that laboratory tests, such as a complete blood cell count and coagulation studies, have been completed and reviewed as ordered. The patient may be ordered nothing by mouth for 6 to 8 hours before the procedure. Baseline vital signs are taken, and a sedative is given if ordered.

During the procedure the nurse assists the physician to position the patient on his or her back or left side and assists the patient to hold very still while the needle is being introduced. The physician may also ask the patient to exhale and hold his or her breath during the needle insertion.

After the biopsy, the patient should remain on bedrest for 24 hours. The patient lies on the right side for the first 2 hours with a small pillow or rolled towel under the biopsy site to provide pressure and prevent bleeding. Vital signs and the site are monitored for signs of bleeding. The patient is advised to avoid coughing or straining. Analgesics are offered for comfort if ordered.

CRITICAL THINKING

Mr. Wozynski

■ Mr. Wozynski is admitted with chronic liver failure and jaundice. What specific laboratory value can you expect to be elevated related to his jaundice? Mr. Wozynski's physician orders a liver biopsy. Why is it important for you to check Mr. Wozynski's laboratory reports before the procedure?

Suggested answers at end of chapter.

THERAPEUTIC INTERVENTIONS

Gastrointestinal Intubation

Gastrointestinal intubation is the placement of a tube within the GI tract for therapeutic or diagnostic purposes (Fig. 32.9). When the GI tube is inserted orally into the stomach it is an orogastric tube. When it is from the nares into the stomach, it is referred to as a nasogastric tube. A nasointestinal tube is a tube inserted from the nares into the intestines. A variety of tubes are available, each designed for

specific purposes (Table 32.9). Orogastric tubes reduce sinus infection risk as they do not block normal drainage of the sinuses as nasal tubes may. Nasogastric and nasointestinal tubes are inserted for a variety of reasons, but the main purposes for their use include the following:

- To remove gas and fluids from the stomach or intestines (decompression)
- To diagnose GI motility and to obtain gastric secretions for analysis
- To relieve and treat obstructions or bleeding within the GI tract
- To provide a means for nutrition (**gavage** feeding), hydration, and medication when the oral route is not possible or is contraindicated
- To promote healing after esophageal, gastric, or intestinal surgery by preventing distention of the GI tract and strain on the suture lines
- To remove toxic substances (**lavage**) that have been ingested either accidentally or intentionally and to provide for irrigation

Feeding tubes include esophagostomy, **gastrostomy**, or jejunostomy tubes (see Fig. 32.9). Nasogastric tubes are usually temporary and short term. Esophagostomy, gastrostomy, or jejunostomy tubes are generally used for longer term nutrition delivery.

FIGURE 32.9 Feeding tubes. (A) Nasogastric tube connected to tube feeding pump. (B) Feeding tube placement sites (esophagostomy, nasointestinal, gastrostomy, and jejunostomy). (C) Gastrostomy tube insertion site.

TABLE 32.9 GASTROINTESTINAL TUBES

Tube	Uses and Description	Nursing Considerations
	Gastric	
<i>Levin Tube</i>	Single lumen, may be used for gastric decompression, irrigations, lavages, and feedings.	Tube is not vented; avoid use with suction to prevent injury to stomach lining.
<i>Salem Sump Tube</i>	Double lumen, “pigtail” acts as an air vent and prevents excess suction, which could damage stomach lining. Air vent must not be plugged off. Used for decompression, irrigations, and lavage.	May be used with continuous suction because of air vent.
<i>Weighted, Flexible Feeding Tubes with Stylets (Nutriflex, Keofeed)</i>	Small-bore tubes for tube feedings only; less injury, remains in place for extended periods.	Suction collapses tube. Use a 10-mL syringe or greater, because smaller syringe creates too much pressure and possible rupture of tube.
	Intestinal	
<i>Miller-Abbott Tube</i>	Double-lumen tube used to drain and decompress the small intestine in cases of partial or complete obstruction; one lumen for aspiration, the other to inflate the balloon with mercury so that the tube is weighted and moves by gravity and peristalsis into the small intestine.	Rarely used, this tube is inserted by the physician or a specially trained nurse. Tube is not secured with tape, but passed through gauze taped to patient’s forehead to allow tube to advance into intestines. Usually the tube advances 1–2 inches every 2 hours until it reaches small intestine; turning and ambulating the patient, if possible, facilitates tube’s advancement.
<i>Cantor Tube, Harris Tube</i>	Single-lumen tubes with distal mercury-filled balloons and proximal drainage ports.	Precautions with mercury disposal.

See Box 32.6 Nursing Care for Insertion and Maintenance of Nasogastric Tubes. Provide emotional support and explanation to the patient and significant others to facilitate the process of tube insertion and maintenance. Assessing tube placement is essential to prevent complications or death from incorrect tube placement. Nasogastric tube placement must be assessed after insertion and then intermittently to ensure that it is in the correct position and not in the lungs (most common), esophagus, pleural space, or brain.

Gastrostomy or jejunostomy tube placement is verified by comparing current length with documented insertion length. The tube may not be in the desired position if the current and insertion tube lengths are different, so the physician should be consulted before using the tube.

Tube Feedings

A tube feeding supplies patients with nutrition when oral intake is not possible. Feedings can be given to the patient as a supplement or to provide the patient’s total nutritional needs. If the esophagus and stomach need to be bypassed, tube feedings are delivered directly into the duodenum or proximal jejunum. Reasons for administering tube feedings include inability to swallow, severe burns or trauma to the face or jaw, debilitation, mental retardation, and oropharyngeal or esophageal paralysis. Complications associated with tube feedings are presented in Table 32.10.

Tube Feeding Formulas

Tube feeding formulas are chosen by the physician based on the patient’s nutritional needs, the consistency of the formula, the size and location of the tube, the method of delivery, and the convenience for the patient at home. Com-

mercially prepared formulas are composed of protein, carbohydrates, and fats. When patients receive tube feedings, their daily water needs in addition to any water supplied by the feeding should be considered. Dietitians can help calculate the patient’s water needs. The water used to flush the tube or administer medications can be considered as satisfying part of the patient’s daily total water needs. Dehydration can occur if the patient’s water needs are not met.

Method of Feeding Delivery

Feedings are administered either by gravity or by a controlled pump that delivers continuous volume through the

(Text continued on page 658)

CRITICAL THINKING

Mrs. Wood

■ Mrs. Wood is receiving a tube feeding because of dysphagia, the cause of which is being investigated. Mrs. Wood is not receiving any medications. You note that Mrs. Wood’s tongue is bright red with deep furrows. She states her mouth is very dry. Her skin remains tented when skin turgor is checked.

1. What do Mrs. Wood’s assessment findings indicate?
2. How would you document your assessment findings?
3. Why might Mrs. Wood be exhibiting this condition?
4. What actions could you take for this condition?
5. How would you record the total of Mrs. Wood’s 8-hour intake which is tube feeding at 50 mL per hour?

Suggested answers at end of chapter.

Box 32.6**Nursing Care for Insertion and Maintenance of Nasogastric Tubes**

1. Explain the procedure and reason for the tube to the patient. Inform the patient how he or she can help by swallowing when instructed to do so if able.
2. Assist patient into high Fowler's position (right side lying as an alternative) as able.
3. Measure tube for correct insertion length: Hold insertion end of tube from nose tip to earlobe to xyphoid process and mark tube with tape at this point.
4. Select naris that is straightest and from which patient breathes the easiest, because tube is inserted more easily in a straight naris.
5. Lubricate tube with water-soluble lubricant before insertion.
6. Insert tube as follows:
 - As tube is inserted, aim it along the floor of the naris and laterally. Rotate the tube gently if resistance is met.
 - Encourage patient to swallow to advance the tube. Drinking water with a straw or ice chips facilitates the swallowing process if patient is able.
 - If patient is unconscious, flex patient's head to bring chin toward chest to help prevent tube from passing into the trachea.
 - Observe for coiling of the tube in patient's mouth.
 - To assist in assessing correct placement, insert tube to level of carina tracheae and listen for air at end of tube. If air is present, remove tube. If no air is heard, advance tube to stomach.
 - If at any time the patient begins to cough uncontrollably, becomes cyanotic, or begins to experience any respiratory distress, remove the tube, allow rest time, and then reattempt insertion.
7. After tube is inserted to premeasured length, confirm gastric placement per institutional policy using the following methods¹:
 - Flexible feeding tubes should have x-ray confirmation.
 - Aspirate for gastric contents with a 30- or 60-mL catheter-tipped syringe:
 - Gastric fluid—green with sediment; colorless and clear with off-white or tan mucus; brown if digested blood is present.
 - Esophageal contents—scant fluid, aspirate is unreliable for confirmation.
 - Intestinal fluid—light to dark golden yellow to brownish green.
 - Respiratory secretions—off-white or tan mucus.
 - Pleural fluid (with stylet perforation)—watery, straw colored, may be blood-tinged from perforation.
 - Measure pH of secretions obtained to rule out respiratory placement:
 - Gastric pH range is acidic (1–5).
 - Respiratory and intestinal secretions are alkaline with pH >6.
 - If any doubts about gastric placement exist, notify physician for x-ray order to confirm tube placement.
8. Secure tube in place with tape so that pressure is not put on the naris. Provide daily skin care to taped area to prevent skin breakdown. Slipknot a rubber band around tube and pin rubber band to patient's gown.
9. If suction is ordered, low intermittent suction is used with nonvented tubes (Levin); vented tubes (Salem) may have continuous low suction.
10. If patient is NPO, provide frequent care to keep oral mucous membranes moist. When suction is used, prevent excessive intake of ice chips, if ordered, because electrolyte imbalances may result when the water is suctioned out along with electrolytes. Normal saline instead of water can be made into ice chips to help prevent imbalances.
11. Gastric placement is periodically confirmed, especially before instilling anything into the tube¹:
 - Review any recent chest or abdominal x-ray report with tube status.
 - Verify tube position marking is in original position. If not, reposition as necessary.
 - Bolus feedings/medications: 4 hours after last feeding, aspirate fluid for pH and appearance.
 - Continuous feedings: Note tolerance. If normal along with correct tube marking and any confirming x-ray reports, continue feeding.
 - For patients at high risk of dislodgement (e.g., those who are vomiting or have severe coughing) with tube movement, consider x-ray examination.
12. The tube is flushed at intervals, every 2–4 hours, to maintain patency. When tube feedings are administered, residual feeding amounts are checked at specified intervals (hourly when begun, every 4 hours thereafter) to ensure the feeding is being absorbed.
13. After tube placement, record accurate intake and output, including drainage, vomitus, and irrigation solution instilled (use only normal saline to prevent electrolyte imbalance).

TABLE 32.10 COMMON MECHANICAL, GASTROINTESTINAL AND METABOLIC COMPLICATIONS OF TUBE-FED PATIENTS AND PREVENTION STRATEGIES

Complication	Prevention Strategies
Mechanical	
<i>Tube Irritation</i>	Consider oral tubes and avoid nasal tubes due to sinus infection risk. Oral tubes also help prevent ventilator associated pneumonia. Consider using a smaller or softer tube. Lubricate the tube before insertion. Ensure tube is secured in place.
<i>Tube Obstruction</i>	Flush tube after use. Do not mix medications with the tube feeding formula. Use liquid medications if available. Crush other medications thoroughly (if not contraindicated to crush). Use an infusion pump to maintain a constant flow (see Fig. 32.9)
<i>Aspiration and Regurgitation</i>	Feeding should not be started until tube placement is radiographically confirmed. Avoid use of blue dye to detect aspiration as it has not been demonstrated to be predictive and the dye can be absorbed in critically ill patients, who then turn blue and can die. Elevate head of the patient's bed more than or equal to 30 degrees at all times. Discontinue feedings at least 30–60 minutes before treatments requiring head to be lowered (e.g., chest percussion). If the patient has an endotracheal tube in place, keep the cuff inflated during feedings. Test pH of aspirate with pH paper or meter. a. pH of tracheobronchial secretions is alkaline, >7.4. b. pH of gastric secretions is acidic, <5.0. c. As the tube moves from the acid stomach to the alkaline duodenum, pH will change from acid to alkaline.
Tube Displacement	Place a black mark at the point where the tube, when properly placed, exits the nostril. Replace tube and obtain physician's order to confirm with x-ray imaging.
Gastrointestinal	
<i>Cramping, distention, bloating, gas pains, nausea, vomiting, diarrhea*</i>	Practice good personal hygiene when handling any feeding product. Bring formula to room temperature before feeding. Initiate and increase amount of formula gradually. Change to a lactose-free formula. Decrease fat content of formula. Administer drug therapy as ordered (e.g., Lactinex, kaolin-pectin, Lomotil). Change to formula with a lower osmolality. Change to formula with a different fiber content. Evaluate diarrhea-causing medications the patient may be receiving (e.g., antibiotics, digitalis preparations).
Metabolic	
<i>Dehydration</i>	Note the patient's fluid requirements before treatment. Monitor hydration status. Provide adequate daily water.
<i>Overhydration</i>	Note the patient's fluid requirements before treatment. Monitor hydration status.
<i>Hyperglycemia</i>	Initiate feedings at a low rate. Monitor blood glucose. Use hyperglycemic medication if necessary.
<i>Hypernatremia</i>	Select a low-carbohydrate formula. Note the patient's fluid and electrolyte status before treatment. Provide adequate fluids.
<i>Hyponatremia</i>	Note the patient's fluid and electrolyte status before treatment. Restrict fluids. Supplement feeding with rehydration solution and saline. Diuretic therapy may be beneficial.
<i>Hypophosphatemia</i>	Monitor serum levels. Replenish phosphorus levels before refeeding.
<i>Hypercapnia</i>	Select a low-carbohydrate, high-fat formula.
<i>Hypokalemia</i>	Monitor potassium levels. Supplement feeding with potassium if necessary.
<i>Hyperkalemia</i>	Reduce potassium intake. Monitor potassium levels.

* The most commonly cited complication of tube feeding is diarrhea.

Modified from Lutz, CA, and Przytulski, KR: Nutritional and Diet Therapy, ed 4. F.A. Davis, Philadelphia, 2006. Reprinted with permission.

feeding tube. Gravity feedings are placed above the level of the stomach and dripped in by gravity slowly or given as a bolus feeding over a few minutes. Intermittent feedings are defined as either being delivered by a pump that runs continuously throughout the day and is discontinued each night or as a 4- to 6-hour volume of feeding given over 20 to 30 minutes. Intermittent feedings via a pump allow the stomach to rest at night and more closely simulate normal eating and nutrient absorption patterns. A continuous feeding administered 24 hours a day through a pump allows for small amounts to be given over a long period. Pumps are set at the specified rate to control the speed of the feeding being delivered to the patient.

When feedings are administered, patients must be positioned in a sitting or high-Fowler's position to reduce the risk of aspiration. Monitor the rate carefully to avoid administering feedings too rapidly, and watch for signs that the feeding is not being absorbed. Abdominal distention, patient report of a feeling of fullness, and nausea or vomiting are indicators that the feeding is not being absorbed and should be stopped to prevent aspiration. A residual check to see how much feeding, if any, has not been absorbed is done hourly when the feeding is initiated, then every 4 hours or before giving any medications or adding more feeding for infusion. If there is more than 100 mL or the amount specified by the agency or physician, the feeding should be stopped to prevent vomiting or aspiration and the physician notified. Continuous or intermittent feedings reduce the risk of aspiration, distention, nausea, vomiting, and diarrhea.

If medications are administered during tube feedings, understand possible drug-nutrient interactions. Some medications cannot be given with certain substances. Other medications, such as enteric-coated or sustained-release medications, should not be crushed. Liquid medications should be used when possible to reduce clogging of the tube. Pharmacists and dietitians should be consulted for special considerations.

Gastrointestinal Decompression

Gastrointestinal decompression may be necessary when the stomach or small intestine becomes filled with air or fluid. Swallowed air and GI secretions enter the stomach and intestines and collect there if they are not propelled through the GI tract by peristalsis. Accumulating air or fluid causes distention, a feeling of fullness, and possibly pain in the abdomen. Gastric distention may occur after major abdominal surgery. Ambulating or turning the patient frequently can help prevent this. However, when GI decompression is necessary, a nasogastric tube or occasionally a nasointestinal tube may be inserted and suction applied. Nasointestinal tubes are more difficult and slower to place and may be uncomfortable, so they are not used often. The tube remains in place until full peristaltic activity (active bowel sounds and passage of flatus) has returned. The diet is then progressed as ordered and tolerated by the patient.

Total Parenteral Nutrition

Total parenteral nutrition (TPN; also known as intravenous hyperalimentation) is a method of supplying nutrients to the patient by an intravenous (IV) route. TPN solutions usually contain dextrose (sugar), amino acids (protein), vitamins, minerals, and fat (intralipid) emulsions. TPN solutions are designed to improve the patient's nutritional status, achieve weight gain, and enhance the healing process. The patient with conditions such as burns, trauma, cancer, acquired immunodeficiency syndrome (AIDS), malnutrition, anorexia nervosa, or fever and those undergoing major surgery may need TPN.

Usually, registered nurses are responsible for administering TPN. A filter must be used with TPN solutions but not with lipid solutions, which are given as a separate infusion along with TPN therapy. TPN is started slowly to give the pancreas time to adjust to increasing insulin production for the high amounts of glucose in the TPN. The TPN rate is increased until the ordered rate, as tolerated by the patient, is reached. When TPN is discontinued, the patient must be gradually weaned to allow the pancreas to adjust to decreasing glucose levels. The patient, as ordered, is fed before the TPN is stopped to help prevent hypoglycemia. Signs of hypoglycemia include weakness, shakiness, sweating, and confusion.

It is important to monitor glucose levels as ordered and to look for signs of hyperglycemia in the patient receiving TPN. Refer to agency policy for obtaining glucose levels when a hyperglycemic reaction is suspected in the patient receiving TPN.

During TPN administration, the following laboratory values, as ordered, are usually monitored:

- Complete blood cell count (CBC)
- Albumin
- Glucose
- Electrolytes
- Platelet count
- Prothrombin time (PT)

TPN can be irritating to the peripheral veins because it is five or six times more concentrated than blood. Therefore, TPN dextrose more than 12% is administered through a central venous catheter into a large vein such as the subclavian or internal jugular (see Fig. 6.8). The volume in the large vein dilutes the TPN solution, so it is less irritating.

Peripheral Parenteral Nutrition

Peripheral parenteral nutrition (PPN) is a method of supplying nutrients to the patient by an IV route that is not a central vein. PPN is used for less than 10 days when the patient does not need more than 2000 calories daily. PPN solutions can contain a mixture of dextrose (of less than 12%), amino acids, and lipids, in addition to electrolytes or water, which can be found in routine IV solutions. The all-in-one PPN system mixes dextrose, amino acids, and lipids all in one container, which causes less irritation of veins.

NURSING CARE TIP

Patients with any of the following may need to be considered for TPN or PPN:

- Any significant weight loss (10% or more of healthy weight)
- A decrease of oral food intake for more than 3 days
- Any significant sign of protein loss: serum albumin levels below 3.2 g/dL
- Muscle wasting
- Decreased tissue healing
- Persistent vomiting and diarrhea

LEARNING TIP

- Patients may respond to TPN with an elevated serum glucose level, even though they do not have diabetes. This is due to the high concentration of glucose used in TPN. These elevated serum glucose levels do not usually indicate that the patient who does not have diabetes has acquired the disease. After the TPN is discontinued, the serum glucose levels should return to baseline or normal levels.
- Regular insulin is given, as ordered, to control hyperglycemia during TPN therapy. The insulin is ordered on a sliding scale (regular insulin given based on blood glucose levels measured at ordered intervals over 24 hours) or as an additive to the TPN solution, or both.
- Administration of insulin according to a sliding scale requires a current blood glucose level. Based on the obtained glucose level, if it is elevated, specified regular insulin units may be ordered. Usually blood glucose is measured before meals, but for a patient who is not eating, as with most

patients receiving TPN, there is no meal time. Instead, specified time intervals are ordered (typically every 6 hours).

- Insulin given on a sliding scale is always regular insulin. Can you figure out why? Regular insulin is rapid acting, which is what is needed to treat the current blood glucose level that was obtained to determine what insulin coverage was needed, if any.

Home Health Hints

- Be familiar with community nutritional support services: Women, Infant's, and Children (WIC) program, elderly nutrition sites, Meals on Wheels, school food programs, and government surplus food programs.
- Observe patient's food preparation facilities to ensure the patient's nutritional needs can be met. Some older patients may have outdated or spoiled food in their refrigerators or cupboards because they are unable to see dates or mold growing on foods.
- Ensure that patients are able to use appliances to heat food safely. Patients with limited vision may not see gas flames and can ignite their clothing. Confused patients might try to heat foods in the cardboard containers. If the patient is able to obtain and learn to use a microwave, it may be a safer cooking appliance.
- A feeding tube can be prevented from kinking by slipping a split straw lengthwise around the area that tends to kink and lightly taping over the split in the straw.
- Wire coat hangers make good hooks for enteral feeding solutions bags. They can be bent and hung over doorways or closet bars.
- If a 60-mL feeding syringe is not available for a bolus tube feeding or tube flushing, a measuring cup and funnel can be used.

REVIEW QUESTIONS

1. The nurse is collecting data on a patient with a ruptured appendix that is painful. Where would the nurse expect the patient's pain to be located?
 - a. Right upper quadrant
 - b. Right lower quadrant
 - c. Left upper quadrant
 - d. Left lower quadrant
2. Which of the following is a function of the liver?
 - a. Synthesis of plasma proteins
 - b. Elimination of carbohydrates
 - c. Concentration of bile
 - d. Secretion of cholecystokinin
3. The nurse is planning care for a 78-year-old patient's elimination needs. Which of the following interventions should the nurse plan to reduce complications from the aging change of slowed motility?
 - a. Decrease ambulation.
 - b. Increase dietary fiber.
 - c. Increase dairy products.
 - d. Decrease fluid intake.

4. The nurse is assessing a patient's bowel sounds. The nurse understands that bowel sounds heard at an irregular rate every 5 to 15 seconds should be documented as which of the following?
 - a. Abnormal
 - b. Hyperactive
 - c. Hypoactive
 - d. Normal

5. Which of the following best describes the technique of palpation?
 - a. Firmly place the hands on the abdomen, depressing the tissues 1-2 inches.
 - b. Lightly depress the abdomen 1/2 to 1 inch.
 - c. Randomly feel the patient's abdomen with fingertips.
 - d. Light palpation should be completed only by an experienced practitioner.

6. Which of the following nursing measures is most important after an upper or lower GI series?
 - a. Offer a laxative as ordered.
 - b. Encourage fluids.
 - c. Check for return of a gag reflex.
 - d. Keep the patient in semi-Fowler's position.

7. A patient is admitted with an order for a Sump tube (Salem sump). The nurse knows this tube is used for :
 - a. Supplemental feeding
 - b. Decompression
 - c. Irrigation
 - d. Lavage
 - e. Gavage

8. A patient has had a flexible feeding tube inserted. Which of the following should be done to confirm placement?
 - a. Aspirate gastric contents for green colored fluid.
 - b. Measure the pH of secretions from tube.
 - c. Obtain x-ray to check placement.
 - d. Look in the back of the mouth to ensure tube has not coiled in the throat.

9. The nurse is caring for a patient who is receiving a TPN infusion. Blood glucose monitoring every 6 hours is ordered to detect which of the following complications?
 - a. Hyponatremia
 - b. Hyperglycemia
 - c. Hypocalcemia
 - d. Hyperkalemia

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Todd

1. Daily aspirin use is the most likely cause of her bleeding.
2. Medication teaching including side effects can help Mrs. Todd prevent future bleeding episodes. Assessment of pain relief needs and consultation with the physician will also help.

■ Mrs. Pearl

Mrs. Pearl is at risk for dehydration and electrolyte loss as a result of the laxative and enema preparation and NPO status. This risk is increased because of her age. Her fluid and electrolyte status should be monitored closely.

Mrs. Pearl will likely have a concern about "making it" to the bathroom during the preparation and should have a bedside commode placed within easy reach. Her call light should be answered promptly. If enemas are ordered "until clear," Mrs. Pearl will be at greater risk for fluid and electrolyte loss. If more than two or three enemas are required, the physician should be notified.

Multiple response item. Select all that apply.

7. A patient is admitted with an order for a Sump tube (Salem sump). The nurse knows this tube is used for :
 - a. Supplemental feeding
 - b. Decompression
 - c. Irrigation
 - d. Lavage
 - e. Gavage

8. A patient has had a flexible feeding tube inserted. Which of the following should be done to confirm placement?
 - a. Aspirate gastric contents for green colored fluid.
 - b. Measure the pH of secretions from tube.
 - c. Obtain x-ray to check placement.
 - d. Look in the back of the mouth to ensure tube has not coiled in the throat.

9. The nurse is caring for a patient who is receiving a TPN infusion. Blood glucose monitoring every 6 hours is ordered to detect which of the following complications?
 - a. Hyponatremia
 - b. Hyperglycemia
 - c. Hypocalcemia
 - d. Hyperkalemia

Elderly patients can become very fatigued during testing and test preparation. Mrs. Pearl should be allowed plenty of rest before and after the test. She may also have a concern about being able to hold the barium in her bowel during the test without having an "accident." She should be assured that the barium is held in with a balloon on the end of the enema catheter and that bathrooms are nearby.

■ Mr. Wozynski

You can expect to find that Mr. Wozynski's serum bilirubin is elevated because his liver is unable to convert or conjugate bilirubin into a water-soluble compound that can be eliminated in feces. Mr. Wozynski is at risk for bleeding because the liver is highly vascular and prone to bleed when a biopsy specimen is taken. In addition, he may not be manufacturing the necessary amount of prothrombin needed for blood clotting and is less likely to stop bleeding once the biopsy has been performed. It will be especially important to check his coagulation studies and report any elevations to the physician before the biopsy.

■ Mrs. Wood

1. Assessment of Mrs. Wood indicates dehydration.
2. Document as follows: “1/20/06 0800 ‘Mouth very dry.’ Tongue bright red with deep furrows, tented turgor. Tube feeding infusing (include solution and rate). Physician notified. K. Ohno LVN.”
3. Mrs. Wood’s daily water needs are not being met. She is not receiving medications that would incidentally provide water during their administration.
4. Consult a dietitian and/or physician to review Mrs. Wood’s daily water needs. Divide the water needs over 24 hours and ensure that water is administered. Ensure tubing is flushed per agency policy, and calculate water used toward daily water needs. Monitor intake and output. Continue assessing Mrs. Wood’s signs and symptoms, and report abnormal findings.
5. $50 \text{ mL} \times 8 \text{ hours} = 400 \text{ mL}$

QUESTIONS TO GUIDE YOUR READING

1. What are anorexia, anorexia nervosa, and bulimia nervosa and their therapeutic interventions and nursing care?
2. What is obesity, and what medical, surgical, and nursing management is used to treat it?
3. What nursing care would you give to a patient with stomatitis?
4. How would you care for patients with acute or chronic gastritis?
5. How would you explain the pathophysiology, signs and symptoms, and diagnostic testing for hiatal hernia, peptic ulcer disease, gastric bleeding, and gastric cancer?
6. Describe current pharmacological treatments for peptic ulcer disease?
7. What nursing care would you provide for patients with hiatal hernia, peptic ulcer disease, gastric bleeding, and gastric cancer?

NAUSEA AND VOMITING

Nausea is the subjective feeling of the urge to vomit. Vomiting is the act of expelling stomach contents from the body through the esophagus and mouth. Nausea and vomiting are common occurrences that most people experience at some time. Vomiting is a protective function to rid the body of harmful substances from the gastrointestinal (GI) tract. This reflex is controlled by the vomiting center of the brain. It is a complex process. Many stimuli and conditions that are directly related to the GI tract or independent of it can trigger nausea and vomiting. Viral GI infection and other infections, motion sickness, stress, pregnancy, medications (narcotics), myocardial infarction, uremia, and other conditions may cause nausea and vomiting.

Therapeutic Interventions

Nausea and vomiting may be self-limited and require no intervention. If it is prolonged, however, dehydration and electrolyte imbalances may occur. The loss of hydrochloric acid from the stomach can result in metabolic alkalosis. “Coffee grounds”—appearing emesis (dark brown) occurs from bleeding in the stomach.

Protection of the airway during vomiting is a priority to prevent aspiration. Those at risk of aspiration are persons who are unconscious, older, and experiencing gag reflex impairments. Place these types of persons on their side when they begin to vomit. This allows the gastric contents to be expelled from the mouth rather than pooling at the back of the throat and being aspirated.

If the cause of vomiting is known, it is treated. Various medications can be given to control the nausea and vomiting (e.g., diphenhydramine [Benadryl], hydroxyzine [Vistaril], metoclopramide [Reglan], promethazine [Phenergan], prochlorperazine [Compazine], ondansetron [Zofran], scopolamine [TransdermScop], thiethylperazine [Torecan], trimethobenzamide [Tigan]). For severe or prolonged vomiting, IV fluids and possibly nutrition need to be provided. A nasogastric (NG) tube with suction may be ordered to decompress the stomach. After the vomiting is resolved, clear liquids are started, with water being preferred. If liquids are tolerated, crackers or dry toast may be tolerated as well.

Nursing Process for the Patient with Nausea and Vomiting

Assessment/Data Collection

The nurse identifies characteristics of the episodes of the nausea and vomiting. Medical conditions, medications, and treatments are documented to aid in diagnosing the cause. Signs of early fluid deficit, such as weakness, headache, muscle cramps, restlessness, inability to concentrate, and postural hypotension, are noted and reported for treatment. Late signs include confusion, oliguria, cold clammy skin, and chest or abdominal pain.

Nursing Diagnoses, Planning, and Implementation

Nausea related to various causes

EXPECTED OUTCOME: Patient will report no nausea.

- Provide quiet, odor-free, visually clean environment *to avoid triggering stimuli.*
- Give antiemetics as ordered.
- Provide frequent oral care *to remove emesis taste and enhance patient comfort.*
- Explain to patient to avoid triggering fluids or foods to prevent nausea and vomiting.

Risk for aspiration related to decreased gag reflex or unconsciousness

EXPECTED OUTCOME: Patient’s airway and lung sounds will remain clear.

- Identify patients who are nauseated and are at risk of aspiration *to plan preventive care.*
- Place patient on side if nauseated and vomiting *to protect airway.*

Deficient fluid volume

EXPECTED OUTCOME: Patient’s vital signs will remain within normal limits.

- Monitor for early signs of hypovolemia in patient with vomiting *to allow treatment and prevent complications.*
- Obtain daily weight on same scale, at same time of day, with same type of clothing *to detect fluid losses. A 1 lb weight loss reflects a fluid loss of 500 mL.*
- Monitor intake and output and vital signs including orthostatic blood pressure per shift or daily or more frequently as patient’s condition indicates *to report changes for prompt treatment.*
- Provide fluids as ordered *to hydrate patient. IV fluids may be used to allow the GI tract to rest. Slightly chilled oral replacement solutions may be used such as sports replacement drinks or ginger ale given in small frequent amounts.*
- Monitor older adults for excess fluid volume during treatment of deficient fluid volume *to prevent and detect fluid overload, which may occur quickly in the older adult.*

Evaluation

The patient’s goals are met if nausea is not present, lung sounds remain clear, and vital signs remain within normal limits.

EATING DISORDERS

Anorexia

Anorexia, which is a lack of appetite, is a common symptom of many diseases and can be caused by noxious food

odors, certain drugs (as an intended or side effect), emotional stress, fear, psychological problems, and infections. Prolonged anorexia with an inadequate nutritional intake can lead to serious electrolyte imbalances, which in turn can lead to cardiac dysrhythmias. Although eating is the preferred method of weight gain, other measures such as tube feedings and intravenous infusion can be used. Ask patients what causes them to lose their appetite and what improves it to plan care. Nursing actions for the patient with anorexia include documenting accurate intake and output; monitoring vital signs, electrolytes, and electrocardiograms; and monitoring the rate of the intravenous infusion and tube feeding.

Anorexia Nervosa

Anorexia nervosa is an eating disorder that is recognized by the American Psychiatric Association (Box 33.1 Diagnostic Criteria for Anorexia Nervosa). This disease most commonly occurs in females between the ages of 12 and 18 who are from the middle and upper classes of Western culture. Males account for less than 10% of the population with anorexia nervosa. Young women with low self-esteem seem to be at highest risk. Anorexia nervosa is thought to be psychological in origin. Patients may have a phobia of weight gain, are afraid of a loss of control, and are mistrusting.

Signs and Symptoms

Early signs and symptoms of anorexia nervosa include severe weight loss, low self-esteem, compulsive dieting, and an altered body image (patients imagine themselves as fat, although they are within or below normal weight range). As the disease progresses, additional symptoms appear, including amenorrhea in females, electrolyte imbalance, cardiac dysrhythmias, constipation, dry skin, lanugo (downy hair covering body), bradycardia, hypothermia, hypotension, muscle wasting, and facial puffiness. Often patients with anorexia nervosa deny the existence of any problem. They may develop bizarre food rituals and sometimes weigh themselves several times a day. Anorexia nervosa sometimes overlaps with **bulimia nervosa** (compulsive eating with self-induced vomiting).

Box 33.1

Diagnostic Criteria for Anorexia Nervosa

1. Refusal to maintain body weight over a minimum normal weight for age and height
2. Intense fear of gaining weight or becoming fat, even though underweight
3. Disturbance in the way in which one's body weight, shape, or size is experienced
4. In females, the absence of at least three consecutive menstrual cycles when otherwise expected to occur

Therapeutic Interventions

Treating this disorder is complex and requires a multidisciplinary approach. Patients often do not see the need for medical intervention. They do not usually seek help on their own and are often resistant to treatment. When treatment is sought, often through a concerned person's urgings, a medical and psychological workup is necessary. Nutritional status is also evaluated to determine the urgency of intervention. Establishing a trusting relationship, which can be difficult, is a key element in initiating treatment. Early treatment results in a better prognosis.

Often the most important initial intervention for anorexia nervosa is the restoration of nutritional health; up to 18% of anorexia patients eventually die as a result of starvation and complications from it. For those who are underweight with severe weight loss, life-threatening electrolyte imbalances and dysrhythmias or other symptoms, nutrition is supplied by intravenous infusions containing electrolytes. Oral food supplements may also need to be given. Restoring normal weight is a long, slow process. Gains may be small with setbacks along the way. Praise and rewards for small achievements in weight gains (not food intake) are positive reinforcements that aid recovery. Programs that treat eating disorders are often set up on a reward system, with privileges being increased as progress occurs.

The patient's damaged self-image and self-esteem are underlying causes of the disorder that must be addressed in conjunction with the nutritional aspect (Box 33.2 Nutrition Notes). Psychotherapy and behavior modification that includes participation of the patient's significant others are included in treatment of anorexia nervosa. The altered body image is the main focus of therapy. Educating the patient on normal body weight can be helpful. Individual or group therapy is used. Family counseling may be used since childhood events often create the negative self-image. During treatment, a support system is vital to success.

Complications

Chronic poor nutritional health takes its toll on the body. Complications from starvation occur as the body tries to conserve energy. Pulse and blood pressure fall. Heart and kidney failure are a risk. Osteoporosis and muscle loss occur. Vitamin and electrolyte imbalances result. Diabetes may develop with a high morbidity.

Bulimia Nervosa

Bulimia nervosa is compulsive eating with self-induced vomiting, which is commonly known as binge-purge. A high percentage of patients with bulimia are young women.

The bulimic patient typically eats massive amounts of food at one sitting and then purges the food by intentionally inducing vomiting so weight is not gained. Laxatives are also sometimes used by the bulimic patient to purge the body of food to avoid weight gain. Excessive exercise may also be used to control weight.

Box 33.2

Nutrition Notes

Supplying Nutrition in Upper Gastrointestinal Conditions

Anorexia Nervosa and Bulimia Nervosa

These eating disorders, which produce severe weight loss, require multidisciplinary treatment. Although correcting the nutritional consequences of these conditions is of major importance, to achieve a cure it is essential to treat the underlying psychological causes.

Obesity

Candidates for gastric banding or gastric bypass surgery should be carefully selected. The procedure should be viewed as one tool to assist with weight control, along with behavioral changes. It is not done to permit overeating because in time the constructed pouch can be stretched, thus negating the surgery. Guidelines include eating three to six small balanced meals daily, chewing thoroughly and eating slowly, drinking most fluids between meals, exercising regularly, and taking a multivitamin-multimineral supplement. Potential complications of these surgeries include nausea, vomiting, bloating, heartburn, staple disruption, obstruction, dumping syndrome, and osteoporosis.

Gastroesophageal Reflux and Hiatal Hernia

Patients with gastroesophageal reflux and hiatal hernia may find symptoms alleviated by protein foods that tighten the cardiac sphincter so normal amounts of dietary protein are suggested. Substances that may be better avoided because they relax the sphincter include fat, caffeine, peppermint, spearmint, chocolate, alcohol, and nicotine. Pepper and decaffeinated coffee may be problematic because they stimulate gastric secretions. Acidic juices may be irritating as well.

Postprandial Hypotension

This refers to a drop in systolic blood pressure of 20 mm Hg or more within 75 to 120 minutes after the beginning of a meal, most often resulting in dizziness and fatigue but also weakness, light-headedness, disturbed speech, and vision changes. Normally the body compensates for the increased blood flow to the digestive tract following meals, but in the elderly, the mechanisms maintaining adequate circulation to the rest of the body become less effective. Most at risk are people with neurological, cardiovascular, or renal diseases. Complications include higher incidence of coronary events, stroke, and total mortality. To prevent postprandial hypotension, a person should limit carbohydrate intake and take frequent small meals. Special additives to delay gastric emptying are sometimes prescribed. Lying in a semirecumbent position for 90 minutes after eating and avoiding excessive exercise for 2 hours after meals can help to manage the condition. Scheduling of antihypertensive medications between rather than just before meals also can be helpful.

Dumping Syndrome

The recommended meal pattern for patients with dumping syndrome includes six small meals per day, high in protein and low in simple sugars; fluids between rather than with meals; and reclining for half an hour after meals. Supplementation with the vitamins B₁₂ and D, folic acid, and the minerals calcium and iron may be necessary to prevent deficiencies.

Gastric Cancer

If a patient has a poor prognosis following a total gastrectomy for cancer, dietary interventions should focus on symptoms the patient wishes to control. An overly restricted diet causing the patient discomfort or distress is inappropriate.

Source: Malozemoff, W, and Gentlemen, B: When dinner's done—postprandial hypotension in older adults. *Nurs Spect Midwest* 5:18, 2004.

Signs and Symptoms

Patients with bulimia nervosa exhibit many of the same signs and symptoms as patients with anorexia nervosa, with a few exceptions. Bulimic patients often have enamel erosion of the front teeth and staining caused by the acid content of the emesis. They also spend a great deal of time locked in the bathroom vomiting, especially after meals. Electrolyte imbalances occur from dehydration. The loss of potassium and sodium may result in dysrhythmias, heart failure, and death. As the electrolyte imbalance worsens, metabolic alkalosis develops as a result of the loss of gastric acid in the stomach contents. Signs and symptoms of meta-

bolic alkalosis include hypokalemia and hypocalcemia. Laxative use results in irregular bowel movements.

Therapeutic Interventions

The treatment for bulimia nervosa is essentially the same as for the patient with anorexia nervosa.

Nursing Process for the Patient with an Eating Disorder

Caring for patients with eating disorders is challenging. Gaining the patient's genuine cooperation by using therapeutic communication and setting realistic, mutual goals is

important in establishing trust and preventing relapse. To work with patients with an eating disorder, a therapeutic relationship must be developed to facilitate effective interactions. Empathy, acceptance of the patient, trust, warmth, and being nonjudgmental are important.

Assessment/Data Collection

Collect data related to inadequate nutrition. Note changes in weight (15% or more below expected weight), poor skin turgor, poor muscle tone, lanugo, amenorrhea, electrolyte imbalances, and hypothermia. Data collection findings may also include a normal weight, enamel erosion of front teeth, and metabolic alkalosis for the patient with bulimia. Note abnormal diagnostic studies such as anemia, electrolyte imbalances, altered endocrine studies, and electrocardiographic (ECG) changes.

Nursing Diagnosis, Planning, and Implementation

Imbalanced nutrition: less than body requirements related to inadequate food intake, self-induced vomiting, and/or chronic/excessive laxative use

EXPECTED OUTCOME: Establish dietary pattern and weight gain toward desired individual weight range.

- Monitor patient's weight to determine baseline and monitor patient's progress toward goal.
- Monitor vital signs and laboratory studies to detect changes in cardiac function related to electrolyte imbalances.
- Promote consistent approach to enhance acceptance of patient and to build trust.
- Promote pleasant eating environment and record intake to enhance patient intake.
- Provide six smaller meals and snacks to prevent gastric dilation.

Body image, disturbed related to psychosocial or cognitive/perceptual changes

EXPECTED OUTCOME: The patient verbalizes satisfaction with body appearance.

- Assess and document patient's verbal and nonverbal responses to own body to provide baseline understanding of patient's perceptions of body image.
- Listen to patient and acknowledge reality of concerns regarding treatment and progress to establish therapeutic relationship.
- Monitor frequency of negative statements about self to determine if interventions are helping patient.
- Assist with referrals to social services or counseling to help patient overcome psychosocial issues.
- Provide care in a nonjudgmental manner to maintain the patient's dignity.
- Use positive praise when patient verbalizes positive comments about own body.
- Encourage patient to verbalize consequences of eating disorder that have influenced self-concept to help patient realize the negative impact of the eating disorder.

Evaluation

The patient's goals are met if the patient gains weight toward expected weight goal and the patient verbalizes satisfaction with body appearance and increases the number of positive statements about own appearance.

OBESITY

Several methods can be used to diagnose a patient as overweight or obese, although there is no one definitive measure of either. Factors such as age, body frame size, and gender can influence these measurements:

- Height-weight chart: Weight 10% to 20% above ideal body weight is overweight; 20% or more above ideal body weight is **obesity**.
- Waist-to-hip ratio: Waist-to-hip ratio is waist measurement divided by hip measurement. If the result is more than 1.0 in men or 0.8 in women, it indicates that the patient is overweight.
- Body mass index (BMI): BMI is one of the best methods for defining obesity. BMI increases with age. Generally, a BMI of 25 to 29.9 kg/m² is defined as being overweight, with more than 30 kg/m² being obese (Fig. 33.1). BMI can be calculated using height-to-weight ratios:

$$\text{BMI} = \text{Weight (kg)} / \text{Height (m)}^2$$

$$\text{Example: BMI} = 68 \text{ kg} / 1.67 \text{ m}^2 = 68 \text{ kg} / 2.7889 \text{ m}^2 = 24.38 \text{ kg/m}^2$$

Obesity is caused by a caloric intake that exceeds energy expenditure. Only a small percentage of obesity is associated with a metabolic or endocrine abnormality within the body. Health risks can result from being overweight. Diseases that are associated with obesity are called comorbidities. Comorbidities include, but are not limited to, atherosclerosis, heart disease, diabetes mellitus, hypertension, sleep apnea, osteoarthritis, decreased mobility, lack of self-esteem, and depression. Obesity that interferes with activities of daily living, such as breathing or walking, is known as morbid obesity. Morbid obesity refers to people whose BMI is above 40, which is about 100 lb overweight for men and about 80 lb overweight for women. Surgery can be an option for people whose BMI is above 40 or for people whose BMI is between 35 and 40 and who have life-threatening obesity-related diseases such as severe sleep apnea or heart disease. For more information, go to the National Heart, Lung, and Blood Institute website at www.nhlbisupport.com/bmi, The American Obesity Association at www.obesity.org, or The North American Association for the Study of Obesity at www.naaso.org. For information about surgery, finding a surgeon, chat rooms, and more, visit www.obesityhelp.com.

Persons who are overweight are at risk for developing other diseases. These can include hypertension, type 2 diabetes, heart disease, degenerative joint disease, sleep apnea, and gallbladder disease. When combined with a high-fat diet, there is also an increased risk of breast, colon, rectum,

FIGURE 33.1 Body mass index ranges and associated level of health risk with obesity.

and prostate cancer. For more information, visit the Centers for Disease Control and Prevention at www.cdc.gov/nccdphp/dnpa/obesity/defining.htm.

Therapeutic Interventions

Initial treatment for obesity is weight loss through exercise and calorie restriction. For weight loss to occur, it is essential that the patient cooperates and has sustained motivation. Support groups such as Take Off Pounds Sensibly (TOPS) and Weight Watchers can help patients be successful. Behavior modification methods that provide rewards for successful weight loss are often included in a weight loss plan. Short-term use of medications that suppress appetite or block fat absorption may also be used. The patient should receive education regarding a healthy and balanced diet.

Surgical Management

Patients who do not respond to medical methods of weight loss or whose BMI is 40 or above may have surgery to reduce their weight if they meet established criteria for the surgery (Box 33.3 Patient Perspective). Established criteria for surgery may include gross obesity for 5 years, failure to reduce weight with other forms of therapy, body weight 100% above ideal weight, absence of other medical conditions, psychiatric and social stability, and presence of a high-risk condition that weight loss would relieve. Surgical techniques produce weight loss by restriction (limiting how much the stomach can hold), or malabsorption (decreased calorie and nutrient absorption) (see Box 33.2 Nutrition Notes). The field of obesity surgery is called bariatric surgery and is designed to treat severe obesity. The word *bariatric* comes from the Greek word *baros*, which means “weight.” Various procedures have been used over the years,

but complications have arisen with some, such as malabsorption, so they are no longer used. For a list of surgical obesity centers and surgical procedures, visit The American Society for Bariatric Surgeons at www.asbs.org.

Gastric Bypass

The **Roux-en-Y** bypass is a common gastric bypass surgery (Fig. 33.2). In the first part of this two-step surgery, a small stomach pouch the size of a thumb is created with staples. This small pouch causes a quick satisfactory feeling of fullness during a meal, which is the key to the success of this procedure. Next, a Y-shaped section of the small intestine is attached to the pouch to allow food to bypass the lower stomach and duodenum. Digestive juice flow is maintained, and food enters the jejunum within 10 minutes of eating. There is little malabsorption of food. This procedure has also been performed laparoscopically.

Vertical Banded Gastroplasty

Vertical banded **gastroplasty** (VBG) is the most commonly used restrictive surgery for weight reduction and control today (see Fig. 33.2). There is little malabsorption of food with this procedure and it is technically easier to perform than gastric bypass surgery. If a reversal procedure is needed, it is easier to reverse the VBG than the gastric bypass. About 30% of patients who have had VBG achieve normal weight. Other methods of gastric banding are currently under study.

Complications of Gastric Restrictive Surgeries

A common side effect of restrictive surgery is vomiting caused by overeating or by not chewing food well. Severe side effects of VBG include erosion of the gastric tissue surrounding the band, breakdown of the staple line, and leaking

gastroplasty: gastro—stomach + plasty—repair

Box 33.3

Patient Perspective

Curtis

I am 47, with 8 children. For many years, I experienced weight control problems. By the time I was in high school, I weighed 250 lb, and the weight just kept building from there. I had tried many weight control programs, including some medications that now have been removed from the market.

When I was about 38, I began to look into weight loss surgeries such as the Roux-en-Y. Many of the older techniques were dangerous and risky. Even the newer procedures are major procedure with many risks.

I had spoken to many people who had bariatric surgery. Many pointed out the psychological aspect, talking about how differently people treated you, and some even ending with a divorce. This was a very scary aspect to me.

However, after much research and after reaching a weight of about 380 lb, I arranged to have the surgery done. I had my surgery at a facility that did only bariatric surgery. I felt very comfortable through the whole process. This included all the presurgical testing, including psychological evaluation and counseling.

One of the nice features was that the facility itself was patient friendly, with large chairs, etc. When I had the surgery I had a rough first 24 hours spent in CCU (critical

care unit). The nursing staff was very professional and understanding. The care was very personal and responsive to my needs. The staff was very courteous and made me comfortable.

I think that understanding the medical field you are working in is very important to this feeling of patient comfort. Several of my nurses had gone through the procedure themselves. This really helped them to know what I was experiencing. Nurses should be well-informed about the procedures.

It has been 6+ years now and I have continued to keep my weight down around 230 to 250 lb, which is a loss of approximately 120 lb. My health has improved a good deal. I would do it again, even though at about day 21 I would have said “never again.”

As nursing professionals, it is very important to treat everyone as a human being and with much respect regardless of the socioeconomic status or medical needs. If patients are treated with respect and caring, it is a step for them in the right direction. I believe it is not only kind but helps in the healing and recovery processes as well. I was treated with a great deal of kindness and respect during my procedure and I greatly appreciated this. Thanks to all the professional nurses out there who do a great job.

of the stomach secretions into the abdomen. Leaking of the stomach secretions can lead to peritonitis, a very serious infection of the peritoneum and requires emergency surgery. Infection or death from any of these complications can occur.

Postoperative Care

Postoperative bariatric patients require care similar to that for most types of gastric surgeries. (See section Nursing Management After Gastric Surgery later in this chapter.) The bariatric diet, however, is very different. Patients are started on a clear liquid diet because of the small stomach pouch that has been created. Then the diet progresses to full liquids, pureed foods, and finally, at about 6 weeks after surgery, regular foods as tolerated.

Nursing Process for the Patient Who Is Obese

Assessment/Data Collection

Assessment for the patient with obesity should include measurements of height, weight, and BMI. Information about eating patterns and exercise patterns should be obtained. The nurse should determine if any problems exist for the patient related to excess weight such as physical limitations, social interaction issues, and personal issues (e.g., changes in sex-

uality or financial status). The nurse should complete a complete physical assessment noting any abnormalities. Assessment should include any areas in which the patient has expressed concerns or problems. Persons who are overweight have an increased risk for other diseases. The nurse should assess for signs and symptoms of these diseases.

Nursing Diagnosis, Planning, and Implementation

Imbalanced nutrition: more than body requirements related to caloric intake greater than metabolic needs and/or decreased activity level

EXPECTED OUTCOMES: The patient will achieve and maintain weight loss to specified weight.

- Establish desired weight goal and monitor weight.
- Modify eating habits and patterns.
- Establish and maintain increased activity pattern.
- In collaboration with a dietician, implement eating plan for patient to *safely reduce weight and maintain adequate protein intake*.
- Discuss realistic weight loss goals of 1 to 2 lb/week to *achieve lasting weight loss effects*.
- Discuss emotions, events, and patterns of eating to *help patient identify when she or he is eating*

FIGURE 33.2 (A) Roux-en-Y gastric bypass. A staple line creates a small pouch at the top of the stomach, which is then attached to the jejunum. Food bypasses most of the stomach and the duodenum and goes into the jejunum. (B) Vertical banded gastroplasty for gastric bypass. A small stomach pouch is made with a staple line and a mesh band. A circular window made with staples allows the band to be placed around the pouch. The band restricts and slows food flow from the stomach pouch. As the small pouch fills, there is a feeling of fullness even with small meals.

to satisfy an emotional need versus a physiological hunger.

- In collaboration with physician, establish increased activity pattern *to promote weight loss.*
- Provide preoperative instructions if surgical interventions are planned, *for understanding.*

Evaluation

The patient's goals are met if the patient maintains progressive weight loss to specified weight goal and safely progresses through the perioperative period if a surgical intervention is completed.

ORAL HEALTH AND DENTAL CARE

Good oral health care is important to overall health. Nutritional needs can be a problem if oral problems interfere with

NURSING CARE TIP

For the patient who is obese, it is often necessary to have on hand special equipment for patient care. Some items you may need include:

- Larger hospital bed, wheelchair, or walker
- Patient lifting devices
- Extra pillows to ease breathing
- Larger hospital gowns
- Larger blood pressure cuff

eating and drinking. Respiratory illness and cardiac disease is associated with pathogens in the mouth. Regular oral hygiene and dental care are important in preventing infections (Box 33.4 Common Concerns in Oral Health and Dental Care). Providing oral hygiene using oral chlorhexidine gluconate washes has been shown to be effective in preventing pneumonia in long-term care residents as well as reducing ventilator-associated pneumonia in cardiac surgery patients. This is an easy and inexpensive way to promote patient health.

Aging changes as well as disease and treatment can result in oral inflammation and infection. Those who are immunosuppressed (AIDS) or undergoing chemotherapy or who have vitamin deficiencies are more at risk. Candidiasis is a common oral infection that is often treated with nystatin oral swish and swallow. During data collection, especially in these higher risk patients, the nurse should note any oral signs of inflammation or infection for prompt treatment. This is important to preserve oral comfort and nutrition.

ORAL INFLAMMATORY DISORDERS

Stomatitis

Stomatitis is the general term for inflammation of the oral cavity. There are many causes of stomatitis, such as an infection or a systemic disease. The most common types of stomatitis are **aphthous stomatitis** (canker sores) and herpes simplex virus type I infection (also known as cold sores or fever blisters).

Aphthous Stomatitis (Canker Sores)

Aphthous stomatitis appears as small, white, painful ulcers on the inner cheeks, lips, tongue, gums, palate, or pharynx and typically lasts for several days to 2 weeks. Self-induced trauma such as biting the lips and cheeks can cause these ulcers to develop, as well as stress or exposure to irritating foods. Application of topical tetracycline several times a day usually shortens the healing time. A topical anesthetic such

stomatitis: stoma—mouth + itis—inflammation

Box 33.4**Common Concerns in Oral Health and Dental Care**

Oral care is important throughout life and has been found to have a link to cardiac health. The importance of daily and ongoing oral care should be considered for all patients, especially older adults.

Patients undergoing dental procedure who have artificial joints or some heart conditions need to take prophylactic antibiotics prior to some dental procedures to prevent bacteria entry and bacterial endocarditis. The dentist should be informed of the patient's history so that appropriate antibiotics can be prescribed.

Xerostomia (Dry Mouth)

As people age, it is not unusual for them to experience a condition known as xerostomia (dry mouth). Also, some medications and radiation treatment of the head and neck areas can cause it. Xerostomia can lead to rampant tooth decay in older adults, putting their dentition at risk.

Prior to any radiation therapy of the head or neck area, a thorough oral examination and any needed restorative dental procedures should be completed.

Although water is used as a common substitute for saliva, it does not contain the necessary compounds such as lubricants to protect the teeth, therefore an artificial saliva substitute should be considered such as Oralbalance gel, Salivart solution, or Salix lozenges.

Dentures

It is helpful to have a person's name implanted into their dentures to avoid lost or mixed up dentures, especially when the person lives in an extended care facility. It can be requested when the dentures are made and the dentist will place a small identity tag in the acrylic of the denture with the person's name on it.

Those with complete dentures still need to be routinely screened by a dentist or dental hygienist for proper denture fit, sore areas, oral cancer detection, and oral fungal infections.

Gingival Recession

As people age, it is not unusual for their gingival (gums) to recede or shrink, exposing the root surfaces of the teeth. This can lead to root sensitivity and/or tooth decay.

In order to protect the teeth from rampant tooth decay due to dry mouth or gingival recession, a fluoride gel or rinse is strongly recommended such as over-the-counter products as Act rinse or Gel-Kam.

Gingivitis

As people get older, the gingivae have a greater tendency to bleed, a condition known as gingivitis. If the supporting tissues in the sockets of the teeth become inflamed, bone loss occurs, resulting in a condition known as periodontitis (pyorrhea). Periodontitis can lead to tooth mobility or loss.

Good oral hygiene habits cannot be overemphasized in the prevention of gum disease. Flossing every day is very important. If the patient is unable to floss due to arthritis or other conditions, an electric toothbrush or a water pic device is helpful in providing oral hygiene.

Candida Albicans Infection (Yeast Infection)

Older adults are susceptible to oral yeast infections (caused by *Candida albicans*) due to certain medications, systemic conditions, or chemotherapy. Nystatin (Mycostatin, Nadostine) as an oral rinse treats this infection.

Angular Cheilosis

A condition known as angular cheilosis (red, raw corners of the mouth) may develop in people, especially older adults. This can be due to infection, riboflavin (vitamin B₂) deficiency, or loss of facial profile due to worn dentures or not wearing dentures. The cause is treated by, for example, anti-infective medications, vitamins, and dentures.

Source: Contributed by Dr. Ralph Kluk and Dr. Cheryl Kluk.

as benzocaine or lidocaine provides pain relief and makes it possible to eat with minimal pain.

Herpes Simplex Virus Type 1 Infection

Herpes simplex virus type I (HSV-I) infection may appear as painful cold sores or fever blisters on the face, lips, perioral area, cheeks, nose, or conjunctivae. These lesions recur over time but last only for a few days each time. The onset can be provoked by fever or stress, among other things. Acyclovir ointment can be used to ease the pain, but it does not cure the lesions. Oral acyclovir may reduce recurrences. These lesions are infectious, and standard precautions should be used when ointment is applied or oral care is given.

ORAL CANCER
Pathophysiology and Etiology

Oral cancer can occur anywhere in the mouth or throat. If detected early enough, it is curable. Oral cancer is found most commonly in patients who use alcohol or any form of tobacco. The highest incidence of oral cancer is found in the pharynx (throat), with the lowest incidence being on the lips.

Signs and Symptoms

Any oral sore that does not heal in 2 weeks should be assessed by the patient's physician. Cancerous ulcers are

often painless but may become tender as the cancer progresses. In the later stages, the patient may complain of difficulty in chewing, swallowing, or speaking or may have swollen cervical lymph glands.

Diagnosis

Biopsy specimens are taken to determine the presence of cancer.

Therapeutic Interventions

Oral cancer treatment varies depending on the individualized diagnosis. Radiation, chemotherapy, and surgery are used alone or in combination to treat oral cancer. Radical or modified neck dissection is performed if the cancer has metastasized to cervical lymph nodes (Fig. 33.3). The tumor is removed along with lymph nodes, muscles, blood vessels, glands, and part of the thyroid, depending on the extent of the cancer. Drains are inserted into the incision to prevent fluid accumulation. A tracheostomy is usually performed to protect the airway and prevent obstruction.

Nursing Management

For the patient undergoing surgery, preoperative and postoperative nursing care is discussed in Chapter 11. Preoperatively, issues that are addressed in planning care include the use of alcohol or tobacco. Referrals to cessation programs and support groups are included in the plan of care. Preoperative teaching would also include how the patient will communicate if a tracheostomy is placed. Postoperatively, major concerns are airway patency, commu-

nication, and nutritional needs. Nursing care for the patient with a tracheostomy is discussed in Chapter 29. The airway must be monitored and secretions controlled to prevent aspiration. Determining that the methods the patient is using for communication are satisfactory is evaluated. Tube feedings are usually given to meet the patient's nutritional needs because swallowing is difficult (discussed in Chapter 32).

ESOPHAGEAL CANCER

Pathophysiology and Etiology

As with oral cancer, esophageal cancer is associated with the use of tobacco or alcohol. Esophageal cancer is usually detected late because of its location near many lymph nodes that allow it to metastasize. As the cancer progresses, obstruction of the esophagus can occur, with possible perforation or fistula development that may cause aspiration. The appearance of signs and symptoms usually means that the cancer is in the late stages.

Signs and Symptoms

Signs and symptoms may include difficulty swallowing, a feeling of fullness, pain in the chest area after eating, foul breath, or regurgitation of foods if there is obstruction.

Diagnosis

Diagnosis of esophageal cancer is usually made by esophagogastroduodenoscopy (EGD) and biopsy. Mediastinoscopy (endoscopic examination of mediastinum) is used to determine whether the cancer has spread to the lymph nodes and surrounding structures.

Therapeutic Interventions

Treatment for esophageal cancer includes radiation, chemotherapy, and surgery alone or in combination. Surgical procedures include esophageal resection (esophagogastrectomy), Dacron esophageal replacement, or use of a section of colon to replace the esophagus (esophagoenterostomy). If the tumor is inoperable, esophageal dilation or stent placement can be done to relieve dysphagia and allow food to pass through the esophagus.

Nursing Process for the Patient with Esophageal Cancer

The patient with esophageal cancer may undergo various forms of treatment: chemotherapy, radiation, or surgery. Nursing care is provided based on the effects of the therapies which are discussed in Chapters 10 and 11.

Assessment/Data Collection

Patient data are collected for risk factors of esophageal cancer, pain, dysphagia, and nutritional status.

Nursing Diagnosis, Planning, and Implementation

Pain related to tumor and pressure exerted on surrounding tissues

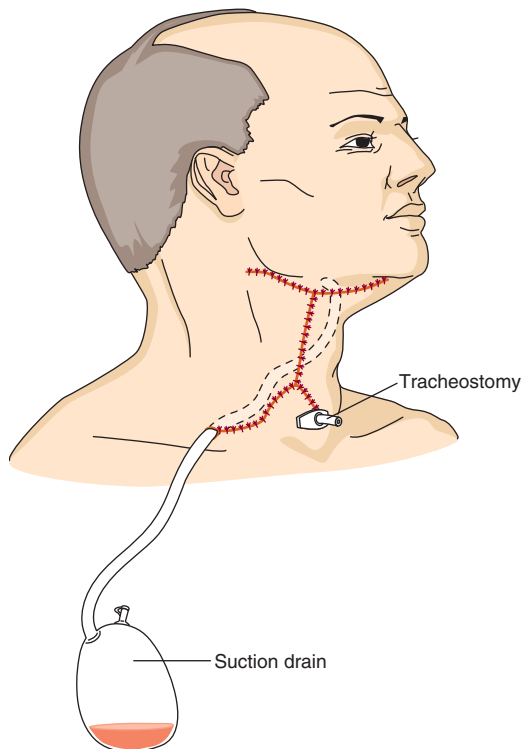

FIGURE 33.3 Radical neck dissection with tracheostomy tube and drains inserted.

EXPECTED OUTCOME: Patient will state a reduction of pain to acceptable level or total relief of pain.

- Assess pain level using pain rating scale to identify pain level.
- If surgery is performed, provide pain medications as ordered to provide pain relief.

Risk for deficient fluid volume related to decreased intake

EXPECTED OUTCOME: Vital signs remain within normal limits and balanced intake and output over 24 hours.

- Assess fluid intake and swallowing ability with fluids to plan care.
- Obtain daily weights to detect changes in fluid volume.
- Provide fluids as able to swallow to ensure adequate intake.
- Monitor intravenous infusion as ordered to prevent hypovolemia.
- Monitor vital signs and report abnormal findings for prompt treatment.

Imbalanced nutrition: less than body requirements related to dysphagia

EXPECTED OUTCOME: Patient will maintain weight within normal limits for body frame and laboratory values such as albumin, electrolytes, and lymphocytes will be within normal limits.

- Obtain patient height and weight, and weigh weekly to monitor changes during care.
- Identify patient's ability to swallow and eat food to determine plan of care.
- Provide oral care frequently to refresh mouth and encourage desire to eat.
- Provide nutrition as ordered in form patient is able to tolerate: liquid supplements, tube feedings, total perenteral nutrition (TPN) to maintain adequate nutrition.

Evaluation

The goals are met if the patient reports pain is relieved and fluid volume and nutritional needs are met.

HIATAL HERNIA

Pathophysiology

The esophagus passes through an opening in the diaphragm called the hiatus. A **hiatal hernia** is a condition in which the lower part of the esophagus and stomach slides up through the hiatus of the diaphragm into the thorax (Fig. 33.4). A sliding hiatal hernia is the most common type in which the stomach slides up into the thoracic cavity when a patient is supine and then usually goes back into the abdominal cavity when the patient stands upright. Hiatal hernia occurs most commonly in women and those who are older than age 60, obese, or pregnant. People with hiatal hernia often have gastroesophageal reflux disease (GERD) as well (discussed later).

Signs and Symptoms

A small hernia may not produce any discomfort or require treatment. However, a large hernia can cause pain, heartburn, a feeling of fullness, or reflux, which can injure the esophagus with possible ulceration and bleeding.

Diagnosis

Hiatal hernias are diagnosed by x-ray studies and fluoroscopy.

Therapeutic Interventions

Medical treatment for symptomatic hiatal hernia includes antacids; eating small meals that pass easily through the esophagus; not reclining for 1 hour after eating; elevating the head of the bed 6 to 12 inches to prevent reflux; and avoiding bedtime snacks, spicy foods, alcohol, caffeine, and smoking (see Box 33.2 Nutrition Notes).

Surgical Management

Surgical procedures can be done to prevent the herniated portion of the stomach from moving upward through the hiatus. Fundoplication, in which the stomach fundus is wrapped around the lower part of the esophagus, is the most common surgical procedure performed (Fig. 33.5).

FIGURE 33.4 Hiatal hernia. (A) Normal esophagus and stomach. (B) Sliding hiatal hernia. (C) Rolling hiatal hernia.

FIGURE 33.5 Hiatal hernia repair: Nissen fundoplication wraps the stomach fundus around the esophagus and then sutures it onto itself to hold it in place.

Nursing Management

Teaching the patient interventions to reduce symptoms of hiatal hernia is included in the plan of care (see section Therapeutic Interventions above). If the patient undergoes surgery, general postoperative nursing care is provided. In addition, following fundoplication, patients are assessed for dysphagia during their first postoperative meal. If dysphagia occurs, the physician should be notified because the repair may be too tight, causing obstruction of the passage of food.

GASTROESOPHAGEAL REFLUX DISEASE

Pathophysiology

Gastroesophageal reflux disease (GERD) is a condition in which gastric secretions reflux into the esophagus. The esophagus can be damaged by acidic gastric secretions and exposure to digestive enzymes. GERD is caused primarily by conditions that affect the ability of the lower esophageal sphincter to close tightly, such as hiatal hernia.

Signs and Symptoms

Signs and symptoms of GERD include heartburn, regurgitation, dysphagia, and bleeding (Table 33.1). Aspiration is a concern. Scar tissue can develop from the inflammation.

Diagnosis

Diagnostic tests include a barium swallow, esophagoscopy, or pH monitoring of the normally alkaline esophagus. GERD often occurs in older people.

Therapeutic Interventions

Interventions for GERD aim to decrease the reflux of gastric secretions into the esophagus. Lifestyle changes are recommended along with medications. Obese patients are encouraged to lose weight. A low-fat, high-protein diet is recommended because fat causes decreased functioning of the lower esophageal sphincter. Caffeine, milk products, and spicy foods should be avoided.

TABLE 33.1 GERD SUMMARY

<i>Signs and Symptoms</i>	Heartburn Regurgitation Dysphagia Bleeding
<i>Diagnostic Tests</i>	X-ray studies, endoscopy, and fluoroscopy
<i>Therapeutic Interventions</i>	Medications to decrease acid, improve gastric emptying, and lower esophageal functioning: antacids, histamine (H ₂) receptor antagonists, cytoprotective agents (sucralfate), and cholinergic drugs Control of symptoms Low-fat, high-protein diet Avoid triggers
<i>Complications</i>	Esophagitis Barrett's syndrome Respiratory symptoms
<i>Possible Nursing Diagnoses</i>	Acute pain Deficient knowledge

Medications may include nonprescription antacids for mild symptoms (Mylanta, Tums, Gaviscon). Histamine (H₂) receptor antagonists (acid reducers) that are available in nonprescription and prescription strengths are used for mild to moderate symptoms (cimetidine [Tagamet], famotidine [Pepcid], ranitidine HCl [Zantac], nizatidine [Axid]). Proton pump inhibitors (PPI) reduce acid in the stomach and are used for frequent, severe symptoms and Barrett's esophagus (esomeprazole [Nexium], lansoprazole [Prevacid], omeprazole [Prilosec], pantoprazole [Protonix], rabeprazole [Aci-plex]). Prokinetic agents, which are not used as a first choice because of side effects, (metoclopramide [Reglan, Maxolon]) improve gastric emptying and function of the lower esophageal sphincter (see Table 33.4). If surgery is necessary to alleviate symptoms, a fundoplication can be done.

Complications

Complications of GERD can result in esophagitis (inflammation of the esophagus) due to acid reflux. Over time this can lead to changes in the epithelium of the esophagus and lead to Barrett's esophagus. This is a precancerous lesion that puts the patient at risk of developing esophageal cancer. The patient with Barrett's esophagus should have regular endoscopic examinations. Respiratory complications such as bronchospasm, laryngospasm, and aspiration pneumonia can also occur owing to aspiration of gastric contents.

Nursing Process for the Patient with GERD

Assessment/Data Collection

Assessment of the patient with GERD should include evaluation of complaints of heartburn. Note the onset, duration, and characteristics of the pain. Note any precipitating factors as well as anything that relieves the pain.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to inflammation of esophageal tissues

EXPECTED OUTCOME: Patient will state a reduction of pain to acceptable level or total relief of pain.

- Monitor pain level using pain rating scale *to identify pain level.*
- Identify factors that increase pain *to develop teaching plan.*
- Instruct patient regarding factors that aggravate pain *to enhance management of condition.*
- Instruct patient to sleep with head of bed elevated 4 to 6 inches, eat small meals, and avoid lying down for 2 hours after eating *to prevent reflux of gastric contents into esophagus.*
- Instruct patient to avoid smoking and alcohol *as they decrease functioning of the lower esophageal sphincter.*
- Instruct patient to avoid foods that cause discomfort *to avoid pain.*
- Review medication schedule and teach patient to take medications even if symptoms are relieved *since the underlying pathology still exists.*
- If surgery is completed, provide pain medications on routine schedule *to provide optimum pain relief and control.*

Evaluation

The goals are met if the patient is able to manage the medications, pain is controlled, and symptoms are relieved.

MALLORY-WEISS TEAR

Pathophysiology

A Mallory-Weiss tear (MWT) is a longitudinal tear in the mucous membrane of the esophagus at the stomach junction (gastric cardia). These tears occur from a sudden powerful or prolonged force due to coughing, vomiting, seizures, prolapse of the stomach into the esophagus, or cardiopulmonary resuscitation (CPR). Hiatal hernia is present in most patients with MWTs .

Signs and Symptoms

Bleeding may result from the tear. Up to 15% of GI bleeding occurs from MWTs. Symptoms include bright red bloody emesis or bloody or tarry stools.

Diagnosis

The tear can be diagnosed with an esophagogastroduodenoscopy (EGD). Hemoglobin and hematocrit are checked to determine amount of bleeding.

Therapeutic Interventions

The tears usually self heal without intervention in several days and bleeding stops within a few hours. It is rare to have it happen again. Medications such as a PPI and an antieme-

tic may be given. Alcohol use should be avoided. Up to 75% of those with MWT use alcohol excessively. Rarely, excessive bleeding may occur resulting in shock and or the need for a blood transfusion. Bleeding is treated with epinephrine injection, and during endoscopy, hemoclips can be placed. The prognosis for MWTs is good. The condition is seen in men more often than in women.

Nursing Management

Monitoring the patient for the signs of bleeding and reporting them to prevent complications from hemorrhage are the focus of nursing care. If excessive bleeding occurs, shock symptoms may occur and require prompt intervention. Teaching about medications and the avoidance of alcohol use is also done. See section Gastric Bleeding later in this chapter for more information.

ESOPHAGEAL VARICES

Esophageal varices are dilated blood vessels in the esophagus. If they rupture, it can be a life-threatening event. Varices develop from portal hypertension. This occurs when pressure rises in the portal vein from blocked blood flow in the liver. This is often due to cirrhosis of the liver. Esophageal varices are discussed in Chapter 35.

GASTRITIS

Pathophysiology

Gastritis is inflammation of the stomach mucosa and can be acute or chronic. Causes are listed in Box 33.5. Gastritis results when the protective mucosal barrier is broken down and allows autodigestion from hydrochloric acid and pepsin to occur. This results in edema of the tissue and possible hemorrhage. With severe gastritis, the gastric mucosa can become gangrenous and perforate, which can lead to peritonitis (infection of the peritoneum). Scarring may also occur, resulting in pyloric obstruction.

Signs and Symptoms

The major symptom of gastritis is abdominal pain, which is often accompanied by nausea and anorexia. The patient may also experience abdominal tenderness, feeling of fullness, reflux, belching, and hematemesis. If the cause of the gastritis is contaminated food, symptoms including diarrhea usually start within 5 to 6 hours.

Therapeutic Interventions

Treatment of gastritis is removal of the irritating substance and provision of a bland diet of liquids and soft foods along with antacids. Medication therapy may include phenothiazines to control vomiting and antacids and/or histamine

gastritis: gastr—stomach + itis—inflammation

- Endoscopic procedures

receptor antagonists to control pain. With a bland diet, the patient usually recovers in a short period of time.

Chronic Gastritis

Chronic gastritis occurs over time and is classified as type A or type B.

Type A

Chronic gastritis type A is often referred to as autoimmune gastritis and occurs in the fundus (body of stomach). Chronic gastritis type A is diagnosed by endoscopy, upper gastrointestinal (GI) x-ray examination, and gastric aspirate analysis (see Chapter 32). Type A gastritis is often asymptomatic. Patients with type A gastritis usually do not secrete enough intrinsic factor from their stomach cells and as a result have difficulty absorbing vitamin B₁₂, which leads to pernicious anemia (discussed later).

Type B

Type B chronic gastritis affects the antrum and pylorus (lower end of the stomach near the duodenum) and is associated with *Helicobacter pylori* bacterial infection. Type B is the most common type of chronic gastritis. Signs and symptoms include poor appetite, heartburn after eating, belching, a sour taste in the mouth, and nausea and vomiting. Type B gastritis can also be diagnosed by endoscopy, upper gastrointestinal x-ray examination, and gastric aspirate analysis. *H. pylori* infection is treated with antibiotics.

PEPTIC ULCER DISEASE
Etiology

Until 1982 the cause of peptic ulcer was poorly understood and thought to be related to stress, diet, and alcohol or caffeine ingestion. However, research results found that **peptic ulcer disease** (PUD) is primarily caused by infection with the gram-negative bacterium *Helicobacter pylori* (*H. pylori*). This bacterium is responsible for 80% of gastric ulcers and more than 90% of duodenal ulcers. Two-thirds of all people are infected with *H. pylori*, and it is most common in those who are elderly, Hispanic, African American, or in lower socioeconomic groups in the United States. The discovery of *H. pylori* has led to changes in treating and curing peptic ulcers. It is not known how *H. pylori* is transmitted, although the oral-oral or fecal-oral route is likely. Contaminated water may also play a role. Vaccines to prevent peptic ulcers are being developed.

Risk factors that contribute to PUD include smoking, chewing tobacco, stress, caffeine, or medications such as steroids, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs). Peptic ulcer development is also influenced by smoking, which increases the harmful effects of *H. pylori*, alters protective mechanisms, and decreases gastric blood flow. For more information on *H. pylori*, visit www.cdc.gov or call 1-888-MY-ULCER (1-888-698-5237).

**LEARNING TIP**

Most peptic ulcers are caused by an infection (*H. pylori*) that can be cured with antibiotics.

Pathophysiology

PUD is a condition in which the lining of the stomach, pylorus, duodenum, or the esophagus is eroded, usually from infection with *H. pylori*. The erosion may extend into the muscular layers or the peritoneum. Peptic ulcers occur in the portions of the gastrointestinal tract that are exposed to hydrochloric acid and pepsin. The erosion is due to an increase in the concentration or activity of hydrochloric acid and pepsin. The damaged mucosa is unable to secrete enough mucus to act as a barrier against the hydrochloric acid. Some individuals have more rapid gastric emptying, which, combined with hypersecretion of acid, creates a large amount of acid moving into the duodenum. As a result, peptic ulcers occur more often in the duodenum. Ulcers are named by their location: esophageal, gastric, or duodenal. Duodenal ulcers are more common than gastric ulcers.

Signs and Symptoms

Symptoms vary with the location of the ulcer (Table 33.2). Symptoms, including pain, may not be experienced with gastric or duodenal ulcers until complications such as hemorrhage, obstruction, or perforation develop. If pain does

TABLE 33.2 PEPTIC ULCER DISEASE SUMMARY

Signs and Symptoms	<p><i>Gastric:</i> Intermittent high left epigastric or upper abdominal burning or gnawing pain, increased 1–2 hours after meals or with food. Variable pain pattern may be made worse by food, antacids ineffective. Can lead to gastric cancer. Patient may be malnourished. Hematemesis is more common than melena.</p> <p><i>Duodenal:</i> Intermittent midepigastric or upper abdominal burning or cramping pain, increased 2–4 hours after meals or in the middle of the night; relieved with food or antacids. Patient generally well nourished. Melena is more common than hematemesis.</p> <p>Anorexia Nausea/vomiting Bleeding (stomach secretions or stool positive for occult blood)</p>

Medical Treatment	Antibiotics Proton pump inhibitors H ₂ antagonists Bismuth subsalicylate Sucralfate (Carafate) Antacids Bland diet Avoiding irritants, such as smoking, caffeine, alcohol
Complications	Bleeding Perforation Obstruction
Nursing Diagnoses	Acute pain related to disruption of GI mucosa Risk for injury related to complications of peptic ulcer activity such as hemorrhage or perforation Deficient knowledge related to lack of exposure to peptic ulcer disease and its treatment

occur, patients with gastric ulcers commonly experience a burning and gnawing pain in the high left epigastric region. There may be more pain with food ingestion or 1 to 2 hours after a meal. Duodenal ulcers produce cramping or burning pain in the midepigastric or upper abdominal area. The pain occurs 2 to 4 hours after meals or in the middle of the night. This intermittent pain may be relieved by the ingestion of food or antacids. Anorexia and nausea and vomiting may also occur with either ulcer location. Bleeding may occur with massive hemorrhaging or slow oozing. Patients often have low hematocrit and hemoglobin levels, and gastric or

fecal occult blood may be found, depending on where the ulcers are located.

Diagnosis

H. pylori can be diagnosed with several tests. The urea breath test is performed by having the patient drink carbon-labeled urea. The urea is metabolized rapidly if *H. pylori* is present, allowing the carbon to be absorbed and measured in exhaled carbon dioxide. An IgG antibody detection test for *H. pylori* identifies whether the patient is infected with *H. pylori*. These are both noninvasive detection tests. Biopsy specimens for the *Campylobacter*-like organism (CLO) biopsy urease test and a histological examination can be obtained during esophagogastroduodenoscopy (EGD). Biopsy is the most conclusive test for *H. pylori*. Cultures of the biopsy specimen may also be done to determine antimicrobial susceptibility.

Peptic ulcers are diagnosed on the basis of symptoms, upper GI series (barium swallow), endoscopy, and EGD.

Therapeutic Interventions

Several treatment options are used to cure *H. pylori* without recurrence (Table 33.3). The first antibiotic treatment for ulcer disease caused by *H. pylori* was approved by the Food and Drug Administration (FDA) in 1996. For better effectiveness, triple therapy with two antibiotics to decrease resistance of the bacteria and a proton pump inhibitor or H₂ antagonist is used. Treatment lasting 14 days has better eradication rates than 10-day treatments. Bismuth subsalicylate (Pepto-Bismol) may also be used for its antibacterial effects. Proton pump inhibitors are powerful agents that stop the final step of gastric acid secretion to reduce mucosa erosion and aid in healing ulcers (Table 33.4). H₂ antagonists block H₂ receptors to decrease acid secretion, although not as powerfully as gastric acid pump inhibitors. A bland diet may

TABLE 33.3 MEDICATION REGIMEN OPTIONS FOR *H. PYLORI* INFECTION

Type of Therapy	Examples of Therapy Options
Triple Therapy*	<ul style="list-style-type: none"> Amoxicillin (Amoxil) + clarithromycin (Biaxin) + omeprazole (Prilosec)
Two antibiotics + proton pump inhibitor	<ul style="list-style-type: none"> Amoxicillin (Amoxil) + clarithromycin (Biaxin) + lansoprazole (Prevacid) (available as Prevpac, combined for convenience)
Dual Therapy	<ul style="list-style-type: none"> Clarithromycin (Biaxin) + omeprazole (Prilosec)
Antibiotic + proton pump inhibitor or Antibiotic + H ₂ antagonist	<ul style="list-style-type: none"> Amoxicillin (Amoxil) + lansoprazole (Prevacid) Clarithromycin (Biaxin) + ranitidine bismuth citrate (Tritec)
Other Therapy	<ul style="list-style-type: none"> Two antibiotics + bismuth subsalicylate + H₂ antagonist Metronidazole (Flagyl) + tetracycline + bismuth subsalicylate (Pepto-Bismol) + H₂ antagonist

*Triple therapy has a better eradication rate.

TABLE 33.4 MEDICATIONS USED TO PROMOTE HEALING OF PEPTIC ULCERS

Drug Class/Action	Examples	Route	Side Effects	Nursing Implications
Hyposecretory Agents H₂ Receptor Blocking Agents Inhibits gastric acid secretion by blocking H ₂ receptors on gastric parietal cells.				
	Cimetidine (Tagamet)	PO, IM, IV	Fever, rash, headaches, dizziness, somnolence, confusion (especially in elderly), hypotension, diarrhea, neutropenia, gynecomastia, and impotence	Monitor mental status of elderly; do not take antacids within 1 hour of Tagamet; take with meals and at bedtime; interacts with theophylline, phenytoin, warfarin, and beta blockers; continue treatment for at least 8 weeks to ensure healing.
	Ranitidine (Zantac)	PO, IM, IV	All side effects rare, including nausea, constipation, bradycardia, increased liver enzymes, and headache	Give antacids at least 1 hour before or 2 hours after Zantac; can be given in single bedtime dose; use cautiously in patients with liver or renal disease; absorption not affected by food; interacts minimally with other drugs.
	Famotidine (Pepcid)	PO, IV	Headache, diarrhea, constipation, nausea, flatulence, increased blood urea nitrogen and creatinine, and rash	Should not be taken longer than 8 weeks without physician's order; may be given with antacids; can be given in single bedtime dose; has no significant drug interactions.
	Nizatidine (Axid)	PO	Diarrhea, rash, bronchospasms, somnolence, joint pain, and sweating	Give as single bedtime dose or, if given twice a day, one dose at bedtime; assess for excessive drowsiness; monitor and record stools; do not give antacids within 1 hour of Axid; must be taken 4 to 8 weeks for ulcer healing; notify physician if somnolence or rash develops.
Proton Pump Binds to enzyme on gastric parietal cells to prevent final transport of hydrogen to block gastric acid secretion.				
	Omeprazole (Prilosec)	PO	Abdominal pain, diarrhea, rash, chest pain, and weakness	Give before meal in morning; swallow capsule whole; assess for abdominal pain and bleeding; monitor complete blood cell count and liver enzymes; may be given with antacids; must be taken 4 to 8 weeks for ulcer healing; notify physician if bleeding, diarrhea, headache, or abdominal pain develops.
	Lansoprazole (Prevacid)	PO	Dizziness, headache, diarrhea, abdominal pain, nausea, rash	Note epigastric or abdominal pain and blood in stool, emesis, or gastric aspirate. Give before meals. Capsules may be opened and sprinkled on applesauce and taken immediately for patients with difficulty swallowing. Do not crush capsule. Tell patient not to chew capsule.
Same as for lansoprazole Antacids Increases gastric pH to reduce pepsin activity; strengthens gastric mucosal barrier and esophageal sphincter tone.				
	Rabeprazole (Aciphex)	PO	Headache	Tell patient to swallow tablets whole.
	Aluminum-magnesium combinations (Riopan, Maalox, Mylanta, Gelusil)	PO	Mild constipation or diarrhea	Do not give to patients with renal disease; monitor bowel movements and signs of hypermagnesemia; Riopan low in sodium; do not give within 1 to 2 hours of H ₂ receptor antagonists, tetracycline, or enteric-coated tablets.
	Calcium carbonate (Tums, Titralac)	PO	Constipation, gastric distention, rebound hyperacidity, hypercalcemia, and hypophosphatemia	Do not give with milk; monitor for symptoms of hypercalcemia and constipation; do not give within 1 to 2 hours of H ₂ receptor antagonists, tetracycline, or enteric-coated tablets.
Mucosal Barrier Fortifiers In presence of mild acid condition, forms viscid and sticky gel and adheres to ulcer surface, forming a protective barrier.				
	Sucralfate (Carafate)	PO	Dizziness, constipation, sleepiness, nausea, and gastric discomfort	Take on an empty stomach, 1 hour before meals and at bedtime; monitor for constipation.

also be recommended, and foods known to cause discomfort to the patient, such as spicy foods, carbonated drinks, and caffeine, should be avoided until the ulcer heals. Alcohol should also be avoided during the healing period.

Complications

Major complications can result from PUD. These include bleeding, perforation, and obstruction. Bleeding can occur in varying degrees from occult blood in stool and emesis to massive bright red bleeding. Hemorrhage tends to occur more often with gastric ulcers in older adults. The patient may experience signs and symptoms of shock. Treatment includes stopping the bleeding, replacing fluid and electrolytes, and possibly administering vasopressin to stop the bleeding.

A perforated ulcer is a medical emergency and usually requires surgical intervention. Gastroduodenal contents escape through the perforation into the peritoneal cavity. This can result in peritonitis, septicemia, and hypovolemic shock. Perforation most often occurs with duodenal ulcers and presents with an acute onset of sharp, severe pain. Surgical treatment includes cleaning the peritoneal cavity, closing the perforation, and possibly a vagotomy and hemigastrectomy or pyloroplasty.

Obstruction may be due to scar tissue because of repeated ulcerations and healing in a patient with long-standing PUD. Obstruction frequently occurs at the pylorus causing pain at night and vomiting. A pyloroplasty is completed to correct the problem.

CRITICAL THINKING

Mr. Smith

■ Mr. Smith is a patient on your medical/surgical unit who has a duodenal ulcer. His wife runs to the nursing station and says that you need to help her husband, he is in terrible pain. As you enter the room, you see Mr. Smith curled up in a knee-chest position on the bed. He is crying and is complaining of excruciating abdominal pain.

1. What additional data would you like to gather?
2. What nursing actions would you complete?
3. What emotional support would you offer to Mrs. Smith?
4. What complication do you suspect Mr. Smith is experiencing?

Suggested answers at the end of chapter

Nursing Process for the Patient with Peptic Ulcer Disease

Assessment/Data Collection

The primary focus of nursing care for peptic ulcer disease is educating patients regarding the importance of this diagnosis because ulcers may be caused by an infection that can be cured with antibiotics. Patients may still believe that all

ulcers are caused by stress, lifestyle, or diet. Assessing the patient's knowledge aids in providing accurate information to assist the patient in managing peptic ulcer disease. Data are also collected about the patient's disease history. Identifying factors that trigger or relieve symptoms is important.

The nurse should assess and monitor for complications of bleeding, such as occult blood in stool or emesis, perforation, including acute onset of severe pain, obstruction, changes in vital signs, and signs of shock

Nursing Diagnosis, Planning, Implementation, and Evaluation

See Box 33.6 Nursing Care Plan for the Patient with Peptic Ulcer Disease. The care plan should focus on the patient's understanding of the importance of taking all medication as directed, even if symptoms are gone. Patient noncompliance with treatment is a major cause of ulcer recurrence.

STRESS ULCERS

A small number of patients who are critically ill may develop gastric or small intestinal stress ulcers from ischemia. The stress response to the illness causes reduced blood flow to the stomach and small intestine, resulting in ischemia and damage to the mucosa. The damaged mucous barrier allows acid secretions to create ulcers. Preventive treatment has dramatically reduced stress ulcers, which have a high mortality rate because of the multiple bleeding ulcer sites. This treatment includes trauma care that quickly restores oxygen to the stomach, as well as early feeding within 24 hours of the trauma. Placement of a nasogastric (NG) tube allows testing of the gastric pH to ensure that it is higher than 5, as well as providing a means for enteral feeding. In addition, medications are given such as antacids and histamine blockers.

GASTRIC BLEEDING

Gastric bleeding may be caused by ulcer perforation, tumors, gastric surgery, or other conditions. Bleeding peptic ulcers are the most common cause of blood loss into the stomach or intestine. Blood loss can be hidden (occult) blood in the stool, observable vomited blood (hematemesis), or black tarry stools (melena). When blood mixes with hydrochloric acid and enzymes in the stomach, a dark, granular material resembling coffee grounds is produced. This material can be vomited or passed through the GI system and mixed with stools. Melena occurs from slow bleeding in an upper GI area.

Signs and Symptoms

With mild bleeding, the patient may experience only slight weakness or diaphoresis (Table 33.5). Severe blood loss (more than 1 L in 24 hours) may result in hypovolemic shock, with signs and symptoms such as hypotension; a weak, thready pulse; chills; palpitations; and diaphoresis.

Box 33.6 NURSING CARE PLAN for the Patient with Peptic Ulcer Disease

Nursing Diagnosis: Acute pain related to gastric mucosal erosion

Expected Outcomes Patient's pain is relieved as evidenced by no report of pain and absence of nonverbal pain cues.

Evaluation of Outcomes Is pain relieved to patient's satisfaction?

Interventions

Ask patient to rate pain level on scale of 0 to 10 every 3 hours and as needed. Note location, onset, intensity, characteristics of pain, and nonverbal pain cues.

Ask about factors precipitating and relieving pain.

Ask patient to help identify techniques for pain relief.

Administer antiulcer medications as ordered.

Provide small, frequent meals four to six times a day.

Encourage nonacidic fluids between meals.

Rationale

Prompt assessment can lead to timely intervention and relief of pain.

Peptic ulcer pain may be relieved by food, antacids, or other interventions.

Gaining the patient's cooperation increases compliance.

H₂ receptor antagonists reduce amount of gastric acid produced, and antacids neutralize gastric acid to help relieve pain.

Small, frequent meals dilute and neutralize gastric acid.

Nonacidic fluids decrease irritation to gastric mucosal.

Evaluation

Does patient rate pain using scale and describe pain?

Is patient able to state precipitating and relieving pain factors?

Is patient willing to participate in planning how to relieve pain?

Do medications reduce patient's symptoms?

Does patient report relief of gastric pain between meals?

Does patient identify and drink nonacidic fluids?

Nursing Diagnosis: Risk for injury related to complications of peptic ulcer activity such as hemorrhage and perforation

Expected Outcomes Patient's vital signs will be maintained within normal limits and bleeding or hemorrhage will be promptly detected.

Evaluation of Outcomes Are patient's vital signs within normal limits?

Interventions

Monitor for signs and symptoms of hemorrhage such as hematemesis (vomiting blood) and melena (blood in the stool).

Monitor vital signs: blood pressure, pulse, respirations, and temperature.

Maintain intravenous infusion as ordered.

Monitor hematocrit and hemoglobin levels as ordered.

Rationale

Rapid assessment can lead to prompt intervention.

Severe blood loss of more than 1 L per 24 hours may cause manifestations of shock such as hypotension; weak, thready pulse; chills; palpitations; and diaphoresis.

Normal fluid balance prevents hypovolemia and shock due to hemorrhage.

Decreased hematocrit and hemoglobin levels indicate a decrease in circulating blood volume and reduced oxygen-carrying capacity to the tissues.

Evaluation

Does patient have any bleeding?

Are vital signs normal?

Are intake and output balanced?

Are hematocrit and hemoglobin levels normal?

TABLE 33.5 GASTRIC BLEEDING SUMMARY

Signs and Symptoms	Occult blood in stool Hematemesis Melena
Diagnostic Tests	Hypovolemic shock Endoscopy
Therapeutic Interventions	Low hemoglobin and hematocrit Treat hypovolemic shock: NPO, IV fluids, oxygen therapy, NG tube Removal or ligation of bleeding area Medications to decrease gastric acid
Complications	Hypovolemic shock
Possible Nursing Diagnoses	Deficient fluid volume Risk for deficient fluid volume

Therapeutic Interventions

The goal of treatment for a massive GI bleed is to prevent or treat hypovolemic shock and prevent dehydration, electrolyte imbalance, and further bleeding. The patient is kept on nothing by mouth (NPO) status. An intravenous (IV) line is started to replace lost fluids and administer blood if necessary. A complete blood cell count is obtained to determine the amount of blood lost. A urinary catheter is inserted to monitor output. An NG tube is inserted to assess the rate of bleeding, decompress the stomach, monitor the pH of gastric secretions, and administer saline lavage if ordered. Oxygen therapy may be required if the patient has lost a large amount of blood. To prevent aspiration with vomiting, the head of the bed is elevated. The physician may perform endoscopy to help control the bleeding. Drugs may also be instilled into the GI tract by use of an endoscope. For severe cases, surgery may be needed to remove the bleeding area or ligate bleeding vessels. Drugs such as ranitidine (Zantac) are given to decrease the secretion of gastric acid.

Nursing Process for the Patient with Gastric Bleeding

Assessment/Data Collection

The nurse should assess patients at risk for bleeding for signs and symptoms of bleeding. Assess any emesis and stool for occult or obvious bleeding. Assess for signs of hypovolemic shock such as hypotension, tachycardia, tachypnea, chills, palpitations, and diaphoresis. The nurse should also assess for changes in level of consciousness, confusion, dry mucous membranes, reports of thirst, and fatigue which could indicate a decrease in circulating blood volume.

Nursing Diagnosis, Planning, and Implementation

Deficient fluid volume or risk for deficient fluid volume related to vomiting and diarrhea

EXPECTED OUTCOME: Vital signs remain within normal limits and balanced intake and output over 24 hours.

- Monitor color, amount, and frequency of fluid loss to determine fluid balance changes.
- Monitor vital signs and report abnormal findings for prompt treatment.

- Monitor level of consciousness, mucous membranes, and skin turgor to assess for changes in fluid volume.
- Obtain daily weights to detect changes in fluid volume.
- Offer oral fluids to ensure adequate intake.
- Monitor intravenous infusion as ordered to prevent hypovolemia.
- Monitor hematocrit and hemoglobin levels as ordered to detect a decrease in circulating blood volume.

Evaluation

If interventions have been effective, vital signs are within the normal range and the patient has a balanced intake and output over 24 hours.

GASTRIC CANCER

Gastric cancer refers to malignant lesions found in the stomach. It is more common in men than in women. *H. pylori* infection plays a role in gastric cancer development. Studies are being done to see whether preventing *H. pylori* infection reduces the development of gastric cancer. Other factors that may be associated with gastric cancer development include pernicious anemia; exposure to occupational substances such as lead dust, grain dust, glycol ethers, or leaded gasoline; and a diet high in smoked fish or meats. A poor prognosis is often associated with gastric cancer because most patients have metastasis at the time of diagnosis (see Box 33.2 Nutrition Notes).

Signs and Symptoms

Gastric cancer is rarely diagnosed in its early stages because symptoms do not appear until late in the disease (Table 33.6). In the early stages, there may not be any symptoms at all, and metastasis to another organ, such as the liver, may have already occurred. The symptoms of gastric cancer are often mistaken for peptic ulcer disease: indigestion, anorexia, pain relieved by antacids, weight loss, and nausea and vomiting. Anemia from blood loss commonly occurs, and occult blood in the stool may be present.

Diagnosis

Diagnosis of gastric cancer is made by upper gastrointestinal x-ray examination, gastroscopy, gastric fluid analysis, and measurement of serum gastrin levels.

Therapeutic Interventions

There is little effective medical treatment available for gastric cancer. Surgical removal of the cancer is the most effective treatment for gastric cancer. Most often the cancer has already metastasized, and surgery is performed only to relieve the symptoms. Chemotherapy and radiation are sometimes used in conjunction with surgery, although they

TABLE 33.6 GASTRIC CANCER SUMMARY

Signs and Symptoms	Rarely detected during early stages Symptoms often mistaken for PUD: indigestion, anorexia, pain, weight loss, nausea, vomiting, anemia Late symptoms include involvement of other organs such as the liver
Diagnostic Tests	X-ray studies Gastroscopy Gastric fluid analysis Serum gastrin levels
Therapeutic Interventions	Medical treatment is not very effective Surgical treatment subtotal or total gastrectomy
Complications	Related to disease and surgery: hemorrhage, acute gastric distention, nutritional problems
Possible Nursing Diagnoses	Acute pain related to gastric erosion and postoperative pain Fear related to body image changes, treatment and life-threatening illness

are not very effective against the cancer. Biological therapies, new cytotoxic agents, and new delivery methods are being studied for use with gastric cancer. Total parenteral nutrition is a method for providing nutrition to the patient who has had a total gastrectomy.

GASTRIC SURGERIES

Subtotal Gastrectomy

Two types of surgical interventions are used to treat upper gastrointestinal diseases. The first type is the subtotal **gastrectomy**, which is used to treat cancer in the lower two-thirds of the stomach. *Subtotal gastrectomy* is a general term used to describe any surgery that involves partial removal of the stomach. There are two types of subtotal gastrectomies: the Billroth I procedure and the Billroth II procedure.

Billroth I Procedure (Gastroduodenostomy)

In the Billroth I procedure, also known as a **gastroduodenostomy**, the surgeon removes the distal portion (75%) of the stomach (Fig. 33.6). The remainder of the stomach is anastomosed (surgically attached) to the duodenum. This procedure is used to treat gastric problems.

Billroth II Procedure

The Billroth II procedure, **gastrojejunostomy**, involves removal of the distal 50% of the stomach and reanastomosis

gastrectomy: gastr—stomach + ectomy—to remove

gastroduodenostomy: gastro—stomach + duoden—duodenum + ostomy—mouth or opening

gastrojejunostomy: gastro—stomach + jejun—jejunum + ostomy—mouth or opening

FIGURE 33.6 Subtotal gastrectomy involves removing the distal portion of the stomach. The remaining portion of the stomach is then sutured (A) to the duodenum (Billroth I procedure) or (B) to the proximal jejunum (Billroth II procedure). Vagotomy may also be performed.

of the proximal remnant of the stomach to the proximal jejunum (see Fig. 33.6). Because it results in bypassing of the duodenum, the Billroth II procedure is used to treat duodenal ulcers. Pancreatic secretions and bile are necessary for digestion and continue to be secreted into the duodenum from the common bile duct even after the partial gastrectomy.

Total Gastrectomy

Total gastrectomy, the total removal of the stomach, is the treatment for extensive gastric cancer. This surgery involves removal of the stomach, with anastomosis of the esophagus to the jejunum (Fig. 33.7).

Vagotomy

A vagotomy, in which a section of the vagus nerve is cut, may be performed with gastric surgery. Vagotomy eliminates the vagal stimulation for hydrochloric acid and gastrin hormone secretion and slows gastric motility.

Nursing Process for the Patient Having Gastric Surgery

Assessment/Data Collection

The patient's vital signs are monitored postoperatively as ordered. Respiratory status is carefully monitored because the high location of the surgical incision may cause pain, which interferes with deep breathing and coughing. Atelectasis or pneumonia can develop as a result of guarding and shallow breathing. The patient's pain is assessed and relieved, which also helps the patient's ability to deep breathe or cough without pain. The patient's IV site and

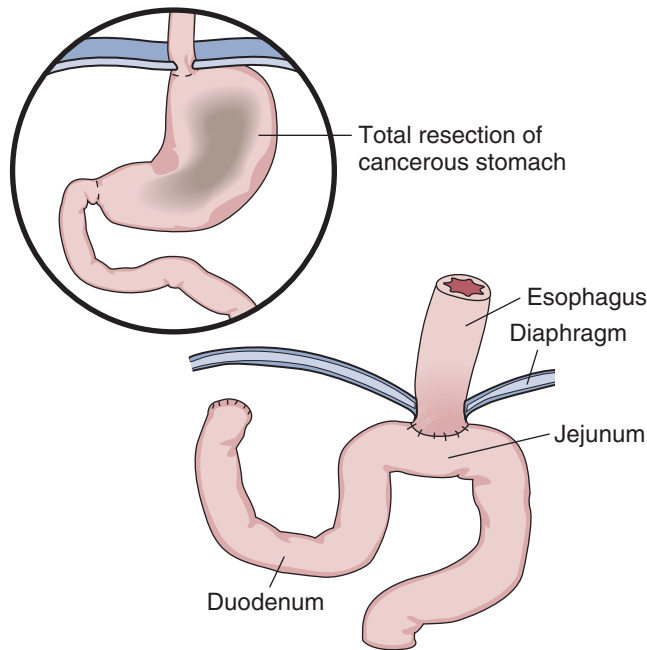

FIGURE 33.7 Total gastrectomy.

infusion are monitored, and intake and output are recorded. The incisional site and dressings are observed for drainage and bleeding.

Bowel sounds are assessed. Patients may have an NG tube inserted during surgery. The drainage from the NG tube is monitored for color and amount. If bleeding or excessive amounts of drainage are noted, they are reported to the physician. Assess the patient for abdominal distention.

Assess patient's reports of fear about the surgery and outcome of the surgery. The patient may report feeling of fear related to the uncertainty of the disease and surgery.

It is important to assess the patient's knowledge about postoperative care and discharge instructions. It is important to teach patients how to assist in their recovery. This includes incisional care, activity or dietary restrictions, and information about prescribed medications. Patients are encouraged to ambulate early to promote a quicker recovery by improving respiratory and gastrointestinal function.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to postoperative pain

EXPECTED OUTCOME: Pain will be controlled or reduced to a tolerable level of 2 to 3 on a pain scale of 0 to 10.

- Evaluate pain regularly, noting characteristics, location, and intensity on pain scale of 0 to 10 *to provide information regarding patient's pain level and effectiveness of interventions.*
- Take vital signs (note if tachycardia, hypertension, or tachypnea is present), *which may indicate acute pain is present.*
- Provide comfort measures such as positioning every 2 hours and backrub *to improve circulation and reduce tension associated with pain.*

- Use relaxation techniques such as deep breathing, guided imagery, music, and distraction therapy *to enhance relaxation and improve pain relief.*
- Medicate as ordered on routine schedule for 24 to 48 hours *to control postoperative pain and prevent pain from becoming unbearable for patient.*
- Ensure functioning of NG tube (usually low-intermittent suction) *to prevent distention and increased pain.*
- Monitor incision noting any drainage, redness, swelling, or increased pain *to assess for postoperative infection, which can increase pain level.*
- Assess religion, culture, beliefs, and circumstances *to determine impact on patient's pain and response to interventions.*
- Instruct patient to inform nurse if adequate pain control is not achieved *to allow for revision of care plan.*
- Notify physician if pain control measures are unsuccessful.
- If NG tube is present, do not irrigate or reposition *to prevent damaging the suture line.*
- Encourage ambulation *to enhance respiratory and gastrointestinal function.*

Evaluation

If interventions have been effective, patient will report a reduction of pain to a tolerable level or total absence of pain.

Fear related to body image changes, treatment, and life-threatening illness

EXPECTED OUTCOME: Patient will understand and discuss disease process and treatment options and possible outcomes of treatment.

- Explain disease process and treatment options, reinforce as needed *to decrease patient's fear of the unknown.*
- Explain all postoperative procedures and interventions (such as medications, NG tube, drains) *to help decrease the patient's fear.*
- Use open communication and convey acceptance of patient's fears *to help patient cope with fears.*

Evaluation

If interventions are effective, the patient will verbalize understanding of the disease process, treatment options, and possible outcomes of treatment.

Complications of Gastric Surgery

Complications that can occur after gastric surgery include hemorrhage, acute gastric distention, nutritional problems, **steatorrhea** (fat in stools), pyloric obstruction, and dumping syndrome.

steatorrhea: steatos—fat + rhea—profuse flow

Hemorrhage

The incidence of hemorrhage after gastric surgery is very low and is most often caused by a dislodged clot at the surgical site or slippage of a suture. The patient experiencing hemorrhage exhibits restlessness, cold skin, increased pulse and respirations, and decreased temperature and blood pressure. The patient may have a change in level of consciousness and become confused. In addition, the patient may vomit bright red blood. To prevent aspiration during vomiting, the patient is turned to one side and the head of the bed is elevated.

Following gastric surgery, patients usually have an NG tube that has been inserted in the operating room. The drainage from the tube should be assessed for color and amount. A small amount of pink or light red drainage may be expected for the first 12 hours, but moderate or excessive bleeding should be immediately reported to the physician. The abdominal dressing should also be assessed for any drainage or bleeding.

Gastric Distention

In the immediate postoperative period, distention of the stomach can occur if an inserted NG tube is clogged or if an NG tube has not been inserted. Symptoms of gastric distention include an enlarged abdomen, epigastric pain, tachycardia, and hypotension. The patient may complain of feeling full and may hiccup or gag repeatedly. These symptoms must be reported to the physician.

The physician usually inserts the NG tube during surgery so that the suture line is not damaged. If suction is desired, a physician's order is required. Irrigating or repositioning the NG tube is not performed by the nurse to prevent harm to the suture line. Any problems with distention or an improperly functioning NG tube are reported to the physician. The physician may need to reposition the NG tube to correct the problem. The patient's vital signs should be monitored until the patient's distention is relieved and the patient is stable.

CRITICAL THINKING

Mr. Wong

■ You are working the evening shift on a surgical unit. A patient, Mr. Wong, has had gastric surgery earlier that morning. He has an intravenous infusion of 1000 mL dextrose 5% 0.45 normal saline over 8 hours and a nasogastric tube to low intermittent wall suction. Mr. Wong is restless and complaining of pain. His bowel sounds are absent, and his abdomen is distended. The suction canister contains no gastric output.

1. What nursing interventions in order of priority are needed to help Mr. Wong?
2. What equipment do you need to care for Mr. Wong?
3. As you monitor the IV, you know it is set for how many drops per minute with a 10-drop factor IV set?

Suggested answers at end of chapter.

Nutritional Problems

Nutritional problems that commonly occur after removal of part or all of the stomach include B₁₂ and folic acid deficiency and reduced absorption of calcium and vitamin D. Also, rapid entry of food into the bowel often results in inadequate absorption of food.

Following gastric surgery, patients are NPO until bowel sounds return (usually 24 to 48 hours) or the physician orders a diet. Intravenous fluid provides hydration. However, if patients are to be NPO for a longer time, they may need additional nutritional intake provided by total parenteral nutrition (TPN) through a central line. TPN is an intravenous solution given to meet caloric needs and provide fluids lost in drainage or emesis. Many patients with gastric cancer are malnourished and may require several days of TPN therapy.

After removal of the nasogastric tube, clear fluids may be ordered with progression to full liquids, then soft foods as the patient tolerates. Foods and fluids should be introduced into the diet gradually following gastric surgery. If the patient eats too much or too fast, regurgitation may result.

PERNICIOUS ANEMIA. Vitamin B₁₂ deficiency can occur after some or all of the stomach is removed because intrinsic factor secretion is reduced or gone. Normally vitamin B₁₂ combines with intrinsic factor to prevent its digestion in the stomach and promote its absorption in the intestines. The parenteral route has traditionally been used. However, vitamin B₁₂ is also now available in oral tablets or as a nasal gel. Vitamin B₁₂ injections are given daily initially, then weekly, and then monthly for life. Lifelong administration of vitamin B₁₂ is required to prevent the development of pernicious anemia, and patients must be taught the importance of complying with this treatment. Symptoms of pernicious anemia include anemia, weakness, sore tongue, numbness and tingling, and gastrointestinal upset.

Steatorrhea

Steatorrhea is the presence of excessive fat in the stools and is the result of rapid gastric emptying, which prevents adequate mixing of fat with pancreatic and biliary secretions. In most cases, steatorrhea can be controlled by reducing the intake of fat in the diet.

Pyloric Obstruction

Pyloric obstruction can occur after gastric surgery as a result of scarring, edema, or inflammation or a combination of these. The signs and symptoms are vomiting, a feeling of fullness, gastric distention, nausea after eating, loss of appetite, and weight loss. As the obstruction increases, it gradually becomes more difficult for the stomach to empty, and symptoms worsen. Conservative methods are used first, such as replacing fluids and electrolytes through intravenous fluids and decompressing the distended stomach using a nasogastric tube. Surgery may be necessary if conservative measures do not relieve the signs and symptoms. Pyloroplasty widens the exit of the pylorus to improve emptying of the stomach.

Dumping Syndrome

Dumping syndrome occurs with the rapid entry of food into the jejunum without proper mixing of the food with digestive juices. On entering the jejunum, the food draws extracellular fluid into the bowel from the circulating blood volume to dilute the high concentration of electrolytes and sugars. This rapid shift of fluids decreases the circulating blood volume and produces symptoms. The symptoms occur 5 to 30 minutes after eating and include dizziness, tachycardia, fainting, sweating, nausea, diarrhea, a feeling of fullness, and abdominal cramping. Additionally, the blood sugar rises, and excessive insulin is excreted in response. This release of insulin causes the patient to have symptoms of hypoglycemia about 2 hours later. Symptoms include weakness, sweating, anxiety, shakiness, confusion, and tachycardia. The patient should immediately eat some candy or drink juice containing sugar to relieve the symptoms.

The treatment for dumping syndrome includes teaching the patient to eat small, frequent meals that are high in pro-

tein and fat and low in carbohydrates, especially refined sugars (see Box 33.2 Nutrition Notes). The patient is also taught to avoid fluids 1 hour before meals, with meals, or for 2 hours after meals to prevent rapid gastric emptying. It is best for the patient to lie down after meals to delay gastric emptying. The patient is told that these symptoms may last for up to 6 months after gastric surgery but usually slowly subside over time.

CRITICAL THINKING

Mrs. Lindsay

■ Mrs. Lindsay has had gastric surgery. You have taught her about dumping syndrome, and she is concerned about what she will eat. Create a 1-day meal plan for Mrs. Lindsay.

Suggested answers at end of chapter.

REVIEW QUESTIONS

- The nurse is planning care for a patient with an eating disorder. The patient is 40 kg, and 68 inches tall. Serum laboratory data: potassium 2.6 mEq/dL, sodium 126 mEq/dL, chloride 95 mEq/dL, calcium 10.8 mg/dL. The nurse understands that which of the following is the most important intervention for this patient?
 - Weigh the patient daily at the same time.
 - Maintain IV of dextrose and electrolytes.
 - Praise intake of any type of food.
 - Document intake and output.
- In planning care for patients, the nurse understands that which of the following patients are considered obese?
 - A 25-year-old woman with body weight 5% above ideal body weight
 - A 45-year-old man with waist to-hip ratio measurement of 0.5
 - A 50-year-old man with body mass index of 31 kg/m²
 - A 16-year-old girl with anorexia nervosa weighing 45 kg.
- A patient is diagnosed with aphthous stomatitis (canker sore). Which of the following actions would be appropriate?
 - Tell patient to avoid brushing teeth until the sore has healed.
 - Encourage patient to use a mouthwash four times a day.
 - Apply acyclovir ointment to ease the pain of the lesion.
 - Teach patient to apply topical tetracycline several times a day to sore.
- The nurse is caring for a patient with gastritis. Which of the following interventions would be appropriate for a patient with gastritis?
 - Administer phenothiazine to control vomiting.
 - Instruct patient that medications such as aspirin rarely cause gastritis.
 - Monitor patient for bloody diarrhea.
 - Encourage a regular diet during the acute phase of gastritis.
- The nurse is planning a teaching session for a patient with a peptic ulcer. Which of the following would the nurse include in the teaching plan as the primary cause of peptic ulcers?
 - Eating spicy foods
 - A stressful life
 - A bacterial infection
 - Excessive caffeine intake
- After a teaching session for a patient with a peptic ulcer, the nurse would evaluate the patient as understanding the teaching if the patient stated the purpose of H₂ antagonists is which of the following?
 - Neutralize gastric acid
 - Form a protective paste
 - Determine gastric pH levels
 - Inhibit secretion of gastric acid
- A patient who has just returned from surgery after a total gastrectomy begins to vomit bright red blood. Which of the following is a priority action for the nurse to take?

- a. Increase the IV rate.
 - b. Take blood pressure.
 - c. Place patient on side.
 - d. Administer oxygen.
8. For the patient with dumping syndrome, which of these foods would the nurse instruct the patient to avoid?
- a. Spinach and avocado salad
 - b. Coffee and glazed doughnut

- c. Sausage and liver
- d. Creamed chipped beef

Fill in the blank (calculation)

9. To deliver 1000 mL of 5% dextrose in 0.45 normal saline (at 150 ml per hour using 10 drop tubings), the nurse would monitor the IV infusion at how many drops per minute?
- _____ drops per minute

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mr. Smith

1. Additional data would include: vital signs: looking for signs of shock; assessment of Mr. Smith's abdomen: looking for location of pain, tenderness, rigidity; assess for any vomiting and characteristics of emesis including any blood; and assess for IV site access.
2. Assist Mr. Smith to a comfortable position and stay with him. Call for help. Inform the RN so the physician can be notified immediately and provide data regarding Mr. Smith's change in condition. Administer oxygen, monitor IV fluids, and continue to monitor vital signs. Medicate for pain as ordered.
3. Explain that you will stay with Mr. Smith as you gather data and take vital signs. State that you have informed the RN who will assess Mr. Smith and report findings to the physician now. Explain that the treatments as ordered by the physician will be started: oxygen, IV fluids, pain medication. State that explanations will be provided related to Mr. Smith's care. Invite questions and have nursing assistant provide Mrs. Smith with comfort needs: beverage, tissues, chair.
4. You suspect a perforated duodenal ulcer, which is a medical/surgical emergency.

■ Mr. Wong

1. Prioritize your interventions:
 - a. Take Mr. Wong's vital signs to determine whether he is stable. Pain can sometimes increase the blood pressure and pulse rate. However, gastric

distention can cause pain, and once the distention is relieved, the pain caused by distention subsides.

- b. Listen to Mr. Wong's bowel sounds. Manipulation of internal organs during abdominal surgery can produce a loss of normal peristalsis for 24 to 48 hours. Expect to hear absent or hypoactive bowel sounds for the first 1 or 2 days.
- c. Next, check placement of Mr. Wong's nasogastric tube by aspirating gastric contents and verifying pH of the contents as ordered. It is important to check for abdominal placement of Mr. Wong's nasogastric tube to make sure it is not misplaced in the lungs. After abdominal placement is determined, if there is a physician's order, the nasogastric tube can be connected to suction equipment, usually set on low intermittent suction.
- d. Next check the suction equipment for ordered settings and to ensure that it is turned on. The suction setting normally is ordered to be on low. A whistling sound is heard when the tube is disconnected from the suction setup. The seals should be tight on the suction canister. When the tubing is hooked to suction, gastric contents should be moving into the suction canister. It is important to make sure equipment is functioning properly to ensure patient safety.
- e. Check the nasogastric tube for clogs only if the physician orders aspiration or irrigation to be done. The tube is gently aspirated with a 60-mL catheter-tipped syringe. If the tube remains clogged, it is gently flushed as ordered with 10 to 20 mL of sterile normal saline.

- f. After the gastric distention has been relieved, Mr. Wong's pain level is reassessed to determine if he needs pain medication. Considering that he is less than 1 day postoperative, he probably needs it.
2. Necessary equipment includes stethoscope, 60-mL catheter-tipped syringe, gloves, goggles, and normal saline for irrigation.
- 3.

$$\frac{1000 \text{ mL} \times 10 \text{ drops/mL}}{(60 \times 8) = 480 \text{ min}}$$
$$= \frac{10,000 \text{ drops}}{480 \text{ min}} = 21 \text{ drops/min}$$

■ ***Mrs. Lindsay***

Although there are many variations, the following is an example of a 1-day meal plan for Mrs. Lindsay:

Breakfast: one egg, any style; 1/2 orange; one glass milk

Snack: one slice toast with apple butter, jelly, or jam

Lunch: 2 oz ham, 1/2 cup cottage cheese, four asparagus spears

Snack: 1/2 serving chicken salad on bed of lettuce

Dinner: 2 oz broiled fish, 1/2 serving corn, 1/2 serving broccoli

Snack: 1/2 cup yogurt or sherbet

QUESTIONS TO GUIDE YOUR READING

1. What are the causes, signs, and symptoms of constipation and diarrhea?
2. What nursing care and teaching do patients with constipation or diarrhea require?
3. What medical treatment, nursing care, and teaching are appropriate for patients with inflammatory and infectious disorders of the lower gastrointestinal tract?
4. How would you describe Crohn's disease, ulcerative colitis, irritable bowel syndrome, and the nursing care for these conditions?
5. What is nursing care for abdominal hernias?
6. What nursing care and teaching do patients with absorption disorders require?
7. What are the causes, signs and symptoms, therapeutic interventions and nursing care of intestinal obstruction?
8. What are therapeutic interventions and nursing care for lower gastrointestinal bleeding?
9. What are the causes, signs and symptoms, therapeutic interventions, and nursing care of colon cancer?
10. What nursing care and teaching does a patient with an ostomy require?

The lower gastrointestinal (GI) system includes the small and large intestines, rectum, and anus.

PROBLEMS OF ELIMINATION

Constipation

Pathophysiology

Constipation occurs when the fecal mass is held in the rectal cavity for a period that is not usual for the patient. While the feces are held for a prolonged time in the rectum, more water is absorbed, making the feces drier, harder, more difficult to pass, and sometimes painful to pass.

If a patient repeatedly ignores the urge to have a bowel movement (laxation), the musculature and rectal mucous membrane become insensitive to the presence of feces. Eventually a stronger stimulus is needed to produce the peristaltic rush required for defecation. Prolonged constipation is called **obstipation**.

Etiology

There are many causes of constipation. Medications such as narcotics, tranquilizers, and antacids with aluminum decrease motility of the large intestine and may contribute to constipation. Rectal or anal conditions such as **hemorrhoids** or **fissures** may lead to a delay in defecation because of the associated pain. Metabolic or neurological conditions such as diabetes mellitus, multiple sclerosis, lupus erythematosus, or scleroderma may interfere with normal bowel innervation and function. Colon cancer may cause an obstruction that prevents normal bowel function and leads to constipation. Low intake of dietary fiber and fluids decreases the bulk of the feces and causes constipation. Decreased mobility, weakness, and fatigue, especially in the elderly, reduce the strength of the muscles used for defecation, increasing the likelihood of constipation. Chronic laxative use can also contribute to constipation because the laxative overrides the bowel's ability to recognize the urge to defecate.

Prevention

Regular exercise and a diet high in fiber and fluids are the best preventive measures for constipation. Laxatives should be used only occasionally to prevent dependence and complications.

Signs and Symptoms

Abdominal pain and distention, indigestion, rectal pressure, a sensation of incomplete emptying, and intestinal rumbling are indications of constipation (Table 34.1). The patient may also complain of headache, fatigue, decreased appetite, straining at stool, and elimination of hard, dry stool.

Complications

A variety of problems can result from constipation. Fecal **impaction** may result when the fecal mass is so dry it cannot be passed. Pressure on the colon mucosa from a mass of stool may cause ulcers to develop. Often, small amounts of liquid stool ooze around the fecal mass and cause inconti-

TABLE 34.1 CONSTIPATION SUMMARY

<i>Signs and Symptoms</i>	Abdominal distention Indigestion Rectal pressure Feeling of incomplete emptying Straining at stool Hard, dry stool Intestinal rumbling
<i>Diagnostic Tests</i>	History Physical examination
<i>Therapeutic Interventions</i>	High-fiber diet 2–3 L fluid daily Strengthening of abdominal muscles Exercise Bulk-forming agents Stool softeners
<i>Nursing Diagnosis</i>	Constipation Deficient knowledge

nence of liquid stools. The incontinence may be treated with an antidiarrheal medication, which will worsen the constipation if a thorough assessment is not performed to rule out impaction. Straining to have a bowel movement (Valsalva's maneuver) can result in cardiac, neurological, and respiratory complications. If the patient has a history of heart failure, hypertension, or recent myocardial infarction, straining can lead to cardiac rupture and death. Grossly dilated loops of the colon, known as **megacolon**, can occur proximal to the dry fecal mass and obstruct the colon. Abdominal distention occurs, and in severe cases, loops of bowel can be palpated through the abdominal wall.

Chronic laxative abuse can lead to colonic mucosal atrophy, muscle thickening, and fibrosis. These conditions can result in perforation of the colon and necessitate an emergency **colectomy**.

Diagnostic Tests

Constipation is usually self-diagnosed or diagnosed by history and physical examination. If complications are suspected, a radiographic examination, sigmoidoscopy, and stool testing for occult blood may be necessary.

Therapeutic Interventions

Treatment of constipation depends on the cause. Fiber should be added to the diet, and exercises to strengthen abdominal muscles should be done. Behavior changes, such as setting a daily defecation time, appropriately responding to the urge to defecate, and drinking 8 oz of warm water every morning and 2 to 3 L of water every day, if it is not contraindicated for other reasons, can help establish a more normal bowel pattern. Chronic laxative use should be discontinued. Bulk-forming agents such as psyllium (Metamucil) or stool softeners such as docusate sodium (Colace) should be used

megacolon: mega—large + colon—colon

colectomy: col—pertaining to colon + ectomy—surgical excision

instead of laxatives. Enemas and rectal suppositories are used only in extreme cases and are discontinued when an acute episode is resolved. A new medication, methylnaltrexone (MNTX), is under study and may be available in the future for use with palliative care patients to treat constipation from opioid use.

Nursing Process for the Patient with Constipation

ASSESSMENT/DATA COLLECTION. The patient may feel self-conscious or embarrassed when interviewed about bowel habits and history. Consideration should be given to the patient's feelings by postponing the discussion until rapport has been established. The nursing history should include the onset and duration of constipation, past elimination pattern, current elimination pattern, occupation, lifestyle (stress, exercise, nutrition), history of laxative or enema use, medical-surgical history, and current medications being taken. The color, consistency, and odor of the stool, as well as any intestinal symptoms, are also important.

After the interview, the patient's abdomen is inspected and palpated for distention and symmetry. Inspection of the perianal area may reveal fissures, external hemorrhoids, or irritation.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Constipation related to irregular defecation habits

EXPECTED OUTCOME: The patient will maintain passage of soft, formed stool every 1 to 3 days without straining.

- Assess normal pattern of defecation, diet and fluid intake, medications, surgeries, and use of laxatives to help identify factors contributing to constipation.
- Setting a specific time for defecation, such as after a meal to facilitate the urge reflex.
- Place feet on a footstool to promote flexion of the hips to aid defecation.
- For constipation caused by decreased motility and muscle tone or a low-fiber diet, a high-fiber, high-residue diet including fresh fruits, vegetables, and whole grains with 2 g of bran added to cereal daily can be eaten to significantly increase bowel movements and decrease the number of laxatives, enemas, or stool softeners required (Box 34.1 Nutrition Notes).
- Increase activity through a daily walking program and abdominal exercises designed to improve the muscle tone to improve peristalsis and promote more spontaneous defecation.
- Determine patient's access to the bathroom and ability to use the toilet to ensure barriers to safe toileting, such as unsafe obstructing furniture arrangement or clutter are removed.
- Increase exercise, fluid if not contraindicated to 2 to 3 L per day, and fiber in the diet to aid in ability to discontinue laxative use.

Box 34.1

Nutrition Notes

Treating Constipation with Food Formula

Constipation may be successfully treated with 1 to 2 oz of the following mixture taken with the evening meal: 1 cup applesauce, 1 cup All-Bran cereal, and 1/2 cup 100% prune juice. Mixture may be stored in the refrigerator for 5 days and then should be discarded. In all cases of constipation, especially when increased fiber is given, adequate fluid intake is essential.

Deficient knowledge related to practices to prevent constipation

EXPECTED OUTCOME: The patient will state understanding and ability to carry out preventive measures for constipation.

- Teach factors leading to constipation and preventive interventions such as increasing fluid intake. *Prevention of constipation may be as simple as correcting the contributing factors.*
- Explain the physiology of defecation and the reason for obeying the urge to defecate when it occurs. *Patient and caregiver education is one of the most important aspects of treatment of constipation.*
- Assure the patient that having a daily bowel movement is not always necessary. *The patient who believes that a daily bowel movement is absolutely necessary needs information and reassurance.*
- Explain that regular laxative use may increase motility and pressure in the bowel and cause further complications to promote understanding and use of other preventive measures.

EVALUATION. The plan has been effective if the patient has established a regular bowel function pattern (Table 34.2), and verbalizes understanding of self-care measures and expresses satisfaction with the outcomes.

CRITICAL THINKING

Mrs. Burns

■ Mrs. Burns is a 93-year-old nursing home resident. You see on her chart that she has not had a bowel movement in 5 days. What action would you take?

Suggested answers at end of chapter.

Diarrhea

Diarrhea occurs when fecal matter passes through the intestine rapidly, resulting in decreased absorption of water, elec-

diarrhea: dia—through + rhea—to flow

TABLE 34.2 CRITERIA FOR REGULAR BOWEL FUNCTION

1. A regular time for defecation is routine.
2. A regular exercise program is followed.
3. Laxative use is avoided.
4. Water consumption is 2–3 L per day.
5. High-fiber and high-residue foods are added to the diet.
6. Consistency of stools reported are soft and formed.
7. Frequency of stools is every 1 to 3 days.

trolytes, and nutrients and causing frequent, watery stools. Classification and severity of diarrhea are based on the number of unformed stools in 24 hours. Large-volume diarrhea occurs when the volume of feces is increased. Small-volume diarrhea is caused by an increase in peristalsis, without an increase in fecal volume.

Pathophysiology and Etiology

The most common cause of acute diarrhea is a bacterial or viral infection. Bacteria (normal flora) are normally found in the intestines. If these bacteria grow out of control or if bacteria or viruses are ingested in contaminated food or water, infection results. Some bacteria release toxins that irritate the intestinal mucosa, causing an inflammatory response and an increase in mucus production. Hyperperistalsis occurs, which lasts until the irritants have been excreted. The most common infectious agents are *Escherichia coli*, *Campylobacter jejuni*, *Shigella* spp., *Clostridium difficile*, *Giardia* spp., and *Salmonella* spp.

Poor tolerance or allergies to certain foods may cause diarrhea. Foods that most commonly cause diarrhea are additives (such as nutmeg or sorbitol), caffeine, milk products, meats, wheat, and potatoes. Acute diarrhea usually resolves in 7 to 14 days.

Chronic diarrhea may result from inflammatory disease, osmotic agents, excessive secretion of electrolytes, or increased intestinal motility. Inflammatory diseases such as Crohn's disease or ulcerative **colitis** (discussed later) may impair absorption, resulting in frequent, watery stools. Osmotic diarrhea results from ingestion of laxatives or other agents that prevent absorption of water or nutrients in the intestine. Additional causes of malabsorption include surgical resection or disease of certain areas of the intestinal tract, such as the terminal ileum or pylorus. Radiation therapy for cancer also may induce a malabsorption syndrome. Enteral tube feedings commonly result in diarrhea, especially when malnutrition has caused edema in the gut wall, which decreases absorption.

Increased secretion of water and electrolytes by the intestinal mucosa associated with certain hormonal disorders results in high-volume fecal output. An irritable bowel or a neurological disorder may cause increased motility problems. Also, as described earlier, diarrhea can indicate fecal impaction.

colitis: col—pertaining to colon + itis—inflammation

Prevention

Proper handling, storage, and refrigeration of all fresh foods minimize contact with infectious agents. Milk and milk products must be kept refrigerated and protected. Hand washing and cleaning of the kitchen and food preparation or serving items are extremely important.

It is best to start enteral feedings slowly with full-strength formula and gradually increase the rate rather than dilute the formula, thus reducing the risk of contaminating the formula by adding to it.

Signs and Symptoms

Initial diarrheal stools are foul smelling and may have undigested food particles and mucus. The stools may also contain blood or pus. Diarrhea resulting from food poisoning usually has an explosive onset and may be accompanied by nausea and vomiting. Abdominal cramping, distention, anorexia, intestinal rumbling, and thirst are common. Fever indicates infection. Weakness and dehydration from fluid loss may occur (Box 34.2 Gerontological Issues).

Diagnostic Tests

The diagnosis of diarrhea is determined by the onset and progression of the disease, absence or presence of fever, laboratory examinations, and visual inspection of the stool. Evidence of bacteria, pus, and blood is checked. Diarrhea mixed with red blood cells and mucus is associated with cholera, typhoid, typhus, large-bowel cancer, or amebiasis. Diarrhea mixed with white blood cells and mucus is associated with shigellosis, intestinal tuberculosis, salmonellosis, regional enteritis, or ulcerative colitis. Bulky, frothy stool is seen in sprue and celiac disease. Pasty stools

Box 34.2

Gerontological Issues

Diarrhea can cause older people to quickly become dehydrated and hypokalemic because both fluid and potassium are lost in stools. The signs and symptoms of hypokalemia include muscle weakness, hypotension, anorexia, paresthesia, and drowsiness. It can also cause cardiac dysrhythmias, such as atrial and ventricular tachycardia, premature ventricular contraction, and ventricular fibrillation, which can be fatal.

If the older person has decreased mobility, quick access to the bathroom is important. Because of poor muscle control, older patients may be incontinent. This might embarrass patients or cause them to hurry, which increases chances of patients falling and causing other problems such as fracture, dislocation, or hematoma. Also, because older patients' skin is more sensitive resulting from poor turgor and a reduction in subcutaneous fat layers, perirectal skin excoriation can occur secondary to the acidity and digestive enzyme content of diarrheal stools.

usually have a high fat content and may be associated with common bile duct obstruction, sprue, and celiac disease. A “butter stool” appearance is seen in patients with cystic fibrosis.

Therapeutic Interventions

Replacing fluids and electrolytes is the first priority. This is done by increasing oral fluid intake, using solutions with glucose and electrolytes if ordered by the physician. Intravenous fluid replacement may be necessary for rapid hydration, especially in the very young or very old. An elimination diet can be tried to identify foods that may contribute to diarrhea. Foods known to cause diarrhea are eliminated to see if a change in bowel function occurs. Each food item is then added back into the diet, one at a time, to see which ones cause diarrhea. The patient is also encouraged to increase fiber and bulk in the diet.

If the patient has three or more watery stools per day, motility of the intestines can be decreased with the use of drugs, such as diphenoxylate (Lomotil), difenoxin HCl (Motofen), and loperamide (Imodium). If diarrhea is thought to be caused by antibiotics that change the normal flora of the bowel, a *Lactobacillus* granules dietary supplement (Lactinex) may be used to restore the normal flora. Antimicrobial agents are prescribed if infectious agents have been documented.

Nursing Process for the Patient with Diarrhea

ASSESSMENT/DATA COLLECTION. Observation of the patient’s behavior and symptoms assists in identifying the cause of diarrhea. Ask the patient to describe any symptoms, when they started, and how long they have been present. Questions should include “Is there any abdominal pain, urgency, or cramping?” and “What time of the day does it happen?” Stool consistency, color, odor, and frequency are documented.

The abdomen is inspected for distention. The patient’s usual dietary habits and any changes or recent exposure to contaminated food or water is assessed. Find out if any medications contributed to the diarrhea. If the patient has traveled recently, discover the geographical location and whether exposure to an infected person or someone with similar symptoms occurred.

Assess for symptoms of dehydration, such as tachycardia, hypotension, decreased skin turgor, weakness, thready pulse, dry mucous membranes, and oliguria. Abnormal laboratory studies that may indicate dehydration include increased serum osmolality, increased specific gravity of urine, and increased hematocrit. Decreased serum potassium may result from intestinal loss of potassium.

Data are collected on the patient’s coping mechanisms for use if the patient needs to express concerns or anxiety regarding incontinence of liquid stools and embarrassment.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Diarrhea related to infection or possible ingestion of irritating foods

EXPECTED OUTCOME: The patient will maintain formed, soft stool every 1 to 3 days.

- Obtain history including medications regarding diarrhea episode *to help identify cause.*
- Monitor and record stool characteristics, amount, and frequency *to plan care.*
- During acute diarrhea nothing is taken by mouth (NPO) *to promote bowel rest.*
- Give antidiarrheal medications as ordered. *Controlling diarrhea controls comfort and fluid balance.*
- Provide clear liquids, such as water, juices, bouillon, and gelatin, with progression to a low-residue diet when acute diarrhea phase is over (Box 34.3 Nutrition Notes).
- Limit caffeine intake *as it stimulates intestinal motility.*
- Keep skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment,

Box 34.3

Nutrition Notes

Deciding When to Refer an Adult with Diarrhea for Medical Care

Most instances of diarrhea in healthy adults are self-limiting and resolve without treatment. Indications for medical consultation include the following:

- Large volumes of stool
- Severe abdominal pain
- Bloody stools
- Protracted duration
- Systemic symptoms such as fever or prostration
- Medical conditions for which fasting, dehydration, or infectious disease are hazardous

Healthy adults at minimal risk of electrolyte imbalance may institute self-treatment as follows:

- For the first 12 hours: Water or oral rehydration solutions at room temperature. Easily absorbed fluids maintain hydration. Hot or cold liquids are more likely to stimulate peristalsis.
- For the second 12 hours: Clear liquids, no caffeine or extremes of temperature. If more than 5% of body weight is lost, seek medical attention.
- For the third 12 hours: Full liquids. Experiment with milk in case temporary lactose intolerance has developed as a result of intestinal inflammation.
- For the fourth 12 hours: Soft diet. Include apple-sauce or banana for pectin and also rice, pasta, and bread without fat (digested by enzymes usually unaffected in gastroenteritis).
- By the 48th hour: Regular diet. If diarrhea has not resolved and regular diet is not tolerated, seek medical treatment.

after each bowel movement to protect perianal skin from contact with liquid stools and their enzymes.

- Consider private patient room to prevent infection transmission.
- Identify potentially infected persons or contaminated foods to prevent the spread of infection.
- Ensure hand washing by patient, family, and health-care staff to prevent the spread of infection.

Risk for deficient fluid volume related to frequent passage of stools and insufficient fluid intake

EXPECTED OUTCOME: The patient will maintain vital signs and urine output within normal limits.

- Intake and output (including diarrheal stools) are recorded to determine fluid balance.
- Weight patient daily to determine fluid loss.
- If output is greater than intake, intravenous fluid replacement may be ordered to maintain fluid balance.
- Encourage fluids when acute diarrhea subsides to maintain fluid balance.
- Teach patient signs and symptoms of dehydration to report to allow prompt treatment.

EVALUATION. Goals have been met if frequency of diarrheal stools is decreased and fluid and electrolyte balance is achieved.

INFLAMMATORY AND INFECTIOUS DISORDERS

Many diseases of the lower GI tract are a result of inflammation in the bowel. Sometimes the inflamed areas become infected, resulting in a worsening of symptoms and necessitating antimicrobial therapy.

Appendicitis

Pathophysiology

Appendicitis is the inflammation of the appendix, the small, fingerlike appendage attached to the cecum of the large intestine. Because of the small size of the appendix, obstruction may occur, making it susceptible to infection. The resulting inflammatory process causes an increase in intraluminal pressure of the appendix.

Signs and Symptoms

Signs and symptoms of appendicitis include fever, increased white blood cells, and generalized pain in the upper abdomen. Within hours of onset the pain usually becomes localized to the right lower quadrant at McBurney's point, midway between the umbilicus and the right iliac crest (Fig.

FIGURE 34.1 Pain at McBurney's point is a symptom of appendicitis.

34.1). This is one of the classic symptoms of appendicitis. Nausea, vomiting, and anorexia are also usually present.

Physical examination reveals slight abdominal muscular rigidity (guarding), normal bowel sounds, and local rebound tenderness (intensification of pain when pressure is released after palpation) in the right lower quadrant of the abdomen. Sometimes there is pain in the right lower quadrant when the left lower quadrant is palpated (Rovsing's sign). The patient may keep the right leg flexed for comfort and experience increased pain if the leg is straightened.

Diagnostic Tests

A complete blood cell count (CBC) reveals elevated leukocyte and neutrophil counts. Ultrasound or computed tomographic (CT) scan reveals an enlargement in the area of the cecum.

Therapeutic Interventions

The patient is kept NPO and surgery is done immediately unless there is evidence of perforation or peritonitis. Ice to the site of pain and maintaining semi-Fowler's position may help reduce pain while the diagnosis is being made. The patient is often readied for an appendectomy by emergency department staff.

If the appendix has ruptured, intravenous fluids and antibiotic therapy are started and surgery may be delayed for 8 hours or more. Laxatives and enemas are avoided because they may trigger or complicate a rupture. The use of a heating pad on the abdomen is avoided because the warmth may increase inflammation and risk of rupture.

After surgery, the patient is usually NPO until GI functioning returns, and if the appendix has ruptured, the patient may have an orogastric or nasogastric tube placed to decompress the stomach. When bowel function returns, the diet initially consists of clear fluids and is advanced as tolerated by the patient. Vital signs and abdominal data are collected to monitor for signs and symptoms of peritonitis. Pain control to promote early ambulation, coughing, deep breathing, and turning help prevent respiratory complications.

appendicitis: appendic—pertaining to appendix + itis—inflammation

Complications

Perforation, abscess of the appendix, and peritonitis are major complications of appendicitis. With perforation, the pain is severe and the temperature is elevated to at least 37.7°C (100°F). An abscess is a localized collection of pus separated from the peritoneal cavity by the omentum or small bowel. This is usually treated with parenteral antibiotics and surgical drainage. An appendectomy is done about 6 weeks later.

Peritonitis

Peritonitis is inflammation of the peritoneum that occurs from a variety of causes. It is a serious condition that can be life threatening.

Pathophysiology and Etiology

Trauma, ischemia, or tumor perforation in any abdominal organ causes leakage of the organ's contents into the peritoneal cavity. The most common cause of peritonitis is a ruptured appendix, but it may also occur after perforation of a peptic ulcer, gangrenous gallbladder, intestinal diverticula, incarcerated **hernia**, or gangrenous small bowel. It may also be a complication of peritoneal dialysis. Peritonitis results from the inflammation or infection that is caused by the leakage. The tissues become edematous and begin leaking fluid containing increasing amounts of blood, protein, cellular debris, and white blood cells. Initially, the intestinal tract responds with hypermotility, but this is soon followed by paralysis (paralytic ileus).

Signs and Symptoms

Generalized abdominal pain evolves into localized pain at the site of the perforation or leakage. The area of the abdomen that is affected is extremely tender and aggravated by movement. Rebound tenderness and abdominal rigidity are present. Decreased peristalsis results in nausea and vomiting. Infection causes fever, increased white blood cells, and an elevated pulse.

Therapeutic Interventions

The patient is NPO because of the impaired peristalsis. Fluid and electrolyte replacement is crucial to correct hypovolemia. Abdominal distention is relieved through insertion of an orogastric (or nasogastric) tube with low intermittent suction. Antibiotics are used to treat or prevent sepsis. Depending on the cause of the peritonitis, surgery may be performed to excise, drain, or repair the cause. An ostomy may be formed to divert feces, allowing resolution of the infection. After surgery, the patient usually has a wound drain, a nasogastric (NG) tube, and a urinary catheter. Pain control is essential to overall recovery. Severely compromised patients may receive total parenteral nutrition (TPN) to meet nutritional needs for increased immune function and healing.

peritonitis: periton—pertaining to peritoneum + itis—inflammation

Complications

Complications of peritonitis are intestinal obstruction (discussed later), hypovolemia caused by the shift of fluid into the abdomen, and septicemia from bacteria entering the bloodstream. Shock and ultimately death may result. Wound dehiscence or evisceration can occur if the patient has had abdominal surgery.

Diverticulosis and Diverticulitis

Pathophysiology

A diverticulum is a herniation or outpouching of the bowel mucous membrane caused by increased pressure within the colon and weakness in the bowel wall. **Diverticulosis** is a condition in which multiple diverticula are present without evidence of inflammation (Fig. 34.2). Many people have diverticulosis without knowing it because it develops gradually. When food and bacteria are trapped in a diverticulum, inflammation and infection develop. This is called **diverticulitis**.

Etiology

Chronic constipation usually precedes the development of diverticulosis by many years. When the patient is chroni-

FIGURE 34.2 A diverticulum is a herniation or outpouching of the bowel mucous membrane. Multiple diverticula are called diverticulosis. If they become inflamed or infected, the condition is called diverticulitis.

diverticulosis: diverticul—blind pouch + osis—condition

diverticulitis: diverticul—blind pouch + itis—inflammation

TABLE 34.3 SYMPTOMS ASSOCIATED WITH DIVERTICULITIS

W —Where is the pain?	Usually in the left lower quadrant
H —How does it feel? (Describe quality)	Tender, crampy
A —Aggravating and alleviating factors	Constipation and low-fiber diet may aggravate; treatment of constipation may alleviate
T —Timing (onset, duration, frequency)	Gradual onset, intermittent, gradual increase in frequency of pain events
S —Severity (0–10)	Usually 5–7
U —Useful other data/associated symptoms	Intermittent rectal bleeding; straining at stool; constipation alternating with diarrhea; elevated white blood cells and sedimentation rate; elevated temperature and pulse rate; and pus, mucus, and blood in stool
P —Patient's perception	Fear diagnosis of cancer

cally constipated, pressure within the bowel is increased, leading to development of diverticula. A major cause of the disease is a decreased intake of dietary fiber. Diverticulosis is most common in the sigmoid colon. A small percentage of patients with diverticulosis develop diverticulitis. People older than age 60 are the most common group to experience diverticulitis.

Prevention

Diverticulitis can be prevented by increasing dietary fiber to prevent constipation and onset of diverticulosis.

Signs and Symptoms

The patient with diverticulosis is generally asymptomatic. When diverticulitis is present, the patient exhibits bowel changes, possibly alternating between constipation and diarrhea (Table 34.3). Steady or crampy pain in the left lower quadrant of the abdomen is the most common symptom. As the condition worsens, bleeding may occur, along with

weakness, fever, fatigue, and anemia. Guarding and rebound tenderness may be present. If an abscess develops, the diverticulum may rupture, leading to peritonitis (Box 34.4 Gerontological Issues).

Diagnostic Tests

Diverticulosis is confirmed with sigmoidoscopy, colonoscopy, or barium enema. The diverticula and specific areas of inflammation can be seen during a colonoscopy or sigmoidoscopy. If an abscess is suspected, a CT scan may be done. Barium enema may show irregular narrowing of the colon and thickened muscle walls. A stool specimen may show occult blood. An abdominal x-ray examination may be done to identify a perforated diverticulum.

Therapeutic Interventions

Diverticulosis is managed by preventing constipation. With acute diverticulitis, the patient may be hospitalized for administration of intravenous antibiotics and pain control. A nasogastric tube, intravenous fluids, and NPO status may be ordered until pain, nausea or vomiting, fever, and inflammation decrease. When the acute period is over, a progressive diet is started. Whether or not perforation occurs, surgical resection with anastomosis or a temporary **colostomy** (discussed later) may be done to allow the inflammation to subside and the diseased portion of the colon to rest.

Dietary considerations for a patient with diverticulosis (without evidence of inflammation) include foods that are soft but high in fiber, such as prunes, raisins, and peas. Unprocessed bran can be added to soups, cereals, and salads to give added bulk to the diet. Fiber should be increased in the diet slowly to prevent excess gas and cramping. Some health-care providers recommend avoiding nuts or foods with small seeds that can get caught in diverticula, such as tomatoes and raspberries, but this has not been shown to prevent diverticulitis.

Nursing Process for the Patient with an Inflammatory or Infectious Disorder

Assessment/Data Collection

Assessment of pain is essential for patients with inflammation or infection. Monitor the patient closely and notify the physician immediately if pain increases, especially if associated with abdominal rigidity. Increased pain may indicate that the bowel has ruptured and peritonitis is developing. Abdominal distention is monitored and recorded. With diverticulitis, a firm mass may be palpated in the sigmoid area.

Vital signs are monitored for fever or signs of septic shock. Intake and output are monitored and recorded accurately so that appropriate fluid replacement therapy is ordered. Monitoring for reduced urinary output, dropping blood pressure, and rising pulse rate can show fluid volume deficit. If a fever is noted, the patient may be developing sepsis. All symptoms are reported to the physician promptly.

colostomy: colo—pertaining to colon + stoma—mouth or opening

Box 34.4

Gerontological Issues

With age-related weakness in the intestinal wall, approximately 40% of adults older than age 80 have diverticular disease. Clinical manifestation of this condition may include abdominal pain, rectal bleeding, nausea, and vomiting. Patients may not notice the abdominal pain until infection is present. Many times the symptoms are not reported early because patients fear it may be cancer. Blood in the stool, which can be an indication of diverticulitis, may not be seen by the older adult due to impaired vision.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to inflammatory process

EXPECTED OUTCOME: The patient will report pain is at an acceptable level.

- Have patient rate pain on objective scale such as 0 to 10 to *determine pain level*.
- Give analgesics or antispasmodic drugs as ordered to *relieve pain*.
- Use position changes, diversion, and relaxation exercises to *help relieve pain*. *Semi-Fowler's position may reduce tension on the abdomen*.
- Provide frequent mouth care if an NG tube is in place to *increase comfort*.

Risk for deficient fluid volume related to diarrhea or fluid shifting from the circulation to the peritoneal cavity

EXPECTED OUTCOME: The patient will maintain vital signs and urine output within normal limits.

- Intake and output are recorded to *determine fluid balance*.
- Weight patient daily to *determine fluid loss*.
- Monitor vital signs and urine output and report changes to *detect changes from within normal limits*.
- If output is greater than intake, intravenous fluid replacement may be ordered to *maintain fluid balance*.

For constipation related to low-fiber diet, see section on constipation above.

Evaluation

The goals are met if the patient reports that pain is controlled, vital signs and urinary output are stable, and patient has regular, comfortable bowel elimination.

INFLAMMATORY BOWEL DISEASE

Crohn's Disease (Regional Enteritis)

Pathophysiology

Crohn's disease, also known as regional **enteritis** or granulomatous enteritis, is an inflammatory bowel disease (IBD) that can involve any part of the intestine but most commonly affects the terminal portion of ileum. The inflammation extends through the intestinal mucosa, which leads to the formation of abscesses, **fistulas**, and fissures. As the disease progresses, obstruction occurs because the intestinal lumen narrows with inflamed mucosa and scar tissue.

Etiology

Although the exact cause of Crohn's disease has not been identified, there is a familial tendency. Other possible influences are autoimmune processes and infectious agents. Crohn's disease is most often diagnosed between the ages of

Box 34.5

Cultural Considerations

Ulcerative colitis and Crohn's disease are more common in Caucasians, persons of Jewish descent, and upper middle class urban populations. The incidence of Crohn's disease is increasing rapidly in western Europe and North America. These findings support possible hereditary or environmental risk factors for inflammatory bowel disease.

15 and 30 and occurs more often in women. There are periods of remissions and exacerbations. Physical or psychological stress may trigger exacerbations (Box 34.5 Cultural Considerations).

Signs and Symptoms

Crampy abdominal pains (unrelieved by defecation), weight loss, and diarrhea occur. Because the crampy pains occur after eating, the patient often does not eat in order to avoid the pain. A lack of eating and poor absorption of nutrients results in weight loss and malnutrition. Chronic diarrhea contributes to fluid deficit and electrolyte imbalance. The inflamed intestine may perforate, leading to the formation of intra-abdominal or anal fissures, abscesses, or fistulas. Some nongastrointestinal symptoms may also occur, including arthritis, skin lesions, inflammatory disorders of the eyes, and abnormalities of liver function.

Complications

In addition to malnutrition, the development of fissures, abscesses, or fistulas is the most common complication of Crohn's disease. Fistulas may include enterovaginal (small bowel to vagina), enterovesical (small bowel to bladder), enterocutaneous (small bowel to skin), enteroentero (small bowel to small bowel), or enterocolonic (small bowel to colon) (Fig. 34.3). Fistulas communicating with organs that then drain externally can cause tremendous skin irritation, as well as increased risk of developing infections. Fistulas are corrected surgically.

Diagnostic Tests

Endoscopy (colonoscopy and sigmoidoscopy), with multiple biopsies of the diseased colon and terminal ileum, is used to diagnose Crohn's disease. Endoscopy identifies areas of normal to severely inflamed mucosa. Crohn's disease is confirmed by granulomas in the biopsy specimen. A barium enema shows a classic "cobblestoning" effect and, as the disease progresses, areas of narrowing in the intestine. A newer test, optical coherence tomography, allows the layers of the bowel to be examined for microscopic inflammation to differentiate this disease from ulcerative colitis.

An elevated sedimentation rate and leukocytosis are present, and serum albumin levels may be low because of malnutrition or poor absorption of protein. A stool examination may reveal fat content and occult blood. Newer diag-

FIGURE 34.3 Fistulas are a common complication of Crohn's disease.

nostic antibody tests may be useful for IBD. They include: antineutrophil cytoplasmic antibody with perinuclear staining (pANCA), anti-*Saccharomyces cerevisiae* antibody (ASCA), outer membrane porin C (Omp C), and I2 antibody (novel homologue of the bacterial transcription factor families).

Therapeutic Interventions

Management of Crohn's disease is aimed at achieving remission and maintaining it as there is no cure. Symptoms are controlled by reducing the intestinal inflammation that is the underlying cause of the symptoms. More medications are available today offering better control of the disease. The classes of medications used to achieve these goals are aminosalicylates, corticosteroids, immunomodulators, biologics, and antibiotics (see Table 34.4). Treatment is individualized. Aminosalicylates reduce inflammation and have various formulations to be delivered to specific sites in the intestines. Corticosteroids are used during an acute inflammation, then tapered and discontinued. They do not prevent acute episodes. A newer class of steroids, which includes budesonide (Entocort EC), are nonsystemic steroids that act locally rather than affect the whole body. Immunomodulators modify the immune system to decrease inflammation. They may be used with steroids to treat acute episodes as they have a longer onset of action. Biologics selectively target agents in the inflammatory process to block their action and effects. Antibiotics are helpful in Crohn's disease as long-term therapy and when fistulas are present. Anti-diarrheal medications such as diphenoxylate with atropine (Lomotil) or loperamide (Imodium) are used. Bulk-forming laxatives may help reduce loose stools and subsequently skin irritation.

Medication is used first for treatment but surgery may eventually be indicated for obstruction, stricture, fistula, abscess, excessive bleeding, perforation, toxic megacolon (loss of muscle tone and dilation in colon), or symptoms that

do not respond to treatment. Surgery does not cure Crohn's disease as it can recur elsewhere in the intestines. Surgical procedures include strictureplasty to widen areas of stricture, resection of the affected area with anastomosis, colectomy with ileorectal anastomosis, or proctocolectomy (rectum and colon) with **ileostomy**. See details regarding intestinal ostomies later in this chapter. Symptoms may be relieved for several years with surgery but may recur in the surgical site area. A Kock pouch is not recommended for those with Crohn's disease as the disease may affect the pouch.

A healthy diet is important in overall health but there is no special diet for Crohn's disease. Malnutrition is a concern if the small intestine is affected and nutrients are not absorbed properly. Folic acid and vitamin B₁₂ supplements may be needed. Calcium intake may be decreased and osteoporosis a concern. Calcium 1500 mg daily and vitamin D supplements are considered. Foods that increase symptoms should be avoided. Enteral feedings may be required and can be done at night through a gastrostomy tube (G tube) or feeding tube. For acute flare-ups, total parenteral nutrition (TPN) may be used to rest the GI tract. Adequate fluid intake is essential to prevent dehydration if diarrhea is present.

New nutritional therapy is looking at helping the GI tract to heal itself. The therapy may include fish or flaxseed oils to reduce inflammation, psyllium that stimulates bacteria to heal the colon, and probiotics that maintain normal intestinal flora. Research is ongoing in this area.

Nursing Process

Because of the similarities between Crohn's disease and ulcerative colitis, the nursing processes for both are discussed together. See section Nursing Process for the Patient with Inflammatory Bowel Disease below.

ileostomy: ileo—pertaining to ileum + stoma—mouth or opening

TABLE 34.4 MEDICATIONS FOR CROHN'S DISEASE AND/OR ULCERATIVE COLITIS

Medication/Action	Examples	Route	Side Effects	Nursing Implications
Aminosalicylates Decrease intestinal inflammation.	Sulfasalazine (Azulfidine)	PO, Rectal	Headache, nausea, anorexia, rash, fever	Contraindicated in sulfa allergy. Some patients do not tolerate sulfasalazine but can tolerate others drugs in this class. Monitor for signs of reduced kidney function.
	Mesalamine (Asacol, Canasa, Pentasa, Rowasa)	PO, Rectal based on drug	Abdominal pain, diarrhea, nausea, hair loss, headache, dizziness	Monitor for signs of reduced kidney function.
	Olsalazine (Dipentum)	PO	Diarrhea, headache, rash, fatigue	Take with food.
	Balsalazide (Colazal)	PO	Headaches, abdominal pain	Continue drugs even if feeling better to maintain remission.
Corticosteroids Decrease inflammation and suppress immune system. May be used with aminosalicylates.	Prednisone (Deltasone)	PO	Hypertension, moon face, infection, mood swings, weight gain, osteoporosis	Teach patient not to stop taking medication abruptly.
	Methylprednisolone (Medrol, Solu-Medrol)	PO, IV		
	Hydrocortisone (Cortenema)	Enema		Patient should lie on left side for 30 minutes and retain enema for 1 hour if not all night.
Nonsystemic steroids Reduce inflammation locally for Crohn's disease.	Budesonide (Entocort EC)	PO	Fewer steroid side effects (e.g., moon face and acne)	Grapefruit juice should be avoided. Take in morning. Swallow whole.
Immunomodulators Immunosuppression to reduce inflammation	Azathioprine (Imuran, Azasan)		Headache, N/V, diarrhea, malaise	Report symptoms of infection when taking any immunomodulators. Monitor for infection.
	6-Mercaptopurine (6-MP, Purinethol)		Headache, N/V, diarrhea, malaise	Monitor for infection.
	Cyclosporine A (Sandimmune, Neoral)	PO	Infections, headache, hypertension	Blood pressure and renal function is monitored.
	Tacrolimus (Prograf)	PO, topically	Infections, headache, hypertension	Blood pressure and renal function is monitored.
	Methotrexate (MTX, Mexate, Rheumatrex)	IM	Bone marrow depression, infections, rash, nausea, diarrhea, stomatitis	Monitor for infections.
Antibiotics In Crohn's disease, reduces intestinal bacteria.	Metronidazole (Flagyl)	PO, IV	Headache, N/V, diarrhea, anorexia, metallic taste, dark urine, tingling of hands, feet	Teach to avoid alcohol. Avoid sun. Interfere with oral contraceptives, warfarin.
	Ciprofloxacin (Cipro)	PO, IV	Headache, N/V, diarrhea, rash, abdominal pain	Do not give with antacids, calcium, iron, zinc. Avoid sun. Interfere with oral contraceptives, warfarin.
Biologics Selectively target inflammatory agents to interfere with inflammatory response.	Infliximab (Remicade)	IV	Headache, chills, fever, hypotension, dyspnea, hives, nausea, rash, sore throat, lymphoma	TB test should be done before therapy begins. Monitor for infections, bone marrow suppression, CNS disorder.

CNS = central nervous system; N/V = nausea and vomiting; TB = tuberculosis.

Ulcerative Colitis

Pathophysiology

Ulcerative colitis is similar to Crohn's disease. Crohn's disease, however, can occur anywhere in the gastrointestinal system, whereas ulcerative colitis occurs in the large colon and rectum. Multiple ulcerations and diffuse inflammation occur in the superficial mucosa and submucosa of the colon. The lesions spread throughout the large intestine and usually involve the rectum. The patient with ulcerative colitis has increased risk of developing colorectal cancer.

Etiology

Several theories exist to explain the cause of ulcerative colitis. These include infection, allergy, and autoimmune response. Environmental agents such as pesticides, tobacco, radiation, and food additives may precipitate an exacerbation. At one time, a psychological component was suggested in the etiology of ulcerative colitis. However, anyone who experiences chronic intestinal cramps and frequent, sometimes painful bowel movements is going to be discouraged, anxious, and depressed. These behaviors may be a result of the disease, not the cause. Psychological stress may trigger or worsen an attack of symptoms. Ulcerative colitis usually begins between ages 15 and 40.

Signs and Symptoms

Abdominal pain, diarrhea, rectal bleeding, and fecal urgency are common symptoms of ulcerative colitis (Table 34.5). Anorexia, weight loss, cramping, vomiting, fever, and dehydration associated with passing 5 to 20 liquid stools a day may also occur. Along with the potential for fluid and electrolyte imbalance, there is a loss of calcium. Anemia often develops as a result of rectal bleeding. Serum albumin may

be low because of malabsorption. Like Crohn's disease, arthritis, skin lesions, inflammatory disorders of the eyes, and abnormalities of liver function may also occur. Symptoms are usually intermittent, with remissions lasting from months to years.

Complications

Malnutrition and its associated problems are complications of ulcerative colitis. Other complications include the potential for hemorrhage during an acute phase, bowel obstruction, perforation, and peritonitis. The risk for colon cancer is also increased in patients with ulcerative colitis. Symptoms outside the GI tract, such as arthritis, skin lesions, and inflammatory disorders of the eyes, may also occur.

Diagnostic Tests

Examination of stool specimens is done to rule out the presence of any bacterial or amebic organisms. The stool is positive for blood. Anemia is often present because of blood loss. Leukocyte levels and erythrocyte sedimentation rate are elevated because of the chronic inflammation. Electrolytes are depleted from chronic diarrhea. There is a protein loss because of liver dysfunction and malabsorption. Endoscopy and barium enema help differentiate ulcerative colitis from other diseases of the colon with similar symptoms. Biopsy specimens taken during sigmoidoscopy and colonoscopy typically show abnormal cells. Optical coherence tomography is used to differentiate this disease from Crohn's disease.

Therapeutic Interventions

Medications are used first as treatment. Foods that cause gas or diarrhea should be avoided. Because the offending foods may be different for each patient, foods are tried in small amounts if they are thought to cause symptoms. In general, high-fiber foods, caffeine, spicy foods, and milk products are avoided. Total parenteral nutrition may be needed to meet nutritional needs during acute exacerbations. Diarrhea may increase the need for fluids to prevent dehydration.

Many of the same medication classes as with Crohn's disease are used (see Table 34.4).

Surgery is considered for excessive bleeding, severe symptoms, perforation, or toxic megacolon. Because ulcerative colitis usually involves the entire large intestine, the surgery of choice is total proctocolectomy with restorative proctocolectomy or ileostomy (discussed later in this chapter). Surgery cures ulcerative colitis if the colon is removed.

A restorative proctocolectomy does not require an ostomy bag to be worn, and is the more common surgery performed. Since the anus and sphincter are saved, stool still passes through the anus. The rectum and colon are removed and the ileum, which is made into a pouch, is attached to the anus. A temporary ileostomy is created to allow the pouch to heal. After about 12 weeks, the ileostomy is closed. Several bowel movements per day occur. The stool is of soft consistency. Surgical complications can include an inflammation of the pouch (pouchitis) which is treated with antibiotics or a bowel obstruction.

TABLE 34.5 INFLAMMATORY BOWEL DISEASE SUMMARY

Signs and Symptoms	Abdominal pain or cramping Weight loss Diarrhea Fluid and electrolyte imbalance Fissures, fistulas, abscesses Arthritis and skin lesions Inflammatory eye disorders
Diagnostic Tests	Abnormal liver function Endoscopy with biopsy Barium enema Laboratory examination Stool examination Absent bowel sounds
Therapeutic Interventions	Medications: anti-inflammatories, antidiarrheal, antibiotics, immunosuppressants, corticosteroids Surgery if necessary Avoidance of offending foods Elemental formula or TPN if required
Possible Nursing Diagnoses	Constipation Diarrhea Deficient knowledge

Nursing Process for the Patient with Inflammatory Bowel Disease

Assessment/Data Collection

A history obtained from the patient should include identification of symptoms, including the onset, duration, frequency, and severity. Ask if there has been any correlation between exacerbations of symptoms related to dietary changes or stress. Determine the presence of any food allergies or intolerances that may increase diarrhea. Also, note the daily and weekly intake of caffeine, nicotine, and alcohol because all these stimulate the bowel and can cause cramping and diarrhea.

Assess the patient for nutritional status and signs of dehydration. Ten to 20 lb can be lost in a 2-month period. Perianal skin should be assessed for irritation and excoriation.

Assessment of emotional status, coping skills, and verbal and nonverbal behaviors is essential. The patient may withdraw from family and friends because of frequent bowel movements. Anxiety, sleep disturbances, depression, and denial can be problems. If surgery involving an ileostomy is planned, the patient is at risk for body image problems.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to increased peristalsis and cramping

EXPECTED OUTCOME: The patient will state pain is relieved or at an acceptable level.

- Document the character of the pain (dull, cramping, burning) and if the pain is associated with meals or activity to *plan care*.
- Give analgesics and medications to *relieve cramping, as prescribed*.

Diarrhea related to inflammatory process

EXPECTED OUTCOME: The patient will maintain formed, soft stool every 1 to 3 days.

- Document characteristics of stools, including color, consistency, amount, frequency, and odor to *plan care*.
- Ensure patient has quick access to the bathroom, or provide a bedside commode to *prevent incontinence*.
- Administer antidiarrheal medication as prescribed. *Controlling diarrhea controls comfort and fluid balance.*
- Encourage bedrest to *decrease peristalsis*.
- Keep the environment clean and odor free to *help alleviate anxiety*.
- Teach the patient to avoid high-fiber foods such as whole grains and raw fruits and vegetables, as well as caffeine, alcohol, and nicotine *because they stimulate intestinal motility*.

Risk for deficient fluid volume related to diarrhea and insufficient fluid intake

EXPECTED OUTCOME: The patient will maintain vital signs and urine output within normal limits.

- Record intake and output (including diarrhea stools) to *determine fluid balance*.
- Weight patient daily to *determine fluid loss*.
- Signs of deficient fluid volume are documented and reported to the physician to *allow treatment*.
- Maintain IV fluids as ordered to *maintain fluid balance*.
- Encourage fluids when acute diarrhea subsides to *maintain fluid balance*.
- Teach patient signs and symptoms of dehydration to report to *allow prompt treatment*.

Anxiety related to symptoms and frequency of stools and treatment

EXPECTED OUTCOME: The patient will report anxiety is reduced.

- Answer questions, talk in a calm, confident manner, and actively listen to the patient to *reduce anxiety, which aggravates symptoms of inflammatory bowel disease*.

Impaired skin integrity related to frequent loose stools

EXPECTED OUTCOME: The patient's skin remains intact.

- Keep perianal skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment, after each bowel movement to *protect perianal skin from contact with liquid stools and their enzymes*.
- Sitz baths may be comforting and helpful in keeping skin clean to *prevent excoriation*.

Ineffective nutrition, less than body requirements, related to malabsorption

EXPECTED OUTCOME: The patient will maintain weight within normal range for height and age.

- Give special liquid (elemental) formula that is absorbed in the upper bowel as ordered to *allow the colon to rest*.
- Maintain TPN as ordered to provide nourishment if the patient is unable to *tolerate oral intake*.
- Weight weekly to *detect weight loss*.

CRITICAL THINKING

Judy Moore

■ Judy Moore is an 18-year-old college student who has just been diagnosed with Crohn's disease.

1. What questions can you ask Judy to identify her symptoms?
2. What nursing diagnoses would be relevant for Judy's condition?
3. What can you do to help her adapt to this disease?
4. If Judy's condition were to worsen what manifestations would be exhibited?

Suggested answers at end of chapter.

See Box 34.6 Nursing Care Plan for the Patient with Inflammatory Bowel Disease.

Evaluation

Goals have been met if pain is relieved, frequency of diarrhea stools is decreased, fluid and electrolyte balance is achieved, anxiety is reduced, skin is intact, and weight is within normal range for height and age.

IRRITABLE BOWEL SYNDROME

Pathophysiology

Irritable bowel syndrome (IBS) is a disorder of altered intestinal motility in which the colon does not contract in a normal pattern. Instead it contracts in a disorderly way that can be violent and last for long times or there can be times when it does not contract at all. The abnormal contractions lead to pattern changes alternating between diarrhea and constipation. Additionally, there is increased abdominal discomfort or pain. Localized prolonged contractions may cause stool to be retained for a long time, causing it to become hardened as water is absorbed from it. Bloating may also occur as air

is unable to be expelled. Mucus may be seen in the stool, although this is not abnormal and does not typically cause a problem. The bowel mucosa is normal. IBS is not a disease but rather a functional problem.

Symptoms may be exacerbated by psychological stress or food intolerances. The nerves in the bowel are overly sensitive in persons with IBS. At times of stress in daily living, abnormal contractions may result.

Etiology

There is a hereditary tendency for IBS. IBS is more common in women and in those who are young to middle aged. Flare-ups can be caused by other illnesses, infections, or the menstrual cycle.

Signs and Symptoms

IBS is characterized by complaints of gas, bloating, constipation, diarrhea, or alternating constipation and diarrhea. The patient also has feelings of abdominal bloating, with or without visible abdominal distention. Other symptoms include the rectal passage of mucus, a feeling of incomplete evacuation, abdominal pain, depression, anxiety, and palpitations.

Box 34.6 NURSING CARE PLAN for the Patient with Inflammatory Bowel Disease

Ineffective coping related to inflammatory bowel disease

Patient Outcomes Patient will identify strategies that will promote effective coping.

Evaluation of Outcomes Is the patient able to state strategies for effective coping?

Interventions

Ask knowledge of Crohn's disease or ulcerative colitis

Encourage the patient to express feelings about the disease and how it may affect his or her life.

Determine whether the patient would like to speak with a person of similar age from the Crohn's and Colitis Foundation of America.

Identify strategies for effective coping that are acceptable to the patient.

Rationale

Many people have little knowledge of a disease unless they know someone who has it. Inaccurate information must be corrected.

Expressing feelings about the disease and its perceived effect enables the patient to identify and talk about concerns. Once identified, these concerns can then be addressed by the health care team.

Speaking with someone close in age with the same disease lets the patient know that he or she is not the only person having to cope with this disorder. It can also help him or her learn some strategies for effectively coping with the disease.

Talking about concerns and possible solutions is a positive step. Coping strategies identified with the patient are more likely to be implemented.

Evaluation

Does the patient verbalize information about ulcerative colitis and its effects on the body?

Does the patient talk about feelings regarding the potential impact of the disease on his or her life?

Does the patient show an interest in speaking with someone with the same disease?

Is the patient able to identify strategies for effective coping that he or she believes will work?

Diagnostic Tests

Diagnosis of IBS is made based on history and physical examination. Stool examination, barium enema, upper GI series, and sigmoidoscopy may be done to rule out other disorders. Avoiding milk products for a time may be advised to rule out lactose intolerance.

Therapeutic Interventions

IBS is a chronic condition, but symptoms can generally be controlled. A high-fiber and high-bran diet (psyllium [Metamucil] or methylcellulose [Citrucel]) may help to form softer, larger stools but may increase other symptoms in some people. Foods that cause distress or gas formation are avoided such as fresh fruits or vegetables, spices, milk, coffee, carbonated drinks, and alcohol. Eating smaller, frequent meals can be helpful in reducing bowel contractions. Stress management, behavioral therapy (biofeedback, hypnosis, psychotherapy), and exercise are helpful in relaxing the bowel as well as contributing to overall health.

Various medications are used depending on the type of IBS. Antidepressants are given to block the brain's perception of abdominal pain. For IBS with constipation, citalopram (Celexa) or paroxetine HCl (Paxil) are examples of selective serotonin reuptake inhibitors (SSRIs) that are prescribed. Tricyclic antidepressants (such as amitriptyline HCl [Elavil]) are used for IBS with diarrhea as they tend to cause constipation. Antispasmodics such as hyoscyamine (Levbid) or dicyclomine (Bentyl) are used in IBS with diarrhea. For women under age 65 with IBS with constipation, tegaserod maleate (Zelnorm) is prescribed short term to help normalize bowel function by coordinating muscle function. Zelnorm is not effective for all women or men with IBS with constipation.

Nursing Process for the Patient with IBS

Assessment/Data Collection

Height and weight are obtained. Data are collected on the symptoms including pain that the patient experiences. Timing of the symptoms, food and fluid intake, elimination patterns, effects on self-esteem, socialization, and personal and family roles are explored since IBS is a significant cause of missed work and school and also causes social withdrawal and embarrassment for people with it. Knowledge of the syndrome and its treatment are determined. Readiness for managing the syndrome is determined to plan care.

Nursing Diagnosis, Planning, and Implementation

Constipation related to irregular motility of GI tract

EXPECTED OUTCOME: The patient will maintain passage of soft, formed stool every 1 to 3 days without straining.

- Assess normal pattern of defecation, diet and fluid intake, and medications *to help identify factors contributing to constipation for planning care.*
- Ensure fluid intake, if not contraindicated, of 2 to 3 L per day *to prevent hard stools.*

- Explain to increase fiber and bran in diet *to promote soft, larger stools that are easier to pass.*
- Give medication as ordered to control symptoms.

Diarrhea related to irregular motility of GI tract

EXPECTED OUTCOME: The patient will maintain formed, soft stool every 1 to 3 days.

- Obtain history including medications regarding diarrhea episodes *to help identify cause.*
- Monitor and record stool characteristics, amount, and frequency *to plan care.*
- Give antidiarrheal medications as ordered. *Controlling diarrhea controls comfort and fluid balance.*
- Limit caffeine intake *as it stimulates intestinal motility.*
- Keep skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment, after each bowel movement *to protect perianal skin from contact with liquid stools and their enzymes.*

Readiness for enhanced therapeutic regimen management related to desire to manage symptoms of IBS

EXPECTED OUTCOME: The patient will state understanding and ability to carry out preventive measures to control symptoms.

- Explain IBS including symptoms, aggravating factors, and treatments *to promote understanding for ability to follow therapeutic regimen.*
- Encourage use of food diary documenting foods eaten and timing of symptom occurrence *to identify food triggers for symptoms including lactose intolerance.* A food diary is available at <http://www.healthywomen.org/presskit/aw/fooddiary.pdf>.
- Consult registered dietitian and share food diary *to allow identification of food connection with symptoms and meal planning to prevent symptoms.*
- If lactose intolerant, avoid dairy products and substitute yogurt *to reduce symptoms.*

Evaluation

The plan has been effective if the patient has regular bowel function pattern, and verbalizes understanding of self-care measures and expresses satisfaction with the outcomes.

ABDOMINAL HERNIAS

Pathophysiology and Etiology

A hernia is an abnormal protrusion of an organ or structure through a weakness or tear in the wall of the cavity normally containing it, which in this case is the abdominal wall. Hernias are caused by a weakness in the abdominal wall along with increased intra-abdominal pressure, such as the pressure from coughing, straining, and heavy lifting. Obesity, pregnancy, and poor wound healing are also risk factors. The hernial sac is formed by the peritoneum protruding through the weakened muscle wall. Contents of the

FIGURE 34.4 Types of hernias.

hernia can be small or large intestine, or the omentum. Indirect hernias are caused by a defect of structural closure. Direct hernias are acquired and arise from a weakness in the abdominal wall, usually at old incisional sites.

There are many types of hernias (Fig. 34.4). Inguinal hernias are located in the groin where the spermatic cord in males or the round ligament in females emerges from the abdominal wall. This common hernia is an example of an indirect hernia and is usually seen in males.

Umbilical hernias are seen most often in obese women and in children. They are caused by a failure of the umbilical orifice to close. Ventral (incisional) hernias usually result from a weakness in the abdominal wall following abdominal surgery, especially in the obese patient, if a drainage system was used, the patient experienced poor wound healing, or the patient received inadequate nutrition.

Prevention

Congenital defects cannot be prevented. However, reducing strain on abdominal muscles is helpful. Those who do heavy lifting, tugging, or pushing should wear a support binder or avoid the lifting. A healthy lifestyle of maintaining normal weight, not smoking, and eating high-fiber foods is recommended.

Signs and Symptoms

Unless complications occur, there are very few symptoms associated with hernias. An abnormal bulging can be seen in the affected area of the abdomen, especially when straining or coughing. It may disappear when the patient lies down. If the intestinal mass easily returns to the abdominal cavity or can be manually placed back in the abdominal cavity, it is called a reducible hernia. When adhesions or edema occur between the sac and its contents, the hernia becomes irreducible or incarcerated. The trapped loop of bowel becomes strangulated with the blood supply cut off.

Complications

An incarcerated hernia may become strangulated if the blood and intestinal flow are completely cut off. Strangulated hernias do not develop in adults very often. Incarceration leads to an intestinal obstruction and possibly gangrene and bowel

perforation. Symptoms are pain at the site of the strangulation, nausea and vomiting, and colicky abdominal pain. Treatment is emergency surgery.

Therapeutic Interventions

Hernias are diagnosed by physical examination. Treatment options include no treatment, observing the hernia, and using short-term support devices or surgery to cure the hernia. A supportive truss or brief applies pressure to keep the reduced hernia in place. Surgery is recommended for inguinal hernias and is indicated if there is strangulation or the threat of bowel obstruction. For symptomatic hernias, surgical procedures include open hernia repair (herniorrhaphy) or hernioplasty (open or laparoscopically). Herniorrhaphy involves making an incision in the abdominal wall, replacing the contents of the hernial sac, sewing the weakened tissue, and closing the opening. Hernioplasty involves replacing the hernia into the abdomen and reinforcing the weakened muscle wall with wire, fascia, or mesh. Bowel resection or a temporary colostomy may be necessary if the hernia is strangulated.

Nursing Management

The patient is instructed to avoid activities that increase intra-abdominal pressure, such as lifting heavy objects. The patient is taught to recognize signs of incarceration or strangulation and the importance of notifying the physician immediately. If a support truss or brief has been ordered, the patient is taught to apply it before arising from bed each morning while the hernia is not protruding. Special attention should be paid to maintenance of skin integrity beneath the truss.

Postoperative Care

Care following inguinal hernia repair is similar to any postoperative care. Patients can perform deep breathing to keep lungs clear postoperatively but should avoid coughing. Coughing increases abdominal pressure and could affect the hernia repair. The male patient may experience swelling of the scrotum. Ice packs and elevation of the scrotum may be ordered to reduce the swelling. Because most patients are discharged the same day as surgery, they are taught to

change the dressing and report difficulty urinating, bleeding, and signs and symptoms of infection, such as redness, incisional drainage, or fever or severe pain. The patient is also instructed to avoid lifting, driving, or sexual activities for 2 to 6 weeks as specified by the physician. Most patients can return to nonstrenuous work within 2 weeks.

ABSORPTION DISORDERS

The process of digestion reduces nutrients to a liquid form that can be absorbed through intestinal mucosa into the portal bloodstream. More than 8000 mL of liquid with nutrients and electrolytes is absorbed, mostly proximal to the ileocecal valve.

Pathophysiology and Etiology

Malabsorption occurs when the GI system is unable to absorb one or more of the major nutrients (carbohydrates, fats, or proteins). Some causes of malabsorption are ileal dysfunction, jejunal diverticula, parasitic disease, celiac disease, enzyme deficiency, and inflammatory bowel diseases such as Crohn's disease and ulcerative colitis. The primary malabsorption disorders are tropical sprue, adult celiac disease (nontropical sprue), and lactose intolerance.

The cause of tropical sprue has not been specifically identified but is thought to be related to bacterial infection of the intestine. In adult celiac disease (sometimes called nontropical sprue), a sensitivity to gluten is thought to cause malabsorption of protein. Gluten is a protein found in wheat, barley, oats, and rye (Box 34.7 Nutrition Notes).

A deficiency in lactase, an enzyme that breaks down lactose (milk sugar), causes lactose intolerance. When lactose is not digested, a high concentration of it occurs in the intestines, causing an osmotic retention of water in the colon and watery stools (Box 34.8 Nutrition Notes).

Signs and Symptoms

Weight loss, weakness, and general malaise resulting in malnutrition are associated with malabsorption disorders. Signs

Box 34.7

Nutrition Notes

Treating Celiac Disease

Celiac disease, or gluten-sensitive enteropathy, requires permanent elimination of wheat, rye, oats, and barley from the diet. Careful selection of prepared foods is mandatory because of the widespread use of these grains as thickeners. If a patient with celiac disease ingests gluten, damage to the intestine continues even in the absence of symptoms. Instruction from and follow-up by a dietitian are indicated to ensure adequate nutritional intake despite the many dietary limitations.

Box 34.8

Nutrition Notes

Managing Lactose Intolerance

Patients with lactose intolerance control their conditions through trial and error because the degree of lactose intolerance varies greatly among patients. Moderate amounts of many lactose-containing foods can be digested when taken with a mixed meal. A dietitian's services may be advised to begin dietary management after diagnosis. Ingredients to avoid include milk, milk solids, lactose, and whey. Low-lactose foods (up to 2 g per serving) include sherbet, cheese aged longer than 90 days, processed cheese, and milk treated with lactate enzyme. In cheese making, the whey containing most of the lactose is removed, so that hard, ripened cheeses such as blue, Brie, Cheddar, Colby, Gouda, Parmesan, and Swiss are classified as low lactose. Some brands of yogurt, a high-lactose food, may be tolerated because they contain bacterial lactate.

and symptoms of sprue include frequent loose, bulky, foul stools that are gray in color and have an increased fat content. (Increased fat in stool is called steatorrhea.) Lactose intolerance causes abdominal cramping, excessive gas, and loose stools after eating milk products.

Complications

Vitamin K deficiency and resulting hypoprothrombinemia can increase the risk of bleeding. Calcium deficiency can be severe enough to cause bone pain and neuromuscular hyperirritability, including tetany. Folic acid, vitamin B₁₂, and iron deficiencies can result in glossitis, stomatitis, anemia, and dry, rough skin.

Diagnostic Tests

See Table 34.6 for the diagnostic studies used to identify malabsorption diseases.

Therapeutic Interventions

Folic acid, broad-spectrum antibiotics, and a high-calorie, high-protein, low-fat diet are ordered for patients with tropical sprue. Adults with celiac disease are ordered a high-calorie, high-protein, gluten-free diet to relieve the symptoms and improve nutritional status. However, because gluten is used as a filler or binder in many products, even those labeled "wheat free," diligence in identifying potentially offending foods is essential.

Lactose intolerance is treated by removing foods from the diet that contain lactose, such as milk and milk products. Some fermented milk products, such as cheese and yogurt, may be lower in lactose and better tolerated. Lactaid is an over-the-counter lactase substitute that can be taken when milk products cannot be avoided. It can be added to milk in

TABLE 34.6 DIAGNOSTIC TESTS FOR DISORDERS OF MALABSORPTION

Diagnostic Test	Test Result and Associated Malabsorption Syndrome
Hemoglobin and hematocrit	Decreased if anemia is present.
Mean corpuscular volume	Decreased values are found with malabsorption of vitamin B ₁₂ .
Upper GI series	Thickening of the intestinal mucosa, narrowed mucosa of the terminal ileum, or a change in fecal transit time are indicative of malabsorption syndrome.
D-Xylose absorption test	Decreased excretion of xylose after 5 hours is indicative of malabsorption.
Sudan stain for fecal fat	Malabsorption can be distinguished from maldigestion if this test shows abnormally large numbers of fat droplets.
72-hour stool collection for fat	Stool fat greater than 5 g per 24 hours after ingestion of 80 g of fat in 2 days implies a fat digestion disorder.

liquid form or taken as a tablet before eating foods containing lactose. Lactaid digests about 70% of the lactose in foods, making them more tolerable.

Nursing Management

Nursing care involves monitoring fluid and electrolyte balance, nutritional status, and skin integrity. Daily weight and intake and output help determine if fluid loss is occurring. Intake of electrolyte-rich fluids is encouraged to replace losses. Antidiarrheal agents are given if ordered. Electrolyte levels, especially potassium, are monitored as ordered. The patient is instructed in dietary limitations. Nutritional supplements may be ordered if necessary. Perianal skin is kept clean and dry, and barrier ointments are used as needed to protect the skin from excoriation.

INTESTINAL OBSTRUCTION

Intestinal obstructions occur when the flow of intestinal contents is blocked. There are two types of intestinal obstruction, mechanical and paralytic, both of which can be either partial or complete.

Mechanical obstruction occurs when a blockage occurs within the intestine from conditions causing pressure on the intestinal walls such as adhesions, twisting of the bowel, or strangulated hernia. Paralytic obstruction occurs when peristalsis is impaired and the intestinal contents cannot be propelled through the bowel. Paralytic obstruction is seen following abdominal surgeries, trauma, mesenteric ischemia, or infection. The severity of the obstruction depends on the area of bowel affected, the amount of occlusion within the lumen, and the amount of disturbance in the blood flow to the bowel (Table 34.7).

TABLE 34.7 BOWEL OBSTRUCTION SUMMARY

Signs and Symptoms	Abdominal pain Blood and mucus per rectum Feces and flatus cease Visible peristaltic waves in thin person Possible fecal vomiting Bowel sounds high-pitched, tinkling or absent Abdominal distention Fluid and electrolyte imbalance
Diagnostic Tests	Abdominal x-ray examination CT scan CBC and electrolytes
Therapeutic Interventions	NPO status Frequent mouth care Nasogastric tube Fluid and electrolyte replacement Medications: antibiotics, antiemetics, analgesics Surgery
Possible Nursing Diagnoses	Pain Constipation Deficient fluid volume

Small-Bowel Obstruction

Pathophysiology

When obstruction occurs in the small bowel, a collection of intestinal contents, gas, and fluid occurs proximal to the obstruction. The distention that results stimulates gastric secretion but decreases the absorption of fluids. As distention worsens, the intraluminal pressure causes a decrease in venous and arterial capillary pressure, resulting in edema, necrosis, and eventually perforation of the intestinal wall.

Etiology

Following abdominal surgery, loops of intestine may adhere to areas in the abdomen that are not healed. This may cause a kink in the bowel that occludes the intestinal flow. These adhesions, or bands of scar tissue, are the most common cause of small bowel obstruction and are usually acquired from previous abdominal surgery or inflammation. Hernias and neoplasms are the next most common causes, followed by inflammatory bowel disease, foreign bodies, strictures, **volvulus**, and **intussusception**. A volvulus occurs when the bowel twists, occluding the lumen of the intestine. Intussusception occurs when peristalsis causes the intestine to telescope into itself (Fig. 34.5). These conditions are mechanical obstructions. Paralytic, or adynamic, ileus is a nonmechanical obstruction that occurs when the intestinal peristalsis decreases or stops because of a vascular or neuromuscular pathological condition. Box 34.9 lists causes of nonmechanical obstructions.

Signs and Symptoms

The patient initially complains of wavelike abdominal pain and vomiting. Initially, flatus and feces that are low in the bowel and blood and mucus may be passed, but this stops as

intussusception intus—within + suscept—to receive

FIGURE 34.5 Mechanical bowel obstructions. (A) Intussusception. (B) Volvulus.

the obstruction becomes worse. The symptoms progress as the obstruction worsens or becomes complete. As the obstruction becomes more extreme, peristaltic waves reverse, propelling the intestinal contents toward the mouth, eventually leading to fecal vomiting. Peristaltic waves may be visible in a thin person. Pain that is sharp and sustained may indicate perforation. In mechanical obstructions, high-pitched, tinkling bowel sounds are heard proximal to the obstruction and are absent distal to it. If the obstruction is nonmechanical, there is an absence of bowel sounds.

Loss of fluid and electrolytes leads to dehydration, with its associated symptoms of extreme thirst, drowsiness, aching, and general malaise. The lower in the gastrointestinal tract the obstruction is, the greater the abdominal distention. An uncorrected obstruction can lead to shock and possibly death.

Diagnostic Tests

Dilated loops of bowel are evident in radiographic studies and CT scans. If strangulation or perforation occurs, leukocytosis is evident. Hemoglobin and hematocrit levels are elevated if the patient is dehydrated, and serum electrolyte levels are decreased.

Therapeutic Interventions

In most cases, the patient is kept NPO and the bowel is decompressed using a nasogastric (or rarely an intestinal) tube, which relieves symptoms and may resolve the obstruc-

tion. An IV solution with electrolytes is initiated to correct the fluid and electrolyte imbalance. Sometimes IV antibiotics are begun. Complete mechanical obstruction requires surgical intervention, such as removal of tumors, release of adhesions, or bowel resection with anastomosis.

Large-Bowel Obstruction

Pathophysiology

Obstruction in the large bowel is less common and not usually as dramatic as small-bowel obstruction. Dehydration occurs more slowly because of the colon's ability to absorb fluid and distend well beyond its normal full capacity. If the blood supply to the colon is cut off, the patient's life is in jeopardy because of bowel strangulation and necrosis.

Etiology

Most large-bowel obstructions occur in the sigmoid colon and are caused by carcinoma, inflammatory bowel disease, diverticulitis, or benign tumors. Impaction of stool may also cause obstruction.

Signs and Symptoms

Symptoms of large-bowel obstruction develop slowly and depend on the location of the obstruction. If the obstruction is in the rectum or sigmoid, the only symptom may be constipation. As the loops of bowel distend, the patient may complain of crampy lower abdominal pain and abdominal distention. Vomiting, if it occurs, is a late sign and may be fecal. High-pitched tinkling bowel sounds may be heard. A localized tender area and mass may be felt on palpation. Large-bowel obstructions, if not diagnosed and treated, can lead to gangrene, perforation, and peritonitis (discussed earlier).

Therapeutic Interventions

Radiological examination reveals a distended colon. If impaction is present, enemas and manual disimpaction may be effective. Other mechanical blockages may require surgical intervention.

Surgical resection of the obstructed colon may be necessary. A temporary colostomy may be indicated to allow the bowel to rest and heal. Sometimes an ileoanal anastomosis is done. A patient who is a poor surgical risk may have a cecostomy (an opening from the cecum to the abdominal wall) to allow diversion of stool.

Nursing Process for the Patient with a Bowel Obstruction

ASSESSMENT/DATA COLLECTION. Each quadrant of the abdomen is auscultated for bowel sounds. The abdomen is palpated for distention, firmness, and tenderness. The amount and character of stool, if any, is documented. Pain is assessed using the institution's pain scale and described according to location and character, such as crampy or wavelike. Daily weight and intake and output are monitored. Skin turgor is assessed for fluid deficit. If a nasogastric tube is in place, the amount, color, and character of drainage is documented. Vital signs are monitored for signs of infection or shock.

Box 34.9

Causes of Nonmechanical Obstruction

- Abdominal surgery and trauma
- Pneumonia
- Spinal injuries
- Hypokalemia
- Myocardial infarction
- Peritonitis
- Vascular insufficiency

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Acute pain related to abdominal distention

EXPECTED OUTCOME: Patient will state pain is relieved or at acceptable level.

- Assess pain level using rating scale *to consistently communicate patient level.*
- Give medication for pain as ordered. *Opioids are given cautiously because they may mask symptoms of perforation and decrease intestinal motility.*
- Position patient in semi-Fowler's position *to reduce tension on the abdomen.*
- Maintain oral/nasogastric tube on low intermittent suction as ordered *to relieve discomfort from distention.*
- Maintain NPO status *to rest the bowel and promote comfort.*

Provide frequent mouth care *to promote comfort.*

Deficient fluid volume related to vomiting

EXPECTED OUTCOME: The patient will maintain vital signs and urine output within normal limits.

- Accurately monitor intake and output *to identify fluid deficit.*
- Maintain fluid replacement as ordered *to prevent dehydration.*
- Give ice chips sparingly if ordered by the physician. *When melted ice mixed with electrolytes and hydrochloric acid is removed from the stomach by suction, electrolyte imbalance and metabolic alkalosis occur.*

EVALUATION. Goals are met if the patient states that pain is controlled and fluid is balanced and electrolytes are within normal limits.

CRITICAL THINKING

Mrs. Loos

■ Mrs. Loos is admitted for abdominal pain. She has a history of diabetes mellitus. You find her abdomen large, firm, and tender to touch. She states that she feels nauseated.

1. What do you do?
2. What do you think is happening?
3. How do you document your findings?

Suggested answers at end of chapter.

ANORECTAL PROBLEMS

Hemorrhoids

Hemorrhoids are varicose veins in the anal canal. They are caused by an increase in pressure in the veins, often from increased intra-abdominal pressure. Internal hemorrhoids

occur above the internal sphincter, and external hemorrhoids occur below the external sphincter. Most hemorrhoids are caused by straining during bowel movements. They are common during pregnancy. Prolonged sitting or standing, obesity, and chronic constipation also contribute to hemorrhoids. Portal hypertension related to liver disease may also be a factor.

Internal hemorrhoids are usually not painful unless they prolapse. They may bleed during bowel movements. External hemorrhoids cause itching and pain when inflamed and filled with blood (thrombosed). Inflammation and edema occur with thrombosis, causing severe pain and possibly infarction of the skin and mucosa over the hemorrhoid.

Preventing constipation, avoiding straining during defecation, and good personal hygiene relieve hemorrhoid symptoms and discomfort. Astringents, such as witch hazel, can be used for symptom relief. Sitz baths increase circulation to the area and aid in comfort and healing. Stool softeners can be used to reduce the need for straining. Other anti-inflammatory medications may be tried, such as steroid creams or suppositories. Alternating ice and heat helps relieve edema and pain with thrombosed hemorrhoids.

If hemorrhoids are prolapsed and are no longer reduced by palliative measures, more aggressive measures may be used. Sclerotherapy involves the injection of a sclerosing agent into the tissues around the hemorrhoids, causing them to shrink. Rubber band ligation uses rubber bands placed around the hemorrhoids until the tissue dies and sloughs off. Cryosurgery uses cold to freeze the hemorrhoid tissue. Surgical hemorrhoidectomy involves surgical removal of hemorrhoids, and is used in severe cases.

The patient should be instructed to consume a high-fiber diet and 2 to 3 L of fluid a day to promote regular bowel movements. The effects and side effects, proper dosage, and frequency of local or topical treatments should be explained. If the patient has surgery, analgesics should be given as needed because the many nerve endings in the anal canal can cause severe pain. Comfort measures such as a side-lying position and fresh ice packs should also be used to relieve pain. After the first postoperative day, sitz baths may be ordered. Unfortunately, a side effect of opioid analgesics is constipation, which needs to be avoided, especially in the immediate postoperative period. Because the first bowel movement can be painful and anxiety provoking, stool softeners are given and analgesics administered before the first bowel movement.

Anal Fissures

Anal fissures are cracks or ulcers in the lining of the anal canal. They are most commonly associated with constipation and stretching of the anus with passage of hard stool, although Crohn's disease or other factors may also play a role. The patient may experience bright red bleeding. Pain may be so severe that the patient delays defecation, leading to further constipation and worsening symptoms. Treatment of anal fissures involves measures to ensure soft stools,

allowing fissures time to heal. Sitz baths may be used to promote circulation to the area to aid in healing. Anesthetic suppositories and nonopioid analgesics may be ordered for comfort. If conservative measures are not helpful, surgical excision may be necessary.

Anorectal Abscess

An anorectal abscess is a collection of pus in the rectal area. Common causative organisms include *Escherichia coli*, *Proteus* spp., staphylococci, or streptococci. Symptoms include pain, redness and swelling, fever, and sometimes drainage. Abscesses are treated with antibiotics and surgical incision and drainage of pus. The area may be left open to drain, with packing placed to assist with drainage and healing.

Nursing Management

Nursing care includes dressing or packing changes as ordered. Sitz baths are used to keep the area clean and promote healing, especially after bowel movements. The patient is instructed in the importance of keeping the area clean and dry. Other postoperative care is similar to care following hemorrhoidectomy.

LOWER GASTROINTESTINAL BLEEDING

Etiology

Major causes of lower gastrointestinal bleeding are diverticulitis, polyps (growths in the colon), anal fissures, hemorrhoids, inflammatory bowel disease, and cancer.

Signs and Symptoms

Bleeding from the GI tract is evident in the stools. When blood has been in the GI tract for more than 8 hours and has come in contact with hydrochloric acid, it causes **melena**, or black and tarry stools. The presence of melena indicates bleeding above or in the small bowel. Bleeding from the colon or rectum is usually bright red (**hematochezia**).

Significant blood loss causes hypotension, lightheadedness, nausea, and diaphoresis. The patient may be pale and have cool skin. The onset of tachycardia and worsening hypotension indicate hypovolemic shock and should be reported to the physician immediately.

Diagnostic Tests

A thorough history is necessary to determine underlying disorders that may be causing the bleeding. Decreased hemoglobin and hematocrit levels result from blood loss. Blood urea nitrogen (BUN) may be elevated as a result of breakdown of proteins in the blood by the GI tract. Stool can be tested for occult blood if it is not evident on inspection. Digital examination, colonoscopy, or sigmoidoscopy may be done by the physician.

hematochezia: hemat—blood + chezia—in stool

Therapeutic Interventions

Treatment involves correction of the cause of the bleeding: surgery to correct diverticulosis, to correct inflammatory bowel disease, or to resect cancer may be considered.

Nursing Management

Stools are checked for the presence and amount of blood. Vital signs are monitored for signs of shock. Declining blood pressure and rising heart rate are reported to the physician immediately. The patient is prepared for diagnostic tests and nursing care for the underlying disorder is provided.

COLON CANCER

Colon cancer is one of the most common types of internal cancer in the United States. People with a family history of colon cancer or ulcerative colitis are at higher risk of developing it themselves.

Pathophysiology and Etiology

Colon cancer originates in the epithelial lining of the colon or rectum and can occur anywhere in the large intestine. People with a personal or family history of ulcerative colitis, colon cancer, or polyps of the rectum or large intestine are at higher risk for developing cancer. Colon cancer has also been linked with previous gallbladder removal and dietary carcinogens. A major causative factor is lack of fiber in the diet, which prolongs fecal transit time and in turn prolongs exposure to possible carcinogens. Also, bacterial flora is believed to be altered by excess fat, which converts steroids into compounds having carcinogenic properties.

Signs and Symptoms

Manifestations of colon cancer vary according to the type of tumor and the location (Fig. 34.6). A change in bowel habits is the most common symptom (Table 34.8). Blood or mucus in stools may occur. Although all tumors cause varying degrees of obstruction, those in the descending colon and rectum generally do not cause anemia, weight loss, nausea, or vomiting.

Diagnostic Tests

Home screening for blood in the stool can be done with a home colon cancer test kit. ColonCare is a newer immunological test that looks for small amounts of blood. If blood is found, a physician should be contacted for follow-up. Most colorectal cancers are identified by biopsy done at the time of endoscopy (proctosigmoidoscopy, sigmoidoscopy, or colonoscopy). A CT scan can perform a virtual colonoscopy to view the inside of the colon. In addition to abdominal and rectal examination, other tests include fecal occult blood testing and barium enema. Carcinoembryonic antigen (CEA), a blood test, is used to assess response to treatment of GI cancer. CEA is present when epithelial cells rapidly divide and provides an early warning that the cancer has returned.

FIGURE 34.6 Symptoms of carcinoma of the colon. Pain usually radiates toward the umbilicus or perianal area. (Modified from Black, JM, and Matassarini-Jacobs, E: *Medical-Surgical Nursing*, ed. 5. Saunders, Philadelphia, 1997, p 1810, with permission.)

Therapeutic Interventions

Small localized tumors may be excised and treated during endoscopy or laparoscopy. These procedures can also be used as palliative care for patients with advanced tumors who cannot tolerate major surgery.

Surgery is performed to either resect larger tumors and anastomose the remaining bowel or create a fecal diversion by forming an ostomy. A variety of surgical procedures can be done depending on the location and extent of the cancer (Table 34.9). In rectal cancer, an abdominoperineal (A&P) resection is done with the formation of a permanent end colostomy (Fig. 34.7). With an A+P resection, the anus, rectum, and part of the sigmoid colon are removed. There is a perineal wound, often with a drain inserted short-term, where the anus was that will heal. Medical management includes radiation therapy and chemotherapy. When both are used, along with surgery, increased survival rates have been demonstrated.

TABLE 34.8 COLON CANCER SUMMARY

Sings and Symptoms	Change in bowel habits Blood or mucus in stools Abdominal or rectal pain Weight loss Anemia Obstruction
Diagnostic Tests	Colonoscopy with biopsy Sigmoidoscopy with biopsy Proctosigmoidoscopy Barium enema Abdominal and rectal examination Fecal occult blood
Therapeutic Interventions	Surgery, possibly colostomy Radiation Chemotherapy and/or radiation Medications: analgesics TPN as necessary Support and education

Complications

Complications include bleeding, complete obstruction of the colon, perforation, anastomosis leaking leading to peritonitis, and extension of the tumor to adjacent organs. Colorectal cancer can metastasize to the lymphatic system and liver.

If the patient has an anastomotic leak, the location of the leak determines the effects that are seen. The patient may need to be NPO for up to 4 weeks to rest the GI tract and prevent more leakage and receive high-dose antibiotic therapy such as ciprofloxacin (Cipro) or metronidazole (Flagyl). Ongoing monitoring includes WBCs, sedimentation rate, and fever. The patient will likely go home with special home care needs. A peripherally inserted central catheter (PICC line) is placed to continue the antibiotic therapy.

Nursing Process for the Patient with Colon or Rectal Cancer

Assessment/Data Collection

Risk factors for colon or rectal cancer are identified by asking questions about the patient's personal and family history: Is there a history of inflammatory bowel disease? What were the patient's dietary habits? What foods were usually eaten, and how much fluid was usually consumed? Prior to diagnosis, did the patient experience constipation or diarrhea? Has there been a change in bowel habits? Has mucus or blood been noted in the stools? What social habits does the patient have? Did the patient smoke, drink alcoholic beverages, exercise? Has there been a recent weight loss? How much and in what time frame? Does the patient admit to unusual fatigue or insomnia? Stool should be checked for mucus or blood.

If the patient has surgery, postoperative assessment includes monitoring vital signs and the return of flatus and bowel movements. Lung sounds are monitored for response to coughing and deep breathing and early ambulation. Dressings are observed for drainage. Large amounts of drainage or bleeding are reported. If a drain is inserted, often

TABLE 34.9 INTESTINAL SURGERIES

Types of Intestinal Surgery	Definition	Effect on Stool Elimination
Partial colectomy	Part of colon removed	Anastomosed ends; stool is passed via rectum and anus.
Right colectomy	Right side of colon removed	Anastomosed ends; stool is passed via rectum and anus.
Ileocelectomy	Right side of colon and diseased portion of ileum removed	Anastomosed ends; stool is passed via rectum and anus.
Abdominoperineal resection	Sigmoid colon, rectum, anus removed	End colostomy
Proctosigmoidectomy	Sigmoid colon and rectum removed	Colorectal anastomosis
Total abdominal colectomy	Entire colon removed; rectum and anus remain	Ileorectal anastomosis; ileal pouch
Total proctocolectomy	Entire colon, rectum, and maybe anus removed	Ileostomy; if anus left, ileal pouch

in the perineal wound, moderate amounts of serosanguineous (light pink) drainage are expected. If the patient has an ostomy, it is monitored (see ostomy section below).

Nursing Diagnosis, Planning, and Implementation
Acute pain related to tissue compression from the tumor

EXPECTED OUTCOME: The patient will report pain relieved or at an acceptable level.

- Have patient identify pain using a rating scale to identify pain level consistently.
- Postoperatively, administer analgesics as prescribed to relieve pain.

Anxiety related to diagnosis of cancer

EXPECTED OUTCOME: The patient will report anxiety relieved.

FIGURE 34.7 Types of stomas.

- Set aside time to allow the patient who so desires to talk, cry, or ask questions about the diagnosis and planned surgery.
- Provide a quiet, relaxing atmosphere to help alleviate anxiety.
- Answer questions accurately to provide a trusting relationship.

Imbalanced nutrition: less than body requirements related to nausea and anorexia

EXPECTED OUTCOME: The patient will maintain weight normal for height and age.

- Give antiemetics as ordered to relieve nausea.
- Identify foods patients like and provide them to stimulate appetite.
- Give total parenteral nutrition as ordered to provide depleted vitamins, minerals, and nutrients if the patient has been anorexic for any length of time or has had a significant weight loss.
- Provide the patient with a high-protein, high-calorie diet, as ordered, that is low in residue to decrease excessive peristalsis and minimize cramping.

Evaluation

Expected outcomes are that the patient verbalizes control of pain and less anxiety, and attains an optimum level of nutrition.

OSTOMY AND CONTINENT OSTOMY MANAGEMENT

An ostomy is a surgically (traditionally abdominal incision or laparoscopically) created opening that diverts stool or urine to the outside of the body through an opening on the abdomen called a **stoma**. A stoma is the portion of bowel that is sutured onto the abdomen. A continent ostomy uses an internal reservoir to collect stool. The types of abdominal ostomies include ileostomy, colostomy, and urostomy. (Urinary ostomies are discussed in Chapter 37.) The stomas can be end, loop, or double barrel. See Figure 34.7 for types of ostomies.

Ileostomy

An ileostomy is an end stoma formed by bringing the terminal ileum out to the abdominal wall following a total proctocolectomy. Two types of ileostomies can be formed: a conventional ileostomy and a continent ileostomy, such as a Kock pouch (sometimes called a Koch pouch) or Barnett's continent internal reservoir which is a modification of a Kock pouch (Fig. 34.8). A conventional ileostomy is a small stoma in the right lower quadrant that requires a pouch at all times because of the continuous flow of liquid effluent.

Continent ileostomies are formed by taking a portion of the terminal ileum to construct an internal reservoir with a nipple valve. A stoma is created and the patient is taught to insert a catheter into the stoma three or four times a day to

FIGURE 34.8 Surgical formation of continent ileostomy (Kock pouch). (A) Loop of terminal ileum. (B) Both limbs of ileum are brought together and sutured into a U shape. (C) Pouch created with nipple valve. (D) Pouch sutured to abdominal wall.

empty the reservoir. A continent ileostomy surgery takes longer and requires additional instruction for the patient to be able to do self-care. It is important that the patient empty the pouch routinely to prevent pouch rupture. Complications can occur, especially for the Kock pouch, such as valve slippage or leaking, pouch rupture, or pouchitis. Corrective surgery may be required.

An ileoanal anastomosis connects the ileum to the anus and avoids the need for a stoma (Fig. 34.9). This is usually a two-step procedure. During the first surgery, the diseased bowel is removed. A reservoir (named by its shape: J [most

FIGURE 34.9 Ileal J pouch–anal anastomosis. The two-loop ileal pouch is simple to construct, provides adequate storage capacity, and is evacuated spontaneously and fully.

common], S, W, or H pouch) is then formed from part of the ileum and connected to the anus. A temporary ileostomy is also formed to divert stool while the reservoir heals. After about 3 months, the temporary ileostomy is reversed and the patient can have bowel movements from the anus. Problems with perianal skin irritation resulting from frequent liquid stools may occur. An ileorectal anastomosis can also be performed, but this may not be a curative procedure for a patient with ulcerative colitis because the rectum may still be diseased.

Colostomy

A colostomy is named according to where in the bowel it is formed: It may be an ascending, transverse, descending, or sigmoid colostomy. The type of effluent is dependent on the location of the bowel used (Table 34.10).

LEARNING TIP

As stool travels through the colon, water is absorbed and the stool becomes firmer. Therefore, an ileostomy produces the most liquid effluent, followed by an ascending colostomy. A descending or sigmoid colostomy produces the firmest stool. Those with an ileostomy are at increased risk for dehydration due to greater water loss.

End Stoma

An end stoma is formed when the proximal end of the bowel is brought to the outside abdominal wall. If an abdominal perineal resection is done (usually for low rectal cancer), the rectum is removed and the proximal sigmoid or descending colon is brought out as a stoma. Another procedure that may be done involves removing the segment of diseased or injured bowel and using the proximal portion to form the stoma. The remaining limb of bowel is sutured closed and left in the peritoneal cavity so that the rectum is intact. This is called a Hartmann's pouch, or mucous fistula, and may be permanent or temporary depending on the diagnosis. Because the rectum is intact, the patient may feel the urge to defecate. This is normal because the colon continues to produce mucus. As the rectal stump fills with mucus, the

sphincter is triggered and alerts the patient as if it were stool.

Loop Stoma

To create a loop stoma, a loop of bowel, usually the transverse colon, is pulled to the outside abdominal wall and a bridge is slipped under the loop to hold it in place. An incisional slit is made in the top of the exposed colon to allow stool to exit. The entire loop of bowel is not cut through.

Double-Barrel Stoma

With a double-barrel stoma, the bowel is completely dissected and both ends of the colon are brought to the outside abdominal wall to form two separate stomas. The proximal stoma is the functioning stoma that expels stool. The distal stoma is called a mucous fistula because mucus produced by the bowel passes from it. A double-barrel stoma is often temporary, allowing the bowel to rest during healing after trauma or surgery.

Preoperative Care

A wound ostomy continence nurse (WOCN) should be consulted before surgery. The WOCN can help prepare the patient both emotionally and physically for the surgery. In addition, the WOCN has expertise in selecting the stoma site for the surgeon to ensure that it is easy to sit with it, care for it, and wear clothing over it. This involves observing the abdomen as the patient assumes different positions and noting how clothing is worn, such as where the belt rides. The site for the stoma can then be chosen so it is visible to the patient for self-care, avoids skin or fat folds, and is where clothing will not interfere with the appliance. Properly planned stoma placement can prevent agony over discomfort when sitting, inability to perform self-care, and uncomfortable, leaking, or poorly fitting appliances postoperatively.

Routine preoperative instruction, including the importance of coughing and deep breathing, splinting, and early ambulation, is provided. Orders for cleansing of the bowel are performed to reduce the risk for infection following surgery. Unless the patient has chronic diarrhea related to IBD, an oral agent to cleanse the bowel (such as Osmoprep, Golytely) is given. Oral and intravenous antibiotics are given as ordered.

Nursing Process for the Patient with an Ostomy or Continent Ostomy

Assessment/Data Collection

The patient with a new ostomy has many nursing care needs. In addition to routine postoperative assessment, a stoma should be inspected at least every 8 hours. The stoma should be pink to red, moist (similar to the inside of the mouth), and well attached to the surrounding skin (Fig. 34.10). A bluish stoma indicates inadequate blood supply; a black stoma indicates necrosis. Either complication should be reported to the physician immediately for treatment, which may require that the patient return to surgery. Note edema of stoma. The stoma size gradually decreases over the first few weeks following surgery.

TABLE 34.10 LOCATION OF STOMA AND TYPE OF EFFLUENT

Location of Stoma	Type of Effluent
Ileostomy	Liquid to mushy
Cecostomy, ascending colostomy	Liquid to mushy, foul odor
Right transverse colostomy	Mushy to semifirmed
Left transverse colostomy	Semifirmed, soft
Descending or sigmoid colostomy	Soft to hard formed

FIGURE 34.10 Types of stomas. Note moist, pink to red appearance of healthy stoma. (Reproduced with permission of Hollister Inc., Libertyville, Illinois)

Skin is assessed for irritation around the pouch and under the pouch each time it is changed. Ostomy discharge (effluent) is monitored and documented. Unexpected changes, such as liquid stool from a descending ostomy, are reported.

For the patient with a continent ostomy pouch, assessing that regular emptying of the pouch is done is important to prevent rupture and leakage. The characteristics of the stool are noted for any type of continent ostomy so that problems can be reported.

Nursing Diagnosis, Planning, and Implementation

See Box 34.10 Nursing Care Plan for the Patient with an Intestinal Ostomy and Table 34.11.

Deficient knowledge related to new ostomy

EXPECTED OUTCOME: Patient will demonstrate how to care for ostomy.

- Determine patient readiness and ability to learn and perform self-care. *The patient experiencing pain,*

nausea, or vomiting is not likely to be ready to look at the ostomy or learn about ostomy care.

- Patients with special needs: blindness, deafness, language barrier, severe arthritis or other physical conditions that limit ability to perform self-care require special instructions or specific type of ostomy appliance *to be able to perform self-care.*
- If the patient is not ready or able to learn, it is important that a family member or caregiver be included in the teaching. *With short hospital stays, teaching time frames are limited and must begin soon after surgery.*
- Ensure referral to home care nurse is made *to continue teaching in the patient's home.*
- Consult a WOCN or equipment supplier if needed for suggestions for appliances *to identify appliances suited to individual patient's needs.* Figure 34.11 shows types of appliances.
- Explain how to change appliance (Fig. 34.12):
 - Depending on the type of appliance used, the appliance will need to be changed as often as every 3 days or rarely every 10 to 14 days.
 - If leakage occurs, the appliance should be changed as soon as possible to avoid **peristomal** skin irritation.
 - The skin barrier that is placed over the stoma on the skin should fit within one-sixteenth to one-eighth inch of the base of the stoma *to prevent skin contact with stool.*
 - The stoma should be measured initially with each appliance change *as the stoma will be edematous until it shrinks over time.*
 - Trace a stoma pattern to teach the patient proper size and shape *because most stomas are not round.*
 - An open-ended or drainable pouch should be used for all colostomies or ileostomies, especially during the first 8 weeks after surgery *to facilitate emptying and comfort.*
- Explain to the patient who has a left-sided (descending or sigmoid) colostomy that the bowel can be regulated either by diet or regular irrigation of the stoma. *Once bowel regulation has been achieved, the patient may use a closed-end pouch or a stoma cap.*
- Explain daily care and hygiene:
 - Empty pouch when it is one-third to one-half full. *The amount of effluent and the frequency of emptying depends on the location of the stoma in the bowel. If the pouch is allowed to get more than half full of stool, the weight of the effluent will pull on the pouch and weaken the seal of the skin barrier.*
 - Once the pouch is emptied, the inside of the tail of the pouch must be cleaned and dried before the clamp is replaced *to help control odor.* *If a two-*

peristomal: peri—surrounding + stoma—mouth or opening

Box 34.10 NURSING CARE PLAN for the Patient with an Intestinal Ostomy

Disturbed body image related to new ostomy

Patient Outcomes Patient will verbalize acceptance of intestinal ostomy before discharge.

Evaluation of Outcomes Is the patient able to verbalize acceptance of the ostomy?

Interventions	Rationale	Evaluation
Ask about knowledge of self-care of ostomies.	Many people have misconceptions regarding ostomies. Identification of misconceptions and “hearsay” knowledge is important to clarify or correct.	Does the patient verbalize appropriate knowledge of ostomy care?
Encourage patient to verbalize feelings about the stoma.	Allowing the patient to express his or her feelings provides opportunity to identify and verbalize concerns, which then can be addressed by health-care providers.	Does the patient discuss his or her feelings regarding the stoma to the nurse or significant other?
Explain the normal characteristics of the stoma before the patient’s first look.	Helping the patient understand what to expect will help relieve anxiety. Being available to answer questions immediately also relieves anxiety.	Does the patient look at the stoma without hesitation?
Demonstrate ostomy appliance change and daily care and encourage patient participation.	When the patient observes and participates in self-care, his or her self-concept improves.	Is the patient participating in self-care? Has the patient performed return demonstration of appliance change and emptying of pouch?

piece system is used, the pouch can be taken off, washed out, and replaced.

- Spray deodorants or chlorophyll tablets can be placed in the pouch *to control odor. Chlorophyll is more effective if taken by mouth.*
- Bathe or shower with the appliance in place

but check seal and retape or change it if it is loosening.

- Explain dietary considerations:
 - Identify foods that contribute to odor and gas. *If foods that are known to cause odor or gas are eaten, the patient should know to empty the pouch*

TABLE 34.11 SUMMARY OF RECOVERY FROM INTESTINAL SURGERY

Intestinal Surgery	Elimination Needs	Discharge Teaching needs	Possible Psychological Needs
Partial colectomy Right colectomy or ileocelectomy	Normal, no appliance needed.	Monitor for constipation. Avoid stress to abdomen: heavy lifting, situps. Soft diet until first doctor visit. Monitor for constipation and report.	Fear of cancer Fear of cancer; chronic sorrow related to IBD
Abdominoperineal resection	Pouch	Ostomy care	Fear of cancer Body image changes Fear of cancer
Proctosigmoidectomy	Normal, no appliance needed	Soft diet until first doctor visit. Monitor for constipation and report.	
Total abdominal colectomy	Normal or continent anal passage	Continent ostomy care. Soft diet until first doctor visit. Monitor for constipation and report.	Chronic sorrow related to IBD
Total proctocolectomy	Continent anal passage or pouch	Continent ostomy care. Soft diet until first doctor visit. Monitor for constipation and report.	Chronic sorrow related to IBD

FIGURE 34.11 Appliances used for ostomies. The long sleeve at the lower left of the photograph is used to drain the bowel following irrigation. (Reproduced with permission of Hollister Inc., Libertyville, Illinois)

of flatus more often and to be aware that more odor is probable.

- Identify foods that contribute to and control diarrhea and what to do for constipation. *A list of foods that may contribute to ileostomy blockage must be given to the ileostomy patient* (Table 34.12; Box 34.11 Nutrition Notes).
- Explain colostomy irrigation:
 - Tell that colostomy irrigation is done *to regulate bowel movements at a regular time*. Candidates for irrigation are those with more formed stool (descending or sigmoid portion of colon).
 - Show how to perform irrigation (similar to an enema), with special equipment used to instill fluid into the bowel via the stoma. *Since a stoma does not have a sphincter, specially designed tubing with a cone at the end is used to irrigate the ostomy. The cone blocks the fluid that is being instilled from flowing back out of the stoma.*

Ineffective Therapeutic Regimen Management related to difficulty carrying out self-care measures

- Identify financial ability to obtain supplies. *The cost and availability of ostomy supplies is problematic for many patients. Most insurers, including Medicare, pay for ostomy supplies, although some limit the type of appliance and number allowed per month. Each state-funded Medicaid system is different. The type of appliance needed to eliminate leakage may not always be covered, requiring the patient to either pay the difference or wear what the insurance company will provide. If the patient has no insurance, costs can be high. Some patients find*

Preparation of the Stomabesive Wafer with Star-Fit Flange

1. Cleanse the peristomal area with water and pat thoroughly dry. Measure your stoma size with the measuring guide provided and trace the proper opening on the white paper backing of the Stomabesive® disc.

2. Leaving the white paper backing of the wafer in place, cut a hole in the wafer to the same shape and size as the base of the stoma. The best result is usually obtained by cutting from the reverse side of the wafer, using curved, short-bladed scissors.

3. Peel the white paper backing from the wafer just prior to application.

4. Gaps between the wafer and the base of the stoma may be further protected by applying Stomabesive® Paste to the wafer.

Application of the Stomabesive Wafer with Star-Fit Flange

5. Center the enlarged hole over the stoma, place on abdomen, and apply light pressure.

FIGURE 34.12 Preparation to apply an ostomy appliance. (Courtesy ConvaTec, a Bristol-Myers Squibb Company, Princeton, NJ, with permission.)

they have to choose whether to purchase ostomy appliances or prescriptions with their limited funds. Fortunately, the pouches in most two-piece systems can be washed out and reused to save money (see Home Health Hints).

Sexual dysfunction related to body image change or erectile dysfunction

EXPECTED OUTCOME: Patient will discuss satisfying acceptable sexual practices for self and partner.

TABLE 34.12 FOODS THAT CAN CAUSE ILEOSTOMY BLOCKAGE

Green leafy vegetables	Mushrooms
Spinach	Nuts
Collards	Dried fruits
Mustards	Raisins
Cole slaw	Figs
Celery	Apricots
Corn, popcorn	Chinese vegetables
Foods with nondigestible peels	Meats with casings
Apples	Sausage
Grapes	Hot dogs
Potatoes	Bologna
Coconut	

- Identify if male patient who had an abdominoperineal resection for cancer of the rectum has erectile dysfunction. *This impotence may be transient, depending on the severity of nerve damage or edema associated with the surgery.*
- Ensure consultation with urologist is made if erectile dysfunction is present.
- Encourage patients to discuss any concerns regarding sexuality with his or her sexual partner. *This may help them work through any fears or embarrassment.*

**Box 34.11****Nutrition Notes****Anticipating Dietary Management of Ostomies**

Ostomy patients receive a soft diet initially, progressing to a general diet as the surgeon prescribes. Stringy, high-fiber foods are avoided initially. These include celery, coconut, corn, cabbage, coleslaw, membranes on citrus fruits, peas, popcorn, spinach, dried fruit, nuts, sauerkraut, pineapple, seeds, and skins of fruits and vegetables. Some patients avoid fish, eggs, beer, and carbonated beverages because they produce excessive odor. Dietary restrictions are usually based on individual tolerance.

Patients with ostomies should be encouraged to do the following:

- Eat at regular intervals.
- Chew food well to avoid blockage at the stoma site.
- Drink adequate amounts of fluid.
- Avoid foods that produce excessive gas, loose stools, offensive odors, and undesirable bulk.
- Avoid excessive weight gain.

- Attractive pouch covers can be purchased and worn to help disguise the pouch and its contents.
- Refer to sexual counselor who can suggest alternative sexual positions that may be satisfying to the partners.

Risk for injury related to skin and stomal complications

- Consult WOCN for complications associated with the care of the ostomy. *A WOCN has had specialized instruction in caring for the stoma and peristomal skin and has a wealth of information to offer.*
- Identify allergies. *Allergic dermatitis from sensitivity to the adhesive may develop.*
- Use a skin barrier such as stomahesive to prevent peristomal skin irritation. *The skin around the stoma may become irritated if the opening in the skin barrier around the stoma is cut too large and exposes skin to the GI effluent. Prolonged contact with effluent can lead to a reaction similar to a chemical burn.*
- Ensure tape and adhesive removal is done only when necessary. *If done frequently, it can lead to skin shearing.*
- Leave pouches on for several days or until leakage occurs to prevent skin shearing from frequent removal.
- Monitor for peristomal hernia. *Hernias may develop around the stoma as a result of weakened abdominal muscles and cause leakage by the change in body contours associated with the hernia.*
- Use a more flexible ostomy appliance if peristomal hernia present to fit body contours better.
- Monitor for and report stomal prolapse, especially in the older adult patient. *Weakened abdominal muscles contribute to the falling down (or out) of the intestinal mucosa which can make pouching difficult.*
- Monitor stoma color and report immediately dusky or blue color *which occurs when there is circulatory compromise. This may arise as a result of vascular collapse, blockage in the mesentery of the intestines, or edema in the intestine from obstruction proximal to the stoma. Usually, necrotic tissue occurs only at the very end of the stoma and will eventually slough off, revealing viable mucosa.*
- Explain signs and symptoms of an ileostomy blockage and how to manage it. *Signs of a blockage are absent stool, abdominal cramping, edematous stoma, and stoma color that is pale or dusky.*
- If blockage occurs, have patient consider what was eaten in the past 24 hours *because certain foods are considered to cause stomal blockage.* (See Table 34.12.)

- For an ileostomy blockage, have the patient get into a tub of warm water (not too hot or cold), get into a knee-to-chest position, and sip on warm liquid, such as coffee, tea, bouillon, broth, or hot chocolate. *If the blockage is partial, relief will occur fairly soon after these measures are taken.*
- Explain to patient that if no relief is obtained, medical treatment should be sought. *For a complete blockage, an ileostomy lavage must be performed by a physician or WOCN.*

Evaluation

The plan of care has been effective if the patient is able to accept the change in body image, competently care for the ostomy (or caregiver will), carry out self-care, is satisfied with sexual practices, and describes self-care measures to prevent or treat complications.

Rehabilitative Needs

Ensuring that the patient is becoming comfortable with self-care, is able to perform the ostomy appliance change, and is able to return to work or civic activities as before are the goals of care. The patient can generally perform any activity he or she was able to do before the ostomy. Several support resources are available (Table 34.13).

Home Health Hints

- Patients with ostomies may be able to have some of their supplies covered by insurance. The home health nurse can work with the medical supply store to assist the patient in receiving the necessary equipment. Most companies will deliver the supplies to the patient's home.
- Foods such as broccoli, cauliflower, Brussels sprouts, and cabbage can cause increased malodorous gas production. Encourage the patient with a colostomy to eat these in moderation. Offer alternative choices such as: green leafy vegetables, carrots, and cucumbers.
- If the patient requires a stool for occult blood test, deliver a collection hat before you visit to assist with obtaining the specimen. Plan to deliver the specimen to the laboratory that day.
- Dietary instruction is important for home health patients with lower GI disorders. Give instructions both verbally and in written format. Written format allows the patient to have the information available for review and to assist with creating a shopping list.

REVIEW QUESTIONS

1. The nurse is collecting data on a patient admitted with a history of severe diarrhea. Findings include cool, pale skin, red tongue with furrows, blood pressure 102/74, pulse 106, respirations 20, temperature 99.9° F (37.7°C). Which of the following actions should the nurse take now?
 - a. Report findings to registered nurse
 - b. Give acetaminophen (Tylenol) as ordered
 - c. Obtain bedside commode
 - d. Apply warm blankets
2. The nurse is planning a teaching session for a patient who has a history of constipation and laxative use. Which of the following statements about laxative use would the nurse include in the teaching plan to promote patient understanding?
 - a. Laxatives may be used as needed.
 - b. Regular laxative use can be harmful.
 - c. Daily use of laxatives prevents constipation.
 - d. Laxative use has no complications.

Multiple response item. Select all that apply.

3. Which of the following interventions should the nurse include in the plan of care for a patient after an appendectomy to prevent respiratory complications?
 - a. Pain control
 - b. Early ambulation
 - c. Bedrest
 - d. Coughing, deep breathing
 - e. Turning in bed
 - f. Incentive spirometer
4. Which of the following foods would the nurse teach the patient with ulcerative colitis to avoid?
 - a. Fresh fruits
 - b. White bread
 - c. Sweet desert
 - d. Meat
5. Following a teaching session, which of the following statements would indicate to the nurse that the patient understood the teaching for postoperative care to prevent respiratory complications after a hernia repair?
 - a. "I will cough every hour while awake to keep my lungs clear."
 - b. "I will deep breathe four times daily."
 - c. "I will cough and deep breathe every hour."
 - d. "I will deep breathe every hour while awake."
6. The nurse would evaluate the patient as understanding adult celiac disease teaching if the patient selected which of the following foods to eat?
 - a. Pancakes with hash brown potatoes
 - b. Tomato juice and waffles
 - c. Hard boiled egg, bacon, and blueberries
 - d. Banana, cream of wheat cereal, and coffee
7. The nurse is caring for a patient with a small bowel obstruction. The patient is NPO with an orogastric tube to low intermittent suction. Which of the following ongoing data would be a priority for the nurse to monitor and collect?
 - a. Intake and output
 - b. Pain level
 - c. Bowel sounds
 - d. Pulse rate
 - e. Temperature
 - f. Edema
8. The nurse is caring for a patient who has a sudden onset of diarrhea. Which of the following terms should the nurse use to document the patient's black, tarry stool?
 - a. Melena
 - b. Hematochesia
 - c. Hematemesis
 - d. Steatorrhea
9. The nurse is developing a teaching plan for a patient who is interested in lifestyle changes to help prevent colon cancer. Which of the following of the patient's dietary habits does the nurse understand may increase the risk for development of colon cancer?
 - a. High-fat, low-fiber intake
 - b. High intake of milk and milk products
 - c. Low-meat and protein intake
 - d. Low-fat, high-carbohydrate intake
10. The nurse is caring for a 1-day postoperative patient who has a new end colostomy. Which of the following findings regarding the stoma would be a priority for the nurse to report?
 - a. Dusky color
 - b. Mucus drainage
 - c. Slight bleeding with touch
 - d. Round shape
11. A patient with Crohn's disease is to receive sulfasalazine (Azulfidine), 500 mg oral suspension qid. The oral suspension is available as 250 mg/5 mL. How many milliliters should the nurse give for the 0800 dose?
 - a. 5 mL
 - b. 10 mL
 - c. 20 mL
 - d. 50 mL

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Burns

You need to assess the situation before intervening. First, ask Mrs. Burns or her caregivers if she had a bowel movement that was inadvertently not charted. Next, ask Mrs. Burns if she feels constipated or if she has abdominal discomfort. Assess Mrs. Burns's abdomen for dis-

attention and presence or absence of bowel sounds. A digital examination may be necessary to determine if a fecal impaction is present. If simple constipation appears to be the problem, the medical record should be checked for as-needed laxative or enema orders. Once Mrs. Burns has had a bowel movement, laxatives should be discontinued and preventive measures such as regular fluids, fiber, and exercise should be instituted.

■ *Judy Morrow*

1. Characteristics of pain: location, quality, intensity, precipitating factors, relieving factors.
 Characteristics of bowel elimination: frequency, characteristic of stool, amount, color, consistency.
 Nutritional status: Weight loss, appetite, daily food intake, food likes/dislikes, irritating foods, fluid intake.
 Anxiety and coping skills: Support systems, usual coping methods.
2. Acute pain related to increased peristalsis and cramping
 Diarrhea related to inflammatory process
 Risk for deficient fluid volume related to diarrhea and insufficient fluid intake
 Anxiety related to symptoms and frequency of stools and treatment.
 Impaired skin integrity related to frequent loose stools
 Ineffective nutrition, less than body requirements, related to malabsorption
 Ineffective coping related to frequency of stools
3. You need to further assess how Judy perceives that Crohn's disease will affect her lifestyle. What does she know about Crohn's disease? What is she concerned about? How has Crohn's disease affected her ability to sleep, what she eats, her participation in sports, and her relationships with other people?
 Convey a caring manner to Judy by being accepting of her, listening actively to her concerns, and helping her to find acceptable ways of resolving them. Provide her with information that she needs about Crohn's disease. Arrange to have a well-adapted person of approximately the same age from the Crohn's and Colitis Foundation of America

meet with her to share coping strategies with her.

4. Increased frequency of stools leading to fluid volume deficit and possibly shock symptoms. Bleeding leading to anemia and hypovolemia and possibly shock symptoms.

■ *Mrs. Loos*

1. You need to further assess Mrs. Loos before deciding what to do. Begin by asking the WHAT'S UP? questions, including exactly where the pain is occurring, how it feels, if there is anything that aggravates or alleviates the pain, when it started, how bad it is on a scale of 0 to 10, whether there are associated symptoms, and if Mrs. Loos has some insight regarding the cause of her problem. Listen for bowel sounds for 5 minutes in each quadrant. Find out when her last bowel movement was.
2. Because of her history of diabetes, you suspect that neuropathy may be causing a nonmechanical bowel obstruction. If assessment findings confirm this possibility, the physician should be contacted. Because of the nausea and the potential obstruction, withhold food and fluids until the physician can be contacted.
3. When documenting, answer the questions what, why, when, where, who, how (either explicitly or implicitly by professional knowledge, in narrative or flow sheet format) for completeness.
 What = Patient is experiencing large, firm, tender to touch abdomen with nausea (additional assessment data should be included).
 Why = Unknown, physician notified
 When = Current date and time
 Where = Abdomen
 How = Unknown
 Who = J. Morgan, LPN

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the causes, risk factors, and pathophysiology of the various types of liver disease?
2. What are current therapeutic interventions for patients with liver disease?
3. What nursing care should you provide for the patient experiencing a liver disorder?
4. What are the causes, risk factors, and pathophysiology of the various pancreatic disorders?
5. What are current therapeutic interventions for pancreatic disorders?
6. What nursing care would you provide for a patient with a pancreatic disorder?
7. What are the causes, risk factors, and pathophysiology of gallbladder disorders?
8. What are current therapeutic interventions for gallbladder disorders?
9. What nursing care would you provide for a patient with a gallbladder disorder?

DISORDERS OF THE LIVER

Hepatitis

Hepatitis is an inflammation of the cells of the liver, resulting from infection by viral agents or exposure to drugs toxic to the liver or occasionally from bacterial infection. Symptoms of hepatitis range from nearly no symptoms to life-threatening symptoms due to death of liver tissue.

Pathophysiology and Etiology

Hepatitis is usually caused by one of six viruses:

- Hepatitis A virus (HAV), sometimes called infectious hepatitis
- Hepatitis B virus (HBV), sometimes called serum hepatitis

hepatitis: hepat—liver + itis—inflammation

- Hepatitis C virus (HCV), sometimes called non-A, non-B (NANB) hepatitis
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)
- Hepatitis G virus (HGV)

The viral agents vary by mode of infection, incubation period, symptoms, diagnostic tests, and preventive vaccines (Table 35.1). The infecting organism causes inflammation of the liver, with resulting damage to liver cells and loss of liver function. If damage involves the bile canaliculi, obstructive jaundice will occur. If complications do not occur, cells regenerate and normal liver function eventually resumes.

There are an estimated 164,000 new hepatitis A, B, and C infections in the United States each year.¹ The incidence of HAV increased nearly 27% in the mid 1980s and is the most common cause of hepatitis. HAV has a low mortality rate. However, HBV is more common among some groups, including health-care workers and intravenous drug users; it

TABLE 35.1 COMPARISON OF TYPES OF VIRAL HEPATITIS

	Hepatitis A Virus	Hepatitis B Virus	Hepatitis C Virus	Hepatitis D Virus	Hepatitis E Virus
Mode of transmission	Oral-fecal contamination of water, shellfish, eating utensils, or equipment	Blood or body fluids such as saliva, semen, and breast milk; equipment contaminated by blood	Blood transfusions, IV drug use, unprotected sex	Blood or body fluids as with HBV; strongly linked as a confection with HBV	Usually, contaminated water
Incubation period	3–7 weeks	2–5 months	1 week to months	Same as HBV	2–9 weeks
Symptoms	Early (prodromal): fatigue, anorexia, malaise, nausea, or vomiting Icteric: jaundice, pale stools, amber or dark urine, RUQ pain	Early (prodromal): 1–2 months of fatigue, malaise, anorexia, low-grade fever, nausea, headache, abdominal pain, muscle aches May have no early symptoms Icteric: jaundice, rashes	Same as HBV, usually less severe	Similar to HAV and to HBV but more severe	Similar to HAV
Diagnostic tests	Elevated serum liver enzymes (ALT, AST), elevated serum bilirubin, HAV antigen	Elevated serum liver enzymes (ALT, AST), elevated serum bilirubin, HBV antigen	Elevated serum liver enzymes (ALT, AST), elevated serum bilirubin, HCV antigen	Elevated serum liver enzymes (ALT, AST), elevated serum bilirubin, HDV antigen	Elevated serum liver enzymes (ALT, AST), elevated serum bilirubin
Preventive vaccine	Immune globulin	Immune globulin or HBIG	None	HBIG	None
Groups at risk	Individuals in military or day care	IV drug abusers, homosexuals, health-care workers, transplant and hemodialysis patients	Same as HBV	Same as HBV	Travelers to endemic areas

ALT = alanine aminotransferase; AST = aspartate aminotransferase; HBIG = hepatitis B immune globulin; IV = intravenous; RUQ = right upper quadrant.

has a mortality rate of about 5%. Hepatitis G virus is a recently discovered virus that is transmitted by blood transfusions and IV drug abuse. It may cause hepatitis, but not a lot is known about it yet.

Prevention

The hepatitis viruses are very resistant to a wide range of anti-infective measures, such as drying, heat, ultraviolet light exposure, freezing, and bleach and other disinfectants. At least 30 minutes in boiling water is required to destroy them. The best methods for preventing the transmission of the hepatitis viruses are careful attention to cleanliness and the use of vaccines such as immune serum globulin (ISG) or vaccines to HBV and HAV. Health-care workers must use standard precautions at all times. Infection control precautions should reflect the usual mode of transmission of the particular hepatitis virus.

Immune serum globulin provides temporary, passive, nonspecific immunity to hepatitis. Permanent, active immunity is acquired from the body's own antibodies in response to actual viral infection. The active immunity is to the specific virus to which the body has developed antibodies. Vaccines to HBV are available and provide permanent, active immunity to HBV. Health-care workers are strongly encouraged (and frequently required by employers as a condition of employment) to be vaccinated for HBV. A vaccine for HAV has also been developed.

Public health measures such as health education programs, licensing and supervision of public facilities, screening of blood donors, and careful screening of food handlers are general measures to prevent the transmission of hepatitis viruses.

SAFETY TIP

Protect yourself! Reduce the risk of health-care-associated infections. Comply with current Centers for Disease Control and Prevention (CDC) (www.CDC.gov) hand hygiene guidelines (2006 National Patient Safety Goals from www.JCAHO.org).

Signs and Symptoms

Hepatitis usually shows a typical pattern of loss of liver function. There are generally three stages:

1. The prodromal, or preicteric (prejaundice), stage lasts about 1 week. The patient complains of flu-like symptoms of malaise, headache, anorexia, low-grade fever, possibly dull right upper quadrant (RUQ) pain, nausea, vomiting, and diarrhea or constipation
2. The icteric stage peaks at 2 weeks and lasts 2 to 6 weeks. The patient continues to have fatigue, anorexia, nausea, vomiting, and malaise. The patient is also likely to have jaundice or noticeable

yellowing of the skin, sclerae of the eyes and other mucous membranes; dark amber urine; and clay-colored stools (see Chapter 32). The liver is usually enlarged and tender on examination.

3. The posticteric, or convalescent, stage lasts from 2 to 6 weeks with complete recovery in 6 months if relapse does not occur. The patient usually feels well during this time, but full recovery as measured by the return to normal of all liver function tests may take as long as 1 year.

Hepatitis is considered a reversible process if the patient complies with a medical regimen of adequate rest, good nutrition, and abstinence from alcohol or other liver-toxic agents for at least 1 year after liver function laboratory values return to normal. See Chapter 32 for a more complete discussion of jaundice.

Complications

Hepatitis may lead to fulminant or acute liver failure (see the following). About 5% of hepatitis patients progress to chronic liver failure. Some patients become asymptomatic carriers of the virus; HBV-infected carrier patients have a greater risk of developing cancer of the liver.

Diagnostic Tests

Serum liver enzymes are elevated. Serum bilirubin and urobilinogen may be elevated. The erythrocyte sedimentation rate is usually elevated from the inflammatory process. In patients with severe hepatitis, prothrombin time may be elevated (Table 35.2). Serological tests may be ordered to determine the specific virus causing the hepatitis. Each virus has specific antigen markers that serological study can reveal. The antigen markers can be further used to determine the degree of healing from the hepatitis. Abdominal x-ray examination may show an enlarged liver.

Therapeutic Interventions

Treatment is aimed at providing rest and adequate nutrition for healing. There are no specific drugs or other medical therapies for hepatitis. Interferon therapy and antiviral medication may be used for hepatitis B or C, but they may not be effective. A new medication is currently being researched that inhibits replication of the hepatitis C virus. Currently the best treatment is proper rest and nutrition.

Patients are restricted from any alcohol or drugs that are known to be toxic to the liver (Box 35.1 Common Hepatotoxic Substances). In addition, patients are generally placed on limited activity with bathroom privileges. Because the patient usually experiences malaise, fatigue, and anorexia, rest is advised. As the patient improves, activity may be increased as tolerated as long as the patient does not become fatigued.

Nursing Process for the Patient with Hepatitis

ASSESSMENT/DATA COLLECTION. Assess the patient for subjective complaints such as malaise, fatigue, pruritus (itching), nausea, anorexia, and RUQ abdominal pain. Objective data, such as baseline weight, vomiting, pale

TABLE 35.2 LABORATORY TESTS FOR HEPATITIS

Test	Normal Range	Significance
Alanine aminotransferase	5–35 IU/mL	Found in high concentrations in liver cells; released with death of liver cells
Aspartate aminotransferase	8–20 U/L	Found in high concentrations in liver cells; released with death of liver cells
Erythrocyte sedimentation rate	Adult: Women, 1–20 mm/hr Men, 1–13 mm/hr	Increased with inflammation and tissue damage
Prothrombin time	8.8–11.6 seconds	Liver can no longer make prothrombin
Serological tests		
Anti-HAV	Negative titer	Indicates exposure and probable infection with virus
Anti-HBV	Negative titer	Indicates exposure and probable infection with virus
Anti-HCV	Negative titer	Indicates exposure and probable infection with virus

stools, amber- or dark-colored (tea-colored) urine, and jaundice, are recorded. The patient's vital signs are taken, and a low-grade fever or any abnormal bruising or bleeding is reported immediately. Assess the patient for knowledge of disease process and how to prevent spread of the disease.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Imbalanced nutrition, less than body requirements related to anorexia, nausea, or vomiting

EXPECTED OUTCOME: The patient's weight will be stable and appropriate for height.

- Monitor weight and nutritional intake. *Patient assessment should guide intervention.*
- Provide a high-calorie, high-protein, high-carbohydrate, low-fat diet. *There are no restrictions on what*

the patient may eat, but the focus is to provide a well-rounded, nutritious diet.

- Administer antiemetic drugs as ordered *to reduce nausea and increase appetite.*
- Provide frequent, smaller meals. *These may be tolerated better than larger meals.*
- Provide larger meals earlier in the day *because nausea tends to increase during the day.*
- Place the patient in an upright or sitting position for meals *to decrease abdominal discomfort.*
- Serve meals in a quiet environment without unpleasant noise or odors *to increase intake by making eating as pleasant as possible.*
- Teach patient to avoid alcohol and vitamin supplements unless specifically prescribed by the physician. *Alcohol and some vitamins are metabolized by the liver.*

Box 35.1

Common Hepatotoxic Substances

Ethyl alcohol
Acetaminophen (Tylenol)
Acetylsalicylic acid (aspirin)
Anesthetic agents
 Halothane (Fluothane)
Diazepam (Valium)
Erythromycin estolate (Ilosone)
Isoniazid (INH)
Methyldopa (Aldomet)
Oral contraceptives
Phenobarbital (Luminal)
Phenytoin (Dilantin)
Tranquilizers
 Chlorpromazine (Thorazine)
Industrial chemicals
 Carbon tetrachloride
 Trichloroethylene
 Toluene

Risk for impaired skin integrity related to itching secondary to bilirubin pigment deposits in skin

EXPECTED OUTCOME: The patient's skin will remain intact and free from secondary infection.

- Administer antihistamines as ordered *to decrease the itching*
- Encourage the patient not to scratch, but to press firmly on the itching area. *Scratching can damage skin and increase risk for infection.*
- Encourage the patient to keep fingernails trimmed short *so that vigorous scratching does not tear the skin.*
- Maintain room temperature at a comfortable level to decrease perspiration, *which may increase itching.*

Pain related to inflammation and enlargement of the liver

EXPECTED OUTCOME: Patient will state that pain level is acceptable.

- Monitor pain level on 10-point scale, including "What's Up?" questions. *A good assessment should guide treatment.*

- Give analgesics as ordered *to control pain*. Lower doses may be necessary for the patient with liver dysfunction. Acetaminophen is generally avoided due to risk of liver toxicity.
- Encourage nonpharmacological pain relief activities, such as distraction, imagery, and relaxation. These can supplement and may decrease the need for analgesics.

Risk for ineffective management of therapeutic regimen related to lack of knowledge of hepatitis and its treatment

EXPECTED OUTCOME: Patient will state how to self-manage the treatment regimen for viral hepatitis, and how to prevent spread of the disease.

- Assess the patient's knowledge of hepatitis. A good assessment should guide teaching.
- Teach the patient the necessity of proper home cleanliness, including hand washing after toileting and using soap and hot water to clean eating utensils, cookware, and food preparation surfaces *to reduce spread of hepatitis to others*. (See Home Health Hints.)
- Teach patients how hepatitis affects the body and the importance of adequate rest and proper nutrition. *The patient is more likely to follow a treatment regimen if he or she understands the rationale.*
- Teach the importance of avoiding alcohol and other liver-toxic drugs. *These can further damage an already compromised liver.*
- Teach patient how to prevent spread of the disease to others. Provide guidelines specific to the type of hepatitis the patient has. *Hepatitis is contagious.*

EVALUATION. Management of the patient with hepatitis has been successful if the patient demonstrates the following:

- Maintenance of body weight to within 2 lb of preillness weight
- No breaks, cuts, or tears in skin, and no secondary infections.
- Abdominal pain or other discomfort reported as not greater than 2 to 3 on a 10-point scale
- The effects of hepatitis, how hepatitis is spread, and the necessity of adequate rest, proper nutrition, and necessary sanitation measures can be stated.

For more information, visit Hepatitis Foundation International at www.hepfi.org, www.cdc.gov, or the American Liver Foundation at www.liverfoundation.org.

Acute (Fulminant) Liver Failure

Acute (fulminant) liver failure is an uncommon but gravely serious complication of liver disease and has a mortality rate as high as 50%.

Pathophysiology and Etiology

Acute liver failure results from the sudden massive loss of liver tissue, or necrosis. The cause of liver damage is usually

CRITICAL THINKING

Carl

■ Carl is a 23-year-old man admitted to your medical-surgical nursing unit. During the admission process, Carl talks about his trip to an African country as a missionary. He returned to this country 4 weeks ago. During his trip he sustained a serious laceration that required many sutures. Carl also mentions his fondness for seafood and that he has had several “feasts” that have included raw oysters. Carl states that since his return he has lost nearly 8 lb, is nauseated, has frequent headaches, and tires easily. Carl also tells you that he is very irritable, which is different from his usual easygoing manner.

1. What information might lead you to suspect hepatitis A? Hepatitis B?
2. What precautions should be instituted for Carl until a diagnosis is made?
3. What nursing actions might you implement to help Carl improve his nutrition?
4. What medications should Carl avoid?
5. What information should be included in a discharge teaching plan for Carl?

Suggested answers at end of chapter.

drug toxicity or HBV in the presence of HDV. The outcome of the disease may be decided within 48 to 72 hours of diagnosis. Possible outcomes are reversal, need for transplantation, or death.

Prevention

Acute liver failure may be avoided by eliminating exposure to hepatitis B or hepatotoxic, liver-damaging substances. Hepatitis B can be transmitted through body fluids, such as blood or semen from unprotected sex; intravenous drug use; blood transfusions; and dialysis. See Box 35.1 for a list of hepatotoxic substances.

Signs and Symptoms

Signs and symptoms of the disorder include hepatic **encephalopathy**, or central nervous system dysfunction (discussed in detail in the section on chronic liver failure). The patient may suddenly lapse into extremely serious illness, starting with confusion and progressing to coma. In a matter of hours the liver shows a rapid reduction in size; a typical sign of onset of acute liver failure. In addition, there is a sudden elevation of liver enzymes and bilirubin. Prothrombin time is elevated. Marked elevation in the prothrombin time is an ominous sign.

Diagnostic Tests

Early diagnosis of acute liver failure is essential so that the process of organ procurement may begin. An otherwise

encephalopathy: encephalo—brain + pathy—disease

healthy patient may be a priority organ recipient depending on age and whether or not the patient is alcohol dependent.

Laboratory tests include the serum liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Levels of ALT and AST may rise from 1000 mU/mL to as high as 4000 mU/mL. The serum bilirubin level is more than 2.5 mg/dL. Urobilinogen levels may be elevated. Serum potassium levels drop below 3.5 mEq/L. Blood glucose drops below 70 mg/dL. The prothrombin time is elevated above 25 seconds.

An abdominal x-ray examination may document the change in size of the liver.

Therapeutic Interventions

Medical treatment is directed toward stopping and reversing the damage to the liver. An attempt is made to put the liver completely at rest. The patient is put on complete bedrest. All drugs are discontinued, since they are metabolized by the liver. Dialysis may be ordered if the liver damage is a result of an overdose of a hepatotoxic substance. The patient is ordered a high-calorie, low-sodium, low-protein diet. Lactulose, neomycin, magnesium citrate, or sorbitol may be given to decrease ammonia levels, but they are not always effective. (For information on how these drugs work, see the section on medical treatment for chronic liver failure.) The patient needs intensive amounts of supportive care. It may be possible to support the patient long enough to stabilize him or her for transplantation.

Complications

The patient with acute liver failure experiences metabolic alkalosis, hypokalemia, hypoglycemia, disruption of blood clotting, and possibly sepsis. Metabolic alkalosis is related to disruption of the urea production cycle and the resulting accumulation of bicarbonate. Patients with acute liver failure also experience electrolyte imbalances. The patient's kidneys excrete potassium rather than hydrogen ions in an attempt to correct the alkalosis. The patient usually has hypoglycemia from loss of glycogen stores in the damaged liver, impaired gluconeogenesis (the manufacture of glucose from other nutrients), and an elevated insulin level caused by the stress response. Further, blood clotting disorders that can lead to disseminated intravascular coagulation (DIC) develop when prothrombin time is elevated.

Finally, the patient is at risk for sepsis because of poor white blood cell migration and other responses to infection. Sepsis, abscess formation, endocarditis, and meningitis account for nearly a quarter of the deaths from acute liver failure. Renal failure accounts for about 30% of deaths. Respiratory problems and hypotension also contribute to the deaths from acute liver failure. The patient progresses through encephalopathy to coma and death.

Nursing Process for the Patient with Acute Liver Failure

Nursing care of the patient with acute liver failure is essentially the same as for the patient with terminal chronic liver failure, which is discussed next.

Box 35.2

Cultural Considerations

The incidence of liver disease is more common among Mexican Americans. Risk factors include working in occupations such as mining, factories using chemicals, and farming using pesticides. Additionally, the use of alcohol is increased in men, and cigarette smoking is common.

Egyptian Americans may suffer from schistosomiasis, known as bilharziasis in Egypt. Schistosomiasis can lead to cirrhosis, liver failure, portal hypertension, esophageal varices, bladder cancer, and renal failure. Thus, the nurse may need to screen newer Egyptian American immigrants for this disease.

Alcohol use and abuse is common among African American communities. For many it is a socially accepted behavior and carries little or no stigma. The mortality rate from cirrhosis of the liver among African Americans is nearly twice that of European Americans. The nurse needs to provide counseling, teaching the detrimental effects of alcohol, and work with African American churches and community leaders to help prevent the detrimental effects of alcohol abuse.

Chronic Liver Failure

Chronic liver failure is also called Laënnec's **cirrhosis**, or portal, nutritional, fatty, or alcoholic liver disease. Chronic liver failure is the tenth leading cause of death among the total population and is more common among men than women (Box 35.2 Cultural Considerations).

Etiology

A variety of problems can result in chronic liver failure:

- Laënnec's cirrhosis is caused by chronic excessive alcohol ingestion, especially when excess alcohol is combined with a lack of dietary protein.
- Postnecrotic liver failure may result from massive exposure to hepatotoxins, viral hepatitis, or infection.
- Biliary liver failure is caused by chronic inflammation and obstruction of the gallbladder and bile ducts.
- Cardiac liver failure is caused by chronic severe congestion of the liver from heart failure. The liver congestion causes death of liver cells from lack of nutrients and oxygen.

Pathophysiology

Chronic liver failure is a progressive disease. Healthy liver cells respond to toxins such as alcohol by becoming

cirrhosis: cirrh—orange yellow + osis—condition

inflamed. The liver cells are infiltrated with fat and white blood cells and are then replaced by fibrotic tissue. As the disease progresses, more and more liver cells are replaced by fatty and scar tissue. The lobes of the liver are disrupted and the liver becomes hardened and lumpy. Early in the disease, the liver is enlarged, firm, and hard from the inflammatory process. Later, the liver shrinks and is covered with gray connective tissue.

Prevention

Chronic liver failure may be prevented by abstinence from alcohol, eating a balanced diet with adequate amounts of protein, and avoiding exposure to infections or hepatotoxic chemicals. Patients are advised that total abstinence from alcohol should be a lifelong goal.

Signs and Symptoms

Signs and symptoms of impaired liver function include malaise, anorexia, indigestion, nausea, weight loss, diarrhea or constipation, and dull, aching RUQ pain. The liver may be enlarged, firm, and tender. Bruising of the skin, bleeding gums, anemia, and jaundice, also known as icterus, may be present. Jaundice is a common finding with hepatitis. The patient's skin may be dry or contain abnormal pigmentation. The patient may complain of severe pruritus (itching). Laboratory values reflect progressive loss of liver function. As chronic liver failure progresses, signs and symptoms of increasing loss of liver function and complications related to the increasing loss of function develop.

Complications

Complications of chronic liver failure include **hepatorenal syndrome**, blood clotting defects, **ascites**, **portal hypertension**, and hepatic encephalopathy.

HEPATORENAL SYNDROME. Hepatorenal syndrome is a secondary kidney failure that occurs in about one-third of liver failure patients. Symptoms of hepatorenal syndrome include oliguria without detectable kidney damage, reduced glomerular filtration rate (GFR) with essentially no urine output or less than 200 mL per day, and nearly total sodium retention. Hepatorenal syndrome is considered an ominous sign.

CLOTTING DEFECTS. Blood clotting defects may develop because of impaired prothrombin and fibrinogen production in the liver. Further, the absence of bile salts prevents the absorption of fat-soluble vitamin K, which is essential for some blood clotting factors. Patients with chronic liver failure have a tendency to bruise easily and may progress to disseminated intravascular coagulation (DIC) or hemorrhage.

ASCITES. Ascites is an accumulation of serous fluid in the abdominal cavity. The fluid accumulates primarily because of low production of albumin by the failing liver. An

insufficient amount of protein in the capillaries causes plasma to seep into the abdominal cavity. The accumulated fluid causes a markedly enlarged abdomen. The fluid may cause severe respiratory distress as a result of elevation of the diaphragm.

PORTAL HYPERTENSION. Portal hypertension is a persistent blood pressure elevation in the portal circulation of the abdomen. Liver damage causes a blockage of blood flow in the portal vein. Increased resistance from delayed drainage causes enlargement of the visible abdominal veins around the umbilicus (called *caput medusae*), rectal hemorrhoids, enlarged spleen, and esophageal **varices** (dilated veins) (Fig. 35.1). The most serious result of portal hypertension is bleeding esophageal varices. The walls of the esophageal veins are thin and tear easily. Varices usually develop from the fundus of the stomach upward and may extend into the upper esophagus. The blood-filled, thin-walled varices may tear easily from sudden excessive pressure, such as the intra-abdominal pressure that results from coughing, lifting, or straining, causing severe bleeding.

HEPATIC ENCEPHALOPATHY. Hepatic encephalopathy is caused by the accumulation of noxious substances in the circulation. The failing liver is unable to make the toxic substances water soluble for excretion in the urine. Ammonia, a by-product of protein metabolism, is most commonly the substance causing symptoms. Signs and symptoms of hepatic encephalopathy include progressive confusion; **asterixis**, or flapping tremors in the hands caused by toxins at peripheral nerves; and **fetor hepaticus**, or foul

FIGURE 35.1 Portal hypertension. Obstruction of normal blood flow through the liver causes blood to back up into the venous system, leading to esophageal varices, splenomegaly, hemorrhoids, and caput medusae.

asterixis: a—not + sterixis—fixed position

fetor hepaticus: fetor—offensive odor + hepat—liver + icas—related to

hepatorenal syndrome: hepato—liver + renal—kidneys + syndrome—group of symptoms

breath caused by metabolic endproducts related to sulfur. Stages of hepatic encephalopathy are *early*, *stuporous* and *confused*, and *comatose*. Signs and symptoms of the stages are as follows:

- **Early:** The patient exhibits subtle changes in personality, fatigue, drowsiness, and changes in handwriting (the best assessment for the early stage).
- **Stuporous and confused:** The patient is often belligerent and irritable and develops asterixis, muscle twitching, hyperventilation, and marked confusion.
- **Comatose:** The patient gradually loses consciousness and becomes comatose.

If levels of toxic substances can be decreased and managed, the patient gradually regains consciousness. Hepatic encephalopathy represents end-stage liver failure and has a mortality rate as high as 90% once coma begins. Figure 35.2 shows signs and symptoms of chronic liver failure.

Diagnostic Tests

Liver serum enzymes, serum bilirubin, urobilinogen, serum ammonia, and prothrombin times are all elevated in chronic

LEARNING TIP

For complications of chronic liver failure, remember the mnemonic **CHEAP**:

P: Portal hypertension

liver failure (Table 35.3). Abdominal radiographs of patients with chronic liver failure may show ascites and enlargement of the liver. An upper gastrointestinal (UGI) series may reveal esophageal varices or evidence of gastric inflammation or ulcers. If the patient is bleeding, other arterial radiological examinations may be done to locate the specific source of bleeding.

A liver scan may be done to show abnormal liver masses or thickening. The physician may order an esopha-

FIGURE 35.2 Signs and symptoms of chronic liver failure.

TABLE 35.3 LABORATORY TESTS FOR CHRONIC LIVER FAILURE

Test	Normal Value	Significance of Abnormal Findings
Blood		
Alanine aminotransferase (ALT)	5–35 IU/mL	Found in high concentrations in liver cells; released with death of liver cells
Albumin	3.5–5.5 g/dL	Decreased because of impaired protein synthesis; edema and ascites may result
Ammonia	15–19 µg/dL	Increased because liver cannot metabolize protein end product; contributes to hepatic encephalopathy
Bilirubin	0.3–3.0 mg/dL	Increased because the liver is unable to use it to produce bile
Aspartate aminotransferase (AST)	8–20 U/L	Found in high concentrations in liver cells; released with death of liver cells
Prothrombin time (PT)	8.8–11.6 sec	Prolonged. Liver can no longer make prothrombin; patient bleeds easily
Urine		
Urobilinogen	<4 mg/24 hr	Increase in urine because of filtration of excessive bilinogen in blood

gastroendoscopy (EGD) to detect any bleeding and to directly observe the esophagus, stomach, and duodenum. Small surface vessels that are bleeding can be treated by injection sclerotherapy during the EGD. The procedure uses sclerosing agents, which are chemical substances that cause the veins to inflame and scar shut.

The physician may do a liver biopsy to determine the extent and nature of the liver damage. Patients with chronic liver failure undergoing a liver biopsy need careful observation for bleeding after the procedure. (See Chapter 32.)

Therapeutic Interventions

Interventions for chronic hepatic failure seek to remove or to treat the underlying causes of the disease. In addition, medical treatment seeks to support liver regeneration and to treat the complications of liver failure.

Ascites is treated with diuretics, albumin infusions, and fluid and sodium restrictions. Paracentesis is sometimes considered as an emergency measure to remove accumulated abdominal fluid, especially when the fluid compromises the patient's breathing, causes abdominal discomfort, or poses a threat of ruptured umbilical hernia. Paracentesis is not commonly done because it removes serous fluid, which contains a large amount of albumin that the liver cannot easily replace. Ascites may be treated by the nonsurgical placement of a shunt between the portal and systemic

FIGURE 35.3 Transjugular intrahepatic portosystemic shunt. A stent is placed to shunt blood from the portal vein to the systemic circulation to divert blood flow around the diseased liver.

venous systems, which is called a **transjugular intrahepatic portosystemic shunt (TIPS)** (Fig. 35.3).

The purpose of the shunt is to sidetrack venous blood around the liver to the vena cava. Shunts are used for patients with severe respiratory compromise and are not as successful as originally hoped. Surgical shunts, sometimes called portacaval shunts, may be used to relieve portal hypertension. When shunts are used, less venous blood circulates through the liver and fewer protein endproducts are metabolized. For this reason, patients are put on a low-protein diet.

The medical goals for managing bleeding from esophageal varices are as follows:

- Stop the bleeding.
- Treat the fluid volume deficit caused by the bleeding.
- Prevent further fluid loss.
- Maintain fluid and electrolyte balance.

Bleeding varices are treated with vasoconstrictors such as vasopressin, with tamponade (direct pressure on the bleeding veins), or with emergency sclerotherapy to close the veins.

Tamponade is usually a temporary measure and is done with a multilumen esophagogastric tube such as the Sengstaken-Blakemore tube (Fig. 35.4). Other multilumen tubes such as the Minnesota tube may be used. The Sengstaken-Blakemore tube is inserted through the nose or mouth to the stomach. First the gastric balloon is inflated with 200 mL of air to secure the tube in its proper location. The esophageal tube is then inflated with 50 mL of air to produce tamponade. One to 2 lb of traction may be applied to the tube. Occasionally the patient may wear a football helmet

transjugular intrahepatic portosystemic shunt: trans—across + jugular—jugular vein + intra—within + hepatic—liver + porto—portal (liver circulation) systemic—systemic (circulation) + shunt—to divert

FIGURE 35.4 Balloon tamponade for bleeding esophageal varices. An esophageal balloon compresses bleeding vessels.

met so that the tube can be secured to the face guard rather than putting pressure on the patient's nose. The Sengstaken-Blakemore tube is then connected to nasogastric suction.

Complications that may occur from the use of esophagogastric tamponade include (1) aspiration, (2) erosion of esophageal gastric mucosa, and (3) suffocation. With the balloons inflated, the patient cannot swallow saliva. Oral suction with a Yankauer catheter should be available. Sometimes a Salem sump tube is placed in the upper esophagus before the esophageal balloon is inflated to drain secretions.

Inflation pressure of the esophageal balloon should be maintained between 20 and 25 mm Hg. Agency procedures should clearly state how long the tube may remain in place and how often (and for how long) the esophageal balloon should be deflated. The gastric balloon remains inflated at all times until the procedure is stopped.

If the gastric tube dislodges into the esophagus, the patient can be suffocated. Keep a pair of scissors at the bedside when esophagogastric tamponade is in progress. If the gastric balloon dislodges, cut the inflation ports of the gastric and esophageal balloons to allow quick release of air.

Unfortunately, recurrence of bleeding occurs in about 20% to 60% of patients after successful tamponade. With each new bleeding episode, the risk of mortality increases. Sclerotherapy may be undertaken to prevent recurrence of bleeding. Sclerotherapy can be done without general anesthesia, which is an advantage for the patient with a severely damaged liver. The procedure is usually done as part of an EGD while the patient is sedated with diazepam (Valium) or midazolam hydrochloride (Versed). A topical anesthetic is used. The varices are injected with a sclerosing agent that causes thickening and closing of the dilated vessels. The procedure usually takes about an hour. After the procedure

the patient may complain of chest pain for up to 72 hours. Give the prescribed analgesics and monitor the patient for pain relief. Report severe pain unrelieved by the prescribed analgesic immediately because the patient may be experiencing an esophageal perforation or ulceration, which is a complication of sclerotherapy.

Hepatic encephalopathy is treated by trying to remove the toxic waste material. Saline or magnesium sulfate ($MgSO_4$) enemas may remove some of the toxic waste. The enemas may be given to cleanse the bowel of the noxious substances. Neomycin, an intestinal antibiotic, may be given by mouth, nasogastric tube, or enema. The antibiotic inhibits ammonia formation by reducing colonic bacteria that change ammonium to ammonia. Lactulose may be given by mouth to reduce the pH of the intestine and to "trap" ammonia, allowing it to be excreted in the stool. Hepatic encephalopathy is also treated by restricting or eliminating dietary protein. In severe cases, dialysis may be considered to remove ammonia (Box 35.3 Nutrition Notes). See Box 35.4 Chronic Liver Failure Summary.

Nursing Process for the Patient with Acute and Chronic Liver Failure

ASSESSMENT/DATA COLLECTION. A complete history and physical assessment are done. Be alert to subjective symptoms of liver dysfunction such as malaise, anorexia, indigestion, nausea, severe itching, and dull, aching RUQ pain. Assess the patient for objective evidence of liver problems, such as weight loss, diarrhea or constipation, and an enlarged, firm, and tender liver. Observe the patient for dryness and bruising of the skin, bleeding gums, anemia, jaundice, and any evidence of alterations in thought processes, such as confusion, disorientation, or inability to make decisions.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Common nursing diagnoses for chronic liver failure include the following:

Excess fluid volume related to portal hypertension (ascites)

EXPECTED OUTCOME: Fluid volume will be controlled as evidenced by stable weight, and abdominal girth within normal limits for patient.

- Weigh the patient on admission and daily. *Daily weights are a good measure of fluid retention.*
- Measure and record the patient's abdominal girth (circumference) daily. Mark the place where you measured so the same site will always be measured during subsequent assessments. *This monitors the amount of ascites.*
- Report any weight gain or increase in girth promptly *so treatment can be ordered and complications minimized.*
- Check the patient's vital signs every 4 hours; report changes and any evidence of difficulty breathing or changes in mental status promptly. *These are signs of fluid overload.*

Box 35.3

Nutrition Notes

Supplying Nutrients to Patients with Liver Disease

A registered dietitian may modify the diet daily for patients with liver disease. Usually these patients suffer from severe anorexia, often displaying their best appetites for breakfast. For early or mild disease, protein is encouraged to support healing; later in liver disease, protein may be restricted. For esophageal varices, foods are soft, in addition to other restrictions. For liver failure, the following dietary considerations are necessary:

- Protein is restricted according to the individual's ability to metabolize it.
- Complete protein foods are selected to provide all the essential amino acids.
- Homogenized milk and eggs are offered because the fat is already emulsified, requiring less bile for digestion.
- Adequate carbohydrates are given to prevent the use of tissue protein for energy.
- Fluid and sodium are likely to be restricted if ascites is present.

Hepatic encephalopathy is associated with increased serum levels of ammonia and aromatic amino acids. Foods producing high ammonia levels may be restricted (e.g., chicken, salami, ground beef, ham, bacon, gelatin, peanut butter, potatoes, onions, lima beans, egg yolk, buttermilk, blue and cheddar cheeses). Vegetable proteins and special enteral feeding formulas (e.g., Hepatic-Aid II and Travasorb-Hepatic) containing branched-chain amino acids may be given in place of foods containing aromatic amino acids that interfere with formation of dopamine and norepinephrine.

- Maintain a low-sodium diet and order fluid restrictions to reduce fluid retention.
- If intravenous fluids or albumin have been ordered, assist in careful monitoring of the rate of infusion. *Rapid fluid administration can increase risk of overload.*
- Administer ordered diuretics as scheduled to reduce fluid volume.

Imbalanced nutrition: less than body requirements related to anorexia and impaired metabolism of needed nutrients

EXPECTED OUTCOME: Patient's (dry) weight will be within normal limits for height.

- Monitor weight; report unexpected (nonfluid) weight loss so timely intervention can be implemented.
- Monitor serum albumin, total protein, vitamin, and

Box 35.4

Chronic Liver Failure Summary

Signs and Symptoms	Malaise, anorexia, nausea Dull RUQ pain Easy bruising Jaundice Ascites
Diagnostic Tests	Elevated ALT, AST, ammonia, bilirubin, PT
Therapeutic Interventions	Treat or remove underlying cause, especially alcohol
Complications	CHEAP (see Learning Tip)
Priority Nursing Diagnoses	Fluid volume excess or deficit Imbalanced nutrition Pain

mineral levels. *These may be better indicators of nutrition if accurate weights are complicated by fluid overload.*

- Assess the patient's bowel sounds, abdominal distention, and evidence of bleeding at least once every 8 hours. *These can signal complications that can further compromise ability to eat.*
- Monitor the patient's diet to ensure that any ordered protein restriction is carried out. *Protein metabolism can contribute to high ammonia levels.*
- Offer the patient frequent, small, high-calorie meals to reduce feeling of fullness that can occur with larger meals.
- Make sure that odors and other unpleasant stimuli are eliminated to prevent further worsening of appetite.
- Offer frequent mouth care to increase comfort and make food more palatable.
- Administer vitamins or supplements as ordered to correct deficiencies.

Pain related to abdominal pressure

EXPECTED OUTCOME: Patient will state pain level is acceptable.

- Monitor pain level using a 10-point scale and "What's Up?" questions. *A good assessment should guide treatment.*
- Give analgesics as ordered to control pain. *Lower doses may be necessary for the patient with liver dysfunction. Acetaminophen is generally avoided due to risk of liver toxicity.*
- Encourage nonpharmacological pain relief activities, such as distraction, imagery, and relaxation. *These can supplement and may decrease the need for analgesics.*

Risk for disturbed thought processes related to elevated ammonia levels

EXPECTED OUTCOME: Patient will remain alert and oriented to person, place, and time.

- Assess the patient's level of consciousness and orientation frequently. *Early recognition of changes allows prompt treatment.*
- Assess neuromuscular function. Neuromuscular function can be assessed by asking the patient to hold his or her arms out straight in front and steady. *If asterixis, or liver flap, is present, the patient's hands will unwillingly dip and return to the horizontal position in a flapping motion.*
- Look for changes in the patient's handwriting. *Changes can indicate altered neuromuscular function.*
- Give lactulose, neomycin, magnesium citrate, or sorbitol as scheduled to decrease serum ammonia levels.
- Be aware that lactulose causes loose stools, and do not withhold the medication when the patient develops diarrhea. *Loose stools are a sign that the medication is working, and not a reason to withhold the medication.*
- Question giving medications such as sedatives, narcotics, and tranquilizers. *These may increase the serum ammonia levels and depress level of consciousness (LOC).*
- Reorient the patient to time and place frequently to reinforce reality.
- Give simple, clear explanations of care and give the patient time to understand the explanation. *Short, simple explanations are easier to process.*
- Provide a safe environment for the confused or unsteady patient to prevent injury.

Risk for ineffective breathing pattern related to excess fluid in the abdomen

EXPECTED OUTCOME: Respirations will be even and unlabored, 16 to 20 per minute.

- Assess the patient's respiratory rate, rhythm, chest movement, skin color, and oxygen saturation frequently to determine if breathing pattern is effective.
- Assist the patient to use an incentive spirometer and to cough gently every 2 to 4 hours to encourage deep breathing and keep airways clear.
- Elevate the head of the patient's bed so that the patient's lungs have maximum room for expansion.
- Reposition the patient at least every 2 hours to ventilate all areas of the lungs.
- Assist with treatments to decrease ascites as ordered to increase room for lung expansion.
- Administer analgesics as ordered if pain is causing shallow respirations. *Reducing pain with breathing allows for a more effective breathing pattern.*

Risk for deficient fluid volume related to bleeding esophageal varices or gastrointestinal bleeding secondary to clotting dysfunction

EXPECTED OUTCOME: Fluid volume will remain within normal limits without bleeding as evidenced by no signs and symptoms of bleeding, and vital signs within normal limits.

- Monitor gastric secretions, stool, and urine at least every 8 hours, and report any signs of bleeding. *Early identification of bleeding is essential to prompt treatment.*
- Monitor blood clotting laboratory studies such as the prothrombin time and report any abnormal values. *Prolonged values increase the risk for bleeding.*
- Caution the patient to use a soft-bristle toothbrush and an electric rather than straight razor to avoid injury.
- Avoid suctioning the patient if possible. *Suctioning can cause varices to bleed.*
- Use a small-gauge needle for injections and apply direct pressure to all puncture sites to avoid bleeding.
- Teach the patient to avoid hot, spicy, or irritating foods. *These may irritate the esophageal mucosa and increase risk of bleeding.*
- Instruct the patient to avoid forceful coughing or nose blowing, straining, vomiting, or gagging if at all possible. Administer medications as ordered to prevent their occurrence. *These can increase pressure and risk of bleeding varices.*

Risk for infection related to impaired immune function

EXPECTED OUTCOME: The patient will be free from infection as evidenced by white blood cell count (WBC) within normal limit, afebrile.

- Monitor for signs of infection and report promptly so treatment can be initiated.
- Carefully evaluate laboratory studies such as the white blood cell count. *The white blood cell count may not elevate or may elevate slowly because the white cell activity is impaired.*
- Be aware that the earliest warning signs of infection may be subtle changes in the patient's behavior, such as sudden restlessness, an increase in confusion, or irritability. *Early recognition is essential to prompt treatment.*
- Teach the patient careful hand washing and avoidance of people who are ill to prevent exposure to infection.

EVALUATION. Nursing care has been effective if the patient demonstrates the following:

- No signs of fluid retention
- Weight stable and appropriate for height
- Abdominal pain or other discomfort reported as not greater than 2 on a 10-point scale
- Alert and oriented demeanor

- Respiratory rate between 16 and 20 respirations per minute with no cyanosis or changes in level of consciousness
- No bleeding, infection, or injuries
- Accurate knowledge of chronic liver failure and proper disease management requirements

PATIENT EDUCATION. Teach patients how chronic liver failure is affecting their bodies. In particular, patients need to know about portal system hypertension and hepatic encephalopathy. In addition, teach:

- How to observe for and report any confusion, tremors, or personality changes
- The importance of adequate rest and avoidance of strenuous activity
- A diet high in calories, low in sodium, and high in protein if hepatic encephalopathy has not developed
- To avoid narcotics, sedatives, and tranquilizers
- To promptly report any bleeding; any sign of low potassium, such as muscle cramps, nausea, or vomiting caused by diuretics; changes in mental status, such as confusion or personality changes; changes in weight; and any increase in current symptoms
- The importance of avoiding alcohol
- The importance of frequent follow-up care and laboratory studies

CRITICAL THINKING

Mary

■ Mary, a 76-year-old retired businesswoman, has lived alone for the past 20 years, since the death of her husband. She has a long history of poor nutritional habits but does not use alcohol. She is admitted to your unit with chronic liver failure.

1. What risk factors does Mary have for chronic liver failure?
2. What symptoms would you expect Mary to exhibit with early chronic liver failure?
3. What values do you expect to see for serum albumin? Prothrombin time?
4. What are the two greatest concerns with portal hypertension?
5. What is the usual treatment for ascites?
6. What complication of esophageal tamponade requires that a pair of scissors be at the bedside at all times while tamponade is in progress?

Suggested answers at end of chapter.

Transplantation

Patients with liver disease who do not respond well to medical or surgical treatment may be candidates for a liver transplant. Patients who have chronic liver failure from hepatitis or biliary disease, metabolic disorders, or hepatic vein obstruction may be evaluated for a liver transplant. In gen-

Box 35.5

Cultural Considerations

Jewish law addresses organ transplantation from the perspectives of the recipient, the living donor, the cadaver donor, and the dying donor. If a recipient's life can be prolonged without considerable risk, transplant is ordained. For a living donor to be approved, the risk to the life of the donor must be considered. One is not obligated to donate a part of himself or herself unless the risk is small. This includes kidney and bone marrow donations. The use of a cadaver for transplant is usually approved if it is saving a life. The use of skin for burns is acceptable, although there is no agreement on the use of cadaver corneas. The nurse may need to help the Jewish patient contact a rabbi when making a decision regarding organ donation or transplantation.

eral, patients who have cancer are not considered for liver transplantation; the drugs used to suppress tissue rejection by the immune system can cause the cancer cells to grow at an increased rate.

The patient with end-stage liver failure who does not have hypertension, bleeding esophageal varices, infection, or severe cardiac disease is placed on a national list as a potential liver recipient. The patient will be evaluated for emotional and physical stability and must realize that he or she will be on daily medications for life (Box 35.5 Cultural Considerations).

After the surgical implantation of a donor liver, the patient must be closely observed for evidence of donor organ rejection. The patient will be in an intensive care unit (ICU) setting until stable enough to be transferred to a medical unit. The patient will be on drugs such as cyclosporine (cyclosporin A), azathioprine (Imuran), and prednisone (Deltasone) to suppress the immune system responses to foreign protein or tissue rejection. Observe the patient for the following signs of impending rejection:

- Pulse greater than 100 beats per minute
- Temperature greater than 101°F (38°C)
- Complaints of RUQ pain
- Increased jaundice
- Decrease in bile from the **T-tube** or change in bile color

In addition, laboratory studies may show increased serum transaminases (ALT and AST), serum bilirubin, alkaline phosphatase, and prothrombin time. Symptoms of acute tissue rejection usually develop between the fourth and tenth postoperative days.

Monitor urine output and lab studies daily. Bowel sounds and passage of flatus must be documented. The patient who has received an organ transplant needs extended medical follow-up. Teach the patient to promptly report to the physician any symptoms of infection, bleeding episodes, or RUQ pain (Box 35.6 Ethical Considerations).

**Box 35.6****Ethical Considerations****Organ Transplantation**

Despite widespread public and medical acceptance of organ transplantation as a highly *beneficial* procedure, ethical questions remain. Whenever a human organ is transplanted, a large number of people are involved, including the donor; the donor's family, nursing and medical personnel, as well as the recipient and the recipient's family. Society in general could also be added to this mix because of the high cost of organ transplantation that usually comes from tax dollars or indirectly in the form of increased insurance premiums. Each one of these persons or groups has *rights* that may conflict with another's rights.

Most institutions that perform transplants and organizations that are involved in obtaining organs have developed elaborate, detailed, and involved procedures to help deal with the ethical and legal issues involved in transplantation. Despite these efforts, there are still some ethical issues that should be considered whenever the issue of organ transplantation is raised.

Despite the best efforts of the medical and legal communities to establish criteria for death, there are still some ethical questions about when a person is really dead. Does brain death, the most widely accepted criterion for death, really indicate that a person no longer exists as a human being? Alternatively, are there other criteria that should be examined? Such organs as hearts, lungs, and liver must come from a donor with a beating heart. Might there not be the tendency to declare brain death before it actually occurs?

One of the most difficult ethical issues involved in organ transplantation is the selection of recipients; this can be considered under the principles of *justice* or *fairness*. There are many fewer organs available than there are

people who need them. Many potential ethical dilemmas arise from this fact. Should someone receive an organ because he or she is rich or famous or knows the right people? The national organ recipient list attempts to list and rank all persons who need organs in a nondiscriminatory manner. Some of the important criteria include need, length of time on the list, potential for survival, prior organ transplantation, value to the community, and tissue compatibility.

Nurses can be and often are involved in some aspect of the organ donation process. Many states have passed laws that require health-care workers to ask family members of potential organ donors if they have ever thought about organ donation for their dead or dying loved one. Many nurses, particularly nurses in critical care units, provide care for patients who are potential organ donors. Nurses in operating rooms may help in the surgical procedures that remove organs from a cadaver and that transplant them into a recipient's body. Many nurses provide postoperative care for patients who have received a transplanted organ. Home health care nurses provide follow-up care for these patients at home.

Nurses working with organ transplantation need to be sensitive to the potential for manipulation. Most people who are seeking organ transplantations are desperately ill or near death. They, and their families, can be very easily manipulated or can be very manipulating. On the other side, the families of potential organ donors are usually emotionally distraught because of the sudden and traumatic loss of a loved one. They too are very vulnerable. As a rule, neither the donor nor the donor's family should play any part in the selection of a recipient. Nurses must avoid making statements or giving nonverbal indications of approval or disapproval of potential recipients.

Cancer of the Liver

Cancer of the liver is usually the result of metastasis from a primary cancer at a distant location. The liver is a likely area of involvement if cancer originated in the esophagus, lungs, breast, stomach, colon, pancreas, kidney, bladder, or skin. For some patients, liver cancer is the primary tumor site. Patients with a history of chronic hepatitis B, hepatitis C, nutritional deficiencies, or exposure to hepatotoxins have an increased risk for cancer of the liver.

Symptoms of cancer of the liver include encephalopathy, abnormal bleeding, jaundice, and ascites. Laboratory tests show an elevated serum alkaline phosphatase. Radiological examinations may include abdominal radiographs or radioisotope scans, which show tumor growth. Liver cancer is definitively diagnosed with a positive needle biopsy combined with an ultrasonogram of the liver. Most patients with liver cancer die within 6 months of diagnosis.

Rarely, a patient with liver cancer may be a candidate for surgical removal of the affected portion of the liver. Care of the postsurgical patient is similar to other abdominal surgery patients. If surgery is not an option, the patient may receive chemotherapeutic drugs by injection directly into the affected lobe of the liver or into the hepatic artery. Intra-arterial injection of chemotherapeutic drugs has the advantage of being less toxic to the rest of the body. (See Chapter 10 for care of patients with cancer.)

**DISORDERS OF THE PANCREAS****Pancreatitis**

Pancreatitis is an inflammation of the pancreas. It may be either acute or chronic. The two forms of pancreatitis have different courses and are considered two different disorders.

Acute Pancreatitis

Pathophysiology

Inflammation of the pancreas appears to be caused by a process called autodigestion. Recall that the pancreas normally secretes digestive enzymes. For reasons not fully understood, pancreatic enzymes can be activated while they are still within the pancreas and begin to digest the pancreas. In addition, large amounts of the enzymes are released by inflamed cells. As the pancreas digests itself, chemical cascades occur. Trypsin destroys pancreatic tissue and causes vasodilation. As capillary permeability increases, fluid is lost to the retroperitoneal space, causing shock. In addition, trypsin appears to set off another chain of events that causes the conversion of prothrombin to thrombin, so that clots form. The patient may develop DIC. (See Chapter 28.)

Etiology

Pancreatitis is most commonly associated with excessive alcohol consumption. Alcohol appears to act directly on the acinar cells of the pancreas and the pancreatic ducts to irritate and inflame the structures. Biliary disease such as **cholelithiasis** (gallstones) or cholangitis (inflammation of the bile ducts) may also trigger pancreatitis. Gallstones may plug the pancreatic duct and cause inflammation from excessive fluid pressure on sensitive ducts. The irritant effect of bile itself may cause inflammation. Blunt trauma to the abdomen or infection may trigger the process by causing ischemia, inflammation, and activation of the pancreatic enzymes. Drugs such as thiazide diuretics (HydroDiuril), estrogen, opioids, corticosteroids, and excessive serum calcium from hyperparathyroidism are less common causes of pancreatitis.

Elderly patients and patients with a first diagnosis of pancreatitis have a higher mortality rate. In addition, patients who have pancreatitis associated with biliary disease have a higher mortality rate than patients with alcohol-related pancreatitis.

Prevention

Caution patients who drink alcohol to stop. Patients with biliary disease need to seek medical treatment for these conditions so that pancreatitis does not develop as a complication. Monitor patients, especially the elderly, for any abdominal complaints when they are placed on medications that are associated with pancreatitis (Box 35.7 Cultural Considerations).

Signs and Symptoms

Patients with acute pancreatitis are very ill, with dull abdominal pain, guarding, a rigid abdomen, hypotension or shock, and respiratory distress from accumulation of fluid in the retroperitoneal space. The abdominal pain is generally located in the midline just below the sternum, with radiation to the spine, back, and flank. The location and degree of pain indicate the area of the pancreas involved and to some extent the amount of involvement. Respirations are likely to be

Box 35.7

Cultural Considerations

Pancreatic disease is more common among Mexican Americans and Chinese Americans. Risk factors include working in occupations such as mining, factories using chemicals, and farming using pesticides. The high use of alcohol and cigarette smoking add to the risk of pancreatic disease.

shallow as the patient attempts to splint painful areas. Eating makes the pain worse.

The patient may have a low-grade fever, dry mucous membranes, and tachycardia. If the primary cause is biliary, the patient may complain of nausea and vomiting, and jaundice may be evident. The islets of Langerhans in the terminal one-third of the pancreas are usually not impaired.

Complications

It may be useful to think of pancreatitis as a chemical burn to the organ. As with other severe burns, death is likely to occur from secondary causes. From the onset of symptoms, cardiovascular, pulmonary (including acute respiratory distress syndrome), and renal failure are the most likely causes of death. Hemorrhage, peripheral vascular collapse, and infection are also major concerns for patients with pancreatitis. A purplish discoloration of the flanks (Turner's sign) or a purplish discoloration around the umbilicus (Cullen's sign) may occur with extensive hemorrhagic destruction of the pancreas.

Diagnostic Tests

Serum amylase (normal: 80 to 180 U/dL) and serum lipase (normal: 0 to 160 U/L) may be elevated 5 to 40 times normal. The levels usually begin to drop within 72 hours. Urine amylase elevates and stays elevated for a longer period of time. Glucose, bilirubin, alkaline phosphatase, lactic dehydrogenase, ALT, AST, cholesterol, and potassium are all elevated. Decreases are measured in serum albumin, calcium, sodium, and magnesium.

X-ray examination may show pleural effusion from local inflammatory reaction to pancreatic enzymes, pulmonary infiltrates, or a change in the size of the pancreas. Computed tomography and ultrasonography can provide more complete information about the pancreas and surrounding tissues.

Therapeutic Interventions

Treatment of acute pancreatitis depends on the intensity of the symptoms. Treatment is concerned with the maintenance of life support until the inflammation resolves, along with preventing or treating complications. Intravenous fluids are administered, such as crystalloid, electrolyte, or colloid (such as albumin) solutions, if the patient experiences hypovolemic shock. Blood or blood products may also be ordered if the patient has significant blood loss from hemorrhage.

cholelithiasis: chole—bile + lith—stone + iasis—condition

The patient may be given anti-anxiety agents to decrease oxygen demand. The patient may require supplemental oxygen if abdominal pressure, pleural effusion, or acidosis cause an impaired gas exchange or ineffective breathing pattern.

The physician usually orders meperidine hydrochloride (Demerol) for pain because some experts believe morphine can cause spasm of the sphincter of Oddi and increase pain. Pain and anxiety increase pancreatic secretion by stimulating the autonomic nervous system. Phenergan may be ordered to potentiate the Demerol; it may also help reduce nausea.

The patient is usually ordered to have nothing by mouth (NPO) to rest the gastrointestinal tract, although recent research indicates that patients may experience fewer complications if enteral feeding is maintained. The patient may have a nasogastric tube inserted into the stomach and attached to low suction to empty gastric contents and gas. IV ondansetron (Zofran) for nausea and a histamine (H_2) antagonist such as famotidine (Pepcid) may help decrease acid stimulation of pancreatic secretion. See Table 35.4 for a summary of medications. If NPO therapy is prolonged or if the patient is malnourished, the patient will need TPN (Box 35.8 Nutrition Notes). A Foley catheter may be inserted to provide accurate output measurements and to assess need for fluid replacement. Strict intake and output must be documented.

Additional typical drug orders include sodium bicarbonate to reverse the acidosis caused by shock, electrolytes such as calcium and magnesium to replace losses, short-

acting insulin to combat hyperglycemia, and antibiotics to treat sepsis. See Box 35.9 Pancreatitis Summary.

Nursing Process for the Patient with Pancreatitis

See Box 35.10 Nursing Care Plan for the Patient with Acute and Chronic Pancreatitis

Chronic Pancreatitis

Chronic pancreatitis is continuing pancreatic cellular damage and decreased pancreatic enzyme functioning usually following repeated occasions of acute pancreatitis.

PATHOPHYSIOLOGY. Chronic pancreatitis is a continuous, progressive disease that replaces functioning pancreatic tissue with fibrotic tissue as a result of inflammation. Pancreatic ducts become obstructed, dilated, and finally atrophied. The acinar, or enzyme-producing, cells of the pancreas ulcerate in response to inflammation. The ulceration causes further tissue damage and tissue death, and it may cause cystic sacs filled with pancreatic enzymes to form on the surface of the pancreas. The pancreas becomes smaller and hardened, and progressively smaller amounts of pancreatic enzymes are produced.

ETIOLOGY AND INCIDENCE. The major cause of chronic pancreatitis in men is excessive alcohol ingestion that causes repeated attacks of acute pancreatitis. The major cause in women is chronic obstructive biliary disease that leads to persistent inflammation of the pancreatic ducts.

TABLE 35.4 MEDICATIONS USED FOR LIVER, GALLBLADDER, AND PANCREATIC DISORDERS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antiemetics Reduce nausea	Metoclopramide (Reglan)	IV, PO, IM	Dry mouth, constipation, drowsiness, extrapyramidal (parkinsonian) symptoms	Monitor for extrapyramidal symptoms. Administer 30 minutes before meals.
	Ondansetron (Zofran)	PO, IM, IV	Headache, constipation, diarrhea, extrapyramidal symptoms	Monitor for hypersensitivity, extrapyramidal symptoms.
	Promethazine (Phenergan)	PO, PR, IM, IV	Dizziness, drowsiness, constipation, urinary retention	May be additive when used with opioids; monitor for sedation. Monitor I&O, urinary retention.
Antihistamines Reduce itching	Diphenhydramine (Benadryl)	PO, IM, IV, topical	Drowsiness, dry mouth, confusion in elderly	If using topical preparation, do not apply to open skin.
Anticholinergics Decrease GI secretions	Propantheline bromide (Pro-Banthine)	PO	Constipation, dry mouth, urinary retention, tachycardia	Contraindicated if patient has glaucoma or prostatic hypertrophy.
	Dicyclomine hydrochloride (Bentyl)	PO, IM		
Gastric acid-pump inhibitors	Pantoprazole (Protonix)	PO, IV	Headache, diarrhea, abdominal pain	Monitor bowel sounds, liver function (AST, ALT)
Histamine (H_2) antagonists Inhibit gastric acid secretion	Famotidine (Pepcid)	PO, IV	Confusion, drowsiness, dizziness	If ordered once a day, give at bedtime. Smoking may interfere with action.
	Ranitidine (Zantac)	PO, IV, IM		

CRITICAL THINKING

Mrs. Samuels

■ Mrs. Samuels, an 85-year-old retired librarian, is admitted to the nursing unit from the emergency department with severe midepigastric pain that radiates to her back. On admission, she is noted to have guarding of the abdomen, and her abdomen is full and tense. Her medical record documents that she had an endoscopic retrograde cholangiopancreatograph (ERCP) 2 days ago for recurrent episodes of RUQ abdominal pain. She has no history of excessive alcohol intake.

1. What is the most common cause of acute pancreatitis? Does Mrs. Samuels fit the description?
2. Why do patients such as Mrs. Samuels have difficulty breathing?
3. Why is Mrs. Samuels at risk for hemorrhage?
4. What laboratory test is most likely to be abnormal in early acute pancreatitis?
5. Why are opioids commonly ordered for acute pancreatitis?
6. Why does the physician usually order a histamine antagonist?

Suggested answers at end of chapter.

Other conditions known to cause chronic pancreatitis are prolonged malnutrition, cancer of the pancreas or duodenum, and prolonged use of enteral feedings, which can cause atrophy of the pancreas. The usual age for chronic pancreatitis to develop is between ages 45 and 60. The patient's mean life span is 25 years after the diagnosis of chronic

Box 35.8

Nutrition Notes

Nourishing the Patient with Pancreatitis

For acute pancreatitis, the patient may be given ice chips made with electrolyte solutions to minimize gastric secretions and subsequent loss through a nasogastric tube. Nourishment is provided intravenously via TPN. If enteral feedings are started, an elemental formula that has been “predigested” may be selected.

In chronic pancreatitis, the meal pattern is six small meals per day, beginning with clear liquids and progressing to a high-carbohydrate, low-fat diet. Medium-chain triglyceride (MCT) oil may be added to foods because it is absorbed without pancreatic lipase or bile. Pharmaceutical preparations of pancreatic enzymes may be prescribed. Vitamin supplements, including parenteral B₁₂, are commonly administered. When monitoring progress, an increase in serum amylase levels may necessitate the return to a more restricted diet.

Box 35.9

Pancreatitis Summary

Signs and Symptoms	Midline abdominal pain Low-grade fever Nausea and vomiting
Diagnostic Tests	Elevated serum amylase and lipase
Therapeutic Interventions	NPO, NG suction IV fluids and/or nutrition Pain control
Complications	Hemorrhage, shock, infection
Priority Nursing Diagnoses	Pain Imbalanced nutrition Risk for ineffective breathing pattern

pancreatitis is made. Death is often not related to pancreatic failure.

PREVENTION. Advise patients with acute pancreatitis from excessive alcohol ingestion that abstinence could prevent recurrence of the pancreatitis and prevent the possibility of chronic pancreatitis. Advise all patients with obstructive biliary disease to seek medical treatment for their condition to prevent the progression from acute to chronic pancreatitis. Carefully monitor patients who are unable to feed themselves for nutritionally adequate diets. Monitor routine laboratory values. Report any trend toward reduced functioning of the pancreas.

SIGNS AND SYMPTOMS. The signs and symptoms of chronic pancreatitis are less severe than acute pancreatitis but more long term. The patient's history will show a pattern of remissions and exacerbations over a period of years. The patient will complain of epigastric or LUQ pain, weight loss, and anorexia. Malabsorption and fat intolerance occur late in the disease. Usually the islets of Langerhans function until late stages of the disease; diabetes mellitus is a late-occurring symptom.

COMPLICATIONS. A variety of complications can result from chronic pancreatitis. Abscesses and fistulas may develop when cysts filled with pancreatic enzymes burst into the abdominal cavity, causing severe inflammation and tissue necrosis. Pleural effusion may develop from inflammation just under the diaphragm. Pancreatic enzymes are essential for normal absorption of nutrients from the intestines. Malabsorption syndrome with fatty stools and diarrhea may develop in response to the limited amount of pancreatic enzymes produced. In addition, biliary obstruction may further complicate fat absorption. As the terminal third of the pancreas becomes involved and the islets of Langerhans

(Text continued on page 738)

Box 35.10 NURSING CARE PLAN for the Patient with Acute and Chronic Pancreatitis

Nursing Diagnosis: Pain related to edema and inflammation

Expected Outcome Patient will state pain level is less than 3 on a scale of 0 to 10.

Evaluation of Outcome Does patient state pain level is less than 3 on a pain scale of 0 to 10?

Interventions

Assess the patient every 2 hours for pain by

- Asking the patient to rate pain on a scale of 0 to 10.
- Observing the patient for pain behaviors such as grimacing, irritability, reluctance to move, or inability to lie quietly.

Administer analgesics as ordered, before pain becomes severe.

Assist the patient to a position of comfort, usually high Fowler's or leaning forward slightly.

Keep the environment free from excessive stimuli.

Teach the patient alternative pain control strategies such as guided imagery and relaxation techniques.

Rationale

Intense pain is likely to occur with acute pancreatitis.

A pain scale allows for a consistent and individual evaluation of pain.

Observation of pain behaviors, such as reluctance to move, shallow respirations, grimacing, or irritability, may be a reliable indicator of pain. However, the patient in pain may have no observable pain behaviors.

Analgesics are most effective if given before pain becomes too great.

An upright position keeps abdominal organs from pressing against the inflamed pancreas.

Quiet, restful, anxiety-free atmosphere permits the patient to relax and may decrease pain perception.

Successful use of pain control strategies may decrease the amount of analgesics needed and give the patient a greater sense of control.

Evaluation

Does patient state that pain is less than 3 on a pain scale of 0 to 10, where 0 = no pain and 10 = worst possible pain?

Does patient exhibit pain behaviors that differ from his or her report of pain?

Are analgesics effective?

Does positioning promote comfort?

Does patient state atmosphere is relaxing?

Are alternative strategies effective?

Nursing Diagnosis: Imbalanced nutrition: less than body requirements related to pain, medical restrictions (NPO), and treatment (suction)

Expected Outcome Patient will experience improved nutrition as evidenced by stable weight, serum albumin greater than 3.5 g/L.

Evaluation of Outcome Is weight stable? Is serum albumin level greater than 3.5 g/L?

Interventions

Assess the patient's nutritional status by

- Weighing the patient every other day.
- Monitoring serum albumin levels as ordered.
- Auscultating for bowel sounds.
- Observing for nausea or vomiting.

Rationale

A loss of 1 lb of body weight occurs when the body uses 3500 calories more than is taken in.

Serum albumin of 3.5–5.5 g/L indicates normal protein metabolism in the absence of liver or renal disease.

Bowel sounds must be present before oral nutrition can be provided.

Nausea, vomiting, and pain are risk factors for inadequate intake.

Evaluation

Has patient lost less than 5% of total baseline body weight? Is patient's albumin above 3.5 g/dL?

Does patient have sufficient energy and strength to carry out activities of daily living?

Interventions

- Monitoring blood sugar at least every 6 hours if the patient is on TPN.
- Observing for diarrhea, bloating, or steatorrhea (fatty stools). Report steatorrhea immediately.

Administer nutritional supplements, including pancreatic enzymes, as ordered.

Teach the patient to avoid alcohol.

Teach the patient and family the signs and symptoms of diabetes mellitus.

Teach the patient and family to self-monitor for symptoms of malabsorption syndrome, such as fatty stools, weight loss, dry skin, or bleeding.

Rationale

Patients on TPN are more likely to have high blood glucose. Diarrhea, bloating, or fatty stools may indicate malabsorption syndrome. Steatorrhea (fatty stools) may indicate that the enzyme replacement doses are not meeting the patient's needs.

Provides adequate nutrition.

Alcohol may trigger another episode of pancreatitis.

Patients with pancreatitis are at great risk for developing diabetes mellitus.

Absence of pancreatic enzymes causes problems with digestion of fats, carbohydrates, and proteins.

Evaluation

Does patient take any supplements?

Does patient verbalize understanding of importance of avoiding alcohol?

Is follow-up support for alcohol avoidance provided?

Does patient verbalize signs and symptoms of diabetes to report?

Does patient verbalize understanding of symptoms of malabsorption to report?

Nursing Diagnosis: Risk for ineffective breathing pattern related to abdominal pressure and pain

Expected Outcome Patient has an effective breathing pattern as evidenced by unlabored respirations, 16–20 per minute, $SpO_2 \geq 95\%$.

Evaluation of Outcome Are respirations unlabored, 16–20 per minute, $SpO_2 \geq 95\%$?

Interventions

Assess the patient's breathing patterns:

- Observe respirations for depth, regularity, and rate.
- Observe respiratory effort.
- Observe for evidence of respiratory distress, such as use of accessory muscles, use of intercostal muscles, $SpO_2 < 95\%$, and rapid or difficult breathing.

Administer oxygen as ordered.

Place the patient in an upright or slightly forward-leaning position.

Prepare the patient's food by opening cartons and lids. Cut food into bite-size portions.

Teach the patient to move slowly and to take frequent rests.

Rationale

Abdominal pressure from inflammation and tissue damage under the diaphragm may cause the patient to take shallow, rapid respirations, which can tire the patient.

Oxygen can decrease the amount of effort the patient must expend to breathe.

Relieves pressure on the diaphragm.

Decreases the demand for oxygen.

Helps decrease the demand for oxygen.

Evaluation

Are patient's respirations 16–20 per minute, unlabored, and regular? Is patient alert and oriented? Has there been a change in the level of patient's arousal? Does patient exhibit signs of distress?

Does oxygen help patient breathe easier?

Is positioning effective?

Does patient accept assistance with food preparation?

Does patient tolerate activity?

(Continued on following page)

Box 35.10 NURSING CARE PLAN for the Patient with Acute and Chronic Pancreatitis (*Continued*)

Nursing Diagnosis: Risk for injury related to hemorrhage, or fluid and electrolyte imbalances

Expected Outcome Patient experiences no injury.

Evaluation of Outcome Is there evidence of injury? Are signs and symptoms of impending injury recognized and reported early?

Interventions	Rationale	Evaluation
Monitor sodium, potassium, calcium, and magnesium levels daily.	Electrolyte levels can become imbalanced in pancreatitis.	Do laboratory studies show that patient's electrolytes are within acceptable ranges?
Evaluate neuromuscular status by checking Chvostek's/Trousseau's signs.	These are signs of calcium depletion (see Chapter 5).	Are signs of calcium depletion present?
Monitor the patient's hematocrit, hemoglobin, and blood clotting times frequently.	Destruction of the pancreas can result in hemorrhage.	Does patient have any abnormal bruising, bleeding gums, or pink urine?
Observe abdomen and flanks for Cullen's and Turner's signs.	These are signs of hemorrhage.	
Weigh the patient daily.	To monitor fluid balance.	Is weight stable?
Measure and record intake and output every shift.	To monitor fluid balance.	Is urinary output greater than 30 mL/h?
Observe for nausea and vomiting.	Vomiting can contribute to fluid loss.	Does nausea need to be treated to prevent vomiting?
Report any drop in blood pressure greater than 5% of the patient's baseline.	May indicate severe fluid loss.	Are vital signs stable? Is patient's blood pressure within 5% of baseline?
Monitor TPN and report any difficulties.	TPN must not be stopped abruptly. Patient's blood glucose may drop sharply.	Are blood glucose levels stable?
Teach the patient to report any weakness or muscle twitching.	May indicate electrolyte imbalance.	Does patient verbalize understanding of signs and symptoms of electrolyte imbalance to report?

are destroyed, the patient exhibits symptoms of insulin-dependent diabetes mellitus (discussed in Chapter 40).

DIAGNOSTIC TESTS. Serum amylase and serum lipase levels are only elevated in acute disease. In chronic pancreatitis, enzymes will be normal or below normal. Fecal fat analysis shows higher than normal amounts of fat.

Both computed tomography and ultrasonography show characteristic pancreatic structural changes such as masses, calcification of ducts, cysts, and change in pancreatic size. Endoscopic retrograde cholangiopancreatography (ERCP) can locate specific obstructions and detect ductal leaks.

THERAPEUTIC INTERVENTIONS. Treatment is aimed at promoting comfort and maintaining adequate nutrition. Pain is managed with analgesics. Nutrition is maintained

with the careful replacement of pancreatic enzymes and specially prepared nutritional supplements.

Surgery may be necessary to repair fistulas, drain cysts, or repair other damage. In some cases, ducts or sphincters may be surgically repaired. In other instances, part or all of the pancreas may be removed.

NURSING PROCESS FOR THE PATIENT WITH PANCREATITIS. See Box 35.10, Nursing Care Plan for the Patient with Acute and Chronic Pancreatitis.

Cancer of the Pancreas

Cancer of the pancreas is the fourth leading cause of cancer death in men in the United States, and the fifth leading cause in women, killing more than 30,000 people each year. Nearly 32,000 new cases of cancer of the pancreas are diag-

nosed yearly²; it most often affects people between ages 65 and 79. About 70% of cancers of the pancreas occur in the head of the pancreas. About 30% of cancers are located in the body and tail of the pancreas.

Pathophysiology

Most primary tumors of the pancreas are ductal adenocarcinomas and occur in the exocrine parts of the pancreas. The tumors in the head and body of the pancreas tend to be large. Cancer of the pancreas spreads rapidly by direct extension to the stomach, gallbladder, and duodenum. Cancer located in the body of the pancreas usually spreads further and more rapidly than do masses in the head. Cancer of the pancreas may spread by the lymphatic and vascular systems to distant organs and lymph nodes.

Etiology

The cause of cancer of the pancreas is not known. Cancer of the pancreas has been associated with chemical carcinogens such as high-fat diets and cigarette smoking, diabetes mellitus, excessive alcohol intake, exposure to chemicals such as coke and benzidine, and chronic pancreatitis. It may also occur as a result of metastasis from a primary cancer of the lung, breast, kidney, or thyroid gland or malignant melanomas of the skin.

Signs and Symptoms

The patient with cancer of the pancreas usually experiences vague symptoms early in the disease process. Weight loss, pain, anorexia, nausea, vomiting, and weakness are among the early symptoms. Detection is often difficult because of the nonspecific complaints offered by the patient. The patient may complain of abdominal pain that is worse at night. The pain is described as gnawing or boring, and it radiates to the back. The pain may be lessened by a side-lying position with the knees drawn up to the chest or by bending over when walking. The pain becomes increasingly severe and unrelenting as the cancer grows.

The patient may complain of a bloated feeling or fullness after eating. If the cancer obstructs the bile duct, the patient may have jaundice, dark urine, pruritus, and light-colored stools. The patient often complains of fatigue and depression. The patient's health history may include a recent diagnosis of diabetes mellitus.

Complications

Complications may occur before or after surgical treatment. Preoperative complications include malnutrition, spread of the cancer, and gastric or duodenal obstruction. Postoperative complications include infection, breakdown of the surgical site, fistula formation, diabetes mellitus, and malabsorption syndrome. If the patient has chemotherapy or radiation therapy, complications specific to those therapies may also occur.

Thrombophlebitis is a common complication of cancer of the pancreas. As the tumor grows, by-products of the tumor growth appear to increase the levels of thromboplastic (clotting) factors in the blood, making clotting easier. The potential for thrombophlebitis increases if the patient is confined to bed or has surgery.

Diagnostic Tests

Serum alkaline phosphatase, glucose, and bilirubin levels may be elevated. Amylase and lipase are elevated if the cancer has caused a secondary pancreatitis. Blood coagulation tests, such as clotting time, may be done. Carcinoembryonic antigen (CEA) may be ordered to confirm the presence of cancer (normal: less than 5 ng/mL).

Abdominal radiographs may be ordered to determine the size of the pancreas and the presence of masses. Computed tomography and ultrasonography may be done to more precisely locate any masses in the pancreas. ERCP can be used to visualize the common ducts and to take tissue samples for microscopic analysis. Pancreatic biopsy is necessary for definitive diagnosis of pancreatic cancer. A tissue sample may be obtained by needle aspiration during ultrasonography. This procedure may cause seeding of the tumor along the needle pathway.

Therapeutic Interventions

Medical treatment depends on the staging of the cancer. If diagnosed early, treatment may be aimed at cure. If the patient's cancer has progressed to distant involvement of other organ structures and lymph nodes, treatment is directed at easing symptoms and making the patient more comfortable.

Surgery may include a total or partial **pancreatectomy** or removal of all or part of the pancreas. This is only possible when the tumor is located at the head of the pancreas; tumors in the body and tail of the pancreas have usually spread to other areas and are not resectable. Whipple's procedure is done to remove the head of the pancreas, parts of the stomach nearby, the lower portion of the common bile duct, and the duodenum (Fig. 35.5). Sometimes the gallbladder is also removed. Potential postoperative problems after Whipple's procedure include failure of the suture lines to hold, causing leakage of pancreatic enzymes and bile into the abdomen; pneumonia or atelectasis from shallow breathing because the incision line is directly under the diaphragm; paralytic ileus; gastric retention or ulceration; wound infection; fistula formation; unstable diabetes mellitus; and renal failure.

Other surgical procedures may remove the entire pancreas, stomach, gallbladder, duodenum, and regional lymph nodes, or merely the distal portion of the pancreas and the spleen for smaller, more localized tumors. Even with surgical resection, 5-year survival rates are poor. Postoperative complications similar to those that occur after Whipple's procedure may develop.

Relief of biliary obstruction can sometimes be accomplished by implanting a stent or plastic tube in the common bile duct during an endoscopic procedure. Pain can be reduced by surgical removal of a portion of the greater splanchnic nerve.

Surgery may be followed by chemotherapy and radiation therapy. In some instances, either radiation therapy

FIGURE 35.5 Pancreatoduodenectomy (Whipple's procedure) for cancer of the head of the pancreas.

or chemotherapy may be used for relief of symptoms if the cancer has become too widespread for surgery. (See Chapter 10 for care of the patient undergoing radiation or chemotherapy.)

Nursing Process for the Patient with Pancreatic Cancer

ASSESSMENT/DATA COLLECTION. Observe the patient with cancer of the pancreas for evidence of malnutrition and fluid imbalance, including weight loss, inelastic skin turgor, vomiting, fatty stools, and complaints of anorexia or nausea. Review laboratory tests, especially blood glucose, liver function studies, and clotting studies. Evaluate the patient every 2 to 4 hours for pain. Observe the skin for bruising, scaling, and yellowing, and question the patient about itching. Evaluate the patient's mental status for evidence of depression.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. The patient with cancer of the pancreas will have numerous problems. Interventions for imbalanced nutrition: less than body requirements related to inability to digest food, anorexia, nausea, and vomiting, and pain related to pancreatic tumor or surgical incision are the same as for patients with pancreatitis and are found in Box 35.10 Nursing Care Plan for the Patient with Acute and Chronic Pancreatitis. Other care is listed below. Additional interventions for patients with cancer, including psychosocial interventions, can be found in Chapter 10.

Risk for deficient fluid volume

EXPECTED OUTCOME: The patient will have adequate fluid volume as evidenced by stable vital signs, elastic skin turgor, and moist mucous membranes.

- Monitor the patient's intake and output carefully. *Low intake increases risk of deficient fluid volume; low output is a sign of deficient fluid.*
- Monitor vital signs. *Tachycardia, tachypnea, and low blood pressure may indicate excessive fluid loss.*
- Monitor laboratory values, especially serum sodium, potassium, calcium, and chloride levels. Report abnormal values. *If electrolyte values are low, the physician may order intravenous replacement solutions.*
- Report low serum albumin level (normal is between 3.4–4.8 g/dL) and assist with monitoring intravenous albumin therapy if ordered. *Low albumin places the patient at risk for fluid imbalances.*
- Carefully observe the patient for signs of blood loss that may indicate abnormal bleeding:
 - Bruising, bleeding gums, or pink-tinged urine
 - Cullen's sign (bluish discolorations around the umbilicus)
 - Turner's sign (bluish discolorations on the flanks)
 - Bleeding at incision and drain sites and in drainage tubing
- Teach the patient to use a soft-bristle toothbrush. Encourage use of an electric razor rather than a straight razor. *These reduce risk of injury and bleeding.*
- Administer vitamin K as ordered to replace deficiency and reduce risk for bleeding.

High risk for impaired tissue integrity related to itching, and leaking around drainage tubes

EXPECTED OUTCOME: The patient's skin will remain intact.

- Assess the patient for any complaints of itching. *Itching leads to scratching, which can cause a break in the skin.*
- Help the patient keep fingernails short to reduce damage to skin with scratching.
- Provide frequent skin care with products free of soap or alcohol to keep the skin clean; soap and alcohol can dry the skin and increase itching and risk for breakdown.
- Protect skin around drains with skin-protective barrier products and ostomy bags. *Drainage may contain pancreatic enzymes which can be very damaging to skin.*
- Apply products such as calamine lotion as ordered to decrease itching.
- Exercise special care of any drains to prevent unnecessary tension that may cause sutures to give way.
- Keep all drains patent, and keep drainage tubing and bags free from kinks. *A kinked drain can cause fluid leakage onto the skin.*
- Place the patient in semi-Fowler's position to help with gravity drainage and reduce risk of fluid leakage.

PATIENT EDUCATION. Teach the patient and family self-care measures such as blood glucose monitoring, insulin administration, signs and symptoms of hyperglycemia and hypoglycemia (see Chapter 40), and the regimen for pancreatic enzyme replacement. Instruct the patient on how to manage dressing changes if he or she is to be discharged with tubes or drains. The patient and family should know the signs and symptoms of hemorrhage, gastric ulceration, infection, and fistula formation. The patient being cared for at home should have a referral for hospice care or home nursing care.

EVALUATION. The plan of care for the patient with pancreatic cancer is successful if the patient exhibits the following:

- Maintains body weight within 5% of normal body weight and experiences no nausea or vomiting.
- States that pain remains at 3 or less on a pain scale of 0 to 10.
- Has urinary output greater than 40 mL/hr, elastic skin turgor, moist mucous membranes, and pulse and blood pressure within 10% of patient's baseline.
- Has no complaints of sudden, excessive abdominal pain or rigidity; incisions heal at the expected rate.
- Can demonstrate the appropriate self-care procedures for tubes, drains, dressings, and medication administration and states the signs and symptoms of complications that are to be reported immediately.

For more information, visit the National Pancreas Foundation at www.pancreasfoundation.org.

DISORDERS OF THE GALLBLADDER

Cholecystitis, Cholelithiasis, and Choledocholithiasis

Gallstones and inflammations of the gallbladder and common bile duct are the most common disorders of the biliary system. These disorders are also common health problems for people in the United States: Nearly 25 million people have gallstones, and about 500,000 people have their gallbladders removed each year.

Pathophysiology

Cholecystitis is an acute or chronic inflammation of the gallbladder. It is most often a response to obstruction of the common bile duct resulting in edema and inflammation. Often bacteria invade the bile and add to the inflammation and irritation of the gallbladder. Chronic cholecystitis may be the result of repeated attacks of acute cholecystitis or chronic irritation from gallstones. The gallbladder becomes fibrotic and thickened and does not empty easily or completely.

Cholelithiasis is characterized by the formation of gallstones in the gallbladder that are usually composed primarily

of cholesterol. **Choledocholithiasis** refers to gallstones in the common bile duct. Although the exact cause of gallstones is unknown, one theory suggests that cholesterol may supersaturate the bile in the gallbladder. After a time, the supersaturated bile crystallizes and begins to form stones. Another type of gallstone is a pigment stone. Pigment stones appear to be composed of calcium bilirubinate, which occurs when free bilirubin combines with calcium.

Etiology and Incidence

Pooling, or stasis, of bile within the gallbladder appears to contribute to the formation of stones. Stasis may be caused by a decreased gallbladder emptying rate or a partial obstruction in the common duct. Excessive cholesterol intake combined with a sedentary lifestyle is linked with an increased incidence of cholelithiasis.

Some low-fat diets have been linked to cholelithiasis because the diet appears to free cholesterol from body tissues; the cholesterol then crystallizes in the gallbladder before it is excreted. Fasting can contribute to cholelithiasis because the gallbladder is less active, and bile becomes concentrated. Further, a family history of cholelithiasis, obesity, diabetes mellitus, pregnancy, some hemolytic blood disorders, and bowel disorders such as Crohn's disease have also been linked to a higher incidence of cholelithiasis.

Cholelithiasis is responsible for about 90% of the cases of cholecystitis, or inflammation of the gallbladder. Women between ages 20 and 50 are about three times more likely to have gallstones than men; especially women with multiple pregnancies, women who are pregnant, or women who are using birth control pills. After age 50, the rate of gallstones is about the same for men and women (Box 35.11 Cultural Considerations). Cholelithiasis is responsible for nearly 800,000 hospital admissions at a cost of more than \$2 billion every year. The incidence of gallstones increases with age.

Signs and Symptoms

Signs and symptoms of cholecystitis and cholelithiasis are similar. Objective symptoms include evidence of inflammation, such as an elevated temperature, pulse, and respirations; vomiting; and jaundice. Subjective symptoms include patient complaints of epigastric pain, RUQ tenderness, nausea, and indigestion, especially after eating foods high in fat. The patient may have a positive Murphy's sign, which is the inability to take a deep breath when an examiner's fingers are pressed below the liver margin.

The epigastric pain caused by cholelithiasis may also be called biliary **colic**. The pain is a steady, aching, severe pain in the epigastrium and RUQ that may radiate back to behind the right scapula or to the right shoulder. The pain usually begins suddenly after a fatty meal and lasts for 1 to 3 hours. If the pain is caused by a stone in the common bile

choledocholithiasis: chole—bile + docho—duct + lith—stone + iasis—condition

colic: colic—spasm

cholecystitis: chole—bile + cyst—bladder + itis—inflammation

**Box 35.11****Cultural Considerations**

Gallbladder disease is more common among Mexican Americans. Risk factors include working in occupations such as mining, factories using chemicals, and farming using pesticides. The disease has a lower incidence in blacks in Africa and in blacks living in the Western world. Native Americans have an increased incidence of pancreatic and gallbladder disease. It is unknown how much increased dietary risk factors may contribute to gallbladder disease. The nurse can positively affect the nutritional status of at-risk patients by teaching food preparation practices that use less fat.

duct (choledocholithiasis), the pain may last until the stone has passed into the duodenum. Jaundice is more commonly present with acute choledocholithiasis because the common bile duct is blocked or inflamed.

The biliary colic caused by cholecystitis typically lasts 4 to 6 hours. The pain is made worse with movement such as breathing. The patient usually has nausea, vomiting, and a low-grade fever with the pain.

Patient complaints of heartburn, indigestion, and flatulence are more common with chronic cholecystitis. Patients often report a medical history that suggests repeated attacks of acute cholecystitis (Table 35.5).

Family history of either cholecystitis or cholelithiasis, dietary habits such as high fat intake or a recent low-fat diet, and complaints of flatulence (gas), eructation (belching), nausea, vomiting, or abdominal discomfort after a high-fat meal are common evidence of a gallbladder disorder.

Complications

Complications of cholecystitis include inflammation of the bile ducts (cholangitis), necrosis or perforation of the gallbladder, empyema (a collection of purulent drainage in the

gallbladder), fistulas, and adenocarcinoma of the gallbladder. A major complication of choledocholithiasis is acute pancreatitis if the pancreatic duct is obstructed.

Diagnostic Tests

The patient may have an elevated white blood cell count (normal: 5000 to 10,000 cells per mm³). Serum amylase level may be elevated (normal: 59 to 190 IU/L) if the pancreas is involved or if there is a stone in the common duct.

An abdominal x-ray examination may be done to determine whether the gallstone is primarily calcium. Calcium-based stones are less responsive to medical treatments. Cholesterol stones are highly responsive to medical therapy.

Further examination may include a nuclear scan. For this procedure, the patient will be given an IV injection of a radioactive isotope that is metabolized by the liver and excreted in the bile. The scanning camera then traces the path of the isotope as it travels through the bile ducts, gallbladder, and intestines. This test may be called a PIPIDA scan, DISIDA scan, or HIDA scan, depending on the isotope used.

Sonograms can detect stones and may be able to determine whether the walls of the gallbladder have thickened. An ERCP can be done to directly visualize the pancreatic ducts and bile ducts to determine the presence of stones in the common duct and occasionally to remove stones from the common duct.

Therapeutic Interventions

Treatment of an acute episode of cholecystitis centers on pain control, prevention of infection, and maintenance of fluid and electrolyte balance. Pain control is achieved by using opioid analgesics. The analgesic agent most often ordered is meperidine hydrochloride (Demerol) because morphine sulfate is believed to cause spasms of the gallbladder, biliary ducts, and the sphincter of Oddi. Antispasmodics or anticholinergic drugs such as propantheline bromide (Pro-Banthine) and dicyclomine hydrochloride (Bentyl) may be ordered to decrease the biliary colic. If the patient has nausea and vomiting, an antiemetic such as

TABLE 35.5 SYMPTOMS OF GALLBLADDER DISORDERS

	Acute Cholecystitis	Chronic Cholecystitis	Cholelithiasis and Choledocholithiasis
Biliary colic	Lasts 4–6 hours Worse with movement	Only during acute attack	Sudden onset
Jaundice	Present (if common bile duct is inflamed or blocked)	Present	Lasts 1–3 hours
Low-grade fever	Present	Present	Radiates to right scapula or shoulder
Nausea, vomiting	Present	Only during acute attack	Present
Repeated attacks		Present	
Heartburn, indigestion, and flatulence		Present	
Complications	Cholangitis Necrosis or perforation Fistulas	Empyema Fistulas Adenocarcinoma	Acute pancreatitis

ondansetron (Zofran) or promethazine (Phenergan) may be ordered (see Table 35.4). Patients are placed on high-protein, low-fat diets after the nausea and vomiting subside (Box 35.12 Nutrition Notes).

Treatment for cholelithiasis usually involves surgical removal of the gallbladder. The surgical procedure may be cholecystectomy via **laparoscopy** or a traditional cholecystectomy. A laparoscopic cholecystectomy is done with a laparoscope through four small puncture wounds in the abdomen.

A traditional cholecystectomy is done through a long, transverse, right subcostal incision. The patient may have a T-tube inserted into the common duct for several days postoperatively to ensure that bile drainage is not obstructed (Fig. 35.6). A Jackson Pratt or Penrose drain may also be inserted at the time of surgery. The drain is removed when drainage is minimal. The patient with a traditional cholecystectomy has incisional pain that creates difficulty with coughing and deep breathing postoperatively because deep breathing causes the diaphragm to press on the operative site. Patients are hospitalized for 2 to 3 days with a traditional cholecystectomy and 24 hours or less with a laparoscopic cholecystectomy.

Some patients are poor surgical risks and have stones in the gallbladder or biliary duct that cannot be removed easily by other methods. Such patients may have a cholecystostomy, which is an incision directly into the gallbladder to remove a stone. If the stone is in the biliary ducts, a choledocholithotomy may be done. The patient usually has a T-tube in place for several days to help remove bile from swollen structures.

FIGURE 35.6 T-tube. A T-tube is used to drain bile after a cholecystectomy until swelling of the duct subsides.

Other methods of treatment include **choledochoscopy**, **extracorporeal shock-wave lithotripsy** (ESWL), oral drugs to dissolve stones, and direct-contact dissolving drugs. The procedure for a choledochoscopy involves the use of an endoscope to explore the common bile duct and in some instances to snare and remove any stones found.

Extracorporeal shock-wave lithotripsy uses shock waves as a noninvasive method to destroy stones in the gallbladder or biliary ducts. Patients who are considered poor surgical risks and who have few cholesterol stones that are not calcified are the most likely candidates for ESWL. The patient lies face down on a water bag over a lithotripter (Fig. 35.7). A conductive gel is placed between the patient and the water bag. Ultrasound is used to locate the stone or stones and to monitor the destruction of the stones. The patient requires sedation and strong analgesics during the procedure to reduce the pain and discomfort of the shock waves. After ESWL, the patient is usually put on a course of oral dissolution drugs to ensure complete removal of all stones and stone fragments.

Dissolution of stones with drugs may be attempted with chenodiol (Chenix) or ursodiol (Actigall). Patients who are poor surgical risks because of advanced age or severe health problems and who have cholesterol stones may be given oral dissolution drugs. The major disadvantages to the use of these drugs are that abnormal liver function studies and diarrhea are common side effects. Patients may also have an increase in serum cholesterol while taking the drugs. Treatment with the dissolution drugs may take from 4 months to 2 years. Patients may need to take cholesterol-lowering drugs in addition to the dissolution drugs to lower serum cholesterol and to decrease the probability of stones reforming.

Direct-contact dissolution drugs are administered directly into the gallbladder through a percutaneous transhep-

Box 35.12

Nutrition Notes

Modifying the Diet for Patients with Gallbladder Disease

During an acute attack of cholecystitis, a full liquid diet with minimal fat is usually allowed. For treatment of chronic cholecystitis, the patient is instructed to do the following:

- Correct obesity.
- Avoid troublesome and gas-forming foods.
- Decrease dietary fat each day by (1) selecting skim-milk dairy products, (2) limiting fats or oils to 3 tsp, and (3) consuming no more than 6 oz of very lean meat.

Cholelithiasis has been associated with a long overnight fast that permits concentrated bile to remain in the gallbladder for an extended period. Eating a light bedtime snack or drinking two glasses of water on arising if breakfast is delayed alter this risk factor.

laparoscopy: aparo—pertaining to flank + scopy—to examine

choledochoscopy: chole—bile + docho—duct + scopy—to examine

extracorporeal shock-wave lithotripsy: extra—outside + tripsy—rub or crush

FIGURE 35.7 Extracorporeal shock-wave lithotripsy. Shock waves are transmitted through water to break up gallstones. (A) Position for stones in gallbladder: Patient is lying on a fluid-filled bag. (B) Position for stones in common bile duct. Patient is in a water bath.

atic catheter. The physician inserts a catheter through the wall of the abdomen into the gallbladder and then injects and aspirates the dissolution agent repeatedly during the treatment. Candidates for this procedure are patients who are poor surgical risks and whose gallbladder can be seen during oral cholecystography. Disadvantages of the procedure include abnormal liver function studies, pain at the catheter site, nausea, and elevations in the white blood cell count. See Box 35.13 Cholecystitis Summary.

Nursing Process of the Patient with a Gallbladder Disorder

ASSESSMENT/DATA COLLECTION. Assess the patient frequently for pain, using the “What’s Up?” questions. Take the patient’s vital signs, particularly the temperature and pulse, frequently to monitor for signs of infection. Weigh the patient and inspect mucous membranes, skin turgor, and urinary output for signs of dehydration. Measure intake and output, including any emesis or drainage from nasogastric tubes or T-tubes. Observe stools and urine for color and consistency. Obstruction of bile flow may result in stools that are clay colored or have a foul, greasy appearance or urine that is dark amber or tea colored. Report either new finding immediately. Evaluate laboratory studies for elevation in the white blood cell count or abnormalities in electrolytes or serum bilirubin levels.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Common nursing diagnoses for the patient with cholecystitis include pain and risk for deficient fluid volume.

Box 35.13

Cholecystitis Summary

Signs and Symptoms

Epigastric/RUQ pain, especially after a fatty meal
Elevated temperature, pulse, respirations
Jaundice if common bile duct blocked

Diagnostic Tests

WBC count
Abdominal x-rays
Nuclear scan (HIDA, PIPIDA, or DISIDA)
Ultrasound, ERCP

Therapeutic Interventions

Pain control
Laparoscopic or open cholecystectomy
Extracorporeal shock-wave lithotripsy
Low-fat diet

Priority Nursing Diagnoses

Pain
Risk for deficient fluid volume
Risk for ineffective breathing pattern
Risk for impaired skin integrity

Additional nursing diagnoses for the patient with cholelithiasis who has a surgical procedure include risk for impaired skin integrity related to surgical incision and T-tube drainage, and risk for ineffective breathing pattern related to abdominal incision.

Acute pain related to biliary colic

EXPECTED OUTCOME: Patient rates pain as 3 or less on 10-point scale.

- Assess the patient frequently for pain. *Treatment should be based on assessment.*
- Administer meperidine (Demerol) or other analgesics as ordered *to reduce pain.*
- Administer antispasmodics or anticholinergics as ordered *for biliary colic.*
- Assist patient with positioning. *The patient should assume whatever position provides the most comfort.*

Risk for deficient fluid volume related to anorexia, nausea, vomiting, or excessive tube drainage

EXPECTED OUTCOME: The patient will have adequate fluid volume as evidenced by stable vital signs, elastic skin turgor, and moist mucous membranes.

- Monitor intake and output, daily weights, and skin turgor *to monitor fluid balance.*
- Monitor T-tube drainage. Carefully observe the T-

tube drainage unit to prevent kinking of the tubing. *About 250 to 500 mL of yellowish green bile is common within the first 24 hours after surgery. The amount of bile diminishes over the next several days. Pressure in the biliary drainage system from poor drainage may greatly increase the patient's pain and the risk for infection.*

- After surgery, maintain nasogastric tube placement as ordered to prevent an ileus from developing.
- Frequently assess for the return of bowel sounds and passage of flatus. *Once bowel sounds return, the nasogastric tube will be removed, and the patient is slowly reintroduced to a solid diet, usually high protein and low fat.*
- Give antiemetics as needed to control nausea and vomiting.
- Assist with administration of intravenous fluids and electrolytes as ordered while the patient is on restricted oral intake to maintain hydration.

Risk for impaired skin integrity related to surgical incision and T-tube drainage

EXPECTED OUTCOME: The patient's skin will remain intact.

- Inspect the patient's skin and the sclerae of the eyes frequently for jaundice. Report new onset of jaundice or patient complaints of excessive itching. *Jaundice is associated with itching, which can lead to scratching and impaired skin integrity.*
- Inspect the cholecystectomy incision frequently for excessive drainage or evidence of infection such as redness, edema, or warmth. *Drainage or infection can irritate and break down skin.*
- Change dressings frequently to protect the skin around the incision site from irritating drainage.
- Use Montgomery straps to secure dressings to prevent skin irritation from repeated or prolonged exposure to adhesive bandages.
- Change the patient's position frequently to reduce risk of pressure ulcers.
- Protect the skin with a skin barrier product or bag such as those used with colostomies if bile is leaking around the T-tube site. An enterostomal therapist (if available) can be consulted for the best choice of dressing. *A skin barrier can protect skin from breakdown due to contact with bile.*

Risk for ineffective breathing pattern related to abdominal incision

EXPECTED OUTCOME: Patient will have effective breathing pattern as evidenced by rate 16 to 20, even, unlabored, depth within normal limits.

- Monitor respiratory rate, depth, and effort, and ability to cough effectively. *The high abdominal incision can cause pain with deep breathing and coughing.*
- After surgery, encourage the patient to cough and deep breathe at every encounter. Instruct the patient

in the proper techniques before surgery and give the opportunity to practice. *Deep breathing and coughing after any surgical procedure help prevent respiratory tract infections and atelectasis.*

- If the patient is reluctant to cough because of pain, evaluate the pain medication regimen. *Pain must be controlled so the patient is able to cough and deep breathe.*
- Assist the patient with splinting when coughing to make coughing less painful.
- Encourage the patient to walk when permitted to help mobilize secretions.

PATIENT EDUCATION. Discharge education focuses on diet. Patients are put on high-protein, low-fat diets. Encourage obese patients to lose weight. After a cholecystectomy, fat should be slowly reintroduced into the diet. Once the duodenum becomes accustomed to a constant infusion of bile, the patient's individual tolerance for fat becomes the only restriction for diet.

EVALUATION. The plan of care for a patient with cholecystitis or cholelithiasis is successful if the patient exhibits the following:

- Reports pain not greater than 3 on a pain scale of 0 to 10, or pain that is tolerable
- No weight loss, urinary output greater than 50 mL/h, moist mucous membranes, elastic skin turgor, and no complaints of excessive thirst
- Intact skin with no warmth, redness, swelling, or purulent drainage at the wound site; no jaundice or complaints of itching
- Clear breath sounds and a normal white blood cell count.

CRITICAL THINKING

Donna

■ Donna, a 23-year-old woman, is diagnosed with possible acute cholecystitis. She is 5 feet, 6 inches tall and weighs 138 pounds. She has recently stopped following an extremely low-fat diet after losing nearly 70 pounds. Her physician wishes to delay surgery until her inflammation has subsided.

1. What risk factors does Donna have for cholecystitis?
2. What diagnostic tests might be ordered to confirm Donna's diagnosis of cholecystitis?
3. What medications can you anticipate that the physician will order for Donna?
4. What type of diet will Donna need to eat after discharge?
5. If the diagnosis of cholecystitis is confirmed, what type of surgical treatment might be ordered?

Suggested answers at end of chapter.

Home Health Hints

- For patients with hepatitis, home health nurses are concerned with proper treatment and patient education to prevent transmission in the community.
- If possible, the patient with hepatitis should have a separate bedroom and bathroom. The person cleaning the bathroom should wear disposable gloves or rubber gloves and then clean the gloves with a 10% bleach solution. The family is advised to use liquid soap instead of bar soap.
- Contaminated linens used by a patient with hepatitis should be washed separately from household laundry and in hot water. One cup of bleach should be added with the detergent to each load. Rubber gloves should be worn to wash the patient's laundry.
- A patient with abdominal ascites needs a hospital bed at home so the patient can be positioned to aid in breathing. A physician's order must be obtained for insurance coverage.
- Measure abdominal girth of the patient with ascites at each visit and record in the nurse's notes. The patient should weigh on the same scale, first thing in the morning, and record the weight so the nurse can document the findings.

REVIEW QUESTIONS

- Which of the following conditions most places a patient with chronic liver failure at risk for bleeding?
 - Encephalopathy
 - Low vitamin K
 - Elevated liver enzymes
 - Hepatorenal syndrome
- A nurse is administering lactulose to a patient with chronic liver disease. The patient states, "That stuff gives me diarrhea. I don't want it." Which response by the nurse is best?
 - "This keeps your ammonia level under control, so it is important to your care. How many stools have you had today?"
 - "Diarrhea can cause dehydration—I'll hold the medication."
 - "I am placing you in charge of your own care, so I will hold this medication at your request."
 - "The diarrhea should stop after a few doses; it is important to keep taking the medication."
- A health care worker is diagnosed with hepatitis C virus. Which question is most important to ask during the admission assessment?
 - "Have you eaten any raw seafood recently?"
 - "Have you experienced a needle stick?"
 - "Have you made beds or handled clothing without gloves?"
 - "Has anyone coughed into your face when you weren't wearing a mask?"
- An elevation in which laboratory test indicates chronic pancreatitis?
 - Serum bilirubin
 - Serum calcium
 - Serum albumin
 - Serum amylase
- A patient with acute pancreatitis is hospitalized and must remain NPO. His serum enzymes are very high. He has been receiving only IV hydration. Which laboratory result indicates the need to consult the dietitian for nutrition support?
 - Potassium 4.2 mEq/L
 - Sodium 130 mEq/L
 - Fasting glucose 82 mg/dL
 - Serum albumin 2.9 g/dL
- In planning care for the newly admitted patient with acute pancreatitis, which patient outcome should receive highest priority?
 - Patient expresses satisfaction with pain control.
 - Patient verbalizes understanding of medications for home.
 - Patient increases activity tolerance.
 - Patient maintains normal bowel function.
- A patient develops jaundice and dark, amber-colored urine. Which of the following is most likely the cause?
 - Encephalopathy
 - Pancreatitis
 - Bile duct obstruction
 - Cholecystitis
- Which meal is most appropriate for the patient with acute cholecystitis?
 - Chicken broth, low fat custard, gelatin dessert
 - Cream of chicken soup, milk, gelatin dessert
 - Meat loaf, mashed potatoes with small amount of gravy, green beans

- d. Turkey and cheese sandwich on whole grain bread, apple, milk
9. Which interventions will help a patient who had an open cholecystectomy 24 hours ago to maintain an effective breathing pattern? Select all that apply.
 - a. Place in a supine position.
 - b. Provide analgesics for pain relief.
 - c. Encourage coughing and deep breathing.
 - d. Monitor bowel sounds.
 - e. Assist with splinting during coughing.
 - f. Maintain bedrest for 48 hours after surgery.
10. The nurse is to administer promethazine 12.5 mg IM and has 50 mg/mL on hand. How many mL should be drawn up? _____

Unit Eight Bibliography

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ **Carl**

1. Foreign travel within the past 2 months, fatigue, nausea, and irritability suggest hepatitis A virus. Recent possible exposure to materials contaminated with blood or body fluids, fatigue, headache, and nausea suggest hepatitis B virus.
2. Careful hand washing and standard precautions when handling any body fluids or feces should be instituted.
3. The nurse should plan to give an antiemetic if Carl is nauseated. Larger meals should be given early in the day, with Carl in an upright or sitting position. The nurse should also ensure that the environment is free of noxious stimulants such as unpleasant odors. The diet should be high calorie, high protein, high carbohydrate, and low fat.
4. Any medication that is known to be hepatotoxic, such as acetaminophen, aspirin, and diazepam (Valium), should be avoided.
5. Carl should be reminded that cleanliness, especially with food preparation, is essential. He should also be reminded that frequent hand washing is crucial. Carl needs to know that alcohol and other liver-toxic substances should be avoided.

■ **Mary**

1. Mary has a history of poor nutrition. Her age also puts her at risk.
2. Mary may report that she has malaise, nausea, weight loss, a change in bowel habits, and dull, aching RUQ pain.
3. Serum albumin is usually less than 3.2 g/dL. Her prothrombin time will probably be greater than 25 seconds.
4. Esophageal varices and ascites are the two greatest concerns for the patient with portal hypertension.
5. The physician will usually order diuretics, intravenous albumin infusions, and a sodium-restricted diet.
6. The possibility of suffocation from having the gastric tube dislodge into the esophagus requires that scissors be kept at the bedside at all times during tamponade.

■ **Mrs. Samuels**

1. The most common cause of acute pancreatitis is excessive alcohol intake. Mrs. Samuels denies alcohol consumption, but she does have the risk factor of having a recent ERCP, which may have dislodged a gallstone or irritated the pancreatic duct.
2. Respiratory distress may result from excess fluid accumulation in the retroperitoneal space and from shallow respirations that seek to decrease pressure from the diaphragm on the inflamed pancreas and surrounding tissues.
3. Pancreatitis is similar to a chemical burn and may cause erosion of major blood vessels in surrounding tissue.
4. Serum amylase may be elevated as much as 40 times more than normal early in acute pancreatitis.
5. Opioids are ordered because pain is intense, and pain with anxiety stimulates the autonomic nervous system, which may stimulate greater production of pancreatic enzymes.
6. Stomach acid stimulates the production of pancreatic enzymes. Histamine antagonists decrease stomach acidity.

■ **Donna**

1. Some low-fat diets have been linked to the development of cholesterol gallstones, which then irritate the gallbladder and cause inflammation.
2. Donna's physician might order a white blood cell count, which will be elevated if she has cholecystitis. In addition, the physician may order an x-ray, nuclear scan, or ultrasound to visualize the gallbladder and its contents and the common bile duct.
3. You can anticipate that the physician will order an antibiotic, a narcotic such as meperidine hydrochloride, and possibly an antispasmodic such as Pro-Banthine.
4. Donna will need to eat a low-fat diet after discharge. Eventually she may be able to add more fats to her diet as her body adjusts.
5. If the diagnosis is confirmed, Donna will probably have a laparoscopic cholecystectomy unless her surgeon decides that she needs a traditional cholecystectomy.

QUESTIONS TO GUIDE YOUR READING

1. What are the effects of aging on the urinary system?
2. What data should you collect when caring for a patient with a disorder of the urinary system?
3. How do you collect a midstream, clean-catch urine specimen, and 24-hour creatinine clearance specimen?
4. What is the preparation and postprocedure for diagnostic tests of the urinary system?
5. What nursing care is given for patients with incontinence?
6. Which nursing actions can be taken to decrease the risk of infection in catheterized patients?

REVIEW OF ANATOMY AND PHYSIOLOGY

The urinary system consists of two kidneys, two ureters, the urinary bladder, and the urethra. The kidneys form urine, and the rest of the system eliminates urine. The purpose of urine formation is the removal of potentially toxic waste products from the blood; however, the kidneys have other equally important functions as well:

- Regulation of the blood volume, composition, and pressure by the excretion or conservation of water
- Regulation of the electrolyte balance of the blood by the excretion or conservation of minerals
- Regulation of the acid-base balance of the blood by the excretion or conservation of ions such as hydrogen or bicarbonate
- Regulation of all of the above in tissue fluid
- Production of erythropoietin, which then stimulates erythrocyte production in the bone marrow.

The process of urine formation thus helps maintain the normal composition, volume, and pH of blood and tissue fluid.

Kidneys

The two kidneys are located in the upper abdominal cavity behind the peritoneum on each side of the vertebral column. The upper portions of both kidneys rest on the lower surface of the diaphragm and are enclosed and protected by the lower rib cage. The kidneys are cushioned by surrounding adipose tissue, which is in turn covered by a fibrous connective membrane called the renal fascia; both help hold the kidneys in place. On the medial side of each kidney is an indentation called the hilus, where the renal artery enters and the renal vein and ureter emerge. The renal artery is a branch of the abdominal aorta, and the renal vein returns blood to the inferior vena cava. The ureter carries urine from the kidney to the urinary bladder.

Internal Structure of the Kidney

A frontal section of the kidney shows three distinct areas (Fig. 36.1). The outermost area is the renal cortex, which contains the parts of the nephrons called renal corpuscles and convoluted tubules. The middle area is the renal medulla, which contains loops of Henle and collecting tubules. The renal medulla consists of wedge-shaped pieces called renal pyramids; the apex, or papilla, of each pyramid points medially. The third area is a cavity called the renal pelvis; it is formed by the expansion of the ureter within the kidney at the hilus. Funnel-shaped extensions of the renal pelvis, called calyces, enclose the papillae of the renal pyramids. Urine flows from the pyramids into the calyces, then to the renal pelvis, and finally into the ureter.

Nephron

The nephron is the structural and functional unit of the kidney. Urine is formed in the approximately 1 million nephrons in each kidney. The two major parts of a nephron

FIGURE 36.1 Frontal section of the left kidney. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. FA. Davis, Philadelphia, 2003, p 401, with permission.)

are the renal corpuscle and the renal tubule; these and their subdivisions and blood vessels are shown in Figure 36.2.

A renal corpuscle consists of a glomerulus surrounded by a Bowman's capsule. The glomerulus is a capillary network that arises from an afferent arteriole and empties into an efferent arteriole. The diameter of the efferent arteriole is smaller than that of the afferent arteriole, which helps maintain a fairly high blood pressure in the glomerulus. Bowman's capsule is the expanded end of a renal tubule; it encloses the glomerulus. The inner layer of Bowman's capsule has pores and is highly permeable; the outer layer has no pores and is not permeable. The space between the inner and outer layers contains renal filtrate, the fluid that is formed from the blood in the glomerulus and that will eventually become urine.

The renal tubule continues from Bowman's capsule and consists of the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule. The distal convoluted tubules from several nephrons empty into a collecting tubule. Several collecting tubules then unite to form a papillary duct that empties urine into a calyx of the renal pelvis. All the parts of the renal tubule are surrounded by the peritubular capillaries, which arise from the efferent arteriole and receive the materials reabsorbed by the renal tubules.

Blood Vessels of the Kidney

The pathway of blood flow through the kidney is an essential part of the process of urine formation. Blood from the abdominal aorta enters the renal artery, which branches extensively within the kidney into smaller arteries. The smallest arteries give rise to afferent arterioles in the renal cortex. From the afferent arterioles, blood flows into the glomeruli (capillaries), to efferent arterioles, to peritubular

FIGURE 36.2 A nephron and its associated blood vessels. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. FA. Davis, Philadelphia, 2003, p 402, with permission.)

capillaries, to veins in the kidney, to the renal vein, and finally to the inferior vena cava. In this pathway are two sets of capillaries; that is, two sites of exchanges between the blood and the surrounding tissues (in this case, the parts of the nephrons). The exchanges that take place in the capillaries of the kidneys form urine from blood plasma.

Formation of Urine

The formation of urine involves three major processes: glomerular filtration in the renal corpuscles, tubular reabsorption, and tubular secretion.

Glomerular Filtration

Filtration is the process by which blood pressure forces plasma and dissolved materials out of capillaries. In glomerular filtration, blood pressure forces plasma, dissolved substances, and small proteins out of the glomeruli and into Bowman's capsules. This fluid is then called renal filtrate.

The blood pressure in the glomeruli is relatively high—about 55 mm Hg. The pressure in Bowman's capsule is low,

and its inner layer is permeable, so that approximately 20% to 25% of the blood that enters glomeruli becomes renal filtrate in Bowman's capsules. The larger proteins and blood cells are too large to be forced out of the glomeruli; they remain in the blood. Waste products such as urea and ammonia are dissolved in plasma, so they pass to the renal filtrate, as do dissolved nutrients and minerals. Renal filtrate is similar to blood plasma except that there is far less protein and no blood cells are present.

The glomerular filtration rate (GFR) is the amount of renal filtrate formed by the kidneys in 1 minute; it averages 100 to 125 mL/min. The GFR may change if the rate of blood flow through the kidney changes. If blood flow increases, the GFR increases, more filtrate is formed, and urinary output increases. If blood flow decreases, the GFR decreases, less filtrate is formed, and urinary output decreases.

Tubular Reabsorption

Tubular reabsorption is the recovery of useful materials from the renal filtrate and their return to the blood in the

peritubular capillaries. Approximately 99% of the renal filtrate formed is reabsorbed, and normal urinary output is 1000 to 2000 mL per 24 hours. Most reabsorption takes place in the proximal convoluted tubules, whose cells have microvilli that greatly increase their surface area. The distal convoluted tubules and collecting tubules are also important sites for the reabsorption of water. The mechanisms of reabsorption are active transport, osmosis, diffusion, facilitated diffusion, and pinocytosis.

Active transport requires energy in the form of adenosine triphosphate (ATP); the cells of the renal tubule use energy to transport useful materials such as glucose, amino acids, vitamins, and positive ions back to the blood. For many of these substances there is a threshold level of reabsorption—that is, a limit to how much the renal tubules can remove from the filtrate. The level of a substance in the renal filtrate is directly related to its blood level. If the blood level of a substance such as glucose is normal, the filtrate level is normal, the threshold level cannot be exceeded, and no glucose appears in the urine.

Passive transport is the mechanism by which most negative ions are reabsorbed. They are returned to the blood after the reabsorption of positive ions because opposite charges attract.

The reabsorption of water by osmosis follows the reabsorption of minerals, especially sodium. The conservation of water is very important to maintain normal blood volume and blood pressure. The hormones that influence the reabsorption of water or minerals are summarized in Table 36.1.

Small proteins in the filtrate are reabsorbed by pinocytosis; the proteins become attached to the membranes of the tubule cells and are engulfed and digested. Normally, all proteins in the filtrate are reabsorbed and none are found in urine.

TABLE 36.1 EFFECTS OF HORMONES ON THE KIDNEYS

Hormone (Gland)	Function
Aldosterone (Adrenal Cortex)	Promotes reabsorption of sodium ions from the filtrate to the blood and excretion of potassium ions into the filtrate. Water is reabsorbed following the reabsorption of sodium.
Antidiuretic Hormone (Posterior Pituitary)	Promotes reabsorption of water from the filtrate to the blood.
Atrial Natriuretic Hormone (Atria of Heart)	Decreases reabsorption of sodium ions, which remain in the filtrate. More sodium and water are eliminated in the urine.
Parathyroid Hormone (Parathyroid Glands)	Promotes reabsorption of calcium ions from the filtrate to the blood and excretion of phosphate ions into the filtrate.

Source: Scanlon, V. and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. F.A. Davis, Philadelphia, 2003, p 406, with permission.

Tubular Secretion

In tubular secretion, substances are actively secreted from the blood in the peritubular capillaries into the filtrate in the renal tubules. Waste products, such as ammonia and creatinine, excess water-soluble vitamins, and the metabolic products of medications may be secreted into the filtrate to be eliminated in urine. Hydrogen ions may be secreted by the tubule cells to help maintain the normal pH of the blood.

In summary, tubular reabsorption conserves useful materials, tubular secretion may add unwanted substances to the filtrate, and most waste products simply remain in the filtrate and are excreted in urine.

The Kidneys and Acid-Base Balance

Other than exhalation of carbon dioxide by the respiratory system, the kidneys are the organs most responsible for maintaining the normal pH range of blood and tissue fluid. They have the greatest ability to compensate for or correct the pH changes that are part of normal body metabolism or the result of disease.

At its simplest, this function of the kidneys may be described as follows. If body fluids are becoming too acidic, the kidneys secrete more hydrogen ions into the renal filtrate and return more bicarbonate ions back to the blood. This helps raise the pH of the blood back to normal. In the opposite situation, when the body fluids become too alkaline, the kidneys return hydrogen ions to the blood and excrete bicarbonate ions in urine. This helps lower the pH of the blood back to normal.

Other Functions of the Kidneys

Some functions of the kidneys are not related to the formation of urine. These include the secretion of renin, activation of vitamin D, and production of erythropoietin. The production of renin influences urine formation and is considered first.

When blood pressure decreases, the juxtaglomerular cells in the walls of the afferent arterioles secrete the enzyme renin. Renin then initiates the renin-angiotensin-aldosterone mechanism, which results in the formation of angiotensin II. (See Chapter 15.) Angiotensin II stimulates vasoconstriction and increases the secretion of aldosterone, both of which help raise blood pressure.

Vitamin D exists in several structural forms, which are converted to calcitriol, the most active form, by the kidneys. Vitamin D is important for the efficient absorption of calcium and phosphate from food in the small intestine.

Erythropoietin is a hormone secreted by the kidneys during states of hypoxia; it stimulates the red bone marrow to increase the rate of red blood cell (RBC) production. With more RBCs in circulation, the oxygen-carrying capacity of the blood is greater and the hypoxic state may be corrected.

Elimination of Urine

The ureters, urinary bladder, and urethra do not change the composition or volume of urine but are responsible for its elimination.

Ureters

The ureters are behind the peritoneum of the dorsal abdominal cavity. Each ureter extends from the hilus of a kidney to the lower, posterior side of the urinary bladder. The smooth muscle in the wall of the ureter contracts in peristaltic waves to propel urine toward the urinary bladder. As the bladder fills, it expands and compresses the lower ends of the ureters to prevent backflow of urine.

Urinary Bladder

The urinary bladder is a muscular sac below the peritoneum and behind the pubic bones. In women, the bladder is inferior to the uterus; in men, the bladder is superior to the prostate gland. The functions of the bladder are the temporary storage of urine and its elimination.

Urethra

The urethra carries urine from the bladder to the exterior. Within its wall, near the bladder, is an involuntary, internal urethral sphincter. Inferior to that is the external urethral sphincter, which is made of skeletal muscle and is under voluntary control.

In women, the urethra is 1.0 to 1.5 inches long and is anterior to the vagina. In men, the urethra is 7 to 8 inches long and extends through the prostate gland and penis. The male urethra carries semen, as well as urine.

Urination Reflex

Urination (micturition) is a spinal cord reflex over which voluntary control may be exerted. The stimulus is the stretching of the detrusor muscle as urine accumulates in the bladder. Sensory impulses travel to the sacral spinal cord, and motor impulses return along parasympathetic nerves to the detrusor muscle, causing contraction. At the same time, the internal urethral sphincter relaxes. If the external urethral sphincter is voluntarily relaxed, urine flows into the urethra and the bladder is emptied.

Characteristics of Urine

Amount

Normal urinary output is 1000 to 2000 mL per 24 hours. Any changes in fluid intake or other fluid output (such as sweating) change this volume.

Color

The color of urine is often referred to as straw or amber. Dilute urine is a lighter color (straw) than is concentrated urine. Freshly voided urine is clear. Cloudy urine may indicate an infection.

Specific Gravity

The usual range of specific gravity of urine is 1.010 to 1.025; this is a measure of the dissolved materials in urine. (The specific gravity of distilled water is 1.000.) The higher the specific gravity, the more dissolved material is present. Specific gravity of urine is a measure of the concentrating ability of the kidneys; the kidneys must excrete the waste products that are constantly formed in as little water as possible.

pH

The pH range of urine is 4.6 to 8.0, with an average of 6.0. Diet has the greatest influence on urinary pH. A vegetarian diet results in a more alkaline urine; a high-protein diet results in a more acidic urine.

Constituents

Urine is approximately 95% water, which is the solvent for waste products and salts. Nitrogenous wastes include urea, creatinine, and uric acid. Urea is formed by liver cells when excess amino acids are deaminated (metabolized) to be used for energy production. Creatinine comes from the metabolism of creatine phosphate, an energy source in muscles. Uric acid comes from the metabolism of nucleic acids—that is, the breakdown of DNA and RNA. Other solutes are present in small quantities: enzymes and hormones, for example.

Aging and the Urinary System

With age, the number of nephrons in the kidneys decreases, often to half the original number by age 70 or 80 (Fig. 36.3). The GFR also decreases; this is in part a consequence of arteriosclerosis and diminished renal blood flow. The urinary bladder decreases in size, and the tone of the detrusor muscle decreases. This may result in the need to urinate more frequently or in residual urine in the bladder after voiding. Elderly people are also more subject to infections of the urinary tract, and the changes of aging may influence medication therapy for elderly people (Box 36.1 Gerontological Issues).

Box 36.1

Gerontological Issues

Age-Related Renal Changes

Certain changes typically occur in the renal system as people age. They include the following:

- The renal mass becomes smaller.
- Renal flow decreases by 50%, with subsequent decreased glomerular filtration rate.
- Tubular function and the exchange of substances decrease.
- Bladder muscles weaken and bladder capacity decreases, leading to increased frequency and nocturia.
- The voiding reflex is delayed.

Also, keep in mind that most drugs are excreted through the kidneys. Consequently, changes in renal function become a serious consideration for older adults who need drug therapy. Decreased renal function could slow the excretion of some drugs, keeping them in the body longer. This can increase the risk of adverse drug reactions, such as toxicity and overdose. It is important to monitor kidney function (such as creatinine and blood urea nitrogen levels) in an older person receiving drug therapy.

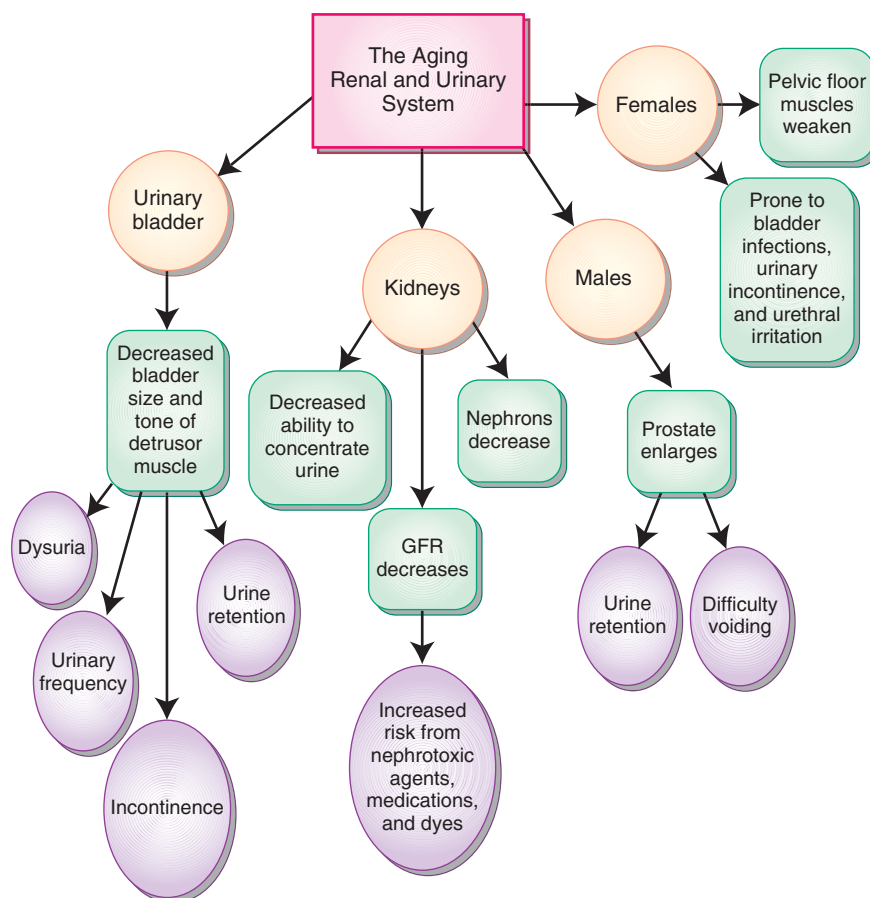

FIGURE 36.3 Aging and the urinary system. This concept map shows the effects the aging process has on the urinary system.

NURSING ASSESSMENT/ DATA COLLECTION OF THE URINARY SYSTEM

Subjective Data: Health History

Table 36.2 describes questions to ask for a health history. Any symptoms should be further assessed using the WHAT'S UP? format found in Chapter 1.

If the patient has impaired kidney function or is in kidney failure, a complete head-to-toe assessment is needed because urinary disease and kidney failure (renal failure) affect every system of the body (see Chapter 37).

Objective Data: Physical Assessment

Objective data to collect is found in Table 36.2. The nurse first inspects the skin for color, texture, edema, or swelling. A patient with chronic renal failure may have a yellow or gray cast to the skin. The presence of crystals on the skin is called uremic frost and is a late sign of waste products building up in the blood (**uremia**). When the wastes are not filtered by the kidneys, they can come out through the skin and look like a coating of frost.

Palpation and percussion of the kidneys is done by physicians and advanced practice nurses. Gentle palpation

and percussion of the bladder may be done by the licensed practical nurse/licensed vocational nurse (LPN/LVN) if urine retention is suspected. If the patient has a feeling of fullness but is unable to urinate, the nurse gently palpates the suprapubic area for a full bladder. Normally, the bladder is not palpable. The bladder may also be percussed. The percussion note sounds dull over a fluid-filled bladder.

Assess for difficulty with cognition, mobility, or manual dexterity. Problems in these areas may be reflected in toileting skill and ability.

Most assessment of the urinary system is done using indirect measures. Assessment of vital signs, lung sounds, edema, daily weights, and intake and output can provide valuable data related to urinary function. The nurse often collects urine specimens for analysis and reports observations about the characteristics of the urine.

Vital Signs

If renal disease is suspected, blood pressure should be assessed and documented while the patient is lying, sitting, and standing. An increase in blood pressure is commonly seen with renal disease. A drop in blood pressure accompanied by a rise in pulse rate as the patient rises to sitting or standing positions is called orthostatic, or postural, hypotension and may indicate fluid deficit (see Chapter 20). A rapid respiratory rate may indicate fluid retention in the lungs.

TABLE 36.2 ASSESSMENT OF THE URINARY SYSTEM

Subjective Assessment		
Category	Questions to Ask During History Assessment	Rationale/Significance
Age	<ul style="list-style-type: none"> How old are you? 	<ul style="list-style-type: none"> Aging is associated with a gradual loss of nephrons. At about age 80 a person may have 40% fewer functioning nephrons. Kidneys become less able to concentrate urine Bladder capacity decreases and may not completely empty with age
Gender	<ul style="list-style-type: none"> Male or female 	<ul style="list-style-type: none"> Women have a high incidence of incontinence. Men are at risk for prostate problems that can affect voiding patterns.
Race, ethnicity	<ul style="list-style-type: none"> What is your ethnic origin? What is the language you speak at home? Do you prefer to speak in a language other than English? 	<ul style="list-style-type: none"> Black males over 40 years of age have a higher incidence of prostate and bladder cancer. Younger men between the ages of 25 and 35 have increased incidence of testicular cancer. Language barriers may exist for patients who speak another primary language that affect expression of problems and understanding of treatments.
Occupation	<ul style="list-style-type: none"> What type of work do you do? Have you had any exposure to chemicals in your present or past jobs or hobbies? Has your job affected your health, if so how? 	<ul style="list-style-type: none"> Renal cancers may occur with occupational exposure to phenol and ethylene glycol which are nephrotoxic chemicals. Textile workers, painters, hairdressers, and industrial workers have a higher incidence of bladder tumors. Stress may predispose hypertension and cardiovascular disease.
Health Habits	<ul style="list-style-type: none"> Do you use alcohol, tobacco, recreational drugs, or caffeine? 	<ul style="list-style-type: none"> Alcohol can irritate the bladder and increase urinary output. Tobacco use is associated with increased risk of renal cancer.
History of Renal or Urinary Problems	<ul style="list-style-type: none"> Do you have any of the following problems with voiding? Pain Increased frequency Blood in urine Bladder or urinary tract infections Have you noticed any changes in your voiding patterns? Urgency Hesitancy Difficulty starting a stream of urine Nocturia Diminished amount of urine Incontinence Have you had kidney or bladder surgery? Describe the surgery. Have you had any changes in the color, odor, clarity or amount of urine? Have you had any pain in the flank area? Have you had any pain in the costovertebral angle (the area formed by the rib cage and the vertebral column)? Have you noticed any swelling of your lower legs in the evening? Have you noted any swelling of your eyes in the morning? 	<ul style="list-style-type: none"> Painful voiding may indicate an infection. Increased urinary urgency with diminished amounts of urine suggests urinary retention. Hematuria may indicate an infection or cancer. Difficulty obtaining a stream of urine may indicate a prostate obstruction. Nocturia may be noted with nephrotic syndrome, diabetes, and heart failure. Changes in the amount of urine voiding may indicate renal disease. Decreased amounts of urine may indicate renal failure. Increased amounts may indicate diabetes or inability to concentrate urine. Changes in color, odor, or clarity of urine indicate the possibility of infection. Flank pain may indicate renal disease. A renal calculus or stone may produce a dull ache in the kidney area or a colicky pain that periodically radiates to the genital area or the leg on the affected side. Edema is noted when there is fluid retention with an increase in circulating fluid volume. Periorbital edema is noted around the eyes in the morning.
Past Medical History	<ul style="list-style-type: none"> Have you been diagnosed in the past with any of the following conditions? Urinary tract infections Renal stones Use of indwelling catheters Diabetes Hypertension 	<ul style="list-style-type: none"> Diabetes is the most common cause of chronic kidney disease worldwide. Hypertension is another significant risk factor. Systemic diseases such as gout, lupus, sickle cell disease, coronary artery disease, and atherosclerosis increase the risk of renal disease. Streptococci infections may precede renal disease.

hematuria: hemat—blood + uria—urine

Subjective Assessment (Continued)

Category	Questions to Ask During History Assessment	Rationale/Significance
Past Medical History <i>(cont'd)</i>	Heart attacks Angina Gout Lupus erythematosus Sickle-cell disease Beta hemolytic streptococci Systemic infections Cancer Glomerulonephritis Polycystic kidney disease • Do you have any history of falls, motor vehicle accidents, or other trauma? • Do you have any history of renal diagnostic tests? • How many children do you have?	<ul style="list-style-type: none"> • Delayed diagnosis of renal trauma increases the risk of renal damage secondary to infection, abscess formation, and strictures. • Previous history or renal tests may indicate a previous problem with the renal system. • Increased parity may affect pelvic floor muscles that may lead to stress incontinence.
Family History of Urinary Disorders	• Has anyone in your family had any problems with their kidneys or urinary system? • Has anyone in your family had hypertension, diabetes, or kidney stones?	<ul style="list-style-type: none"> • The presence of certain renal abnormalities in families increases the likelihood of similar problems occurring in the patient. • Often genetic abnormalities go undetected until later in life with the onset of symptoms. • Positive family history is a risk factor for renal disease. • Polycystic kidney disease is a hereditary disorder where grapelike cysts replace normal kidney tissue. • Many drugs may lead to increased risk for renal failure: <ul style="list-style-type: none"> Gentamicin Amphotericin B NSAIDs ACE inhibitors Rifampin Aminoglycosides • “Chinese herbs” have been reported to cause kidney failure and cancer. These substances contain aristolochic acid, which may be renal toxic. • Contrast media is often used with x-rays to diagnose renal disease.
Current Medications, Over-the-Counter Medications, or Herb Use	• What prescribed medications are you taking? • What over-the-counter medications are you taking? • What herbs or minerals are you taking? • Do you have any allergies to antibiotics, contrast media, or dyes?	<ul style="list-style-type: none"> • “Chinese herbs” have been reported to cause kidney failure and cancer. These substances contain aristolochic acid, which may be renal toxic. • Contrast media is often used with x-rays to diagnose renal disease.
New Onset of Symptoms	• Have you noticed any new onset of any of the following symptoms? Fatigue Shortness of breath Fever or chills Nausea, vomiting, or anorexia Headaches or blurred vision Lethargy Impaired mentation or confusion Itchy skin Facial swelling around the eyes Metallic taste in your mouth Bone or joint problems	<ul style="list-style-type: none"> • Fatigue and shortness of breath may be from anemia. Erythropoietin produced in the kidney is necessary to produce red blood cells. • Fever is associated with urinary tract infections. • Uremic toxins may produce itching skin, headache, bone pain, numbness, nausea, and vomiting. • Facial swelling is due to edema. • Metallic taste in the mouth may be due to imbalances of electrolytes. • Bone and joint problems may be due to problems with calcium and vitamin D metabolism. • Obesity often leads to diabetes, hypertension, and renal disease. • Obese individuals have less body water in relation to weight than a lean person does. This predisposes the obese person to greater risk for renal ischemia from fluid losses and dehydration. • Large intake of protein or dairy products may lead to kidney stone formation. • Anorexia and nausea may be present as renal insufficiency progresses toward renal failure. • Hyperlipidemia is a risk factor for renal disease. • Inability to take care of shopping and cooking can have a direct effect on diet.
Diet and Fluid Intake	• Describe your appetite and nutritional status. • Have you noticed any changes in weight over the last year? • How many cups of fluid do you drink daily? • What types of fluid do you drink? • Are you able to shop and cook for yourself?	<ul style="list-style-type: none"> • Large intake of protein or dairy products may lead to kidney stone formation. • Anorexia and nausea may be present as renal insufficiency progresses toward renal failure. • Hyperlipidemia is a risk factor for renal disease. • Inability to take care of shopping and cooking can have a direct effect on diet.

TABLE 36.2 ASSESSMENT OF THE URINARY SYSTEM (Continued)

Subjective Assessment (Continued)		
Category	Questions to Ask During History Assessment	Rationale/Significance
Pain	<ul style="list-style-type: none"> • Have you had recent pain in the back, over the bladder, lower abdomen, or perineum? • Have you had any pain or burning with urination? • Have you had any back or leg pain? 	<ul style="list-style-type: none"> • Flank pain or lower abdominal pain may indicate infection, obstruction, or inflammation of the urinary system. • Kidney pain is dull, aching, and steady, and located in the flank area. • Ureteral pain begins in the costovertebral angle and radiates into the lower abdomen and groin. • Bladder pain may be felt over the symphysis pubis. • Back or leg pain may be due to prostrate or metastasis of cancer.
Objective Assessment		
Category	Possible Abnormal Findings	Possible Causes
General Survey <ul style="list-style-type: none"> • Height • Weight • Ethnicity • Posture • Gait • Apparent State of Health 	<ul style="list-style-type: none"> • Hyperlipidemia • Obesity • Ambulation difficulty • Lethargy • Weakness 	<ul style="list-style-type: none"> • Lipids may accumulate in the glomerular cells and promote glomerular fibrosis. • Obesity leads to hypertension and diabetes, both high risks for renal disease. • Weight gain may be secondary to edema • Weight loss may be secondary to renal failure and muscle wasting. • Difficulty ambulating may interfere with voiding patterns and promote incontinence.
Vital Signs <ul style="list-style-type: none"> • Blood pressure • Pulse • Respiratory rate • Pulse oximetry 	<ul style="list-style-type: none"> • Hypertension • Orthostatic hypotension • Tachycardia • Bradycardia 	<ul style="list-style-type: none"> • Hypertension is related to renal disease and fluid volume overload • Orthostatic hypotension may be due to dehydration. • Hyperkalemia causes arrhythmias.
Cognitive Function and Neurological Status	<ul style="list-style-type: none"> • Irregular heart rates • Confusion • Lethargy • Insomnia • Diminished deep tendon reflexes • Hyperesthesia • Paresthesias • Peripheral neuropathy • Decreased mentation • Headaches 	<ul style="list-style-type: none"> • Changes in level of consciousness may be due to changes in electrolytes and fluid balance. • Sleep disorders and neuropathies are common and may be a result of altered fluid balance. • Increased levels of urea, creatinine, and parathyroid hormone may interfere with nerve function and contribute to neuropathies. • Headaches occur from fluid volume overload and uremic toxins.
Skin, Hair, and Nail Assessment	<ul style="list-style-type: none"> • Skin pallor, color, yellow gray cast • Excoriations • Changes in turgor • Bruising • Changes in skin texture • Dry skin • Distal portion of nail beds white • Capillary refill less than 3 seconds • Impetigo—a streptococcal infection of the skin 	<ul style="list-style-type: none"> • Pallor may be due to anemia. • Scratching from pruritus may lead to excoriations. • Dehydration is associated with oliguria. • Edema contributes to nocturia and results from fluid volume overload. • Distal portion of nail beds turn white with renal failure • Increased capillary refill may result from poor blood flow to the extremity or anemia. • Streptococcal infections may precede glomerulonephritis.
Eyes	<ul style="list-style-type: none"> • Conjunctival pallor • Corneal calcification • Retinal arteriosclerotic changes • Blurred vision 	<ul style="list-style-type: none"> • Anemia • Corneal calcification results from phosphate retention • Retinal changes in blood vessels results from prolonged hypertension or diabetes. • Retinitis pigmentosa may accompany hereditary nephropathies
Ears, Nose, and Throat	<ul style="list-style-type: none"> • Deafness • Strep throat 	<ul style="list-style-type: none"> • High-frequency deafness may accompany hereditary nephritis • Acute glomerulonephritis may be accompanied with pharyngitis or group A hemolytic streptococcal infections.
Cardiovascular	<ul style="list-style-type: none"> • Hypertension • Friction rub • Cardiac enlargement of the left ventricle • Dysrhythmias • Angina or chest pain 	<ul style="list-style-type: none"> • Hypertension is the most frequent cause of renal disease. • Hypertension may also be a result of renal disease from alterations of sodium and renal secretion of vasoconstrictors.

Objective Assessment (Continued)

Category	Possible Abnormal Findings	Possible Causes
Cardiovascular (cont'd)	<ul style="list-style-type: none"> • Pericardial effusion • Heart failure • Pulmonary edema • Distended neck veins • Edema 	<ul style="list-style-type: none"> • Elevation of blood pressure in glomerular capillary circulation has an adverse effect on the progression of renal disease. • Friction rubs may occur with uremia. • Cardiac enlargement may occur from hypertension or increased fluid volume. • Angina may occur from chronic anemia. • Dysrhythmias may occur as a result of imbalances of K, Mg, and Ca. • Heart disease is the leading cause of death in patients with renal failure. • Edema will occur from decreased albumin in the blood.
Respiratory	<ul style="list-style-type: none"> • Shortness of breath • Tachypnea • Rales • Acid–base disturbances • Kussmaul’s respirations 	<ul style="list-style-type: none"> • Shortness of breath, tachypnea, and rales are often a result of fluid volume overload. • Metabolic acidosis occurs early in renal disease.
Hematological	<ul style="list-style-type: none"> • Anemia • Bruising • Bleeding tendencies • Infections 	<ul style="list-style-type: none"> • Anemia is a result of decreased erythropoietin production in the kidneys. • Red blood cells have a shortened life span.
Gastrointestinal	<ul style="list-style-type: none"> • Weight loss • Anorexia • Vomiting • Loss of appetite • Constipation • Diarrhea • Malnutrition • Gastroparesis • Metallic taste in the mouth • Foul urine odor to breath • Ascites • Gastritis • Gastrointestinal bleeding 	<ul style="list-style-type: none"> • Metabolic and hormonal changes in renal disease lead to malnutrition and decreased nutrient intake. • Nausea and changes in taste may lead to diminished appetite. • Urea build-up causes metallic taste in the mouth or foul odor of breath. • Malabsorption of calcium from the intestine.
Genitourinary	<ul style="list-style-type: none"> • Nocturia • Enuresis • Hematuria • Dysuria • Oliguria • Anuria • Polyuria • Interrupted urine stream • Straining • Hesitancy • Frequency • Dribbling • Urgency • Retention • Bladder distention • Incontinence • Stress incontinence • Cloudy urine • Odor to urine • Fever • Chills • Perineal pain 	<ul style="list-style-type: none"> • Kidneys lose concentrating ability that may result in changes in urine volume. • Obstruction of lower urinary tract, failure to concentrate urine, or urinary tract infection. • Blood in the urine may indicate infection, irritation, obstruction, or cancer in the renal system. • Anticoagulation with medications may produce bloody urine. • Dysuria is a sign of urinary tract infection or interstitial cystitis. • Urine output of 100–400 mL in 24 hours. Oliguria is noted in severe dehydration, shock, transfusion reactions, and end-stage renal disease. Less than 100 mL of urine in 24 hours may be seen in acute renal failure, end-stage renal disease, and bilateral ureteral obstruction. • It is normal to void every 3–4 hours in the day, and once at night. • 1000–1500 mL of urine is excreted daily. Polyuria may be noted with diabetes, diabetes insipidus, and chronic renal failure. • Coffee and alcohol may have a diuretic effect. • Urine flow difficulty may be due to prostate problems. • Acutely inflamed bladder, retention with overflow, and excess fluid intake may increase frequency. • Urinary hesitancy may indicate blockage of the prostate. • Urinary urgency may indicate cystitis. • Urinary retention can lead to renal failure as fluid causes increased pressure in the kidney. • Incontinence may be a sign of urological disorders or neurological disease. • Cloudy, strong-smelling urine may indicate a urinary tract infection. • Urinary tract infections may cause sepsis in the elderly. • Pain may be due to infection, foreign body in urinary tract, urethritis, pyelonephritis, and renal colic or stone.

(Continued on following page)

TABLE 36.2 ASSESSMENT OF THE URINARY SYSTEM (Continued)

Category	Objective Assessment (Continued)	
	Possible Abnormal Findings	Possible Causes
Musculoskeletal	<ul style="list-style-type: none"> • Osteoporosis • Bone and joint problems • Muscle weakness • Gait disturbances • Fractures 	<ul style="list-style-type: none"> • Vitamin D synthesis decreases with the increase of parathyroid hormone causing changes in the calcium phosphorus ratio and hyperparathyroidism. • Osteodystrophy occurs from low calcium levels, high phosphorus levels, and inability to produce vitamin D. • Physical mobility is necessary to move to a toilet in a timely manner.
Endocrine System	<ul style="list-style-type: none"> • Hyperlipidemia • Hyperglycemia • Anemia • Hypertension 	<ul style="list-style-type: none"> • Renal disease impairs the kidneys' ability to produce erythropoietin which stimulates red blood cell production in the bone marrow. • Renin produced in the kidney activates angiotensin II which is a potent vasoconstrictor that elevates blood pressure.

Lung Sounds

If the patient retains more fluid than the heart can effectively pump, fluid may be retained in the lungs. This is manifested as crackles, which are popping sounds heard on inspiration and sometimes on expiration when the chest is auscultated. Wheezes may also be present. New-onset crackles and wheezes should be reported to a physician (see Chapter 29 for assessment of the respiratory system).

Edema

Fluid retention may be manifested as edema (excess fluid in tissues). The nurse assesses and documents the degree and location of edema (see Chapter 20). Edema may be generalized in renal failure. The nurse also looks for edema in the area around the eyes (periorbital edema).

Daily Weights

Weight is the single best indicator of fluid balance in the body. Patients with renal disease often have fluid imbalances. The patient should be weighed at the same time each day, in the same or similar clothing, and with the same scale. The nurse is careful not just to document the weight, but also to look at trends in weight gain or loss. If the patient's weight is steadily increasing, fluid retention is suspected and should be reported. A patient undergoing diuresis is expected to have decreasing weights.

Intake and Output

All patients with renal disease should have careful measurement of intake and output with each voiding. The nurse measures and records all liquids taken in, including oral, intravenous, irrigation, tube feeding, and other fluids. Output includes urine, emesis, nasogastric effluent, wound drainage if it is copious, and any other drainage. The nurse should also examine the urine for any abnormalities.

Intake and output totals are analyzed and recorded every 8 or 12 hours or more often for unstable patients. As with daily weights, the nurse notes trends in retention or loss of fluid and reports significant changes to the physician. Accurate documentation is vital because the physician may base medication and intravenous fluid orders on intake and output results.

CRITICAL THINKING

Mr. Nolan

■ It is the end of the shift. As you empty Mr. Nolan's indwelling catheter bag, you find that it has only 50 mL of concentrated urine in it. What do you do?

Suggested answers at end of chapter.

DIAGNOSTIC TESTS OF THE RENAL SYSTEM

Laboratory Tests

Urine Tests

URINALYSIS. A urinalysis (urine analysis) is a commonly performed diagnostic test for the renal system. Urinalysis is an invaluable tool in the diagnosis of kidney disease and other systemic diseases that may affect the kidneys. The results of the urinalysis give information regarding kidney function and various body functions. Table 36.3 lists normal and abnormal findings on a urinalysis.

A routine urinalysis specimen may be collected at any time of day; however, the first morning specimen is best. First morning specimens are usually concentrated and more likely to contain abnormal constituents if they are present. The specimen should be examined within 1 hour of urinating. Urine that cannot be examined promptly should be refrigerated. Urine standing at room temperature longer than 2 hours has more bacteria present, changes in pH, and hemolysis of RBCs. Urine collected for cytology should not be a first morning specimen due to changes in epithelial cells in urine held overnight. Random specimens are done for cytology.

To collect a voided specimen for urinalysis, the nurse has the patient wash the perineum using soap and water or a special towelette from a clean-catch midstream urine collection kit. Women should be directed to wash from the front to the back of the perineum. The patient is instructed to begin

TABLE 36.3 URINALYSIS RESULTS

Test	Normal Results	Abnormal Results and Significance
<i>Color of Urine</i>	Pale yellow to amber	Dark-amber urine suggests dehydration. Yellow-brown to green urine indicates excessive bilirubin. Dark, smoky color suggests hematuria. Orange-red or orange-brown caused by phenazopyridine (Pyridium). Cloudiness of freshly voided urine indicates infection. Nearly colorless urine is seen with a large fluid intake, renal disease, or diabetes insipidus.
<i>Odor of Urine</i>	Aromatic	With infection, urine becomes foul smelling. In diabetic ketoacidosis, the urine has a fruity odor. Urine that has been standing for a while develops a strong ammonia smell.
<i>pH</i>	4.6–8.0	The pH is greatly affected by the food eaten. pH below 4.6 is seen with metabolic and respiratory acidosis. pH above 8.0 is seen when urine has been standing or with infection because bacteria decompose urea to form ammonia.
<i>Specific Gravity</i>	1.010–1.025	Low specific gravity indicates excessive fluid intake or diabetes insipidus. High specific gravity is seen with dehydration. A specific gravity fixed at 1.010 indicates kidney dysfunction. The specific gravity of glomerular filtrate is 1.010.
<i>Protein</i>	0–18 mg/dL 0–150 mg/24 hr	Persistent proteinuria is seen with renal disease from damage to the glomerulus. Intermittent protein in the urine can result from strenuous exercise, dehydration, or fever. As a general rule, protein in the urine is a significant sign of renal problems. Vaginal secretions may contaminate urine and give a positive reading.
<i>Glucose</i>	None	Glucose in the urine indicates diabetes mellitus, excessive glucose intake, or low renal threshold for glucose reabsorption.
<i>Ketones</i>	None	Ketones in the urine indicate diabetes mellitus with ketonuria or starvation from breakdown of body fats into ketones. Can also be seen with carbohydrate-free diets, severe diarrhea, dehydration, and vomiting.
<i>Bilirubin</i>	None	Bilirubin in the urine indicates liver disorders causing jaundice. Bilirubin may appear in the urine before jaundice is visible.
<i>Nitrite</i>	Negative	Nitrites in the urine indicate infection. Bacteria in the urine convert nitrate to nitrite, which gives a positive reading.
<i>Leukocyte Esterase</i>	Negative	A positive leukocyte esterase in the urine indicates infection in the urine. It determines the presence of an enzyme released by WBCs in the urine.
<i>Red Blood Cells</i>	0–4/hpf	Blood in the urine may be caused by kidney stones, infection, cancer, renal disease, or trauma.
<i>White Blood Cells</i>	0–5/hpf	WBCs in the urine indicate infection or inflammation in the urinary tract.
<i>Casts</i>	None to occasional hyaline cast	Casts are formed when abnormal urine contents settle into molds of the renal tubules and may be made of protein, WBCs, RBCs, or bacteria. A few hyaline casts may be found in normal urine. The presence of casts generally indicates renal damage or infection.

hpf = high-power field; RBC = red blood cells; WBC = white blood cells.

to void into the toilet, and then move the collection container under the stream, and then finish voiding into the toilet. This is called a clean-catch midstream specimen. It is used to obtain the cleanest possible specimen. Female patients should be told to separate the labia with one hand and keep them separated while washing and collecting the specimen to decrease the risk of contamination of the specimen. If the female patient is menstruating, this should be specified on the laboratory form. A tampon may be used to prevent contamination of the specimen. The uncircumcised male patient

should be directed to retract the foreskin with one hand and keep it retracted while cleansing and voiding. At least 10 mL of urine should be collected.

If a urinalysis is ordered for a patient with a urinary catheter, the nurse obtains the urine specimen. This specimen is considered sterile because it is coming directly from the bladder into the urinary catheter tubing. To obtain the specimen, wear clean gloves and use an alcohol swab to clean the sample port on the catheter tubing. Insert a blunt needle of a syringe (usually 10 mL) into the port and with-

draw urine from the tubing into the syringe. Then empty the urine from the syringe into a collection container and safely dispose of the syringe.

Composite urine specimens are collected over a period of time that may range from 2 to 24 hours. These specimens are usually used to examine the urine for specific components such as glucose, electrolytes, protein, 17-ketosteroids, catecholamines, creatinine, and minerals. These specimens may need refrigeration or may have preservatives added to the collection container.

The patient is instructed to void and discard this specimen. The time is noted and is the start time of the test. All subsequent voiding is saved in the container for the designated time period. At the end of the time frame, the patient is asked to void and this is added to the container as the last amount to be added. Reminding the patient to save all of the urine is critical for accurate results. Incomplete collections do not result in accurate results.

Renal Function Tests

A number of blood and urine tests reflect kidney function (Table 36.4). If the kidneys are not functioning adequately, these test results will be elevated. These tests are useful because they provide information about the severity of a patient's kidney disease and also the patient's response to any treatments or medications being used. In this way, clinical progress can be monitored. Renal function tests may still be within the normal range until the glomerular filtration rate is less than 50% of normal. The most accurate way to assess kidney function is to use several tests and analyze the results together.

Diagnostic Procedures

Table 36.5 summarizes diagnostic procedures for the urinary system.

Radiological Studies

With all contrast studies, the patient should be questioned for allergies to iodine and contrast media before the test.

LEARNING TIP

A handy approximation to determine kidney function is to equate the creatinine clearance result to percentage of renal function. For example, a creatinine clearance of 100 mL per minute = 100% renal function, 30 mL per minute = 30% renal function, and 5 mL per minute = 5% renal function.

Contrast media may be **nephrotoxic** and can worsen renal function. The most severe complication in patients who have allergies is an anaphylactic reaction that causes cardiac and respiratory distress or arrest. When contrast media is used, Metformin hydrochloride (Glucophage) must not be given before and 48 hours after administration of contrast media. Severe lactic acidosis as well as renal failure may occur. MRI and nuclear medicine studies have the advantage of not requiring contrast media to be used.

Endoscopic Procedures

Endoscopic procedures examine the inside of hollow organs with an endoscope. The endoscope is a device consisting of a tube and an optical system. The observations can be done through a natural body opening such as the urethra or a small incision through the skin.

Renal Ultrasound

Ultrasonography is a noninvasive study using sound waves passed into the body through a transducer to detect abnormalities. It is commonly used to examine the anatomy of the urinary tract. Ultrasound requires no contrast media and no preparation. There are also no contraindications to ultrasound.

(Text continued on page 769)

TABLE 36.4 DIAGNOSTIC LABORATORY TESTS FOR URINARY SYSTEM

Test Urine Studies	Definition/Normal Value	Significance of Abnormal Findings
<i>Urinalysis</i>	<ul style="list-style-type: none"> Used to establish baseline information, confirm or establish a diagnosis, or determine if further testing needs to be done. 	<ul style="list-style-type: none"> May be used to monitor the progress of an existing condition or plan a program of care.
<i>Urine Culture</i>	<ul style="list-style-type: none"> A urine culture is done to determine the number of bacteria present in the urine and to identify the organism causing infection in the urine. The urine should be collected before antibiotic treatment is begun to avoid affecting results. The midstream clean-catch system is used to obtain voided specimens. A physician may order a catheterized specimen if there is a risk of contamination from the vagina, if a female patient is menstruating, or if the patient is incontinent. 	<ul style="list-style-type: none"> Reference value: <ul style="list-style-type: none"> <10,000 negative 100,000 positive A bacterial count of 100,000 or more per milliliter of urine indicates a urinary tract infection. An amount less than 100,000 may result from contamination during specimen collection. The urine is cultured to grow and identify the kind of bacteria present. Often a sensitivity test is also ordered to determine what kind of antibiotic will be most effective in eradicating the offending bacteria.

Test Urine Studies	Definition/Normal Value	Significance of Abnormal Findings
Urine Concentration Test or Specific Gravity	<ul style="list-style-type: none"> This study evaluates the concentration of urine with specific gravity readings. 	<ul style="list-style-type: none"> Reference value: 1.05–1.35 A low specific gravity may be noted in patients with diabetes insipidus, glomerulonephritis, and severe renal damage. A high specific gravity may occur from diabetes mellitus and high sugar concentrations in the urine, nephrosis, congestive heart failure, and dehydration.
Residual Urine	<ul style="list-style-type: none"> This study looks at the amount of urine left in the bladder after voiding. Increased residual volume may be noted with urethral strictures, sphincter impairment, urethral strictures, or neurogenic bladder. 	<ul style="list-style-type: none"> Reference value: <50 mL (amount increases with age) The patient is catheterized immediately after voiding. If a large amount of urine is present, a urinary catheter may be left in place. Bladder ultrasound equipment may also be used to determine the amount of urine remaining after voiding.
Quantitative Test for Protein	<ul style="list-style-type: none"> A 12- or 24-hour collection is obtained. Persistent proteinuria is usually seen with glomerular renal disease. 	<ul style="list-style-type: none"> Reference values: <ul style="list-style-type: none"> <150 mg/24 in 24 hours <0.15 g in 24 hours Reference value: 85–135 mL/min The creatinine clearance is computed in the laboratory and is expressed in volume of blood that is cleared of creatinine in 1 minute. A minimum creatinine clearance of 10 mL per minute is needed to live without dialysis. To carry out the test, urine is collected for a 24-hour period, and a sample for serum creatinine is collected sometime during the 24 hours. It is an excellent indicator of renal function. The following procedure should be followed: <ol style="list-style-type: none"> When the test is begun, the patient is directed to void and discard that urine. Urine is collected for 24 hours, keeping the urine in a large container provided by the laboratory. The container is kept on ice. Twenty-four hours after the test was begun, the patient is instructed to void again. This urine is added to the collection container. The laboratory collects a serum creatinine during this 24-hour period.
Creatinine Clearance	<ul style="list-style-type: none"> The creatinine clearance test measures the amount of creatinine cleared from the blood in a specified period by comparing the amount of creatinine in the blood with the amount of creatinine in the urine. 	<ul style="list-style-type: none"> Atypical cells indicate the need for further testing.
Urine Cytology	<ul style="list-style-type: none"> Microscopic examination of urine to detect atypical epithelial cells shed from the surface of the urinary tract. Used as a screening for people with high risk for the development of cancer within the urinary system. 	<ul style="list-style-type: none"> Reference value: <ul style="list-style-type: none"> BTA <14 units/mL NMP22 <10 units/mL No special preparation necessary. A single voided specimen collected before noon is taken directly to the laboratory.
Urine Bladder Cancer Markers (Bladder Tumor Antigen) BTA NMP22	<ul style="list-style-type: none"> Bladder tumor antigen is a protein that is produced by bladder tumor cells. NMP22 is a protein deposited into the urine during nuclear disruption (apoptosis) of bladder cells. 	<ul style="list-style-type: none"> Reference values: 0.6–1.5 mg/dL A serum creatinine level above 1.5 mg/dL means there is kidney dysfunction. The higher the creatinine level, the more impaired the kidney function.
Blood Chemistry Studies Kidney Function Tests Serum Creatinine	<ul style="list-style-type: none"> Creatinine is a waste product from muscle metabolism and is released into the bloodstream at a steady rate. Creatinine levels are a very good indicator of kidney function. 	

(Continued on following page)

TABLE 36.4 DIAGNOSTIC LABORATORY TESTS FOR URINARY SYSTEM (Continued)

Test Urine Studies	Definition/Normal Value	Significance of Abnormal Findings
Cystatin C (Cys C)	<ul style="list-style-type: none"> Cystatin C is a proteinase inhibitor. It is a small molecule that is produced by all cells with chromosomes and genetic material at their center. It is produced at a constant rate and filtered out of the blood by the glomerulus and reabsorbed by the tubular epithelial cells. Cystatin C is a sensitive marker that reflects the glomerular filtration rate independent of body weight and height. 	<ul style="list-style-type: none"> Reference values: 0.53–0.95 mg/dL <0.70 mg/mL or <0.9 μmol/mL young adults <0.85 mg/mL or 3.5 μmol/mL elderly adults Cystatin C levels increase with impaired renal function.
Blood Urea Nitrogen (BUN)	<ul style="list-style-type: none"> Urea is a waste product of protein metabolism. The blood urea nitrogen is not as sensitive an indicator of kidney function as the creatinine level. This is because it is readily affected by increased protein intake, dehydration, and other factors in the body. 	<ul style="list-style-type: none"> Reference value: 8–20 mg/dL An elevated BUN level can be caused by the following factors: Kidney dysfunction or failure Decreased kidney blood supply, such as when the patient is in a state of shock or in severe heart failure Dehydration, because the loss of water makes the blood more concentrated (decreased BUN level is seen with overhydration) High-protein diet, because urea formation increases Gastrointestinal bleeding, because blood is absorbed as protein and converted into urea Steroid use, because steroids increase the rate of protein breakdown in the body Reference value: 2–7 mg/dL An elevated uric acid level can be caused by the following: Kidney disease Gout (patients with gout metabolize uric acid abnormally) Malnutrition Leukemia Use of thiazide diuretics (because of impairing uric acid clearance by the kidney) Reference value: About 10:1 An elevated ratio is seen with hypovolemia. A normal ratio with an elevated BUN and creatinine is seen with intrinsic renal disease.
Uric Acid	<ul style="list-style-type: none"> Uric acid is an end product of purine metabolism and the breakdown of body proteins. Uric acid is not as diagnostic as creatinine because many factors can cause an elevated uric acid level. 	<ul style="list-style-type: none"> Reference value: 2–7 mg/dL An elevated uric acid level can be caused by the following: Kidney disease Gout (patients with gout metabolize uric acid abnormally) Malnutrition Leukemia Use of thiazide diuretics (because of impairing uric acid clearance by the kidney) Reference value: About 10:1 An elevated ratio is seen with hypovolemia. A normal ratio with an elevated BUN and creatinine is seen with intrinsic renal disease.
BUN-to-Creatinine Ratio	<ul style="list-style-type: none"> Evaluates hydration status. 	<ul style="list-style-type: none"> Reference value: About 10:1 An elevated ratio is seen with hypovolemia. A normal ratio with an elevated BUN and creatinine is seen with intrinsic renal disease.
Blood Chemistries		
Electrolytes		
Sodium (Na⁺)	<ul style="list-style-type: none"> Sodium is an extracellular electrolyte regulating blood volume. 	<ul style="list-style-type: none"> Reference value: 135–145 mEq/L Sodium values usually remain within normal ranges until late stages of renal failure. Reference value: 3.5–5.5 mEq/L Elevated levels of K >6 mEq/L can lead to muscle weakness and cardiac arrhythmias.
Potassium (K⁺)	<ul style="list-style-type: none"> Kidneys are responsible for excreting potassium. In renal disease K⁺ is one of the first electrolytes to become abnormal. 	<ul style="list-style-type: none"> Reference values: 4.5–5.5 mEq/L and 9–11 mg/dL
Calcium (Ca²⁺)	<ul style="list-style-type: none"> Calcium is the main mineral in bone and aids in muscle contraction, neurotransmission, and blood clotting. In renal disease decreased reabsorption of calcium leads to renal osteodystrophy. 	<ul style="list-style-type: none"> Reference values: 2.8–4.5 mg/dL and 0.95–1.45 mmol/L
Phosphorus	<ul style="list-style-type: none"> Phosphorus balance is inversely related to calcium balance. In renal disease phosphorus levels are elevated. 	<ul style="list-style-type: none"> Reference values: 22–28 mEq/L
Bicarbonate (HCO₃⁻)	<ul style="list-style-type: none"> Most patients in renal failure have metabolic acidosis and low serum HCO₃⁻ levels. 	<ul style="list-style-type: none"> Reference value: 1.3–2.1 mEq/L Symptoms of elevated magnesium levels include lethargy, nausea and vomiting, and slurred speech.
Magnesium	<ul style="list-style-type: none"> Magnesium is found in the bone and intracellularly. Most of the serum magnesium is excreted by the kidney. Chronic renal disease causes magnesium elevations. 	
Serum Albumin	<ul style="list-style-type: none"> Low levels may be seen with nephrotic syndrome. 	Reference value: 3.5–5.0: g/dL

TABLE 36.5 DIAGNOSTIC PROCEDURES FOR URINARY SYSTEM

Procedure	Definition/Normal Finding	Significance of Abnormal Findings	Nursing Management
Renal Ultrasound or Ultrasonography	<ul style="list-style-type: none"> High-frequency sound waves are used to image the kidneys, ureter, and bladder. Structures of the urinary system can be visualized on a screen. Ultrasound may also be used for mapping of the kidneys before a biopsy is done. A portable ultrasound instrument is able to compute bladder volume from 12 cross-sectional readings. A radiological procedure This test is also known as a flat plate of the abdomen. This study examines the size, shape, and position of the kidneys, ureters, and bladder. A radiological procedure The computer constructs images of the area scanned from a series of tomograms or cross-sectional slices and displays them on a screen. CT scans are able to distinguish subtle differences in the density of tissues. A CT scan of the abdomen and pelvis may be done to discover tumors, metastatic cancers, renal cysts, or abscesses. The scan may also be used for tumor staging or identifying masses. A radiological procedure Computer-generated films produced by the interaction of radio waves and magnetic fields. Is used to visualize the kidneys, bladder, prostate, testes, and retroperitoneum. 	<p>Noninvasive</p> <ul style="list-style-type: none"> A renal ultrasound is used to help diagnose congenital disorders of the kidney, renal abscesses, hydronephrosis, kidney stones, or tumors. The images identify enlargement of the kidneys, and changes of renal structures with chronic infection. The bladder is scanned for residual urine volume, bladder wall thickness, bladder calculi, tumors, and diverticula. May help to discover renal calculi, kidney size, or masses in the kidney. The kidneys, ureters, bladder, abdominal and pelvic organs can be evaluated for kidney size, tumors, abscesses, malignant masses, metastases, or lymph node enlargement. Cysts or abscesses can be identified. Other uses include identification of non-functioning kidneys, renal stones, obstructions, and infections. May be used for staging of cancers of the kidney, bladder, and prostate. 	<ul style="list-style-type: none"> A transducer is passed over the skin, which has been covered with a conductive gel. There is no special preparation or aftercare, and there are no known complications. Because this study does not expose the patient to radiation frequent studies can be done if necessary. Is used to determine postresidual voiding accurately. May diminish the number of catheterizations for bladder distention. No special care is usually necessary. If done as preliminary study, bowel prep may be done. The patient is NPO for 4 hours before the procedure. The patient is asked to hold very still during the procedure. Contrast media may be given. If contrast media is given, check for allergies to the dye or iodine. Push fluids post test to remove dye. Glucophage should not be given before for 48 hours after contrast is given. MRI is contraindicated in any patient with metallic objects in the body, surgical clips, or pacemakers. Patient preparation includes removal of any metal objects, jewelry, or clothing with metal clips. Patients with a history of claustrophobia may need to be sedated. Contrast media may be used. Assess patient for allergies to iodine or contrast media prior to the test. The dye can cause allergic and anaphylactic reactions in people who are allergic to these substances, although this problem is less common since the introduction of a newer radiopaque dye.
Bladder Ultrasound			
Kidney-Ureter-Bladder X-ray Study			
Computed Tomographic (CT) Scan			
Magnetic Resonance Imaging (MRI)			
Intravenous Pyelogram (IVP)	<ul style="list-style-type: none"> A radiological procedure The intravenous pyelogram (IVP) is a common test. X-ray examination that visualizes the renal tissue, calyces, pelvises, ureters, and the bladder after the intravenous injection of contrast media or dye. 	<p>Invasive</p> <ul style="list-style-type: none"> During the test, a radiopaque dye is injected into a large vein. The dye is cleared from the blood by the kidneys. Because the x-rays cannot penetrate the dye, the dye outlines the renal structures. 	

pyelogram: pyelo—pelvis of the kidney + gram—radiograph

(Continued on following page)

TABLE 36.5 DIAGNOSTIC PROCEDURES FOR URINARY SYSTEM (Continued)

Procedure	Definition/Normal Finding	Significance of Abnormal Findings Invasive (Continued)	Nursing Management
IVP (cont'd)	<ul style="list-style-type: none"> • Test provides a rough estimate of renal function. 	<ul style="list-style-type: none"> • Radiographs are taken at frequent intervals to see the dye filling the renal pelvis and going down the ureters into the bladder (see Fig. 36.4). • The dye outlines the renal system and identifies: <ul style="list-style-type: none"> Abnormal size or shape of kidneys Absent kidneys Polycystic kidney disease Tumors Hydronephrosis Renovascular hypertension 	<ul style="list-style-type: none"> • NPO for 8 hours prior to test. • Enemas may be given the evening before the test to empty the colon. • The patient should be warned about a warm, flushing sensation up the arm and sometimes all over the body when the dye is injected. A strange taste may occur as well. • Aftercare for an IVP includes having the patient drink large amounts of fluids to help clear the dye from the kidneys. • On rare occasions, people can develop acute renal failure because the dye is highly concentrated and can obstruct the kidney tubules. • Urine output should be monitored after the test. • IVP is not recommended for patients with renal insufficiency or failure.
Renal Angiography or Arteriogram	<ul style="list-style-type: none"> • A radiological procedure • Purpose is to visualize renal blood vessels. • The femoral artery is pierced with a needle, and a catheter is threaded up through the femoral and iliac arteries into the aorta and then the renal artery. • A contrast agent is injected to make the renal arterial supply visible on x-ray examination. • The test helps the physician see blood flow to the kidneys to determine the cause and treatment of kidney disease. 	<p>Is useful if renal insufficiency is caused by renal vascular disease.</p> <p>The test reveals hypervascular tumors, renal cysts, renal artery stenosis, renal artery aneurysms, pyelonephritis, obstructions, renal infarction, and evaluates renal trauma.</p>	<ul style="list-style-type: none"> • Angiography is done in the x-ray department with the patient awake during the procedure. • Before the procedure check for allergies to iodine or contrast media. • The patient should be NPO for 4 to 8 hours prior to the test. • An enema or cathartic may be given the evening prior to test. • Patient care following angiography includes bedrest for up to 12 hours to prevent bleeding at the injection site. • Check distal pulses in leg every 30–60 minutes after the procedure. • The patient is instructed not to bend the leg, and the head of the bed is not raised more than 45 degrees. • The nurse monitors vital signs, dressing, and pulses in the affected extremity frequently. • Institution policy should be consulted for specific care guidelines. • Complications of the procedure include: <ul style="list-style-type: none"> Vessel injury, embolus or clot formation, and allergic reactions.

Procedure

Nephrotomogram

- A radiological procedure using intravenous contrast media.
- A series of x-rays taken from different angles to create a three-dimensional image of the kidney.

Renal Scan

- Nuclear scan
- Nuclear scans work on the principle that radioactive substances called radioisotopes injected into the bloodstream can be detected by a special camera called a gamma camera similar to an x-ray machine.
- A radioactive isotope that is rapidly excreted by the kidneys is injected intravenously.
- Radiation detectors (cameras) placed over the kidney monitor the radioactive material in the kidney.
- As the isotope passes through the kidney and into the urine the two kidneys “light up.”

Renal Biopsy

- Renal tissue is obtained for laboratory analysis.
- **Percutaneous** renal biopsy is done with a needle through the skin.
- Open renal biopsy is done through a surgical incision.
- A percutaneous biopsy may be done in the operating room, the radiology department, or the patient’s room.
- A computed tomographic (CT) scan or ultrasound is done first to locate the kidney for biopsy.

Significance of Abnormal Findings

Invasive (Continued)

- Test is useful in the identification of renal cysts, tumors, areas of nonperfusion, and renal fractures or lacerations following renal trauma.
- Measures kidney function.
- Measures renal blood flow, glomerular filtration rate, tubular function, and excretion of urine.
- Outlines kidneys size and shape.
- Abscesses, cysts, and tumors may appear as cold spots because of the presence of nonfunctioning kidney tissue.
- The main use is for the diagnosis of renovascular hypertension.
- May also determine vascular supply to the kidneys in patients with renal trauma, dissecting aneurysm, and other disorders affecting blood flow to the kidneys.
- Renal biopsy is indicated when microscopic examination of kidney tissue is needed to diagnose or treat a renal disorder.
- The type of renal disease present or the progress of renal disease is determined.
- Biopsy is used to diagnose benign and malignant masses, causes of renal failure, renal transplant tissue, or lupus.

Nursing Management

- Prepare patient as for an IVP.
- Check for allergies to contrast media and iodine.
- Push fluids post test.
- Monitor fluid intake and output before and after the test.
- Advantages include the ability to determine kidney function without exposure to contrast agents and the ability to obtain quantitative information that may not be obtainable by other procedures.
- Assesses the kidneys ability to perfuse blood and secrete urine.
- No special preparation is usually necessary.
- Determine if any medications the patient is taking will interfere with the test such as nonsteroidal anti-inflammatory drugs or antihypertensive medications.
- The patient may be asked to drink two glasses of water prior to the test.
- The level of radiation is very low and has no side effects.
- Pregnant and nursing mothers are advised to be cautious.
- Before the biopsy, the patient is NPO for 6 to 8 hours.
- A mild sedative is given.
- The patient should not take anticoagulants before the biopsy because of the risk of bleeding.
- A complete blood cell count and coagulation studies are performed prior to the biopsy.
- The patient is in a prone position, usually with a sandbag under the abdomen, and the biopsy is taken through the flank area.
- For a percutaneous biopsy, a local anesthetic is used.
- During the test the patient is instructed to take a breath in and hold it while the needle is being inserted. This prevents the kidney from moving.
- Following the biopsy, the patient may be kept in a prone position.
- Observe closely for bleeding, because the kidney is highly vascular.
- A bandage is applied, and the patient is maintained on bedrest for 24 hours or more.
- Urine is inspected for blood with each voiding and compared to the previous voidings for 24 hours.

TABLE 36.5 DIAGNOSTIC PROCEDURES FOR URINARY SYSTEM (Continued)

Procedure	Definition/Normal Finding	Significance of Abnormal Findings Invasive (Continued)	Nursing Management
Renal Biopsy (<i>cont'd</i>)			
Cystoscopy	<ul style="list-style-type: none"> A cystoscopy and pyelogram (C&P) is a minor surgical procedure that involves a rigid or fiberoptic instrument (cystoscope) inserted into the bladder through the urethra. A light at the end of the instrument allows a physician to visualize the interior of the bladder. Commonly a pyelogram is done as well. This involves insertion of a ureteral catheter into the pelvis of the kidney. Radiopaque dye is injected through the catheter and radiographs are taken. A C&P is done for both diagnostic and therapeutic reasons. 	<ul style="list-style-type: none"> Cystoscopy allows diagnostic inspection of the urinary tract for urinary calculi, infection, vesicoureteral reflux, prostatic obstruction, bladder tumors and urethral strictures. As part of the diagnosis, a physician can do the following: <ul style="list-style-type: none"> Inspect the inside of the bladder. Collect a urine specimen from either kidney. Visualize the renal structure with x-rays. Biopsy any suspicious growths in the bladder or ureter. Therapeutic interventions that can be done during a C&P include the following: <ul style="list-style-type: none"> Removal of small bladder tumors Removal of stones from the bladder Dilation of the ureters Abnormal findings include enlarged prostate, urethral strictures, tumors, polyps, and congenital abnormalities. The test is done to evaluate the filling and emptying of the bladder. The purpose is to visualize the bladder and evaluate vesicoureteral reflux. Incomplete bladder emptying, distention, or reflux is determined. Obstruction to urine outflow may be determined. 	<ul style="list-style-type: none"> Vital signs are monitored frequently for 24 hours according to agency policy. Grossly bloody urine, falling blood pressure, and rising pulse are signs of bleeding and are reported immediately. Fluids are encouraged if not contraindicated. Complications include gross hematuria, pain, infection, hypotension, pneumothorax, and hemorrhage. No heavy lifting for 2 weeks when the patient goes home. Instruct the patient to notify the physician if flank pain, hematuria, lightheadedness, or fainting occurs. The preparation for a C&P is the same as for any surgery. Care following a C&P includes measuring urine to make sure the patient has not developed urinary retention from swelling of the urinary meatus and encouraging fluid intake. The patient should expect some dysuria for 24 hours following a C&P, and the first one or two voidings may be blood tinged. Complications that can result include urinary tract infection, urinary retention, and perforation of the bladder.
Cystogram or Voiding Cystourethrogram	<ul style="list-style-type: none"> A cystogram is an x-ray of the bladder and lower urinary tract. Contrast media or a radioisotope is instilled into the bladder via a catheter or cystoscope. 	<ul style="list-style-type: none"> No medication, fasting, or special diets are necessary. The patient is prepared accordingly for either catheter or cystoscope insertion. After the scan there may be slight dysuria and pink urine for 1–2 days. Bright red urine, fever, or persistent discomfort should be reported to the physician. 	

cystoscopy: cysto—bladder + scopy—to examine

FIGURE 36.4 Intravenous pyelogram x-ray.

Renal Biopsy

A renal biopsy may be done to diagnose or gain more information about kidney disease.

Nursing Process for Diagnostic Tests of the Renal System Assessment

The patient is assessed for baseline understanding of and comfort with testing procedures to plan teaching sessions. Possible contraindications to testing such as renal function and the use of dyes or MRI and metal in the body are assessed and reported.

Nursing Diagnosis, Planning, and Implementation

Anxiety related to unfamiliar environment, procedure, diagnostic test, health status, or severity of disease

EXPECTED OUTCOME: The patient will report increased familiarity or knowledge with the environment, procedure, or diagnostic test prior to the procedure.

- Assess the patient for signs and symptoms of anxiety: verbalization, tenseness, tachycardia, elevated blood pressure, facial pallor, and self-focused behaviors. Anxiety may be manifested by increases in vital signs, pallor, or self-focused behaviors. *A high level of fear may interfere with learning and cooperation.*
- Introduce staff who will be caring for the patient. *Familiarity with staff will decrease anxiety.*
- Orient patient to the environment, equipment, and routines to *decrease anxiety.*
- Include family members or significant others in ori-

entation and teaching sessions *to encourage their support of the patient.*

- Assess the patient's understanding of the procedure *to provide a baseline for teaching.*
- Explain all activities that will take place in the diagnostic area and afterward. *This will reduce fear and promote cooperation during testing.*
- Provide information based on the patient's current needs at the level the patient can understand.
- Reinforce physician's explanations and clarify misconceptions about the diagnostic test or procedure *to help alleviate anxiety.*
- Encourage family members or significant others to provide support to patient without obvious anxiousness. *Anxious family members will convey those feelings to the patient.*
- Identify allergies the patient may have to contrast agents, or drugs prior to diagnostic testing. *This will prevent allergic responses and provide for patient safety.*
- Provide information about injections or invasive procedures that may be done to the patient *to reduce anxiety.*
- Explain any unfamiliar machines or equipment to the patient *to reduce anxiety.*
- Explain that the patient may have to drink increased fluids after the test and that the patient's intake and output will be closely monitored. *Increased fluids help rid the patient of the contrast media after the procedure.*
- Provide information about self-care following the procedure or diagnostic test. *This will facilitate the patient in self-care at home.*

EXPECTED OUTCOME: The patient will experience reduction in anxiety concerning health status or severity of disease.

- Assess the patient for signs and symptoms of anxiety: verbalization, tenseness, tachycardia, elevated blood pressure, facial pallor, and self-focused behaviors. A high level of fear will interfere with teaching and learning as well as diminish cooperation during testing.
- Examine patient's health beliefs. *Health beliefs provide insight to patient behaviors that may affect outcome.*
- Maintain a calm, supportive, and confident manner when interacting with the patient. *This will reduce anxiety.*
- Respond to patient call signals as soon as possible *to reduce anxiety.*
- Acknowledge the patient's anxiety and the perceived threat of the situation *to facilitate communication and trust.*
- Encourage the patient to verbalize feelings or concerns *to provide a baseline of information to develop a teaching plan.*

- Encourage the patient to verbalize specific stressors that may be causing anxiety *to allow individualized care specific to meet patient's needs.*
- Encourage patient to ask questions. *Teaching will be guided by patient-specific needs.*
- Provide the patient with access to timely information regarding the outcome of diagnostic testing *to facilitate trust and promote comfort.*
- Provide consistent reinforcement of information to the patient *to facilitate trust and promote comfort.*
- Reinforce explanations and clarify misconceptions the patient has about diagnostic tests or disease condition *to facilitate trust and promote comfort.*
- Encourage the patient to ask questions concerning self-care and decision making if possible.
- Engage the support of the patient's family throughout diagnostic testing *for patient's coping.*
- Provide a calm environment *to reduce anxiety.*
- Instruct the patient in relaxation techniques and facilitate their use *to reduce anxiety.*
- Evaluate urine for color, odor, consistency, and quantity *to assess for complications from diagnostic testing.*
- Observe the patient for hypersensitivity reactions to contrast media or injectable materials.
- Assess the patient for pruritus, rashes, breathing difficulties, generalized edema, or urinary retention *to detect possible reaction symptoms.*

Evaluation

If interventions have been effective, the patient will report reduced anxiety, increased understanding of procedure, maintain urine output greater than 30 mL per hour, and decrease in pain.

THERAPEUTIC INTERVENTIONS

Management of Urinary Incontinence

Urinary **incontinence** is defined as the involuntary leakage of urine and is very common. More than 17 million adults have urinary incontinence. The incidence is rising. Incontinence affects approximately 45% of all American women. The highest incidence, 55%, is noted in the 80- to 90-year-old women. An estimated 3.4 million men over the age of 60 are also affected with incontinence. Urinary incontinence is often underdiagnosed because many patients are too embarrassed to talk about the problem.

Most patients do not seek treatment until the problem profoundly affects quality of life. At times, urinary incontinence can be prevented by patient teaching or physician intervention. Incontinence that cannot be prevented is managed by the use of padding and absorptive products worn by the patient. With all kinds of incontinence, it is helpful for the nurse or patient to keep a voiding diary for at least several days to determine when incontinence occurs and to look for any predisposing events. The patient should be referred to a urologist specializing in the area of incontinence for a careful examination to determine the cause and identify potential medical or surgical treatment. Some areas of the country have continence clinics, which can be helpful for patients with this problem. There are several types of incontinence.

Stress Incontinence

Stress incontinence is the involuntary loss of less than 50 mL of urine associated with increasing abdominal pressure during coughing, sneezing, laughing, or other physical activities. Stress incontinence is commonly seen in women following childbirth and after menopause. In men, stress incontinence is associated with prostatectomy and radiation.

Urge Incontinence

Urge incontinence is the involuntary loss of urine associated with an abrupt and strong desire to void. The patient typically complains of being “unable to make it to the bathroom in time.” Urge incontinence is the most common type of urinary incontinence in older adults. Patients with stress incon-

Acute pain related to infection, edema, obstruction, or bleeding along the urinary tract or to invasive diagnostic tests

EXPECTED OUTCOME: Patient will report a decrease in pain and absence of discomfort.

- Assess level of pain, **dysuria**, burning on urination, or abdominal or flank pain *to provide baseline data to evaluate progression of pain and effectiveness of treatment plan.*
- Assess voiding patterns. *Delayed emptying of the bladder or frequent voiding of small amounts or abdominal distention may reflect infection or distention.*
- Evaluate urine for color, odor, consistency, and quantity *to assess for infections or other problems.*
- Encourage fluid intake unless contraindicated *to facilitate dye removal.*
- Provide comfort measures *to relieve pain.*
- Provide analgesics and antispasmodics as prescribed *for pain relief.*
- Report severe pain to the primary care provider. *Severe pain may indicate complications are present or the need for a change in pain control medications.*

Impaired urinary elimination related to complications from diagnostic tests of the urinary system

EXPECTED OUTCOME: The patient will maintain urine output greater than 30 mL per hour in the postprocedure period.

- Encourage fluid intake after renal diagnostic testing *to facilitate dye or contrast removal from the body.*
- Monitor fluid intake and output closely *to ensure adequate renal function.*

dysuria: dys—difficult or painful + uria—urination

Box 36.2**Patient Education for Kegel Exercises**

The purpose of Kegel exercises is to decrease the incidence of incontinence by strengthening the pubococcygeal muscle, which supports the pelvic organs. By increasing the tone of this muscle, the patient has an increased ability to tighten the muscle that encircles the urinary meatus and stop the flow of urine. This exercise can also help prevent uterine prolapse, enhance sensation during sexual intercourse, and hasten postpartum healing. It may be used by the elderly male patient to control dribbling.

1. Establish awareness of pelvic muscle function by instructing the patient to “pull in” the muscles in the perineum as if to control urination or defecation. The muscles of the buttocks, inner thigh, and abdomen are not used to do Kegel exercises.
2. To help identify the correct muscles to tighten, ask the patient to tighten the muscles that control urination. It can be helpful to use an analogy of an elevator: start squeezing at the bottom floor and then squeeze upward to the top floor.
3. Instruct the patient to tighten the pelvic muscles for 10 seconds, followed by at least 10 seconds of relaxation.
4. Advise the patient to perform these exercises 30 to 80 times per day. Help the patient determine cues to remind the patient to perform the exercises, such as stopping the stream of urine 10 times each time the patient urinates.

Source: Adapted from Urinary Incontinence in Adults: Clinical Practice Guideline. Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services (AHCPR Pub No 92-0038), Rockville, MD, 1992.

tinence or urge incontinence can be taught Kegel exercises to increase perineal muscle tone. Box 36.2 Patient Education for Kegel Exercises explains how to teach patients to perform them.

Functional Incontinence

Functional incontinence is the inability to reach the toilet because of environmental barriers, physical limitations, loss of memory, or disorientation. People with functional incontinence are often dependent on others and have no other urinary problems. This is a common cause of incontinence in the elderly who are institutionalized.

Overflow Incontinence

Overflow incontinence is the involuntary loss of urine associated with overdistention of the bladder. It occurs with acute or chronic urinary distention with dribbling of urine. The bladder is unable to empty normally despite frequent urine loss. Spinal cord injuries or an enlarged prostate may cause this type of incontinence.

Total Incontinence

Total incontinence is a continuous and unpredictable loss of urine. It usually results from surgery, trauma, or a malformation of the ureter. Bladder training has been tried and proven ineffective. Often the patient with total incontinence is neurologically impaired. In these situations, the nurse's priority is to keep the patient clean and dry using absorptive products. For the male patient, an external condom catheter can be effective in some situations.

NURSING PROCESS FOR THE PATIENT WITH STRESS OR URGE INCONTINENCE. The medical diagnoses of stress and urge incontinence are also nursing diagnoses. Many nursing interventions can be helpful to decrease these kinds of incontinence. See Box 36.3 Nursing Care Plan for the Patient with Stress Incontinence or Urge Incontinence and Box 36.4 Nursing Care Plan for the Patient with Functional Incontinence.

Management of Urine Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Urine retention can be caused by many factors. It can be acute, with a sudden onset of retention and no urine output, or chronic, with a slower onset of retention of urine and some urine being expelled. Acute retention often results from surgery and is caused by anesthesia, medications, or local trauma to the urinary structures. Acute retention can be a medical emergency causing extreme pain, a large bladder, and the possibility of bladder rupture or acute renal failure. Chronic urine retention may be related to an enlarged prostate gland, diabetes, pregnancy, a medication effect, strictures, or other causes of obstruction of the urinary tract.

To assess for urinary retention, urine output is determined and the lower abdomen is palpated. Symptoms noted may include urinary frequency and absent or decreased urine output. An enlarged bladder can be palpated, and the dull percussion notes may extend up to and beyond the umbilicus.

A bladder scan assesses the volume of urine in the bladder (Fig 36.5). Sound waves estimate the amount of urine in the bladder. It is painless, noninvasive, and requires no patient preparation. The nurse performs this scan at the bedside. It helps guide the need for catheterization, thereby reducing unnecessary catheterizations and associated risks. The bladder scan may be used instead of catheterization (the gold standard for determining urine retention) after the patient urinates to determine the amount of urine remaining in the bladder. Normally the bladder contains less than 50 mL after urination. A residual volume of 150 to 200 mL of urine indicates the need for treatment for urinary retention. Bladder scanning may also be used as a tool for incontinent patients to plan their care.

Urinary Catheters**Indwelling Catheters**

Indwelling urinary catheters (Foley catheters) may be inserted into hospitalized patients for various justifiable

Box 36.3 NURSING CARE PLAN for the Patient with Stress Incontinence or Urge Incontinence

Nursing Diagnosis: Stress incontinence or urge incontinence related to decreased tone of perineal muscles

Expected Outcomes Patient will be continent of urine. Patient will state three actions that can be taken to decrease incidence of stress or urge incontinence.

Evaluation of Outcomes Is the patient continent? Is the patient able to state three actions that can be taken to decrease the incidence of stress or urge incontinence?

Interventions	Rationale	Evaluation
	Stress Incontinence or Urge Incontinence	
Ask about the history of incontinence; have patient keep a voiding journal.	A journal helps identify the severity and timing of incontinence.	Does patient complete the voiding journal?
Instruct patient on how to perform Kegel exercises (see Box 36.2).	Kegel exercises increase perineal muscle tone and help prevent incontinence.	Does patient explain how to perform Kegel exercises?
Work with the patient to incorporate Kegel exercises into normal activities of daily living (e.g., do 10 pelvic muscle contractions during each voiding).	An excellent time to perform Kegel exercises is when voiding because the correct muscles are used.	Does patient perform Kegel exercises when voiding or at other cued times during the day?
Encourage patient to drink at least 2000 mL of fluid per day, preferably 3000 mL per day unless medical reason for fluid restriction.	Concentrated urine is irritating to the urinary tract and can increase the incidence of urge incontinence and dribbling.	Is urine dilute?
Encourage patient to avoid alcohol and caffeine.	Alcohol serves as a diuretic, and caffeine is irritating to the urinary tract.	Does patient explain the need to avoid alcohol and fluids containing caffeine?
Discuss use of and provide small adhesive peripads to wear in underclothing.	Peripads provide protection in case of incontinence.	Does patient have and use peripads if desired?
Refer patient to a continence clinic or to a physician specializing in incontinence.	Specialists in the area of incontinence can use medical or surgical interventions to decrease the incidence of incontinence.	Does patient know resources available to further assist with treatment of incontinence?
Refer patient to supportive and educational groups such as Help for Incontinent People (HIP).	Support groups can help patients deal with the embarrassment of incontinence and learn methods and resources to prevent incontinence.	Does patient know the names and addresses of support groups to help with incontinence?
	Urge Incontinence	
Teach patient to void at frequent intervals (every 2 hours), then gradually increase length of time between voidings.	By emptying the bladder at frequent intervals, the incidence of urge incontinence can be decreased.	Does patient follow a frequent voiding schedule?
Teach urge inhibition techniques (distraction), such as counting back from 100 by sevens and relaxation breathing.	These distraction techniques can help patients reach the bathroom in time to prevent incontinence.	Do distraction techniques help patient prevent incontinence?

Box 36.4 NURSING CARE PLAN for the Patient with Functional Incontinence

Nursing Diagnosis: Functional urinary incontinence related to interference with rapid voiding

Expected Outcomes Patient will be continent of urine. Patient will state three measures to increase continence.

Evaluation of Outcomes Is the patient continent of urine? Is the patient able to state three measures to increase continence?

Interventions	Rationale	Evaluation
Ask about the history of incontinence. Keep a voiding log of when patient is incontinent.	A voiding log helps demonstrate when incontinence is most likely to occur and can help determine the cause of incontinence.	Does the patient cooperate so that a voiding log can be kept?
Determine any acute causes of incontinence, including new onset of urinary tract infection, constipation or impaction, medication effect, or poor fluid intake.	These may be readily treatable causes of incontinence.	Does the patient have any easily treatable causes of incontinence?
Determine if clothing is inhibiting timely voiding. If necessary, Velcro fasteners can be appropriate, or sweat shirts and sweat pants.	Clothing can be difficult to remove for the elderly, resulting in voiding before the clothing can be removed. Clothing can be modified so that it comes off quickly.	Does the patient have easy-to-remove clothing?
Determine if there are any obstacles to reaching appropriate urine receptacle, such as poor lighting, busy bathroom, lack of assistive devices.	Obstacles can make it impossible for the patient to reach the voiding receptacle in time to prevent incontinence.	Does the patient have ready access to a voiding receptacle?
Provide appropriate urinary receptacles, such as a three-in-one commode, female or male urinal, or no-spill urinal.	Assistive devices can be helpful for the patient to increase continence.	Does the patient need and have access to an appropriate assistive device?
Initiate a voiding schedule of every 2 hours, or base schedule on voiding log. Always assist patient to the toilet when patient first awakens and before sleep. Use prompted voiding techniques: check patient regularly, provide positive reinforcement if dry, prompt patient to toilet, praise patient after toileting, return patient to toilet in a specified time.	Frequent scheduled voiding using prompting techniques can increase continence.	Does the patient receive help to do bladder training with prompted voiding?
Teach patient to set up schedule of voiding using environmental cues such as meals, bedtime, and television shows.	Environmental cues help the patient remember when it is time to void.	Can the patient indicate cues throughout the day that prompt voiding?

FIGURE 36.5 A bladder scan can be used to determine the volume of urine in a patient's bladder.

reasons, such as shock, heart failure, or urinary tract obstruction. As a general rule, catheters should be avoided if possible because of the high risk of urinary tract infections. Urinary incontinence is not justification for insertion of a catheter. Urinary catheters result in infection of the urinary tract in up to 44% of patients within 72 hours of catheterization, and up to 90% of patients who have indwelling catheters for 17 days develop significant bacterial infection.¹

Bacteria enter the bladder mainly in one of two ways with an indwelling catheter: (1) through the outlet at the end of the drainage bag contaminating the urine, which is then inadvertently drained back into the bladder; or (2) around the catheter up the urethra and into the bladder. Routine perineal care during the daily bath is sufficient to minimize infection from an indwelling urinary catheter. It has been demonstrated that the incidence of infection is decreased when intermittent straight catheterization is used instead of indwelling urinary catheters. Box 36.5 Guidelines for Care of the Patient with an Indwelling Catheter outlines steps that should be followed to decrease infection in the patient with a catheter (see Home Health Hints).

After an uncircumcised male is catheterized, it is essential that the foreskin is properly positioned over the glans penis and not left retracted to prevent injury. If left retracted, subsequent swelling may make it impossible to pull the foreskin over the glans penis later. This can then cause ischemia of the glans penis, which is an emergency. A physician must be notified immediately and may need to perform an emergency circumcision if the foreskin cannot be properly positioned. Always make sure that the foreskin is positioned properly following catheterization or perineal care.

Intermittent Catheterization

For the patient who is unable to void, the best intervention is intermittent catheterization. A postoperative patient or a patient with a neurological disorder or urine retention may benefit from intermittent catheterization. It reduces the risk of infection as long as the bladder is not allowed to overfill.

Box 36.5

Guidelines for Care of the Patient with an Indwelling Catheter

1. Maintain a closed system. Do not separate the catheter from the tubing of the bag. Instead, collect specimens and irrigate through the sample port in the tubing.
2. Keep the catheter securely taped or fastened to the leg. This decreases traction on the catheter with back-and-forth movement of the catheter that can help bacteria enter the bladder.
3. Encourage fluids to internally irrigate the catheter, if fluids are not contraindicated because of heart or kidney disease.
4. Use good aseptic technique when emptying the drainage bag by hand washing, wearing clean gloves, and using a container designated for that patient only to collect the urine.
5. Wash the perineum with soap and water at least once a day, and again if there is any bowel incontinence.
6. Keep the tubing coiled on the bed and positioned to allow free flow of urine. Keep the catheter bag below the level of the bladder at all times.
7. Do not clamp catheters. Clamping a catheter results in obstruction, which increases infection. Periodic clamping has not been found to be effective in bladder retraining.
8. Remove indwelling catheters as soon as possible.

A full bladder stretches the muscle fibers, which in turn reduces circulation to the bladder and increases the risk of infection.

Intermittent catheterization involves the use of a straight plastic or rubber catheter that is inserted into the urethra every 3 hours or more to empty the bladder. Once the bladder is empty, the catheter is removed. Patients may be taught to do intermittent self-catheterization (ISC) at home. Patients doing ISC may be taught to wash and reuse the same catheter repeatedly when they are in their own environment. In the hospital, however, sterile technique is used.

Suprapubic Catheter

After some surgeries of the urinary tract and in some long-term situations, a suprapubic catheter may be used. This is an indwelling catheter that is inserted through an incision in the lower abdomen directly into the bladder.

Nursing care of a suprapubic catheter involves keeping the area clean and dry, changing the dressing when the site is new, and keeping the catheter taped to prevent tension. A skin barrier such as Stomahesive may help protect the skin from urine leakage. All other care is the same as for any indwelling catheter.

Home Health Hints

- The home health nurse should always have a sterile specimen container. This provides a quick way to get a specimen to the physician's office without the nurse having to obtain the container, saving time and money.
- When catheters plug and irrigation fails, families can be taught to take the catheter out. A syringe for removing water from the balloon should be left in the home for this purpose. The family is instructed to avoid cutting the valve stem. The family should contact the nurse to reinsert the catheter; but in the meantime, the patient's bed or chair can be padded with towels or diapers. Garbage or dry cleaners' bags can be used to line the mattress. The family must be instructed to notify the nurse immediately if the catheter is plugged or has been removed.
- Not all homes have adequate lighting, which is a must for inserting a catheter. If lighting is inadequate, a caregiver can be asked to hold a flashlight while the nurse inserts the catheter. The nurse should always have a flashlight with him or her. Having two catheters and catheter trays is also wise in case of a defect or contamination.
- Urinary bags can be used safely for up to 4 weeks. Instruct the patient or family to cleanse the bag daily with a 1:10 bleach solution to decrease bacteria.²
- To encourage fluid intake, the patient should keep a large container of water (1 to 2 quarts) next to the place the patient sits most of the day. The goal is to drink 2 quarts of water by the end of the day, unless contraindicated by other medical problems. This also simplifies measuring intake. A sports bottle helps to keep water at hand while moving about the home.

REVIEW QUESTIONS

1. A home health nurse visits a patient who is 82 years old, uses a cane, and is not incontinent. Which of the following interventions should be included in the plan of care, based on an understanding of normal age-related changes of the urinary system, to promote patient safety?
 - a. Encourage fluids after 6 p.m.
 - b. Limit fluids to 1000 mL per day.
 - c. Provide a nightlight in the bathroom.
 - d. Provide adult briefs to prevent dribbling.
 2. Which of the following is the most accurate assessment of fluid balance in the patient with renal failure?
 - a. Voiding pattern
 - b. Daily weight
 - c. Laboratory studies
 - d. Skin turgor
 3. Which of the following should be included in patient teaching for collecting a midstream urine specimen for culture and sensitivity?
 - a. A second voided specimen is preferred.
 - b. A 24-hour urine specimen is needed.
 - c. As soon as the urine starts to flow, it should be collected in a sterile container.
 - d. Women should keep the labia separated while voiding.
- Multiple response item. Select all that apply.
4. Which of the following care should the nurse provide following an intravenous pyelogram test?
 - a. Maintain NPO
 - b. Encourage fluids
 - c. Check gag reflex
 - d. Measure urine output
 - e. Position patient prone
 - f. Maintain bedrest for 24 hours
 5. A patient is experiencing stress incontinence with frequent involuntary loss of urine. Which of the following directions would be most appropriate when teaching the patient how to perform Kegel exercises?
 - a. "Tighten your rectum at frequent intervals throughout the day."
 - b. "Keep your abdominal muscles tightened; do this every time you stand up."
 - c. "Do at least 20 sit-ups per day."
 - d. "When urinating, stop and start the stream of urine by tightening the perineal muscles."

6. Which of the following is the most important nursing action for the nurse to take to prevent urinary tract infection in the catheterized patient?
 - a. Force fluids to 4000 mL every 24 hours.
 - b. Empty the Foley bag every 4 hours around the clock.
 - c. Maintain a closed catheter system.
 - d. Wash the perineum every 8 hours.
7. What is the patient's total output for the past 8 hours?
 - 8 a.m. voided 165 mL
 - 11:30 a.m. voided 450 mL
 - 1 p.m. emesis 42 mL
 - 3 p.m. voided 255 mL
 - _____ mL

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. Nolan*

You should realize that 50 mL of concentrated urine for 8 to 12 hours is not normal. Further investigation is necessary to determine the cause and seriousness of the problem. Some items to assess follow.

1. Consider Mr. Nolan's diagnosis. Is he in renal failure? Is he severely dehydrated and retaining water?
2. Ask if anyone emptied Mr. Nolan's bag earlier in the shift.
3. Look at the trends in Mr. Nolan's intake and output

record. Has his output been decreasing? Is this a change?

4. Has Mr. Nolan been taking in enough fluids?
5. Look at trends in daily weights. Is Mr. Nolan's weight increasing? Is this an expected finding?
6. Listen to Mr. Nolan's lung sounds. Check for edema. Do findings indicate fluid retention?
7. Palpate Mr. Nolan's bladder. Is it distended? Maybe the catheter is blocked.
8. If a problem is identified, the physician should be contacted.

QUESTIONS TO GUIDE YOUR READING

1. What are the predisposing causes, symptoms, laboratory abnormalities, and treatment of urinary tract infections?
2. What are the predisposing causes, symptoms, treatment, and teaching for kidney stones?
3. What are symptoms of cancer of the bladder and cancer of the kidneys?
4. How do you provide care for a patient with an ileal conduit or continent reservoir?
5. How would you explain the pathophysiology associated with diabetic nephropathy, nephrosclerosis, hydronephrosis, and glomerulonephritis?
6. What is the nursing care for patients with diabetic nephropathy, nephrosclerosis, hydronephrosis, and glomerulonephritis?
7. What is the difference between acute renal failure and chronic renal failure?
8. What are common symptoms experienced by the patient in renal failure?
9. What nursing care should be given to patients in renal failure and with a hemodialysis blood access site?
10. How does hemodialysis and peritoneal dialysis work to replace the function of the kidney?

Disorders of the urinary tract include a variety of problems involving the kidneys, ureters, bladder, and urethra. These problems may arise from infection, obstructions, cancer, hereditary disorders, and metabolic, traumatic, or chronic diseases. Some may lead to renal failure if not treated or controlled. Infection may be found in three different anatomical parts of the urinary tract: the urethra, resulting in **urethritis**; the bladder, with a diagnosis of **cystitis**; or the kidneys, with a diagnosis of **pyelonephritis**.

URINARY TRACT INFECTIONS

Urinary tract infection (UTI), a general term, refers to invasion of the urinary tract by bacteria. Normally, the urinary tract is sterile above the urethra. Urinary tract infection is the second most common bacterial disease. More than 100,000 people are hospitalized because of urinary tract infections. In the hospital, urinary tract infections are the most common nosocomial infections. Urinary tract infections are described by their location in the urinary tract. Lower urinary tract infections include urethritis, prostatitis, and cystitis. Upper urinary tract infections include pyelonephritis and ureteritis. Infections may result in chronic renal failure, sepsis, or damage to the kidney.

Predisposing Factors for Urinary Tract Infections

Urinary tract infections are almost always caused by an ascending infection, starting at the external urinary meatus and progressing toward the bladder and kidneys. The majority of UTIs are caused by the bacterium *Escherichia coli*, which is commonly found in stool. Predisposing factors for UTIs include the following:

- Stasis of urine in the bladder can be caused from obstruction such as a clamped catheter or simply from not voiding frequently enough. Urine overdistends the bladder, decreasing the blood supply to the wall of the bladder, which keeps white blood cells (WBCs) from fighting contamination that may have entered the bladder. The standing urine then serves as a culture medium for bacterial growth. Incomplete emptying of the bladder prevents flushing out of the bacteria and allows bacteria to ascend to higher structures.
- Contamination in the perineal and urethral areas can be from fecal soiling, from sexual intercourse in which bacteria are massaged into the urinary meatus, or from infection in the area, such as vaginitis, epididymitis, or prostatitis.
- Instrumentation, or having instruments or tubes inserted into the urinary meatus. The most common

cause is urinary catheterization. Bacteria ascend around or within the catheter, causing infection. Within 48 hours of catheter insertion, bacterial colonization begins. Many patients develop a UTI within 2 weeks of placement of an indwelling catheter.

- Reflux of urine from the urethra to the bladder or the bladder to the ureter because of faulty valves to maintain one-way flow. Reflux can be congenital, or it may be acquired as a result of previous infections.
- Previous UTIs are thought to provide a reservoir of persistent bacteria that causes reinfection.
- Women are more susceptible than men due to the short length of the female urethra and close proximity to anus and vagina. Pregnant women may have asymptomatic bacteruria. Untreated, 40% to 50% will develop pyelonephritis. Pregnant women may be prone to infection with group B streptococci. Most commonly, infection occurs in the second and third trimesters.

Older adults have an increased incidence of UTIs due to diminished immune response, diabetes, and neurogenic bladder. Aging increases the risk of lower UTIs and may also mask the symptoms. UTI is the most common cause of acute bacterial sepsis in the patient over 65 years of age. Older men are predisposed to infection because an enlarged prostate causes obstruction of urine flow. In older women, the decline in estrogen can contribute to the risk of UTI.

Signs and Symptoms

UTIs are characterized by common symptoms of dysuria, urgency, frequency, incontinence, nocturia, hematuria, back pain, and cloudy, foul-smelling urine (Box 37.1 Urinary Tract Infections Summary). In the elderly, the most common presenting symptom of UTI is generalized fatigue. The elderly may experience atypical symptoms or present with a change in cognitive functioning, especially noted in patients without dementia. A decline in mental status and fever in any patient with an indwelling catheter meets the diagnostic criteria for a UTI.

Types

Urethritis

Urethritis is inflammation of the urethra that may be due to a chemical irritant, bacterial infection, trauma, or exposure to a sexually transmitted disease. Posttraumatic urethritis can occur with intermittent catheterization or instrumentation of the urethra. Bubble bath and bath salts are common urethral irritants and should not be used by anyone with a history of UTIs. Urethritis can also be caused by spermicidal agents. Gonorrhea and chlamydiosis are sexually transmitted diseases that can cause urethritis in men. It is common to have some degree of urethritis in association with bladder or prostatic infections.

Symptoms of urethritis include urinary frequency, urgency, and dysuria. The male patient may have discharge

urethritis: urethr—urethra (canal that discharges urine from bladder) + itis—inflammation

cystitis: cyst—closed sac containing fluid + itis—inflammation

pyelonephritis: pyelo—pelvis + nephro—kidney + itis—inflammation

Box 37.1**Urinary Tract Infections Summary***Urethritis, Cystitis, Pyelonephritis*

Signs and Symptoms	Urinary urgency, frequency, dysuria Flank pain, fever, chills, costovertebral tenderness Cloudy urine with casts, bacteria, and WBCs Urine is positive for nitrites
Diagnostic Tests	Urinalysis culture greater than 100,000 bacteria Elevated WBCs Elevated sedimentation rate Increased neutrophils
Therapeutic Interventions	Antibiotic therapy sensitive to organism cultured from urine
Complications	Pyelonephritis Urosepsis Renal failure
Possible Nursing Diagnosis	Pain Impaired urinary elimination: frequency Ineffective health maintenance

from the penis. A urinalysis or urine culture is done to diagnose urethritis.

The treatment of urethritis is removal of the cause if the cause is a chemical irritant. If urethritis is caused by bacteria, an antibiotic is prescribed based on the results of a culture. Possible organisms include gram-negative rods, gram-positive cocci, and *Chlamydia*. Phenazopyridine (Pyridium), a urinary analgesic, is often used to treat dysuria. The patient should be forewarned that their urine will turn orange while on phenazopyridine. If urethritis is sexually transmitted, it is important that the sexual partner also be treated.

Cystitis

Cystitis is inflammation and infection of the bladder wall. It can be caused by bacteria, viruses, fungi, or parasites. Fungal infections can occur during long-term antibiotic therapy. About 90% of UTIs are caused by *Escherichia coli*. In most cases, the causative organisms first grow in the perineal area and then ascend into the bladder. Catheters are the most common predisposing factor for UTIs in the hospital setting.

Symptoms include dysuria, frequency, urgency, and cloudy urine. Cystitis infection acquired outside the hospital is diagnosed with a routine urinalysis collected as a clean-catch midstream specimen. Changes seen in the urinalysis include cloudy urine and the presence of WBCs, bacteria, and sometimes red blood cells (RBCs) in the specimen.

Nitrites are usually positive. Some laboratories also examine for leukocyte esterase, which is positive if infection is present in the urine. In complicated UTIs, such as one acquired in the hospital or a repeat infection, a urine culture and sensitivity should be done. Hospital-acquired UTIs are often caused by bacteria that are resistant to the usual antibiotics used for UTIs. A sensitivity test can identify which antibiotics will be effective against the offending organism.

The treatment of uncomplicated cystitis is most often a combination of sulfa medication, such as sulfamethoxazole and trimethoprim (Bactrim, Septra). Complicated cystitis is often treated with ciprofloxacin (Cipro). Other antibiotics may be prescribed depending on the results of the urine culture and sensitivity. Estrogen used as an intravaginal cream may prevent recurrent UTIs in postmenopausal women. The patient is told to finish all prescribed medications, force fluids unless contraindicated, and return for a follow-up urinalysis or culture after the antibiotic course is complete to ensure that the infection is gone.

Pyelonephritis

PATHOPHYSIOLOGY. Pyelonephritis is infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Pyelonephritis usually begins with colonization and infection of the lower urinary tract by means of the ascending urethral route. A preexisting condition is usually present such as obstruction, strictures, stones, or vesicoureteral reflux. Risk factors include urological surgery, lymphatic infection, urinary stasis, and decreased immunity. Acute pyelonephritis begins in the renal medulla and spreads to the adjacent cortex. Pathophysiology includes formation of small abscesses throughout the kidney and gross enlargement of the kidney. On occasion, kidney infection is caused by bacteria spreading from a distant site through the bloodstream and entering the kidney through the glomerulus. Urosepsis is a systemic infection arising from a source within the urinary system. Prompt diagnosis and treatment is essential to prevent septic shock and death. Urosepsis can occur in the elderly or persons susceptible to infection.

SIGNS AND SYMPTOMS. Symptoms include fatigue, urgency, frequency, dysuria, flank pain, fever, and chills. Costovertebral tenderness on the right or left side (tenderness posteriorly at angle where rib and vertebrae join when struck gently with heel of examiner's closed fist) is noted which is associated with renal disease. The urine is cloudy with increased WBCs, bacteria, casts, RBCs, and positive nitrites. In contrast to cystitis, the patient with pyelonephritis is much sicker and shows signs of systemic disease. In acutely ill patients, blood cultures may be obtained.

DIAGNOSTIC TESTS. Several tests are helpful to differentiate pyelonephritis from cystitis. With kidney infection, the urinalysis will show casts. Casts are microscopic particles formed in the kidney from abnormal constituents in the urine such as WBCs, RBCs, or pus. The urine specimen will have greater than 100,000 colonies of bacteria per

milliliter. The presence of casts always indicates a problem in the kidneys. The complete blood cell count (CBC) will show an elevated WBC count. There will also be an increase in sedimentation rate.

THERAPEUTIC INTERVENTIONS. Treatment of pyelonephritis includes antibiotics based on the results of the culture and sensitivity (Table 37.1). With severe gram-negative infections, the patient is hospitalized for intravenous (IV) antibiotics. The patient with acute pyelonephritis generally heals completely after treatment and has no lasting

kidney damage. Men who have recurrent UTIs require a 6-week regimen of antibiotic therapy.

COMPLICATIONS. Repeated kidney infections can result in scarring and loss of kidney function, leading to renal failure. Septicemia may occur from bacteria invading the bloodstream. When septicemia results from a urinary cause, it is called **urosepsis**. In the elderly, urosepsis can be the cause of new-onset confusion. The elderly or immuno-

urosepsis: uro—urine + sepsis—infection in the blood

TABLE 37.1 MEDICATIONS FOR URINARY TRACT INFECTIONS

Medication/Classification	Action	Route	Side Effects	Nursing Considerations
Cinoxacin (Cinobac) Urinary antiseptic	Antibacterial action in the urine, not systemic. Effective against <i>E. coli</i> , <i>Klebsiella</i> , and other gram-negative organisms.	PO	Monitor for photosensitivity, GI upset, and rash	Avoid sunlight, push fluids, may discolor urine.
Methenamine (Mandelamine)* Urinary antiseptic, anti-infective	Effective against gram-negative and gram-positive the organism <i>E. coli</i> .	PO	Nausea, vomiting, rash	Do not use with sulfa drugs because it may cause crystalluria.
Trimethoprim-sulfamethoxazole (Bactrim, Septra) Sulfonamides*	Effective against <i>E. coli</i> and <i>Pseudomonas</i> . Used for uncomplicated UTIs.	PO	Monitor for photosensitivity, GI upset, hemolytic anemia, and rash. Severe hypersensitivity* erythema multiforme or exfoliative dermatitis, sometimes called Stevens-Johnson syndrome.	Requires alkaline urine for best effectiveness. Give with large amounts of water. Contraindicated in severe renal or liver disease.
Sulfisoxazole (Gantrisin) Sulfonamide		PO	Same as above	Requires alkaline urine for best effectiveness. Give with large amounts of water. Contraindicated in severe renal or liver disease.
Ciprofloxacin (Cipro) Fluoroquinolone	Antibacterial action against <i>Pseudomonas</i> and other enterobacteria. May be given IV.	PO IV	GI upset, dry mouth, oral and vaginal fungal infections	Avoid aluminum antacids, which may hinder absorption. Avoid in pregnancy. Give with large amounts of water.
Aztreonam (Azactam) Antibiotic	Antibacterial action against <i>E. coli</i> , <i>Klebsiella</i> , <i>Serratia</i> .	PO	GI upset	Contraindicated in patients allergic to penicillins and cephalosporins or if creatinine clearance is less than 30 mL/min. Check BUN and creatinine prior to administration.
Phenazopyridine (Pyridium)* Urinary analgesic	Topical analgesic. Relieves pain urgency and frequency associated with UTI.	PO	GI upset, rash, and blue to purple skin discoloration. Nephrotoxic and hepatotoxic.	Urine color changes to red orange.* Avoid in renal insufficiency. Changes urine glucose testing.

compromised patient may develop septic shock from infection in the urinary tract that has invaded the bloodstream, which may result in death.

Nursing Process for the Patient with a Urinary Tract Infection

Assessment/Data Collection

It is important to listen to the patient's concerns about the diagnosis. The patient is asked about pain on urination, flank pain, or general symptoms of infection such as fever, chills, and malaise. The patient's usual pattern of voiding is assessed. Urinary frequency, burning, or pain on urination is noted. Assess the patient for pain in the lower abdomen, flank, or costovertebral angle. The presence of a catheter, recent instrumentation, surgery, or other predisposing factor is determined. The urine is examined for volume, color, concentration, cloudiness, blood, or foul odor. Urinalysis and culture results are examined.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to inflammation of the urethra, bladder, and other urinary structures

EXPECTED OUTCOME: The patient will report relief of pain and discomfort.

- Encourage fluids 2 to 3 L per day *to flush bacteria from urinary tract and promote renal blood flow.*
- Give antimicrobial therapy as ordered *to relieve pain and discomfort from inflammation and infection.*
- Teach patient to finish all prescribed medications *to prevent recurrent infection.*
- Give antispasmodic agents as ordered *to relieve bladder irritability and pain.*
- Administer antipyretics *to relieve fever, pain, and discomfort.*
- Encourage voiding every 3 hours *to empty the bladder and lower bacterial counts, reduce stasis, and prevent reinfection.*
- Teach to avoid cola, coffee, tea, alcohol *as they are urinary irritants.*
- Suggest cranberry juice or vitamin C 500 to 1000 mg per day *to acidify the urine to reduce bacterial growth.*
- Apply heat to suprapubic area *to relieve discomfort.*
- Empty bladder as soon as urge is felt and after sexual intercourse *to flush bacteria out of the body.*
- Avoid substances such as bubble bath and scented toilet paper, which can be irritating.
- Teach to practice good perineal hygiene, and to wipe front to back.
- Teach to wear cotton underwear *to reduce perineal moisture.*

Impaired urinary elimination: frequency, nocturia, dysuria, and incontinence

EXPECTED OUTCOME: Patient will return to previous voiding patterns.

- Monitor urinary elimination including frequency, consistency, volume, and color *to identify signs and symptoms.*
- Administer antimicrobial drugs as ordered *to eliminate symptoms exhibited by microbial growth.*
- Teach patient signs and symptoms of UTI *to monitor effectiveness of treatment and recognize symptoms of recurrence.*
- Encourage adequate fluids *to prevent infection and dehydration.*
- Women should be encouraged to void after sexual intercourse *to flush bacteria out of the urethra.*

Risk for injury related to sepsis, renal failure, kidney injury

EXPECTED OUTCOME: The patient will be free from injury due to sepsis, renal failure, or recurrent infection.

- Administer antimicrobial drugs as prescribed *to prevent recurrent infection or complications from occurring.*
- Teach symptoms of UTI *to monitor symptoms of recurrence or complications.*
- Monitor the patient for signs of bacteriuria and bacteremia such as fever, chills, recurrent pain.
- Explain need for follow-up urine culture and imaging studies *when indicated by recurrent symptoms.*
- Monitor intake and output *to ensure adequate intake and normal output.*
- Teach need for adequate fluid intake *to prevent dehydration and renal impairment.*

Evaluation

The outcomes have been met if the patient verbalizes relief of pain and discomfort, returns to previous voiding patterns, and is free from injury related to sepsis, renal failure, or recurrent infection.

CRITICAL THINKING

Mrs. Milan

■ Mrs. Milan is a 25-year-old woman who recently spent a 3-day weekend getaway with her husband. On Monday she notices that she has symptoms of dysuria, frequency, and urgency. She visits her family practitioner and is diagnosed with a UTI. She is placed on an antibiotic.

1. What do you think could have predisposed Mrs. Milan to developing a UTI?
2. What should Mrs. Milan be taught to prevent further occurrences of a UTI?
3. What urinalysis findings would you expect for Mrs. Milan?
4. What should you include in her teaching plan based on her therapeutic regimen?

Suggested answers at end of chapter.

Patient Education

It is very important that patients be advised to take all of the prescribed antibiotic until it is gone. Commonly, patients take medication for several days until they no longer have symptoms and then stop. Stopping the antibiotic too early allows the infection to continue. It may become chronic and resistant to antibiotics as a result.

Patients who have one UTI commonly develop repeat infections. It is important that they receive health teaching to prevent repeated infections of the urinary tract (Box 37.2 Patient Teaching to Prevent Urinary Tract Infection and Box 37.3 Nutrition Notes).

UROLOGICAL OBSTRUCTIONS

Obstruction of urine flow in the urinary tract is always a significant problem. Urinary tract obstruction is an interference with the flow of urine at any location along the urinary system. The obstruction of urine flow causes dilation and thinning of the renal tubules with eventual atrophy of renal tissues. When urine does not drain normally from the kidney, local compensation occurs initially. The area decompresses and damage occurs moving the pressure along the continuum of the renal system. The resulting backup of urine and pressure causes dilation and thinning of renal tissue. Renal blood flow is compromised. Eventually renal tissue is destroyed by the compression. The causes of urological obstructions include strictures, stones, and tumors.

Box 37.2

Patient Teaching to Prevent Urinary Tract Infection

1. Void frequently—at least every 3 hours while awake.
2. Drink up to 3000 mL of fluid a day if there are no fluid restrictions from the physician. Preferably drink water.
3. Drink one glass of cranberry juice (10 oz) per day.
4. Take showers; avoid tub baths.
5. Wipe perineum from the front to the back after toileting.
6. Urinate after sexual intercourse.
7. Avoid bubble bath and bath salts, perfumed feminine hygiene products, synthetic underwear, and constricting clothing such as tight jeans.
8. Take prescribed medication for UTIs until it is all gone.
9. If UTI is associated with another source of infection such as vaginitis or prostatitis, ensure that both infections are treated.

Box 37.3

Nutrition Notes

Urinary Tract Infections

An effective intervention for urinary tract infections is increasing fluid intake both for its flushing effect and to excrete urinary drugs. Instructions to increase fluid intake should specify amounts to consume or amount of urine resulting. Patients have developed electrolyte imbalances by overenthusiastically forcing fluids.

Verifying anecdotal evidence of the effect of cranberry juice in preventing urinary tract infections, certain compounds have been identified in cranberries that prevent *E. coli* from adhering to cells in the urinary tract. Cranberry juice has been useful in preventing urinary tract infections and daily intake of 8 to 16 oz of cranberry juice (at least 30% concentration) is recommended for patients with indwelling catheters to prevent UTI.

Urethral Strictures

A urethral stricture is a narrowing of the lumen of the urethra caused by scar tissue. Urethral strictures are becoming more prevalent due to the rising incidence of sexually transmissible diseases. Increasingly in young adults, gonococcal and chlamydial infections may result in urethral strictures. Most strictures are acquired from injury or infection. Strictures from urethral injury tend to be localized to the area where the injury occurred. Some strictures are a result of trauma from insertion of catheters or surgical instruments. Strictures may also be caused by trauma from straddle injuries, a result of direct application of force to the perineal area, as well as untreated gonorrhea and congenital abnormalities.

The patient with a urethral stricture has a diminished urinary stream and is prone to develop UTIs because of obstruction of urine flow. Urethral strictures are often seen in elderly men. The problem becomes more apparent when attempts to insert a urinary catheter are unsuccessful because of the narrowed lumen.

Initially the treatment of a urethral stricture is mechanical dilation by a urologist, who inserts instruments to stretch open the urethra and then inserts a urinary catheter. If the stricture continues to be a problem after dilation, the area can be surgically repaired (**urethroplasty**).

The dilation process is often done at the bedside when the patient is awake. This is a painful experience for the patient, and it is helpful and caring to encourage the urologist to order pain medication before the procedure. The nursing diagnosis of acute pain is very relevant. An indwelling catheter is generally inserted after the dilation, so the nursing diagnosis of risk for infection is also present. Patients need teaching about how to prevent UTIs (see Box 37.2 Patient Teaching to Prevent Urinary Tract Infection).

urethroplasty: urethro—urethra + plasty—surgical repair

FIGURE 37.1 Location of calculi in the urinary tract.

Renal Calculi

Renal **calculi** (kidney stones; one stone is a calculus) are hard, generally small stones that form somewhere in the renal structures. The stones are masses of crystals and protein that form when the urine becomes supersaturated with a salt capable of forming solid crystals. Symptoms occur when the stones become impacted in the urinary tract. When stones are found in the kidneys, the condition is called nephrolithiasis (Fig. 37.1).

Pathophysiology

Normally, the dissolved substances in urine, including urinary salts, are diluted and readily excreted from the body. Calculi are formed when urinary salts are concentrated enough to settle out; there is often a nucleus around which the salts collect and deposit. Substances that can serve as a nucleus include pus, blood, dead tissue, a catheter, and crystals. Stones usually grow on the papillae or in the renal tubules, calyces, or renal pelvis. Stones may also form in the ureter or bladder. Stones less than 5 mm are readily passed in the urine. The following are common urinary salts that make up renal calculi, which are arranged in order of frequency:

1. Calcium oxalate
2. Calcium phosphate
3. Magnesium ammonia
4. Uric acid
5. Cystine

The majority of renal calculi contain calcium, either in the form of calcium oxalate or calcium phosphate, but it is also possible to have combination stones (Table 37.2).

Etiology

Causes of calculi formation include a family history of stones, chronic dehydration (causing more concentrated urinary salts), and infection, because the latter provides a nucleus for stone formation (Table 37.3). Additional causes of calcium stones include dietary factors (Box 37.4 Nutrition Notes). Excessive amounts of calcium in the water in some geographical areas may also be a factor. Immobility causes stone formation because of the resulting urinary stasis; in addition, calcium leaves the unstressed bones during immobility, so more calcium is in the blood, which is then filtered through the kidneys. Stones are more common in men than women. The risk peaks between the ages of 30 and 50.

Signs and Symptoms

Symptoms of renal calculi include excruciating flank pain and renal colic; when the stone is lodged in the ureter, it is common to have pain radiate down to the genitalia. The pain results when the stone prevents urine from draining. Additional symptoms include hematuria from irritation by the stone, dysuria, frequency, urgency, and enuresis. The patient may also have costovertebral tenderness. Some patients develop nausea, vomiting, and diarrhea because of the proximity of the gastrointestinal structures (Box 37.5 Renal Calculi Summary).

Diagnostic Tests

The diagnosis of renal calculi may be made initially by doing a kidney-ureter-bladder (KUB; flat plate of the abdomen) examination or an intravenous pyelogram. Both of these tests will identify the anatomical location of the stone. Renal ultrasound may be done to identify a stone in the renal pelvis, calyx, or ureter. Urinalysis may indicate gross or microscopic hematuria and could indicate abrasion of the urinary tract. The presence of crystals or urinary pH may indicate calculus type.

Therapeutic Interventions

Renal calculi are treated medically if possible. Most stones are flushed out of the body during urination. Patients can pass stones in the urine if they are 5 mm or smaller; larger stones do not pass. If patients experience severe renal colic, they are admitted to the hospital. Intravenous fluids are administered to hydrate the patient and help flush the stone out of the body. All urine is strained to detect passage of stones, and pain medication such as morphine is given. If the patient is unable to pass the stone and infection, impaired renal function, or severe pain continues, intervention is needed. The solubility of stone-forming substances can be changed by altering the pH of the urine. Calcium stones may be treated with thiazide diuretics and allopurinol (Alloprim, Zyloprim). Surgical removal may be required for large stones, obstructions, or intractable pain.

LITHOTRIPSY. Lithotripsy therapy is the use of sound, laser, or dry shock-wave energies to break the stone into small fragments. The stones can then be removed or urinated out. Forms of lithotripsy include extracorporeal shock-wave lithotripsy (ESWL), electrohydraulic lithotripsy, laser

TABLE 37.2 OVERVIEW OF RENAL CALCULI

Type of Stone	Features	Possible Causes	Interventions
Calcium oxalate, calcium phosphate, or mixture	Accounts for two-thirds of stones Small, rough, and hard Shaped like needles Colors vary from gray to white	Excessive calcium Excessive urea Hyperparathyroidism, Cushing disease, immobility, osteolysis from tumors of the breast, lung	Force fluids Restrict protein and sodium in the diet Administer hydrochlorothiazide Treat hyperparathyroidism (Calcibind) cellulose sodium phosphate may prevent calcium stones by binding calcium from food in the GI system
Struvite—magnesium ammonium phosphate	Second most common type of stone Calculi crumble easily Stones have a yellow color Dye enhancement needed for x-ray visualization	Infection by urea splitting microbes, usually <i>Proteus</i> . May cause abscess formation in the kidney.	Force fluids Decrease urine pH Administer antibiotics
Uric acid stones	Dye enhancement needed for x-ray visualization Small Color varies from yellow to red Hard	Gout High uric acid levels Decreased fluid intake	Force fluids Administer sodium citrate to alkalinize urine Administer allopurinol to reduce urinary uric acid levels Low-purine diet. Avoid shellfish, anchovies, asparagus, organ meats, and mushrooms.
Cystine stones	Small, smooth calculi Smooth, waxy stones	Cystine-containing crystals appear in the urine	Force fluids Low-protein diet, urine is alkalinized Penicillamine given to decrease amount of cystine in urine
Triamterene	Type of stone recently identified	Triamterene ingestion	Withhold triamterene (Dyrenium) from at-risk patients.

lithotripsy, and percutaneous ultrasonic lithotripsy. With ESWL, the patient is immersed in a tub of water and ultrasonic shock waves are used to break up the stone into sand particles (Fig. 37.2), which are then urinated out. The

TABLE 37.3 MEDICATIONS AFFECTING STONE FORMATION

Acetazolamide (Diamox)	Decreases urinary citrates and increases uric acid concentration in urine.
Adrenocorticosteroids	Increases urinary calcium.
Allopurinol	Used to prevent uric acid calculi. May cause the rarer xanthine calculi.
Antacids such as magnesium trisilicate (Gaviscon)	May cause rare silicon based calculi. Phosphate finding nonabsorbable antacids can increase urinary calcium.
Aspirin	Increases urinary uric acid levels in patients with hyperuricemia.
Chemotherapeutic agents and external radiation	May cause cellular breakdown and cause acute hyperuricemia.
Hydrochlorothiazide (used to prevent calcium calculi)	May cause uric acid calculi by increasing urinary uric acid levels.
Furosemide (Lasix)	May cause hyperuricemia.
Vitamin C in large doses	Increases oxalate excretion in urine.
Vitamin D	Increases calcium and oxalate excretion in urine.

patient is anesthetized for the procedure. Some of the newer lithotripters do not require submersion and use other means of initiating shock waves. After the procedure, the patient is usually discharged home after being told to increase fluid intake to help flush the sand particles out and to notify the urologist if there are any problems. Blood in the urine is common after lithotripsy. The patient is told to strain all urine to identify passage of stone fragments. Occasionally, a stent is put in place to facilitate the passage of the stone fragments.

SURGERY FOR RENAL CALCULI. For some patients, surgery may be necessary. The surgical procedure depends on the location of the stone. With any of these surgical procedures, postprocedure bleeding is a concern. Endoscopic procedures or open surgery can be used. Endoscopic procedures for the bladder include a cystoscopy for small stones and a cystolitholapaxy for larger stones. For cystolitholapaxy, an instrument is inserted through the urethra to the bladder to crush the stone; the stone is then washed out with an irrigating solution. If the stone is lodged in a ureter, the urologist may insert an instrument into the ureter through a cystoscope to crush the stone or use an ultrasonic lithotripsy instrument to break the stone into fragments. Postoperative care following these procedures is similar to care following any cystoscopy (see Chapter 36). The open surgery procedure for stones in the bladder is a cystotomy and for the ureter is a ureterolithotomy.

Box 37.4

Nutrition Notes

Renal Calculi

Concentrated urine enhances the formation of crystals so sufficient fluid should be consumed to produce 2000 mL of urine per day. About 3000 mL or 13 cups of water per day are necessary to produce this amount of urine.

Approximately 80% of kidney stones are composed of calcium oxalate, which led to early prescriptions for low-calcium diets, but it was later found that a high-calcium intake binds dietary oxalate in the gastrointestinal tract and prevents its absorption, thereby reducing urinary oxalate formation. If a low-oxalate diet is prescribed, foods such as beets, rhubarb, spinach, cocoa, and instant coffee may be restricted.

Uric acid kidney stones can be a complication of gout, which is a disorder of purine metabolism. Purines are endproducts of digestion of certain proteins and are present in some medications. High-purine foods include organ meats, anchovies, herring, sardines in oil, meat extracts, consommé, and gravies. Low-purine foods include fruits, milk, cheese, eggs, refined grains, sugars, coffee, tea, carbonated beverages, tapioca, yeast, and vegetables (except asparagus, beans, cauliflower, mushrooms, peas, and spinach).

For kidney stones, a percutaneous **nephrolithotomy** is performed, in which a scope is inserted through the skin into the kidney to aid in breaking up the stone and to irrigate the renal pelvis. Often a nephrostomy tube is left in place at first to prevent the stone fragments from passing through the urinary system. If the stone is very large, it may be necessary to do a nephrolithotomy, which is a surgical incision into the kidney to remove the stone. A pyelolithotomy is done to remove stones lodged in the renal pelvis.

Prevention of Renal Calculi

The patient may be advised to avoid foods that increase the risk of recurrent calculus development. Box 37.4 (Nutrition Notes) discusses foods that may contribute to calculi (see also Box 37.6 Cultural Considerations). Encourage fluid intake to prevent dehydration. Consult with the physician and dietitian to determine which foods should be avoided, depending on the type of stone found. Encourage the patient to walk, which promotes the excretion of stones and reduces bone calcium resorption (release).

Complications of Renal Calculi

The presence of renal calculi increases the risk for UTIs because of obstruction of the free flow of urine. Untreated obstruction of a stone in a ureter or the urethra can also

nephrolithotomy: nephro—kidney + lith—stone + otomy—incision

Box 37.5

Renal Calculi Summary

Signs and Symptoms

Costovertebral angle pain
Groin pain
Renal colic
Flank pain radiating to genitalia
Hematuria
Anuria
Restlessness
Pallor
Temperature
Diminished or absent bowel sounds with ileus

Diagnostic Tests

Urinalysis
Crystals and urine pH
24-hour renal creatinine clearance
BUN
Creatinine
KUB—reveals most calculi
Retrograde pyelography
Ultrasound

Therapeutic Interventions

Treat pain to prevent shock
Chemolysis—stone dissolution using infusions of chemicals to dissolve stone
Surgery—lithotripsy
Nephrolithotomy
Pyelolithotomy
Percutaneous nephrostomy tube

Complications

Shock
Sepsis
Hydronephrosis
Hydroureter
Renal failure

Possible Nursing Diagnosis

Acute pain related to calculi
Risk for infection related to obstructed urinary flow and instrumentation
Deficient knowledge related to lack of knowledge about renal calculi

result in retention of urine and damage to the kidney. This process is called **hydronephrosis** (discussed later).

Nursing Process for the Patient with Renal Calculi

ASSESSMENT/DATA COLLECTION. Patients with stones are often in extreme pain and should be monitored routinely

hydronephrosis: hydro—pertaining to water + nephrosis—degenerative change in kidney

FIGURE 37.2 Extracorporeal shock-wave lithotripsy.

for pain. A health history may identify a family history or patient history of previous stone formation. People who have had stones usually have a recurrence. Also, patients over 60 years of age should be ruled out for abdominal aneurysms. Renal colic usually begins suddenly, progresses rapidly, and peaks over a 30-minute period. Flank pain may radiate to the genitalia. Diminished or absent bowel sounds may progress to an ileus. The patient may also be restless, pale, and lightheaded. Nursing care of a patient with a renal calculus always involves careful measurement of intake and output and observation of the urine for abnormalities such as hematuria, pyuria, or passage of a stone. Obstruction may occur at the bladder neck or urethra. With obstruction, **anuria** or **oliguria** is noted. This is an emergency and must be treated immediately to preserve kidney function. Temperature is monitored for onset of fever, which would indicate infection. Blood pressure may decrease if severe pain causes shock. A special strainer is used to strain all urine for stones. If a stone is found, it is saved for analysis in the laboratory. The patient is also asked about a recent history of infection, dietary or activity changes, or other risk factors for renal

anuria: an—without + uria—urine

oliguria: olig—small + uria—urine

Box 37.6

Cultural Considerations

Recurrent Calculus Development

Filipino immigrants are at high risk for developing renal stones, hyperuricemia, and gout. A shift from a traditional Filipino diet to a U.S. diet increases the occurrence of hyperuricemia, with some older Filipinos developing gout. The nurse may need to assist Filipino patients to identify food choices that will help prevent these conditions.

calculi. If the cause can be identified, teaching can be done to help prevent recurrent calculi.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Acute pain related to the presence of, obstruction, or movement of a stone within the urinary system

EXPECTED OUTCOME: Patient verbalizes the relief of pain or ability to tolerate pain.

- Ask severity, location, and duration of pain using pain scale. *Pain is typically in the flank or costovertebral angle and may radiate to the pelvic, groin, or abdominal area.*
- Monitor patency of drains, and catheters in preoperative and postoperative patients. *Obstruction of urine flow will increase and intensify pain.*
- Encourage fluid intake unless contraindicated to promote the passage of stone, dilute the urine, and reduce the risk of further stone formation.
- Administer pain medication as ordered to promote comfort.
- Apply heat to flank area to reduce pain and promote comfort.
- Monitor vital signs and blood pressure; observe for bleeding in preoperative and postoperative patients. *Abnormalities may indicate an infection.*
- Strain urine through gauze or strainer to identify any stones that may have been passed.
- Monitor urine amount, color, clarity, and odor to ensure patency of urinary system or tubes. *Foul smelling or cloudy urine may indicate an infection.*
- Ambulate if possible to facilitate the passage of the stone through the urinary system.

Risk for infection related to the introduction of bacteria from obstructed urinary flow and instrumentation

EXPECTED OUTCOME: Patient will remain infection free.

- Monitor urine amount, color, clarity, and odor to

ensure patency of urinary system or tubes. Foul smelling or cloudy urine may indicate an infection.

- Assess for elevation in temperature, chills, cloudy, foul-smelling urine as indicators of infection.
- Encourage fluids to flush bacteria and stones, and prevent further stone formation.

Deficient knowledge related to lack of knowledge about prevention of recurrence, diet, and symptoms of renal calculi

EXPECTED OUTCOME: Patient will verbalize an understanding of the factors related to the recurrence of renal calculi, infection, and treatment options.

- Monitor for recurrence of renal stones. *Recurrence may indicate knowledge deficit.*
- Note family history of renal stones. *Stones have a higher incidence in patients with a positive family history.*
- Determine the relationship between activity and stones. *Sedentary lifestyle or limited mobility may increase risk of stone formation.*
- Ask the patient's understanding of possible courses of therapy to treat renal stones.
- Teach the patient the importance of maintaining a fluid balance of 3000 mL per day. *Low-solute urine prevents stasis and stone formation.*
- Teach patient about medications used to prevent recurrence of renal stones.
 - *Diuretic agents (thiazide type) increase tubular reabsorption of calcium, making it less available for calculi formation in the urinary tract.*
 - *Allopurinol (Zyloprim) reduces uric acid production.*
 - *Antibiotics are used to prevent chronic urinary tract infections which may precede renal calculus formation.*

- As applicable, teach patient about management of stones. *Most stones pass spontaneously. There may be pain, nausea, and vomiting. Management consists of fluids, pain management, and antibiotics. Mechanical interventions with percutaneous catheters and nephroscopic procedures or surgery can be used to eliminate stones.*
- Teach patient to strain all urine. *Stone fragments may continue to pass for weeks after stone crushing or lithotripsy.*
- Teach patient to report signs of infection, pain not relieved by medication, nausea, chills, or the appearance of foul-smelling urine *for treatment.*

EVALUATION. Outcomes have been achieved if the patient remains comfortable, free from infection, and gains understanding about prevention of the reoccurrence of renal stones.

Hydronephrosis

Hydronephrosis is a condition that results from untreated obstruction in the urinary tract. The kidney enlarges as urine collects in the pelvis and kidney tissue. It is usually treatable once the condition is detected. The obstruction of urine flow can be from a stricture in a ureter or the urethra, from kidney stones, from a tumor, or from an enlarged prostate. Because of the unrelieved obstruction, urine backs up and distends the ureters and then progresses to the kidney (Fig. 37.3). The capacity of the renal pelvis is normally 5 to 8 mL. Obstruction in the pelvis quickly distends the renal pelvis. Kidney pressure increases as the volume of urine increases. This enlargement of the kidney can be either unilateral or bilateral. The unrelieved pressure on the kidneys from the urine causes the kidneys to become sacs filled with urine instead of functioning kidneys. Sometimes, in a matter of hours, the blood vessels and renal tubules can be damaged extensively.

FIGURE 37.3 Hydronephrosis. Progressive thickening of bladder wall and dilation of ureters and kidneys results from obstruction of urine flow.

If the onset of obstruction is gradual, the patient initially may be asymptomatic. Patients often develop UTIs because of the obstruction of urine flow and may have symptoms of frequency, urgency, and dysuria. As the disease progresses, flank and back pain may occur. Eventually the patient develops symptoms of renal failure (discussed later).

The treatment of hydronephrosis always involves relieving the obstruction. Initial removal of the obstruction may be done by insertion of an indwelling urinary catheter. Long-term correction of the obstruction depends on the cause and includes treatments and surgeries to relieve obstruction from strictures, stones, tumor, or an enlarged prostate. At times, the obstruction cannot be relieved because a stone is too large or removal of tumor growth would result in death of the patient. In these situations, **stents**, which are tiny tubes, may be placed inside the ureters during a cystoscopy and pyelogram (C&P) to hold them open or a **nephrostomy** tube may be inserted directly into the kidney pelvis to drain urine. A nephrostomy tube exits through an incision in the flank area and allows urine to drain into a collecting bag, so that function of the kidney can be maintained. Figure 37.4 shows a stent in place in a ureter and a nephrostomy tube.

Complications associated with hydronephrosis include increased incidence of UTIs because of obstruction of urine flow and kidney failure from unrelieved pressure on the kidneys.

Intake and output are carefully measured. Urine retention can worsen the condition and must be recognized and reported promptly. If the patient has a nephrostomy tube, ensure that it is draining adequately and prevent kinking or clamping of the tube. Kinking of the tube results in continuation of the hydronephrosis, and the resulting pressure will destroy kidney function. If both a nephrostomy tube and urinary catheter are present, output from each should be measured and documented separately.

TUMORS OF THE RENAL SYSTEM

Cancer of the Bladder

Cancer of the bladder is the most common kind of cancer of the urinary tract. It is more commonly seen in men ages 50 to 70. Bladder cancer is twice as common in men as in women. Bladder cancer is rare in men and women younger than 40 years of age. It is more common in whites than in African Americans.

Etiology

There is a strong correlation between cigarette smoking and bladder cancer. Specific chemicals that cause bladder cancer have been found in cigarette smoke. The more cigarettes smoked, the greater the risk. The lung absorbs the chemicals

nephrostomy: nephr—pertaining to the kidney + ostomy—surgically formed artificial opening to the outside

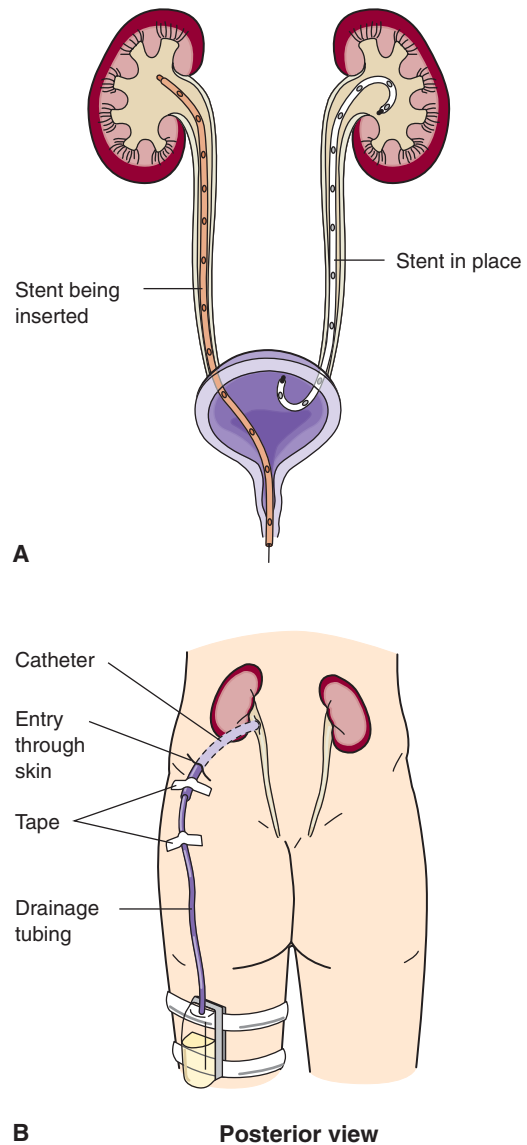

FIGURE 37.4 (A) Ureteral stents. (B) Nephrostomy tube inserted into renal pelvis; catheter exits through an incision on flank.

from tobacco. These chemicals are then passed via the bloodstream to the kidneys and collected in the urine. These chemicals accumulate in the urine and damage the cells that line the bladder. Exposure to industrial pollution such as aniline dyes, benzidine and naphthylamine, leather finishings, metal machinery, and petroleum processing products also increases the incidence. It can take about 25 years after exposure to chemicals for bladder cancer to develop. Cancer may also arise from the prostate, colon, and rectum in males and the lower reproductive tract in women. Bladder cancer is often diagnosed at a later stage in women.

Pathophysiology

Cancer of the bladder often starts as a benign growth on the bladder wall that undergoes cancerous changes. Most bladder cancers begin in the inner lining of the bladder called the urothelium. The cancers are called transition cell cancers.

They come in a variety of forms and can behave in different ways. Some occur as small wartlike growths on the inside of the bladder. Others form large tumors that grow into the muscle wall of the bladder and require surgical removal. If the bladder cancer affects only the inner lining of the bladder, it is known as a superficial cancer. If the cancer has spread to the muscle wall, it is called an invasive cancer. Common sites for metastasis include the liver, bones, and lungs.

Signs and Symptoms

Cancer of the bladder usually causes painless hematuria. The patient may notice that the urine is darker or more reddish in color than usual. Blood in the urine is one of the seven warning signs of cancer from the American Cancer Society. Initially the bleeding is intermittent, which often causes the patient to delay seeking treatment. As the disease progresses, the patient experiences frank hematuria, bladder irritability, urinary retention from clots obstructing the urethra, and fistula formation (an opening between the bladder and an adjoining structure such as the vagina or bowel). Other common signs and symptoms of bladder cancer include pelvic pain, pain in the lower back, painful urination, changes in bladder habits, and inability to void.

Diagnostic Tests

Routine urinalysis can detect signs of bladder cancer. A urine test for the enzyme telomerase has been found to be 90% accurate in detecting bladder cancer in early and late stages. Urine for cytology can be obtained to determine if cancer cells are present in the urine. Urine culture should also be done. Symptoms of bladder infection may be similar to those that accompany bladder cancer. Diagnosis of cancer of the bladder may also be made with a cystoscopy and transurethral biopsy. An intravenous pyelogram (IVP) may also be done.

Therapeutic Interventions

Treatment depends on the kind of bladder cancer and the severity. For small, confined tumors, chemotherapeutic agents are instilled into the bladder through a urinary catheter, allowed to dwell, and then removed along with the catheter. Systemic chemotherapy is also used and can be helpful to prolong life when other treatments are no longer indicated. The bacille Calmette-Guérin (BCG) vaccine may be instilled into the bladder to prevent recurring tumors.

Photodynamic therapy in which drugs are given that make tumors sensitive to light may be used. When light is applied to the tumor area, cancer cells are killed.

Surgical treatment of cancer of the bladder includes a number of procedures. A cystoscopy and pyelogram with fulguration (destruction of tissue with electrical current) may be done to burn off cancerous tissue. An alternate method is use of a laser to destroy tumor tissue. Advances in surgical techniques involve robotic and laparoscopic techniques. If the bladder requires removal, then robotic laparoscopic radical cystectomy with urinary diversion is an option. In this robotic procedure, surgical robotic equipment, which imitates surgical movements guided by the

surgeon, allows more precision, steadiness, and maneuverability, as well as the use of small openings rather than larger incisions into the abdomen. Recovery time is reduced as a result.

INCONTINENT URINARY DIVERSION. If it has been determined that the patient has a potentially curable disease with significant bladder involvement, complete removal of the bladder and creation of a urinary diversion may be done. A urinary diversion means that urine leaves the body in a different manner. A common incontinent surgery for urinary diversion is called an ileal conduit, an involved surgery in which a 6- to 8-inch section of the ileum or colon is removed and used as a conduit for urine. The remaining portions of the bowel are stitched back together. The surgeon is careful to keep the blood and neurological supply intact to the section of bowel that has been removed. The isolated section of bowel is closed off on one end, the ureters are stitched into it, and the other end is brought out as a stoma on the abdomen that almost continuously drains urine (Fig. 37.5). The urine from an ileal conduit contains mucus because it comes through the ileum, which normally secretes mucus. The patient must wear an ostomy appliance at all times over the stoma to collect urine. Box 37.7 (Application of a Disposable Pouch to an Ileal Conduit) explains how to apply an appliance to an ileal conduit stoma.

CONTINENT URINARY DIVERSION. Continent urinary diversion surgeries are being done for patient convenience. One version is the Kock pouch (continent internal ileal reservoir), which is created from a segment of ileum that has been made into a reservoir for urine (see Fig. 37.5). The ureters are implanted into the side of the reservoir. A special nipple valve is constructed and is the passageway through which the patient inserts a catheter at 4- to 6-hour intervals to drain urine. Another type of this surgery is the Indiana pouch (see Fig. 37.5). A reservoir is created using a portion of the ascending colon and terminal ileum, making a larger pouch than the Kock pouch. Additional versions of this type of surgery use other parts of the bowel and include the Mainz pouch or Florida pouch.

ORTHOTOPIC BLADDER SUBSTITUTION. The newest surgery is formation of an orthotopic bladder using a section of the intestines to make a neobladder (*neo* = new) and implanting both the ureters and the urethra into the neobladder. Various types of orthotopic bladder substitution surgery include the Studer pouch, hemi-Kock pouch, and ileal W-neobladder. After this surgery, the patient can void through the urethra, although incontinence may be a problem and intermittent catheterization may be needed.

Nursing Management

Nursing care of the postoperative patient is similar to care following any major surgical procedure. (See Chapter 11.) Specific postoperative care should be aimed at preventing complications of shock, atelectasis, deep vein thrombosis, and paralytic ileus. It is important to ensure that there is ade-

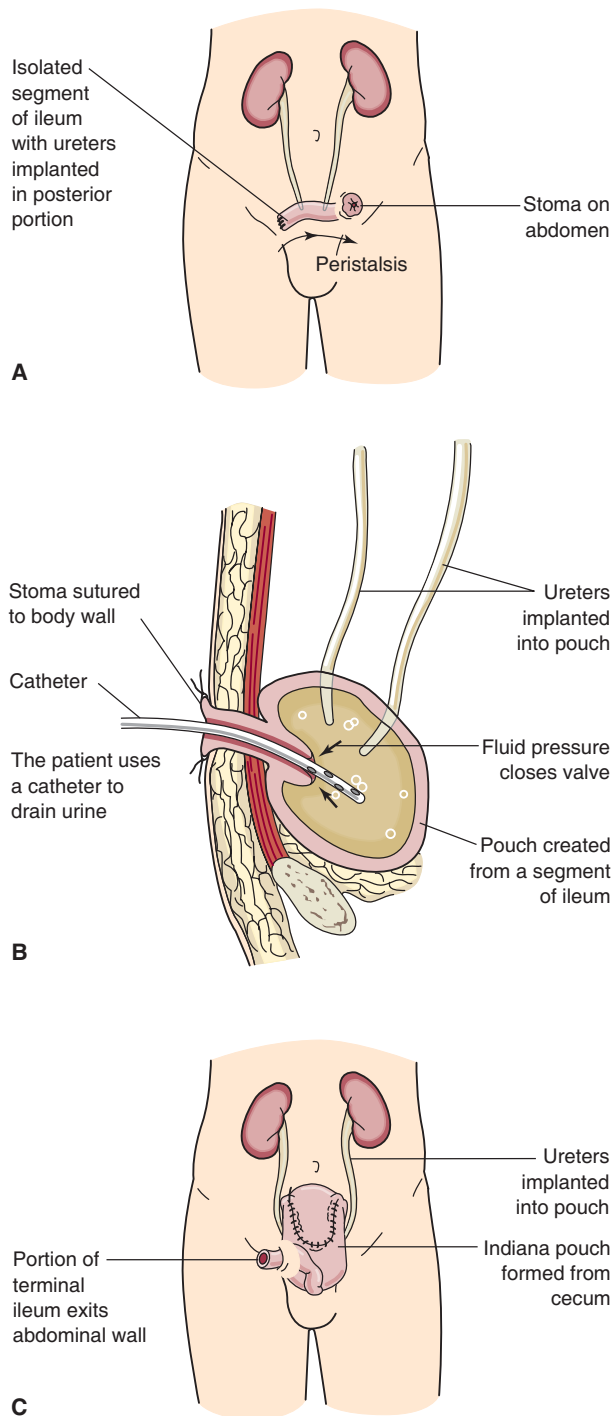

FIGURE 37.5 Urinary diversion surgery. (A) Ileal conduit. (B) Kock pouch. (C) Indiana pouch.

quate urinary output and to detect and report any obstruction of urine drainage early to prevent complications. The skin around the stoma will require special care to prevent skin breakdown. The patient needs to be taught how to care for the urinary diversion after surgery, either by frequent draining with a catheter or by wearing an appliance. Be sensitive to the patient's anxiety about caring for the urinary diversion. Body image disturbance may occur because of the change in body function. A consultation with a nurse

Box 37.7

Application of a Disposable Pouch to an Ileal Conduit

1. Gather all supplies: a washcloth and towels and water, a pouch to apply with a stomahesive flange, and wicks such as gauze to absorb continually flowing urine. Wear clean gloves.
2. Empty the old pouch.
3. Gently remove soiled pouch by pushing down on skin while lifting up on the flange. Discard soiled pouch and flange.
4. Place a towel around the stoma to catch urine.
5. Cut an opening in the flange that is only 1/16 to 1/8 inch larger than the stoma. Once stomal shrinkage is complete, a presized pouch can be used that fits the stoma.
6. Remove paper backing from the stomahesive and set the flange to one side.
7. Clean the skin around the stoma with water. Pat dry. Immediately wrap the stoma in wicks to absorb urine. Otherwise urine will leak onto the skin, and the flange will not adhere.
8. Center the flange over the stoma, remove the wick, and immediately apply the flange. Then snap the pouch onto the flange. **NOTE:** The flange and pouch may be snapped together before application to the stoma.
9. Use the heat of your hand to compress the flange to ensure a good seal.
10. Ensure that the bottom of the pouch is closed off, or connect to a urinary catheter bag at night or if patient is in bed most of the time.

who specializes in wound, ostomy, and continence care (WOC nurse, or sometimes referred to as an enterostomal therapy nurse, which was the original name for this specialty) or an ostomy support group may be helpful both before and after surgery.

Cancer of the Kidney

Pathophysiology and Etiology

Cancer of the kidney is rare but serious. Kidney cancer accounts for 3% of all adult malignancies. Risk factors include smoking, obesity, hypertension, years of kidney dialysis, radiation exposure, asbestos, and exposure to industrial pollution. Most patients are between 50 and 70 years of age. During the last 30 years there has been an increased incidence in renal cell cancer, with an increase of 43% since 1973. This is probably due to the use of CT scans and ultrasound evaluation of the abdomen. More than 50% of tumors are found incidentally. Males have twice the incidence of females. Often the cancer has metastasized before it is diagnosed because the kidney has such a large volume of circu-

lating blood, which increases the risk for spread of the tumor. In addition, there are few early symptoms of the disease.

Signs and Symptoms

The three classic symptoms of kidney cancer are hematuria, dull pain in the flank area, and a mass in the area. Often symptoms of kidney cancer do not occur until there is invasion of the surrounding tissue by the tumor. Less specific symptoms include fever, weight loss, night sweats, hypertension, anemia, polycythemia, swelling in the legs, fatigue, anorexia, and constipation. Symptoms of metastasis may be the first manifestation of kidney cancer and include weight loss, cough, bone fractures, liver abnormalities, and increasing weakness.

Diagnostic Tests

A number of diagnostic tests will be done, including an IVP, cystoscopy and pyelogram, ultrasound examination of the kidneys, computed tomographic (CT) scans of the abdomen, and magnetic resonance imaging (MRI). A definitive diagnosis is made with a renal biopsy.

Therapeutic Interventions

Surgery is the commonly used treatment for cancer of the kidney. A radical **nephrectomy** removes the entire kidney along with the adrenal gland and other surrounding structures, including fascia, fat, and lymph nodes, in the area. Radiation therapy, immunotherapy, or chemotherapy may be used following the surgery. Newer surgical techniques allow nephron sparing surgery in which only the tumor is removed and the healthy part of the kidney is saved.

Nursing Management

Nursing care of the nephrectomy patient is similar to postoperative care following any major surgery. (See Chapter 11.) Because the kidney is highly vascular, it is essential that the nurse observe for onset of bleeding and any signs of hypovolemic shock. Urine output is monitored. Changes in urine amount or color, bleeding, and signs of infection are reported. The patient should be assessed for shortness of breath or diminished breath sounds on the affected side. Surgically induced or spontaneous pneumothorax may occasionally occur after a nephrectomy.

RENAL SYSTEM TRAUMA

Renal trauma is the most common injury to the urinary system. The kidneys are highly vascular and have a lot of mobility so they are vulnerable to vascular and tissue damage. There are many causes of trauma to the kidney, ureters, and bladder, such as motor vehicle accidents, sports injuries, falls, gunshot wounds, and stabbing. Young males are at greatest risk for renal system trauma. Patient assessment includes a history of the injury, inspection of the abdomen and flank for asymmetry and bruising, or swelling of the

flank area. Flank pain and hematuria may be present. Diagnostic tests include urinalysis, IVP, ultrasound, CT, and MRI. Treatment depends on the extent of the injury and ranges from bedrest to surgical intervention. Nursing care includes measuring intake and output, monitoring vital signs, and providing IV fluids and pain relief.

Bladder trauma may occur with pelvic fractures and multitrauma from a blow to the lower abdomen when the bladder is full. The weakest part of the bladder wall, which is the dome located at the top of the bladder, may rupture. Urine leaks out of the peritoneal cavity and around the bowel. The patient may have symptoms of hematuria, abdominal pain, inability to void, shock, and pelvic hematoma noted on rectal examination. IVP and x-ray of the abdomen may be done. A urinary or suprapubic catheter should be in place until the bladder heals.

POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease is a hereditary disorder that can result in renal failure. The disease affects men and women equally. Polycystic kidney disease is characterized by formation of multiple cysts in the kidney that can eventually replace normal kidney structures. The cysts are grapelike and contain serous fluid, blood, or urine. The patient generally first shows signs of the disease in adulthood. The initial symptoms include a dull heaviness in the flank or lumbar region and hematuria. Other symptoms include hypertension and urinary tract infections. People with the inherited type of polycystic kidney disease may also experience aneurysms in the brain and diverticulosis in the colon. As the disease progresses, the patient develops symptoms of renal failure (discussed later). The renal cysts are usually diagnosed with ultrasound imaging. Ultrasound uses no dyes or radiation so it is safe for all patients including pregnant women. Often there is a strong family history of polycystic kidney disease.

There is no treatment to stop the progression of polycystic kidney disease. Complications such as urinary tract infections are treated as needed. Headaches that are severe due to hypertension or seem to feel different might be caused by aneurysms in the brain. The patient should see a physician with severe or recurring headache. As the disease progresses, treatment for hypertension and eventual renal failure may be necessary. Because polycystic disease is hereditary, patients should be counseled about the risks of children inheriting it.

CHRONIC RENAL DISEASES

Diabetic Nephropathy

Diabetic **nephropathy** is the most common cause of renal failure. It is a long-term complication of diabetes mellitus in

nephrectomy: nephro—kidney + ectomy—excision

nephropathy: nephro—pertaining to the kidney + pathy—disease

which the effects of diabetes result in damage to the small blood vessels in the kidneys. Microalbuminuria may be detected within 5 years of the onset of type 1 diabetes and 10 to 15 years after the onset of type 2 diabetes. Renal damage shows up approximately 15 to 20 years after onset of type 1 diabetes (insulin dependent), but it may also be a complication of type 2 diabetes (non-insulin dependent). Risk factors for the development of diabetic nephropathy include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Careful control of blood glucose levels reduces the risk of nephropathy in patients with diabetes.

Pathophysiology

Multiple factors contribute to diabetic nephropathy. Diabetic nephropathy begins with increased osmotic pressure due to hyperglycemia, increases diuresis and compensatory cell growth and expansion, and increases the glomerular filtration rate. Widespread atherosclerotic changes occur in the blood vessels of patients with diabetes, decreasing the blood supply to the kidney. Abnormal thickening of glomerular capillaries damages the glomerulus, allowing protein to leak into the urine. Patients with diabetes also commonly develop pyelonephritis and renal scarring. Another complication of diabetes, neurogenic bladder, causes incomplete bladder emptying. This results in retention of urine, which can cause infection or obstruction of urine, further damaging the kidneys.

Initially patients lose only small amounts of protein in their urine (microalbuminuria); this disease can be detected only with careful watching by the physician, utilizing frequent examinations of the urine. As the disease progresses, high-output renal failure (nonoliguria) can develop, in which a large amount of diluted urine is excreted without the usual amounts of waste products dissolved in the urine. The patient can lose large amounts of protein in the urine and may develop nephrotic syndrome, which causes massive edema because of low levels of albumin in the blood. As renal function decreases, the patient needs smaller doses of insulin because the kidney normally degrades insulin. Because the kidney is no longer able to break down insulin and excrete it, small doses of insulin circulate in the body for long periods.

Symptoms

The progression of nephropathy is marked by microalbuminuria advancing to proteinuria. Hypertension accelerates the renal damage. As diabetic nephropathy progresses, urine output decreases, toxic wastes accumulate, and the patient develops chronic renal failure. See Chronic Renal Failure section below for symptoms.

Diagnostic Tests

Diabetic nephropathy is diagnosed by careful watching of the patient with diabetes for onset of protein spillage or microalbuminuria in the urine, which is an early sign of the disease. Serum creatinine levels and 24-hour creatinine clearance tests are then done to confirm the presence and extent of diabetic nephropathy.

Therapeutic Interventions

In the early stages of diabetic nephropathy, strict control of blood glucose levels and blood pressure and a restricted-protein diet can help slow the progress of the disease and reduce symptoms. As the disease progresses to renal failure, the patient needs dialysis to maintain life. Unfortunately, other complications related to diabetes cause patients to tolerate dialysis less well than patients with renal failure from other causes. Kidney or kidney-pancreas transplant, when available, is the treatment of choice for the patient with diabetic nephropathy and often improves the patient's chance for a healthier life.

Complications

Patients with diabetic nephropathy often have a guarded prognosis because they are vulnerable to all the complications of long-term diabetes in addition to kidney disease. The risk of cardiovascular disease is significant with the progression of protein spilling in the urine.

Nephrotic Syndrome

Nephrotic syndrome is the excretion of 3.5 g or more of protein in the urine per day. Nephrotic syndrome may occur as a result of other disease processes. In nephrotic syndrome, large amounts of protein are lost in the urine from increased glomerular membrane permeability. As a result, serum albumin and total serum protein are decreased. Normally, albumin and other serum proteins maintain fluid within the vascular space. When levels of these proteins are low, fluid leaks from the blood vessels into tissues, resulting in edema. With very low levels of protein, ascites and massive widespread edema (anasarca) occur. In response to the low protein levels, the liver produces lipoproteins. As a result, serum cholesterol, low-density lipoproteins, and triglyceride levels are elevated. Urine may appear foamy from lipoproteinemia. Loss of immunoglobulins may lead to increased susceptibility to infection. Elevated blood pressure readings are noted.

Treatment is focused on the cause and symptoms of nephrotic syndrome. To control edema, sodium intake is restricted. A low to moderate protein intake is ordered to prevent build-up of nitrogen wastes (nitrogen wastes result from protein metabolism) from impaired kidney function. Protein intake is based on the severity of urinary protein loss. Diuretics may be used. Lipid-lowering drugs may be tried. Anticoagulants are given for thrombosis. In some cases, corticosteroids may be used.

Complications of nephrotic syndrome include impaired immune function, nutritional imbalances, and most importantly increased blood coagulation. Nursing care focuses on the edema and preventing infection. For edema, daily weights, careful intake and output measurement, and abdominal girth measurement are performed and documented. Edematous tissue must be protected from injury. Preventing malnutrition is challenging but important in maintaining normal body functions.

Nephrosclerosis

Hypertension damages the kidneys by causing sclerotic changes in the small arteries and arterioles, such as arteriosclerosis with thickening and hardening of the renal blood vessels (**nephrosclerosis**). The arteriosclerotic changes in the kidney blood vessels result in a decreased blood supply to the kidney (ischemia of the kidney) and can eventually destroy the kidney. The remaining nephrons try to compensate with vasodilation to increase blood flow to the glomeruli. This results in increased glomerular pressure and filtration, which thickens the blood vessels. The high pressure within the kidneys causes the vessels to weaken and hemorrhage. Large areas of the kidney become damaged. Symptoms of nephrosclerosis include proteinuria, hyaline casts in the urine, and, as it progresses, symptoms of renal failure.

The treatment of nephrosclerosis is to reduce blood pressure and treat the hypertension. The patient is placed on antihypertensive medications or, if already on these, changed to stronger antihypertensive medications. The patient is placed on a low-sodium diet. If the patient develops renal failure, dialysis will be used to maintain life.

The prognosis is often poor because by the time the patient has developed nephrosclerosis, there is widespread arteriosclerosis throughout the body. Arteriosclerosis makes the patient prone to myocardial infarctions or cerebrovascular accidents.

The major nursing diagnosis that is relevant when the patient develops nephrosclerosis is impaired health maintenance. The priority is to help the patient learn as much about the control of hypertension as possible. The patient should also be taught the symptoms of renal failure. Once the patient has lost renal function, the nursing care plan for renal failure is appropriate.

CRITICAL THINKING

Mr. Stevens

■ Mr. Stevens is a 35-year-old African American man admitted to the intensive care unit with uncontrolled hypertension. His blood pressure is controlled by intravenous medication. His laboratory tests show protein and hyaline casts in the urine. He is diagnosed with nephrosclerosis.

1. What data should the nurse collect as part of the morning evaluation of the patient's condition?
2. What other renal function tests are appropriate for the nurse to check?
3. What teaching does Mr. Stevens need when his condition is more stable?

Suggested answers at end of chapter.

nephrosclerosis: nephro—pertaining to the kidney + sclerosis—hardening

GLOMERULONEPHRITIS

Pathophysiology

Glomerulonephritis is an inflammatory disease of the glomerulus. It can be caused by a variety of factors including immunological abnormalities, toxins, vascular disorders, and systemic diseases. Inflammation occurs as a result of the deposition of antigen-antibody complexes in the basement membrane of the glomerulus or from antibodies that specifically attack the basement membrane. The resulting immune reaction in the glomerulus causes inflammation, which in turn causes the glomerulus to be more porous, allowing proteins, white blood cells, and red blood cells to leak into the urine.

Etiology

Acute Poststreptococcal Glomerulonephritis

Glomerulonephritis can be caused by a variety of factors but is most commonly associated with a group A beta-hemolytic streptococcal infection following a streptococcal infection of the throat or skin. This is the most common cause in children and young adults. Antibodies form complexes with the streptococcal antigen and are deposited in the basement membrane of the glomerulus, inducing damage from inflammation. Damaged glomeruli become unable to filter blood correctly and protein leaks into the urine. Edema, oliguria, and hypertension result. Glomerulonephritis generally develops about 6 to 10 days after the preceding infection. The disease has an abrupt onset. Other kinds of bacteria and viruses can also be the offending infectious agent.

Goodpasture's Syndrome

Occasionally glomerulonephritis is caused by an autoimmune response, in which the person for some unknown reason forms antibodies against his or her own glomerular basement membrane. Glomerulonephritis caused by an autoimmune response usually progresses rapidly and often leads to renal failure.

Chronic Glomerulonephritis

Chronic glomerulonephritis occurs over years as a result of glomerular inflammatory disease. There may be no history of renal disease before the diagnosis. Often proteinuria and hematuria may have been noted previously before the diagnosis. Lupus erythematosus and insulin-dependent diabetes mellitus may precede chronic glomerular injury. It is often discovered during an examination for another concern. Ultrasound, CT scan, or renal biopsy is used to diagnose the cause.

Symptoms

The symptoms of glomerulonephritis include fluid overload with oliguria, hypertension, electrolyte imbalances, and

glomerulonephritis: glomerulo—glomerulus + nephro—kidney + itis—inflammation

Box 37.8**Glomerulonephritis Summary**

Signs and Symptoms	Fluid volume overload Hypertension Electrolyte imbalances Edema Periorbital edema Flank pain
Diagnostic Tests	Urinalysis shows red cells, WBCs, protein, and casts Urine dark or cola colored Foamy urine from protein Creatinine, urea level elevated
Therapeutic Interventions	Treatment is symptomatic Nonsteroidal antiinflammatory drugs Steroids
Complications	Renal failure
Possible Nursing Diagnosis	Fluid volume excess related to compromised renal regulation Decreased tissue perfusion related to anemia, CHF, edema

edema (Box 37.8 Glomerulonephritis Summary). Edema may begin around the eyes (periorbital edema) and face and progress to the abdomen (ascites), lungs (pleural effusion), and extremities. Flank pain may be present. Blood urea nitrogen (BUN) and creatinine levels may be elevated. Urinalysis shows red blood cells, white blood cells, albumin, and casts. The urine is dark or cola colored from old red blood cells and may be foamy because of proteinuria.

Diagnostic Tests

Glomerulonephritis is diagnosed with urinalysis, which shows protein, casts or RBCs, and elevated serum levels of nitrogenous wastes (creatinine, urea). Hypertension may be present. Kidney ultrasound, x-ray, or biopsy may be done to determine abnormal kidney shape, size, blood flow, inflammation, or scarring of the glomeruli.

Therapeutic Interventions

Most cases of acute glomerulonephritis resolve spontaneously in about a week, but some progress to renal failure. Treatment is primarily symptomatic. Sodium and fluid restrictions may be ordered along with diuretics to treat fluid retention. Medications may be given to control hypertension. If associated with a streptococcal infection, antibiotics are given to treat any remaining infection. If fluid overload is severe, dialysis may be done.

Complications

The prognosis is good for acute glomerulonephritis acquired in childhood, and the majority of children recover completely. Adults who develop glomerulonephritis may recover renal function or progress to chronic glomerulonephritis. Some patients develop rapidly progressive glomerulonephritis, which can quickly lead to renal failure. Chronic glomerulonephritis is a slow process characterized by hypertension, gradual loss of renal function, and eventual renal failure.

Nursing Management

Nursing care for a patient with glomerulonephritis focuses on symptom relief. Vital signs are monitored because the patient may be critically ill. During the acute phase, rest is encouraged. Edema is controlled with fluid and sodium intake restrictions. Protein intake may be limited if the kidneys are not filtering protein waste products (as seen by increased serum BUN and creatinine levels). Other care is discussed in the section Chronic Renal Failure. Teaching the patient about preventing glomerulonephritis is important. Antibiotics for diagnosed streptococcal throat infections should be taken for prevention.

RENAL FAILURE

Renal failure, also called kidney failure, is diagnosed when the kidneys are no longer functioning adequately to maintain normal body processes. This results in dysfunction in almost all other parts of the body as a result of imbalances in fluid, electrolytes, and calcium levels, as well as impaired RBC formation and decreased elimination of waste products. Renal failure can be acute, with sudden onset of symptoms, or chronic, occurring gradually over time. For more information on kidneys, visit the American Kidney Fund at <http://www.kidneyfund.org/>, the National Kidney Foundation at www.kidney.org, and the American Association of Kidney Patients at www.aakp.org.

Acute Renal Failure

Acute renal failure (ARF) is the sudden (hours to days) loss of the kidneys' ability to clear waste products and regulate fluid and electrolyte balance. There is a rapid accumulation of toxic wastes from protein metabolism in the blood (**azotemia**). In azotemia, the serum urea level (measured by BUN) and creatinine levels are elevated. Most types of acute renal failure are reversible if diagnosed and treated early; however, ARF can lead to chronic renal failure. Acute renal failure is often associated with a urine output of less than 30 mL/hr or 400 mL/day. It may be caused by hypotension, vascular obstruction, glomerular disease, acute tubular necrosis (ATN) in which the tubules are damaged after administration of diagnostic contrast media.

azotemia: azo—nitrogenous waste products + temia—blood

NURSING CARE TIP

To protect patients' kidneys, be aware of the following:

- The patient's renal function status: Serum BUN and creatinine levels will tell you this.
- Nephrotoxic substances:
 - Diagnostic contrast media (dyes) in presence of dehydration or renal impairment
 - Medications—IV aminoglycosides (gentamicin [Garamycin], tobramycin [Tobrex], amikacin [Amikin], cisplatin [Platinol])
 - Chemicals—arsenic, carbon tetrachloride, lead, mercuric chloride
- Preventive measures:
 - Before administering nephrotoxic dyes or medications, check serum BUN and creatinine levels.
 - With contrast media (dye) tests, encourage fluids before and after to dilute and flush, flush, flush the dye away!

Make sure peak and trough drug levels of nephrotoxic drugs are obtained on an ongoing basis per institutional policy.

Pathophysiology

In acute renal failure, rapid damage to the kidney causes waste products to accumulate in the bloodstream, resulting in the symptoms of renal failure. The patient becomes oliguric, with urine output decreasing to less than 20 mL/h. Treatment is directed toward correcting the cause, supporting the patient with dialysis, and prevention of complications that may lead to permanent damage. Many patients with acute renal failure recover completely. Approximately 50% of patients with intrarenal ARF die as a result of complications of infection, pneumonia, or septicemia.

ARF can progress through four stages, with an intrarenal cause taking a longer recovery time frame since there is actual renal damage. Once an event causes ARF in the initial phase, symptoms occur in hours to days.

OLIGURIC PHASE. In the oliguric phase, less than 400 mL of urine in 24 hours is produced. Fifty percent of those with ARF experience this phase, which occurs from 24 hours to 7 days after the initial phase. This phase can last up to 2 weeks to several months. Prognosis for renal recovery is decreased the longer this phase lasts.

In the oliguric phase, fluid is retained, electrolytes become imbalanced, and waste products are not excreted as urine output decreases. Signs of fluid overload are seen. Serum potassium rises while sodium is lost in the urine, creating a normal or low serum sodium level. The longer this

phase lasts, the more effects are seen. These may include metabolic acidosis from reduced hydrogen ion excretion and sodium bicarbonate levels, increased phosphate and decreased calcium levels, abnormal blood cells (RBC, WBC, platelets), neurological effects ranging from confusion, seizures to coma, and finally effects on all body systems as is seen in CRF (discussed later).

DIURETIC PHASE. As the kidneys begin to be able to again excrete waste products, 1 to 3 L/day of urine is produced. The osmotic diuresis occurs from the elevated waste products (urea) which the body is attempting to eliminate. The kidneys are not yet able to concentrate urine and so dehydration and hypotension are a concern. It is important for the nurse to monitor for hypovolemia, hyponatremia, and hypotension in this phase. Serum BUN and creatinine levels are high until the end of this phase, at which time they begin to return to normal. This phase may last from 1 to 3 weeks.

RECOVERY PHASE. In this final phase, recovery begins as the glomerular filtration rate rises. Waste product levels (BUN, creatinine levels) decrease greatly within the first 2 weeks of this phase. However, recovery can take up to 1 year. Those who do recover usually do so without complications. Older adults are more at risk for reduced recovery of renal function. In those who do not recover renal function, chronic renal failure occurs.

Etiology

Acute renal failure is often classified as prerenal, intrarenal, or postrenal. These categories relate to the causes leading to acute renal failure. Each category is associated with the location of the cause in the kidney. Understanding the cause can point to the direction of treatment plans helpful to the patient.

PRERENAL FAILURE. Prerenal (before the kidney) failure is associated with a decrease or interruption of blood supply to the kidneys. This type of renal failure accounts for 55% to 60% of all cases of acute renal failure. The causes may include a decrease in blood pressure as a result of dehydration, blood loss, shock, or trauma to or blockage in the arteries that carry blood to the kidneys. When the nephrons receive an inadequate blood supply, they are unable to make urine and the waste products are not adequately removed. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX) inhibitors can also lead to prerenal failure. These drugs impair the autoregulatory responses of the kidney by blocking prostaglandin, which is necessary for renal perfusion.

Prerenal failure can be diagnosed by evaluating possible causes. If dehydration is the cause, then an IV fluid challenge may be given. With increased IV fluid, more blood flows to the kidneys for filtering, which increases urine output and waste product filtering. An arteriogram of the renal arteries is helpful to determine if the blood supply to the kidneys is decreased or blocked; angioplasty may be used to open the blockage. The serum creatinine increases and cre-

ACE = angiotensin-converting enzyme.

atinine clearance decreases. Urinalysis may be helpful in determining the cause as well.

INTRARENAL FAILURE. Intrarenal failure (inside the kidney) occurs when there is damage to the nephrons inside the kidney. The most common causes are ischemia, reduced blood flow, and toxins. Other causes are from infectious processes leading to glomerulonephritis, trauma to the kidney, exposure to **nephrotoxins**, allergic reactions to radiographic dyes, and severe muscle injury, which releases substances that are harmful to the kidneys (Table 37.4).

A number of substances can be toxic to the kidneys (nephrotoxic) when they enter the body. Kidney damage is most likely to occur when these substances enter the body in high concentrations or when there is preexisting kidney damage for some other reason. Environmental nephrotoxins, such as insecticides and lead paint, may be ingested by children. Many commonly administered medications can be nephrotoxic. Aminoglycosides are nephrotoxic antibiotics; when they are administered, blood levels of the drugs are carefully monitored to avoid toxic levels.

Contrast media used during tests such as intravenous pyelograms and CT scans can cause kidney damage when the patient is dehydrated or has preexisting renal damage. The medium can precipitate out in the tubules, damaging the kidney. It is important for the patient to be adequately hydrated before and after any diagnostic test using a contrast medium to decrease the incidence of toxicity.

POSTRENAL FAILURE. Postrenal (after the kidney) failure is associated with an obstruction that blocks the flow of urine out of the body. Only 5% of cases of acute renal failure are classified as postrenal. In this case, the blood supply to the kidneys and nephron function initially may be normal, but urine is unable to drain out of the kidney, resulting in back-up of urine and impaired nephron function. Common causes are kidney stones, tumors of the ureters or bladder, and an enlarged prostate that blocks the flow of urine.

Diagnosis of causes of postrenal failure can be done with x-ray examination of the kidneys, ureters, and bladder. Cystoscopy will show presence of tumors, stones, or prostate enlargement. Renal ultrasound can measure the kidney size, detect tumors and blockages, and reveal cystic disease. Surgical intervention may be needed to correct the problem.

nephrotoxins: nephro—kidney + toxin—poison

Therapeutic Interventions

Acute renal failure is treated by relieving the cause. Prevention of permanent damage is the goal of treatment. Signs and symptoms are managed as they develop and supportive care is given. Treatment may include restoring fluid and electrolyte balance, discontinuing nephrotoxic drugs that may have caused the problem, bypassing urinary tract obstructions with catheters, or short-term continuous renal replacement therapy to filter blood and restore potassium and other electrolytes to normal. Some symptoms such as anemia may not have time to develop in the patient with ARF as they do in CRF. The care of the patient with acute renal failure is similar to care of the patient with chronic renal failure, as explained in the next section.

CONTINUOUS RENAL REPLACEMENT THERAPY (CRRT)

CRRT is a therapy to remove fluid and solutes in a controlled, continuous manner in unstable patients with acute renal failure. Unstable patients may not be able to tolerate rapid fluid shifts as occurs in hemodialysis so CRRT provides an alternative therapy that results in less dramatic fluid shifting. CRRT can be used along with **hemodialysis**, which is necessary if severe symptoms of **uremia** (hyperkalemia) are present. CRRT is not as complex as hemodialysis and can be done for more than a month if needed. Temporary vascular access is used with CRRT.

During CRRT, a permeable hemofilter is attached to the vascular access. Blood flows through the hemofilter and excess fluids and solutes move into a collection bag. The remaining blood returns to the patient via the venous access. If desired, replacement fluid and electrolytes can be given through the vascular access. Monitoring intake and output, fluid and electrolytes, daily weights, hourly vital signs, and vascular access is important.

Chronic Renal Failure

Chronic renal failure (CRF) affects approximately 290,000 people in the United States. The incidence is on the rise. It is a progressive, irreversible deterioration in renal function where the body is unable to maintain metabolic, fluid, and electrolyte balance. It occurs with a gradual decrease in the

hemodialysis: hemo—blood + dialysis—passage of a solute through a membrane

uremia: ur—urea + emia—in the blood

function of the kidneys over time. The result is nitrogenous waste products in the blood and uremia. Chronic renal disease affects every body system (Box 37.9 Renal Failure Summary).

Etiology

The causes of chronic renal failure are numerous; the most common ones include diabetes mellitus resulting in diabetic

nephropathy, chronic high blood pressure causing nephrosclerosis, glomerulonephritis, and autoimmune diseases. Diabetes and hypertension account for close to 70% of all chronic renal disease.

Pathophysiology

When a large proportion of the nephrons are damaged or destroyed because of acute or chronic kidney disease, renal

Box 37.9

Renal Failure Summary

Signs and Symptoms	Decreased urine output Acute renal failure symptoms appear rapidly Fatigue Nausea and vomiting Shortness of breath Platelet dysfunction

failure occurs (Table 37.5). As the nephrons die off, the undamaged ones increase their work capacity and take over the work previously done by the dead ones, so the patient may experience significant kidney damage without showing symptoms of renal failure.

Chronic renal failure is a progressive disease process. In the early, or silent, stage (decreased renal reserve), the patient is usually without symptoms, even though up to 50% of nephron function may have been lost. This stage is often not diagnosed.

The renal insufficiency stage occurs when the patient has lost 75% of nephron function and some signs of mild renal failure are present. Anemia and the inability to concentrate urine may occur. The BUN and creatinine levels are

slightly elevated. These patients are at risk for further damage caused by infection, dehydration, drugs, heart failure, and use of diagnostic x-ray dyes. The goal of care is to prevent further damage, if possible, by control of blood sugar levels and blood pressure.

End-stage renal disease (ESRD) occurs when 90% of the nephrons are lost. Patients at this stage experience chronic and persistent abnormal kidney function. The BUN and creatinine levels are always elevated. These patients may make urine but not filter out the waste products, or urine production may cease. Dialysis or a kidney transplant is required to survive.

Uremia (urea in the blood) is present in chronic renal failure. Patients eventually develop problems in all body systems (Table 37.6). If left untreated, the patient with uremia dies, often within weeks.

Symptoms of Renal Failure

Patients in either acute or chronic renal failure have multiple symptoms. Some of the more common symptoms associated with renal failure are explained next (Fig. 37.6).

Disturbance in Water Balance

Patients with renal failure experience disturbances in the removal and regulation of water balance in the body and

TABLE 37.6 EFFECTS OF RENAL FAILURE ON BODY SYSTEMS

Body System	Disease Process
Cardiovascular	Hypertension due to fluid overload and accelerated arteriosclerosis Congestive heart failure/pulmonary edema due to fluid overload, increased pulmonary permeability, left ventricular failure Angina due to coronary artery disease, anemia Dysrhythmias due to electrolyte imbalance, coronary artery disease Edema due to fluid overload and a decrease in osmotic pressure Pericarditis due to presence of waste products in the pericardial sac
Gastrointestinal	Stomatitis due to fluid restriction, presence of waste products in the mouth, secondary infections Anorexia, nausea, vomiting due to uremia Gastritis/gastrointestinal bleeding due to urea decomposition in gastrointestinal tract releasing ammonia that irritates and ulcerates the stomach or bowel; patient is also under stress, increasing ulcer formation, and may have platelet dysfunction Constipation due to electrolyte imbalances, decrease in fluid intake, decrease in activity, phosphate binders Diarrhea, hypermotility due to electrolyte imbalance
Hematopoietic	Anemia due to impaired synthesis of erythropoietin, a substance needed by the bone marrow to stimulate formation of RBCs; also due to decreased life span of RBCs from uremia and interference in folic acid action Bleeding tendency due to abnormal platelet function from effects of uremia Prone to infection due to a decrease in immune system function from uremia; renal patients can rapidly become septic and die from septic shock
Integumentary	Dry, itchy, inflamed skin due to calcium-phosphate deposits in the skin and urochrome, and a pigment of uremia, causes the skin to be pale gray, yellow bronze; skin will have an odor of urine because skin is an organ of excretion and the body attempts to remove toxins; there is also a decrease in function of oil and sweat glands
Neurological	Confusion due to uremic encephalopathy from an increase in urea and metabolic acids Peripheral neuropathy due to effects of waste products on neurological system Cerebrovascular accidents due to accelerated atherosclerosis
Pulmonary	Pleurisy/pleural effusion due to waste products in the pleural space causing inflammation with pleurisy pain and collection of fluid resulting in effusion
Reproductive	Loss of libido, impotence, amenorrhea, infertility due to a decrease in hormone production
Skeletal	Bone disease due to renal osteodystrophy from hyperphosphatemia and hypocalcemia

FIGURE 37.6 Symptoms of chronic renal failure.

show signs of fluid accumulation. An early symptom is edema (swelling) of the extremities, sacral area, and abdomen. Patients may complain of being short of breath. Crackles and wheezes may be present on auscultation of the lungs, which are signs of fluid accumulation in the lungs. The blood vessels in the neck may be distended, and the patient may be hypertensive. These patients may produce a large amount of dilute urine (**polyuria**), small amounts of urine (oliguria), or no urine (anuria).

Disturbance in Electrolyte Balance

As kidney function decreases, the kidneys lose their ability to absorb and excrete electrolytes. Important electrolytes are sodium, potassium, and magnesium. When the kidneys are unable to maintain normal amounts of electrolytes in the blood, these substances accumulate at high levels and may be life threatening.

When the kidneys are unable to regulate sodium levels adequately, the patient may show signs of hypernatremia, an excessive sodium level in the blood, which causes water retention, edema, and hypertension. Hyponatremia, too little sodium, may occur when too much sodium is lost. This can occur when the patient has experienced prolonged episodes of vomiting or diarrhea or is urinating large amounts of diluted urine. Patients with hyponatremia may show signs of confusion. The sodium may be normal or low in renal failure due to being diluted from excess fluid.

Hyperkalemia (high level of potassium) presents a life-threatening situation. The patient may exhibit signs of dysrhythmia and cardiac arrest if the potassium level is too

high. Patients complain of muscle weakness, abdominal cramping, and diarrhea. The nurse may identify that the patient is confused or demonstrates disinterest in care. Hyperkalemia exists when the potassium level exceeds 5 mEq/L. These patients should be placed on a cardiac monitor and observed for cardiac dysrhythmias. A potassium level above 7 mEq/L may be life threatening. A high potassium level in the patient with renal failure may be caused by a diet high in potassium-rich foods, injuries, or blood transfusions. Monitoring daily laboratory values, restricting potassium intake, and reporting abnormalities are important. Intravenous insulin, glucose, or calcium gluconate may be used as a temporary measure to drive excess potassium into the cells. Sodium polystyrene sulfonate (Kayexalate) may be given either orally or as a retention enema; it causes the potassium to be eliminated through the stool. The definitive treatment for hyperkalemia is hemodialysis, which removes potassium from the body. Dietary education is extremely important. The patient is instructed to avoid foods that are high in potassium (Box 37.10 Foods High in Potassium).

Calcium levels decrease because the kidneys are unable to produce the hormone that activates vitamin D, the vitamin that is necessary for the absorption of calcium. Hypocalcemia exists when the calcium level falls below 8.5 mg/dL. Also associated with a low calcium level is hyperphosphatemia, a phosphorus level above 5 mg/dL. These imbalances cause the bones to release calcium, causing patients to be prone to fractures. These patients should ambulate regularly to prevent further calcium loss from the bone. Many patients with chronic renal failure who are on dialysis develop hypercalcemia due to hyperparathyroidism (excess release of parathyroid hormone). Cinacalcet (Sensipar) reduces excess levels of parathyroid hormone, which reduces calcium levels.

Phosphates are also found in some foods. Medications to bind phosphate are given to patients with high phosphate levels. Calcium carbonate (Tums, Caltrate), calcium acetate (PhosLo), sevelamer hydrochloride (Renagel), or lanthanum (Fosrenol) are examples of commonly ordered phosphate binders. These must be given to the patient with meals, so that the medicines can bind with the phosphates in the stool and be eliminated. High phosphorus levels may cause severe

Box 37.10

- Citrus fruits and juices
- Bananas
- Salt substitutes
- Potatoes, sweet and white
- Excessive dairy products
- Excessive meats
- Chocolate

polyuria: poly—much + uria—urine

itching, and patients may have open sores from scratching, placing them at risk for infections. Patients may also have muscle cramps and aches.

Disturbance of Removal of Waste Products

With azotemia, the patient may show signs of weakness and fatigue, confusion, seizures, twitching movements of extremities (asterixis), nausea, vomiting, and lack of appetite and may complain of a metallic or bad taste in the mouth. There may be a smell of urine on the patient's breath. The patient may have yellowish pale skin and complain of itching due to urea crystals on the skin. Dialysis to remove the excessive waste products in the blood is the only treatment of the underlying causes of these symptoms.

Disturbance in Maintaining Acid-Base Balance

Renal failure affects hydrogen ion excretion, causing a disturbance in the acid-base balance that results in metabolic acidosis. Patients may complain of a headache, fatigue, weakness, nausea, vomiting, and lack of appetite. As the acidosis progresses, the patient shows signs of lethargy, stupor, and coma. Respirations become fast and deep as the lungs attempt to blow off carbon dioxide to correct the acidosis (Kussmaul's respirations). See Chapter 5 for a more detailed discussion of acid-base balance.

Disturbance in Hematological Function (Primarily Seen in CRF)

Over time, disturbances in blood cells occur from chronic renal failure. Usually with treatment there is not time for this to occur in ARF. Failing kidneys do not produce adequate erythropoietin, the hormone that stimulates red blood cell production. Nutritional deficiencies and blood loss during dialysis also contribute to anemia. Regular injections of epoetin (Epogen, Procrit), a synthetic form of erythropoietin, help restore RBC production and prevent anemia. A common side effect of erythropoietin is the development of hypertension.

Impaired white blood cell and immune functions contribute to an increased risk for infection. The patient should be protected from potential sources of infection.

Impaired platelet function creates a risk for bleeding. The patient should be protected from injury, and signs of bleeding, such as blood in stool or emesis, are reported.

Therapeutic Interventions for Renal Failure

Renal insufficiency and early renal failure are treated based on symptoms with a restricted diet and fluid intake, medications, and careful monitoring for onset of serious problems that warrant initiation of dialysis. In later stages, dialysis is necessary to replace lost kidney function. A kidney transplant, when available, may return the patient to a nearly normal state of health.

Diet

Dietary recommendations are individualized by the dietitian and physician based on the patient's needs. Calories are high

to maintain weight and energy needs. Protein is usually restricted to limit nitrogen intake but may be increased for the patient on dialysis because protein is lost during the dialysis process. Sodium is restricted to minimize sodium and fluid retention. Potassium is restricted, especially later in the disease when the kidneys are unable to eliminate it. Calcium is increased or supplemented because of poor absorption related to faulty vitamin D activation. Phosphorus is restricted because of high blood levels related to hypocalcemia. Saturated fat and cholesterol are restricted for patients with hyperlipidemia. Fluids are restricted to prevent overload. Most patients are given iron, folic acid, vitamins, and minerals to supplement the restricted diet (Box 37.11 Nutrition Notes).

Because restrictions are complex, the diet is a source of frustration for many patients. The nurse should assist the patient to identify foods that are palatable yet within the diet plan. The dietitian should be consulted for instruction and assistance.

Medications

Early in the disease, diuretics are given to increase output, and angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, or beta-blocking agents may be used to control hypertension. Phosphate binders are given with meals to reduce phosphate levels. Calcium and vitamin D supplements are used to raise calcium levels. Agents to lower potassium levels are used if necessary. All drug therapy is closely monitored because diseased kidneys are unable to effectively remove medications from the body. The patient with diabetes needs less insulin since one of the functions of the kidneys is to break down insulin. Since it is not being broken down, it remains in the body longer, and therefore less is needed as the kidney disease progresses.

Dialysis

Dialysis is started when the patient develops symptoms of severe fluid overload, high potassium levels, acidosis, pericarditis, vomiting, lethargy, fatigue, or symptoms of uremia that are life threatening. Both peritoneal and hemodialysis involve the movement and diffusion of particles from an area of high concentration to an area of low concentration through a semipermeable membrane. The substances move from blood through the semipermeable membrane into the dialysate. Fluid and electrolyte imbalances can be corrected with dialysis. Dialysis can also be used to treat drug overdoses.

HEMODIALYSIS. Hemodialysis involves the use of an artificial kidney to remove waste products and excess water from the patient's blood. During the dialysis procedure, the patient's blood and the dialyzing solution flow in opposite directions through the dialyzer across an enclosed semipermeable membrane. The dialysate contains electrolytes and water in a balanced mix that resembles blood plasma. On the other side is the patient's blood with metabolic waste products, excess water and electrolytes. The waste products from the patient's blood move into the dialysate by diffusion

Box 37.11

Nutrition Notes

Understanding Dietary Changes in Renal Disease

Patients with impaired renal function require careful coordination of diet with current physiological status, which may change frequently, necessitating the services of a dietitian who specializes in renal treatment. Six national meal-planning systems were developed for renal insufficiency with/without diabetes, hemodialysis with/without diabetes, and peritoneal dialysis with/without diabetes. The following principles are offered as general guidelines.

- Maintaining caloric intake is essential to avoid catabolism of tissue for energy.* Simple carbohydrates and monounsaturated and polyunsaturated fats are given freely because their endproducts, carbon dioxide and water, are less likely than protein to tax the kidney. Patients with diabetes and uremia may receive more sugar than usual because treatment of the uremia may take precedence over the diabetes; however, patients with type IV hypertriglyceridemia may have to limit carbohydrates.
- Protein may be restricted when the patient's kidneys are failing but increased when the patient is treated with dialysis to compensate for losses in the dialysate.

*A special oral supplement such as *ReNeph LP/HC* (low protein, high calorie) from Ross Laboratories may be prescribed for patients who are unwilling to eat enough food.

Lutz, CA, and Przytulski, KR: *Nutrition and Diet Therapy*, ed. 4. F.A. Davis, Philadelphia, 2006.

Sometimes proteins of high biological value (e.g., eggs, meat, and dairy products) are prescribed because they are more easily converted to body protein than those of low biological value. In other situations, vegetarian diets may be given, with the plant proteins carefully selected to manage potassium and phosphorus serum levels.

- Sodium may be restricted, depending on blood pressure, edema, and laboratory findings.
- Potassium may be restricted for patients with oliguria. Salt substitutes are often potassium compounds that are to be avoided. Potassium content in foods varies with processing and preparation methods so patients should choose from prescribed foods only.
- Fluid restriction may be altered daily according to output. Renal insufficiency patients may receive 500 mL plus the amount of the previous day's output.

In short, renal diets are individualized for the patient's current condition. Nurses should not expect different patients to be served the same meals or even the same patient to require the same restrictions from one day to the next.

through the membrane because of the difference in their concentrations. The dialysate solution carries the waste products away, and the cleansed blood is returned back into the patient's body through another tube (Fig. 37.7). A hemodialysis treatment takes 3 to 4 hours and is done three or four times a week. Hemodialysis is done at a hemodialysis center (Fig. 37.8) or in the hospital if the patient develops a complication and needs hospitalization.

Hemodialysis provides a rapid and efficient way to remove waste products from the blood. It is also an excellent means to correct excessive fluid-overloaded states such as occur in heart failure.

Hemodialysis is not without side effects. Following a treatment, the patient normally feels weak and fatigued, sometimes even too tired to eat. Sudden drops in blood pressure may cause the patient to become weak, dizzy, and nauseated. Cardiac dysrhythmias and angina may occur. Fluid and electrolyte levels drop rapidly and cause the patient to feel lethargic and have muscle cramps. Patients are given large amounts of heparin, an anticoagulant used to keep the blood from clotting while it is in the artificial kidney; this may cause bleeding from the puncture sites, gastrointestinal tract, nose, or other sites if injury occurs.

See Box 37.12 Nursing Care of the Patient Receiving Hemodialysis.

Vascular Access. Hemodialysis requires a permanent way to access the bloodstream for blood removal and return to the body during dialysis. Typical vascular access options are a vascular access graft or an arteriovenous (AV) fistula. Grafts and fistulas are placed in the arm when possible. It is imperative that IV angiocaths are not placed in a cephalic or basilic vein in patients who may need grafts or fistulas in the future.

FIGURE 37.7 Hemodialysis.

FIGURE 37.8 Patient undergoing hemodialysis at dialysis center.

A temporary access is used for patients requiring hemodialysis before a graft or fistula is placed or is usable. A central venous catheter with two or three ports is placed in the subclavian vein, the jugular vein, or the femoral vein for temporary access. Central catheters cannot be used long term due to the risk of infection. A newer access system is the LifeSite Hemodialysis Access system, which is

Box 37.12

Nursing Care of the Patient Receiving Hemodialysis

1. Consult with the physician about medications to hold before hemodialysis. Some medications, such as antihypertensives, can be harmful when they become effective during dialysis and can reduce blood pressure to dangerously low levels. Other medications are water soluble and will be dialyzed out of the body, and thus are not effective.
2. Ensure that the patient is weighed both before dialysis in the morning and after dialysis to document weight loss as a result of fluid removal.
3. If the patient has laboratory tests ordered and blood needs to be drawn, coordinate this process with the dialysis nurse, who can obtain the blood samples and save the patient unnecessary needle sticks.
4. Try to get morning care done early and breakfast given before dialysis. After dialysis, patients are often exhausted and need rest.
5. When the patient returns from dialysis, weigh the patient, assess the access site for bleeding, and make sure the vital signs are stable. Administer medications that were held if not contraindicated and vital signs are stable.
6. Protect the patient's dialysis access as outlined in Box 37.13 Care of Blood Access Graft or Fistula.

an implantable port for blood access. Two systems are implanted for hemodialysis. No maturation time is required. This system can be used longer than temporary access catheters.

An arteriovenous graft (AV graft) uses a tube of synthetic material to attach to an artery and a vein. Needles are inserted into the graft to access the patient's blood. Traditional graft material is not self-sealing and requires time for tissue growth to serve as a plug for the hole that the needle makes before it can be used. This may take 1 to 2 weeks. The Vectra vascular access graft is self-sealing and does not require tissue growth so it can be used almost immediately after surgical implantation. This self-sealing property also decreases postdialysis bleeding time and reduces time required for the dialysis session.

An AV fistula is made by sewing a vein and artery together under the skin (Fig. 37.9). AV fistulas may take 2 to 4 months to mature. A temporary access device is usually needed until the fistula matures.

Vascular Access Care. Arteriovenous grafts and fistulas are regularly checked for patency by palpating for a thrill (a tremor) and auscultating for a bruit (swishing sound) at the site of the graft or fistula. Any decrease or cessation of bruit or thrill indicates occlusion. If a thrill or bruit is diminished or not present, the physician is notified immediately by the nurse. Special care of the access site must be taken because this is the patient's only way to eliminate waste products (Box 37.13 Care of Blood Access Graft or Fistula). It is important that the site be carefully monitored per institution policy to detect any clotting or problems at the site. Early detection of clotting allows the surgeon an opportunity to save the access by performing a declotting procedure rather than a total revision.

FIGURE 37.9 Hemodialysis access sites. (A) Arteriovenous fistula. (B) Arteriovenous graft.

Box 37.13**Care of Blood Access Graft or Fistula**

Dialysis access sites should not be utilized for any purpose other than dialysis.

1. Watch for signs of bleeding or infection at the site.
2. Listen for a bruit at the site by placing the diaphragm of a stethoscope gently on the site. A bruit is a swishing sound made as the blood passes through the access site.
3. Gently palpate the site for a thrill, which is a buzzing or pulsing feeling that indicates good blood flow through the access site.
4. *Do not* take blood pressure, use a tourniquet, draw blood, or start any intravenous lines in the affected arm. Injections should be avoided if possible.
5. Many hospitals have the patient wear a red arm bracelet to signify that the arm should be protected. A sign above the bed may also be used.
6. Teach the patient to keep the site clean and not to bump or cut it.
7. Teach the patient not to lift heavy objects or carry a purse on the access arm.
8. Teach the patient to avoid wearing constrictive clothing or jewelry over the site.
9. Teach the patient to avoid prolonged bending or sleeping on the arm with an access.
10. Notify the physician if signs of bleeding, reduced circulation, or infection occur in the access extremity: coldness, numbness, weakness, redness, fever, drainage, or swelling.

Postoperative Care. Initially, neurovascular checks are performed hourly for vascular surgery. Neurovascular checks include extremity movement and sensation, presence of numbness or tingling, pulses, temperature, color, and capillary refill (less than 3 seconds normally). Peripheral pulses are palpated to feel the thrill and auscultated to hear the bruit. If a pulse is absent or weak or the extremity is cool or dusky, the physician is notified immediately. Dressings or incisions are checked, and any drainage, hematoma, or infection development is documented and reported as needed. Vascular surgery pain is usually mild. Severe pain may indicate an occlusion of the graft. Arteriovenous grafts can cause distal ischemia or “steal syndrome” because too much of the arterial blood is being “stolen” from the distal extremity. This is usually seen postoperatively and may require surgical correction to restore blood flow to the extremity.

Blood pressure readings and IVs should not be done in

the extremity in which the access is placed. The extremity with the vascular access should be elevated postoperatively. Range of motion exercises should be encouraged. Patients are taught care of the access (see Box 37.13).

PERITONEAL DIALYSIS. **Peritoneal dialysis** provides continuous dialysis treatment and is done by the patient or family in the home. The peritoneal membrane is used as a semipermeable membrane across which excess wastes and fluids move from blood in peritoneal vessels into a dialysate solution that has been instilled into the peritoneal cavity. A peritoneal catheter is placed into the patient’s peritoneal space between the two layers of the peritoneum below the waistline. This catheter is used to perform an exchange. The exchange process has three steps: filling, dwell time, and draining.

The fill step involves instilling a bag of sterile dialyzing solution (dialysate) into the patient’s peritoneal cavity through the catheter. The amount of solution is usually 1500 to 2000 mL. The solution is left to dwell in the abdomen for several hours, allowing time for the waste products from the blood to pass through the peritoneal membrane into the dialysate solution (Fig. 37.10).

The solution is then drained out of the body and discarded. This process is repeated three or four times a day and is continuous for the patient. Several different treatment plans use this exchange process; the treatment plan that best suits the patient’s needs is determined by the patient and the dialysis team.

Continuous ambulatory peritoneal dialysis (CAPD) is the most commonly used treatment plan. Usually three exchanges are done during the day and one before bedtime. Other treatment plans allow for the use of a computerized machine called a cycler to regulate the exchanges during sleeping hours. Sometimes medications are added to the dialyzing solutions, such as heparin to prevent clotting of the catheter, insulin for the patient with diabetes, or antibiotics if there is infection.

Patient and family education is extremely important for peritoneal dialysis to be successful. The patient must be taught and be able to demonstrate that he or she is able to do a successful exchange. Sterile technique while performing the exchanges is imperative and the exchanges should be done in a clean environment. A major complication is peritonitis (infection of the peritoneum), which can be life threatening. The major cause of peritonitis is poor technique when connecting the bag of dialyzing solution to the peritoneal catheter. The first sign of peritonitis is usually abdominal pain. Refer to Chapter 34 for additional signs and symptoms of peritonitis. If any symptoms of peritonitis occur, the patient must contact the physician immediately, so that antibiotic treatment can begin. The patient should be taught to care for the exit site (the site where the

peritoneal dialysis: peritoneal—peritoneum + dialysis—
passage of a solution through a membrane

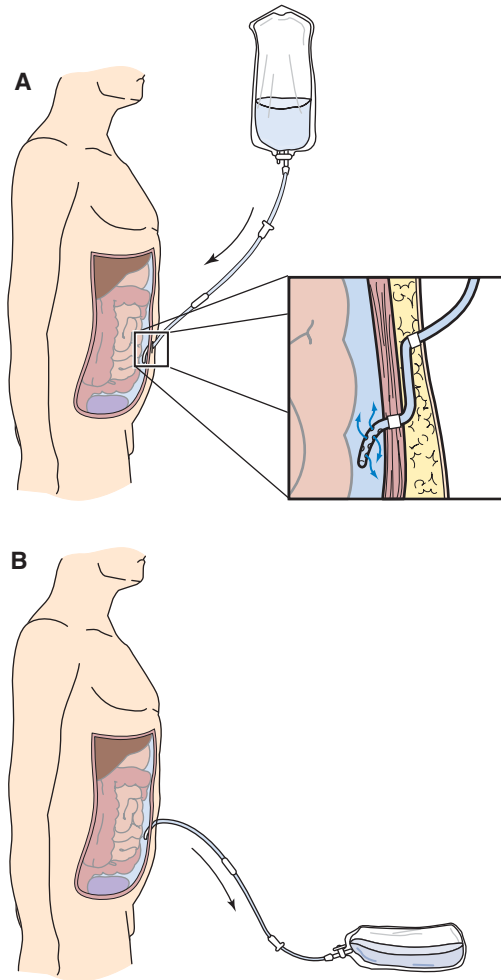

FIGURE 37.10 (A) Peritoneal dialysis works inside the body. Dialysis solution flows through a tube into the abdominal cavity, where it collects waste products from the blood. (B) Periodically the used dialysis solution is drained from the abdominal cavity, carrying away waste products and excess water from the blood.

catheter comes out of the abdomen) and the need to inspect both the site and the dialysate solution for any signs of infection.

Dietary education is also important. A dietitian can assist the patient in making appropriate choices for adequate calories, protein, and potassium intake. The peritoneal dialysis patient generally has fewer dietary and fluid restrictions than the patient on hemodialysis because dialysis is continuous and maintains serum waste levels. Proteins are lost through the peritoneal membrane into the dialysate fluid, so increased dietary protein is needed. This loss increases with peritonitis, which further increases permeability.

Kidney Transplantation

Kidney transplantation is another treatment for renal failure. Kidney transplantation is extremely successful. An advan-

LEARNING TIP

Differences between hemodialysis (HD), peritoneal dialysis (PD), and continuous renal replacement therapy (CRRT) include the following:

- *Patient Access:* HD requires vascular access either temporary (acute renal failure) or permanent surgical graft or fistula (chronic renal failure). PD requires insertion of a catheter into the peritoneal cavity. CRRT requires temporary vascular access such as a central line.
- *Equipment:* HD requires a specialized complex dialyzer. PD and CRRT do not require the specialized dialyzer, although machines are available for these therapies.
- *Training:* HD requires a skilled HD nurse. CRRT can be done by a non-HD nurse in a critical care setting. PD can be done by the patient.
- *Timing:* HD is intermittent. PD and CRRT are continuous.
- *Solute removal:* HD and PD use the principles of osmosis and diffusion, which require a dialysate solution. CRRT uses convection, so no dialysate is needed.
- *Cardiovascular effects:* HD may cause hypotension, which is a risk in the unstable patient. PD and CRRT have few cardiovascular effects. CRRT can be used on the unstable patient.

tage of transplant compared to dialysis is that it reverses many of the physiological changes noted with renal failure. The patient is also not dependent upon dialysis and dietary restrictions.

A kidney transplant is a procedure in which a donor kidney is placed in the abdomen of a patient with chronic renal failure (Fig. 37.11). This healthy transplanted kidney functions as a normal functioning kidney does. The donated kidney can come from a family member, a living, non-related donor, or a cadaver donor. Tissue and blood types must match so that the body's immune system does not reject the donated kidney. Patients receive special drugs to help prevent rejection; these drugs must be taken for the rest of the patient's life. Sometimes even with these drugs, the body rejects the kidney and the patient needs to go back on dialysis (Box 37.14 Cultural Considerations and Box 37.15

FIGURE 37.11 A transplanted kidney is placed in the abdomen. The patient's kidneys are usually left in place.

Patient Perspective). For more information, visit the Transplant Society at www.a-o-t-a.org.

Nursing Process for the Patient with Renal Failure

Assessment/Data Collection

Renal failure progressively affects all body systems. There may be fewer effects in ARF if it is short term and there is not time for some effects to develop. In chronic renal failure,

Box 37.14

Cultural Considerations

Renal Function and Assessment

Because many Vietnamese people believe that the body must be kept intact, even after death, they may object to removal of body parts or organ donation.

Jewish law views organ transplantation from the recipient, the living donor, the cadaver donor, and the dying donor differently. If the recipient's life can be prolonged without considerable risk, transplant is ordained. For a living donor to be approved, the risk to the life of the donor must be considered. One is not obligated to donate a part of himself or herself unless the risk is small. The use of a cadaver for transplant is usually approved if it is saving a life. The nurse may need to assist the Jewish patient to contact a rabbi when making a decision regarding organ donation or transplantation.

Box 37.15

Patient Perspective

Kidney Transplantation: Pat

My experience with a kidney transplant spans three decades, but my overall renal illness experience also spans several years of illness and dialysis before the transplant. I think the biggest changes I have seen over the years are the involvement of patients in their own care options, as well as increased technical advances that allow transplantation to be much more successful. Some of the feelings experienced before transplantation are fear, uncertainty, and—if awaiting a donor—the guilt of knowing someone must die before you can live.

Thirty years ago there were no support groups and no one to talk to except family and doctors. Today, there are many support mechanisms in place for patients and families both before and after transplantation. As a nurse, you can help patients by knowing these support resources for referral. After a transplant, it is wonderful to feel better, almost immediately. However, as wonderful as transplantation is, the side effects of the antirejection medications may be immediately felt, while other problems take years to develop. Unfortunately, no patients escape the side effects of the medications. I have had breast cancer, osteoarthritis, cataracts, ulcers, skin cancer, anemia, weight gain, and other side effects of prednisone and Imuran (azathioprine). However, I can assure you that this is much better than the alternative of dialysis.

more effects are seen since the disease has time to progress. Data should be collected for signs and symptoms in all body systems. Family history of renal disease and patient history of health problems such as hypertension, diabetes, systemic erythematous lupus, or urinary disorders are noted in the history. Also noted are medications the patient takes as they may be nephrotoxic and require adjustments. Recent changes in weight are documented.

Signs and symptoms vary depending on the severity of renal failure and cause. Common signs are hypertension, abnormal laboratory values (creatinine, BUN), or changes in urine. See signs and symptoms section for other effects of renal failure.

Nursing Diagnosis, Planning, Intervention, and Evaluation

See Box 37.16 Nursing Care Plan for the Patient with Renal Failure for nursing care.

Box 37.16 NURSING CARE PLAN for the Patient with Renal Failure

Nursing Diagnosis: Excess fluid volume related to kidney's inability to excrete water

Expected Outcomes Fluid volume will be stable as evidenced by stable weight, absence of edema, lung sounds clear, and blood pressure within patient's normal parameters.

Evaluation of Outcomes Is weight stable? Is edema absent? Are lungs clear? Is blood pressure within patient's normal parameters?

Nursing Interventions

Monitor weight daily at same time; report gain of greater than 2 pounds.
Monitor intake and output.

Monitor and report shortness of breath, tachycardia, crackles in lungs, frothy sputum, heart irregularities, hypotension, cold clammy skin.

Watch for new onset of jugular vein distention with patient's head raised to 30- to 45-degree angle.

Monitor vital signs, including orthostatic blood pressure.

Monitor for edema.

Monitor activity tolerance.

Monitor serum protein and albumin levels.

Maintain sodium and fluid restrictions (often 600 mL plus the previous day's urine output) as ordered.

Develop a plan with specific allotted amounts of fluid at each meal and for medications. Teach patient importance of each.

Rationale

Those retaining fluid will have weight gain.

This monitors degree of fluid retention.

These are symptoms of heart failure that may accompany fluid overload.

Fluid overload causes right-sided heart failure resulting in distended jugular veins.

Blood pressure changes reflect fluid volume.

Edema is a symptom of fluid overload.

Reduced activity tolerance may indicate heart failure related to fluid retention.

Low serum protein and albumin levels contribute to edema.

For those on dialysis, fluid intake is adjusted so that weight gains are no more than 1–3 kg between dialysis sessions.

Evaluation

Is weight stable? Should physician be notified of change?

Is output less than intake? Is this a change?

Are symptoms of heart failure present?

Are jugular veins distended? Is this a new finding?

Is blood pressure increased?

Is edema present? Is this a change?

Is patient's tolerance of activity stable? Worsening?

Are levels within normal limits?

Does patient understand and maintain sodium and fluid restriction?

Nursing Diagnosis: Impaired skin integrity related to dryness, excess fluid, crystal deposits

Expected Outcomes Patient will maintain intact skin.

Evaluation of Outcomes Does patient report no itching or dryness? Is patient's skin intact?

Interventions

Observe skin for open areas and signs of infection.

Bathe with tepid water, oils, or oatmeal.

Apply lotion to skin after bathing.

Rationale

Detects early signs of problems.

Bathe regularly to reduce crystals with nondrying items to reduce itching and dryness and promote comfort.

Lotion is used for itching to reduce dry skin.

Evaluation

Is skin intact?

Does patient report no itching or skin dryness?

Is skin dry?

Nursing Diagnosis: Activity intolerance related to anemia secondary to impaired synthesis of erythropoietin by the kidneys

Expected Outcomes Patient will be able to perform activities important to him or her.

Evaluation of Outcomes Does patient state satisfaction with level of activity tolerance?

Interventions

Assess for pale mucous membranes and skin color, dyspnea, chest pain.
Monitor hemoglobin (Hgb), hematocrit (Hct).
Watch for signs of bleeding.
Administer erythropoietin as ordered. Assist with blood transfusion as necessary.
Have patient space activities with rest periods.

Rationale

These are signs and symptoms of anemia.
Low hemoglobin and hematocrit indicate anemia.
Bleeding will worsen anemia.
Erythropoietin stimulates production of red blood cells by bone marrow.
Rest periods decrease demand for oxygen.

Evaluation

Does patient exhibit symptoms of anemia?
Are Hgb and Hct within normal limits?
Are signs of bleeding present?
Are Hgb and Hct rising with use of erythropoietin?
Is patient able to tolerate activities with rest periods?

Nursing Diagnosis: Risk for injury related to bleeding tendency from platelet dysfunction and use of heparin during dialysis, and tendency for gastrointestinal bleeding

Expected Outcomes Patient will not experience bleeding. If bleeding occurs, it will be recognized and stopped quickly.

Evaluation of Outcomes Are signs and symptoms of bleeding absent or recognized and reported quickly?

Interventions

Observe for and report blood in stool or emesis, easy bruising, bleeding from mucous membranes or puncture sites and report immediately if present.
Monitor Hgb, Hct, clotting studies, and platelets and report results.
Monitor vital signs.
Avoid giving injections if possible.
If bleeding, apply gentle pressure to site if possible.
Teach patient to prevent injury to self and symptoms of bleeding to report.
Protect patient from injury if confusion or seizures occur.

Rationale

Bleeding must be recognized quickly to prevent complications.
Declining Hgb and Hct indicate blood loss.
Declining platelet count or rising clotting times indicate increased risk for bleeding.
Falling blood pressure and rising pulse may indicate volume deficit from bleeding.
Injections can cause bleeding into tissue.
Pressure promotes hemostasis.
Injury can cause bleeding.
Understanding of symptoms of bleeding encourages early reporting.
Waste product accumulation or hypotatremia puts patient at risk of altered mental status or seizures.

Evaluation

Does patient exhibit signs of bleeding?
Are lab results stable?
Are vital signs stable?
Can medications be given by another route?
Does pressure stop bleeding?
Does patient verbalize understanding of instruction?
Does patient require protection such as seizure precautions?
Is patient free from injury?

(Continued on following page)

Box 37.16 NURSING CARE PLAN for the Patient with Renal Failure (*Cont'd*)

Nursing Diagnosis: Risk for infection related to impaired immune system function

Expected Outcomes Patient will not develop infection as evidenced by WBCs and temperature within normal limits, no signs and symptoms of infection.

Evaluation of Outcomes Are WBCs and temperature within normal limits?

Interventions

Monitor for signs and symptoms of infection and report promptly to physician.

Protect patient from any source of infection, including infected room-mates, visitors, or nursing staff.

Maintain skin integrity.

Staff and patient practice good hand-washing technique.

Culture any suspected site of infection as ordered by physician.

Consult with physician about influenza and pneumonia vaccines.

Teach patient and family signs and symptoms of infection to report to physician.

Rationale

Early recognition of infection and prompt treatment help prevent complications.

Exposure to pathogens increases risk for infection.

Intact skin protects against infection.

Handwashing helps control spread of infection.

A culture identifies pathogens and guides treatment.

Patients with impaired immune function are at risk for influenza and pneumonia.

Early reporting of symptoms allows for prompt initiation of treatment.

Evaluation

Does patient exhibit symptoms of infection?

Does anyone in contact with the patient have an infection?

Is skin intact?

Is good handwashing being practiced?

Is a culture necessary?

Has the patient been vaccinated?

Do patient and family verbalize understanding of symptoms to report?

Nursing Diagnosis: Imbalanced nutrition, less than body requirements related to restricted diet, anorexia, nausea, and vomiting, and stomatitis secondary to effect of excessive urea on the gastrointestinal system

Expected Outcomes Patient will maintain ideal weight. Serum protein and albumin levels are within normal limits.

Evaluation of Outcomes Are weight and lab values at desired levels?

Interventions

Monitor weekly weight and serum protein and albumin levels.

Consult dietician for low-protein diet planning and teaching.

Initiate a calorie count—consult dietitian for assistance.

Provide frequent oral care.

Offer frequent small feedings and dietary supplements.

Offer medications ordered for nausea before meals.

Ensure bowel movement daily or according to patient's usual pattern.

Rationale

Weight and laboratory results provide information about nutrition status.

Low-protein diets decrease formation of waste products (urea, creatinine).

A calorie count can provide information about the adequacy of the patient's diet.

Oral care enhances appetite and reduces urine taste in mouth.

Smaller feedings are better tolerated and reduce risk of nausea.

Nausea reduces appetite and must be controlled.

Constipation can interfere with appetite.

Evaluation

Are weight and laboratory values stable?

Does patient understand low-protein diet?

Is patient receiving adequate calories?

Does oral care enhance appetite?

Does patient tolerate small feedings?

Are antiemetics effective?

Are patient's bowels functioning normally for him or her?

CRITICAL THINKING

Mrs. Jackson

■ Mrs. Jackson is a single, 56-year-old woman with a 20-year history of type 1 diabetes, hypertension, hyperlipidemia, chronic anemia, and a total knee replacement. She has been diagnosed with chronic renal failure. She was admitted to a medical unit for treatment of shortness of breath and renal failure which will include hemodialysis. She has had increasing shortness of breath, has pitting edema, urine output of about 375 mL/day, and is having premature ventricular contractions (PVCs) as seen on the cardiac monitor. Her admitting laboratory values are: Na 131, K 6, Cl 97, Ca 10, iron (Fe) 64, WBC 4000, RBC 3.12, Hgb 10.1, Hct 32, creatinine 7, BUN 30. Her blood glucose level yesterday was: 7 a.m. 154 mg/dL, noon 122 mg/dL, 5 p.m. 188 mg/dL. She has sliding-scale insulin ordered. She is

having an echocardiogram and chest x-ray done. She is having a two-tailed subclavian catheter placed for blood access. She is withdrawn and quiet.

1. What would be the first thing the nurse would address after getting the report?
2. What do her physical symptoms indicate and the laboratory values reflect?
3. What should the nurse say to Mrs. Jackson related to her withdrawn behavior?
4. What should the nurse identify related to Mrs. Jackson's understanding of self-care?
5. What teaching is needed for the diagnostic tests?
6. What care is required for the blood access?
7. What type of insulin is used for sliding-scale insulin coverage? Why?

Suggested answers at end of chapter.

REVIEW QUESTIONS

Multiple response item. Select all that apply.

1. When teaching a patient about preventing urinary tract infections, which of the following information should the nurse include?
 - a. Void frequently.
 - b. Drink large amounts of citrus juices.
 - c. Eat large amounts of vegetables.
 - d. Wash the perineum every 8 hours.
 - e. Void after sexual intercourse.
2. A patient is admitted to the hospital with a diagnosis of a kidney stone. Which of the following interventions should be included in the plan of care?
 - a. Restrict fluids.
 - b. Strain all urine.
 - c. Increase calcium intake.
 - d. Maintain bedrest.
3. The nurse is taking a history on a patient with a diagnosis of bladder cancer. Which of the following would the nurse expect to find in the patient's history?
 - a. Tobacco use
 - b. Vegetarian diet
 - c. Caffeine use
 - d. Alcohol use
4. While changing the pouch at the stoma site of an ileal conduit, the nurse notes the stoma is constantly spilling urine. Which of the following actions should the nurse take?
 - a. Notify the physician of the constant spillage.
 - b. Continue changing the pouch.
 - c. Remove the overflow of urine with a straight catheter.
 - d. Irrigate the stoma with a sterile solution of normal saline.
5. The nurse is caring for a patient with glomerulonephritis. Which of the following interventions would the nurse recommend be included in the patient's plan of care?
 - a. Increase fluid intake.
 - b. Decrease sodium intake.
 - c. Increase potassium intake.
 - d. Decrease carbohydrate intake.
6. The nurse is planning a teaching session for a patient with diabetic nephropathy. Which of these should the nurse include in the teaching plan to aid in slowing the progress of the disease?
 - a. Increase protein in diet.
 - b. Restrict protein in diet.
 - c. Increase potassium intake.
 - d. Decrease potassium intake.
7. The nurse is caring for a postoperative patient who is receiving 0.9% normal saline IV at 125 mL/hour, morphine for pain control, and garamycin IVPB every 8 hours for 24 hours. The patient is allergic to iodine. Morning labs are WBC 8500, Hgb 12.4 g/dL, creatinine 2.2 mg/dL. Which of these findings is a priority for the nurse to report to the RN?
 - a. WBC
 - b. IV rate of 125 mL/hour

- c. Allergies
 - d. Creatinine level
8. A patient with renal failure who is on hemodialysis asks for a snack in the afternoon. His potassium level remains high. Which of the following foods would be contraindicated?
 - a. Banana
 - b. Gelatin dessert
 - c. Clear carbonated beverage
 - d. Cranberry juice
 9. A patient is returning to the medical unit after a dialysis session. The nurse notes bleeding from the patient's vascular access in the left arm. Which of the following is the nurse's first action?
 - a. Call the physician.
 - b. Notify the dialysis nurse.
 - c. Apply pressure to site.
 - d. Take patient's blood pressure.
 10. The nurse is assessing a patient who has had a new right AV fistula created. How is the patency of the fistula checked?
 - a. Auscultate the left brachial pulse.
 - b. Auscultate and palpate the right radial pulse.
 - c. Measure blood pressure in the right arm.
 - d. Palpate for thrill and auscultate bruit over the fistula.
 11. A patient is to receive 1600 mg of Renagel (sevelamer) orally with meals. Renagel 400-mg tablets are available. How many tablets should the nurse give?
 _____ tablets

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Milan

1. Sexual intercourse can be a predisposing factor to UTI, especially if the patient does not urinate after intercourse.
2. Mrs. Milan should be cautioned to always urinate after intercourse. See also Box 37.2 Patient Teaching to Prevent Urinary Tract Infection.
3. The urinalysis will show WBCs, bacteria, RBCs, and positive nitrites.
4. Teaching should include the need to take all of the medication until it is gone even if she feels better. The reason for this is to ensure the infection is completely resolved so it does not return due to some remaining bacteria. She should return for a urine culture after the therapy is complete.

■ Mr. Stevens

1. Weight, intake and output, blood pressure, and laboratory tests should be assessed as part of the morning evaluation.
2. BUN, serum creatinine, and potassium levels should also be checked.
3. Mr. Stevens should be taught that he needs to take antihypertensive medications, keep his follow-up visits to his physician, follow a low-sodium diet, and restrict fluids if ordered.

■ Mrs. Jackson

1. Collect data related to her breathing and respiratory status first. Then address the cardiovascular system to see how she is tolerating the dysrhythmia. Obtain

Mrs. Jackson's weight and intake and output to monitor fluid balance.

2. Shortness of breath and pitting edema related to fluid overload; urine output 375 mL/day is due to renal failure; PVCs are due to elevated K. Na is low due to dilutional effect of excess fluid. K is retained due to renal failure. WBC low due to renal failure. RBC, Hgb, Hct low due to anemia from renal failure. Creatinine and BUN are not excreted and are elevated due to renal failure. Blood glucose is elevated due to diabetes.
3. Therapeutic conversation suggestions: "Mrs. Jackson, would you like to talk about your diagnosis?" "How do you feel about your diagnosis?" "Do you have questions or concerns?" "What are your usual coping methods?" Provide explanations for procedures and interventions.
4. Determine Mrs. Jackson's understanding of what renal failure is, how it is treated, how to follow the renal diet and fluid restrictions, and the action and importance of medications. Identify barriers to self-care and her support systems.
5. Teaching includes that the chest x-ray and echocardiogram require no preparation and are not painful.
6. A two-tail subclavian blood access is dedicated for hemodialysis. It is not used for any other purpose. Monitoring includes observing the site for signs of infection—redness, warmth, swelling, tenderness, drainage, and fever.
7. Regular insulin because it is rapid acting. Sliding-scale insulin is used to treat a current blood glucose. A rapid-acting insulin will affect a current blood glucose so only rapid-acting insulin is used.

QUESTIONS TO GUIDE YOUR READING

1. What are the glands of the endocrine system?
2. What is the function of each of the hormones in the endocrine system?
3. What are the effects of aging on endocrine system function?
4. What data should you collect when caring for a patient with a disorder of the endocrine system?
5. What nursing care should you provide for patients undergoing testing for an endocrine disorder?

NORMAL ANATOMY AND PHYSIOLOGY

The endocrine system consists of the endocrine (ductless) glands, which secrete chemicals called hormones. Unlike other organ systems, the glands of the endocrine system are anatomically separate (Fig. 38.1). Their hormones are involved in the composition and volume of interstitial fluid; all aspects of metabolism, energy balance, and growth/development; contraction of smooth and cardiac muscle; glandular secretion; reproduction; and the establishment of circadian rhythms. Each hormone is secreted in response to a particular and specific stimulus, is circulated by the blood throughout the body, and exerts its effects on certain target tissues that have receptors for that hormone. The effects of the hormone often reverse the stimulus and ultimately lead to decreased secretion of the hormone. This is called a negative feedback system; many hormone secretions are regulated this way. Some hormones are secreted in response to hormones from other endocrine glands.

Pituitary Gland

The pituitary gland, called the hypophysis, is suspended by a short stalk from the hypothalamus in the brain. The two major regions are the posterior pituitary (neurohypophysis) and anterior pituitary (adenohypophysis).

Posterior Pituitary Gland

The posterior pituitary gland stores antidiuretic hormone (ADH; sometimes called vasopressin) and oxytocin, which are actually produced by the hypothalamus. Their release is stimulated by nerve impulses from the hypothalamus.

Antidiuretic hormone increases the amount of water reabsorbed by the kidney tubules, which decreases urinary output. The water is reabsorbed back into the blood, thereby maintaining normal blood volume and normal blood pressure. The stimulus for secretion of ADH is a decrease in the water content of the body—that is, dehydration. When body water is lost and not replaced, specialized cells in the hypothalamus called osmoreceptors detect the elevated blood osmotic pressure (increased concentration) and transmit impulses to the posterior pituitary to secrete ADH to prevent

FIGURE 38.1 Glands of the endocrine system. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 5. FA. Davis, Philadelphia, 2007, with permission.)

the further loss of water in urine. In cases of great fluid loss, as in severe hemorrhage, the large amount of ADH secreted is especially important because it causes arteriole vasoconstriction, which increases blood pressure to homeostatic levels.

Oxytocin causes contraction of the smooth muscle in the uterus and mammary glands. At the end of pregnancy, stretching of the cervix generates sensory impulses to the hypothalamus, which then transmits impulses to the posterior pituitary for the release of oxytocin. Oxytocin causes strong contractions of the myometrium to bring about delivery of the baby and the placenta. This is an example of a positive feedback mechanism. During breastfeeding, the sucking of the baby generates sensory impulses from the mother's nipple to the hypothalamus. The subsequent release of oxytocin causes contraction of the smooth muscle cells around the mammary ducts. This release of milk is called milk ejection (or letdown).

Anterior Pituitary Gland

The anterior pituitary gland secretes its hormones in response to releasing hormones from the hypothalamus. The anterior pituitary synthesizes and secretes growth hormone, thyroid-stimulating hormone, adrenocorticotropic hormone, prolactin, follicle-stimulating hormone, and luteinizing hormone.

Growth hormone (GH, or somatotropin) increases cell division in those tissues capable of mitosis, which is one of the ways it is involved in growth. It also increases the transport of amino acids into cells and their use in protein synthesis. Growth hormone also increases the release of fat from adipose tissue and the use of fats for energy production; this is important even after growth in height has ceased. The secretion of GH is regulated by growth hormone-releasing hormone (GHRH) and by growth hormone-inhibiting hormone (GHIH, or somatostatin), both from the hypothalamus. GHRH is produced during hypoglycemia or when there is a high blood level of amino acids (to be turned into protein). GHIH is secreted during hyperglycemia, when carbohydrates are available for energy production and the mobilization of fat is not necessary.

Thyroid-stimulating hormone (TSH, or thyrotropin) has only one target organ: the thyroid gland. TSH stimulates growth of the thyroid and the secretion of two of its hormones, thyroxine (T_4) and triiodothyronine (T_3). The secretion of TSH is stimulated by thyrotropin-releasing hormone (TRH) from the hypothalamus when the metabolic rate decreases and there is a need for thyroxine.

Adrenocorticotropic hormone (ACTH) stimulates the secretion of cortisol and related hormones from the adrenal cortex. Corticotropin-releasing hormone (CRH) from the hypothalamus stimulates the release of ACTH. CRH is produced during any type of physiological stress situation, such as injury, disease, exercise, or hypoglycemia.

Prolactin initiates and maintains milk production by the mammary glands. The hypothalamus produces both prolactin-releasing hormone (PRH) and prolactin-inhibiting

hormone (PIH). Prolactin is not secreted in high enough levels to produce milk until pregnancy is over and the levels of estrogen and progesterone (from the placenta) have dropped. The action of a nursing infant reduces PIH, thus the prolactin level rises.

Follicle-stimulating hormone (FSH) is a gonadotropic hormone; that is, its target organs are the ovaries or testes. In women, FSH initiates growth of ova in ovarian follicles and secretion of estrogen by the cells of those follicles. In men, FSH initiates sperm production in the seminiferous tubules of the testes. FSH is secreted in response to gonadotropin-releasing hormone (GnRH) from the hypothalamus. Another hormone called inhibin (from the ovaries or testes) decreases the secretion of FSH.

Luteinizing hormone (LH) is another gonadotropic hormone whose secretion is increased by GnRH from the hypothalamus. In women, LH causes ovulation and stimulates the ruptured ovarian follicle to become the corpus luteum and begin secreting progesterone, as well as estrogen. In men, LH stimulates the secretion of testosterone by the interstitial cells of the testes.

Thyroid Gland

The thyroid gland consists of two lobes connected by a middle piece called the central isthmus; the gland is located on the front and sides of the trachea just below the larynx. Three hormones are produced by the thyroid gland. T_4 and T_3 are produced in the thyroid follicles, require iodine (T_4 has four iodine atoms, T_3 has three iodine atoms), and have the same functions. Calcitonin is the third hormone produced by the thyroid gland; it is produced by parafollicular cells.

T_4 and T_3 increase energy production and protein synthesis. They increase cellular respiration of glucose and fatty acids, which increases the metabolic rate—that is, energy and heat production. These hormones are the most important daily regulators of metabolic rate; their activity is reflected in the functioning of the heart, brain, muscles, and virtually all other organs. They are essential for normal physical growth, mental development, and reproductive maturation.

The direct stimulus for secretion of T_4 and T_3 is TSH from the anterior pituitary. The sequence of events is as follows: A decrease in the metabolic rate (energy production) is detected by the hypothalamus, which secretes TRH. TRH stimulates the anterior pituitary to secrete TSH, which stimulates the thyroid to increase secretion of T_4 and T_3 , which increase energy production to raise the metabolic rate. As the metabolic rate rises, negative feedback decreases the secretion of TRH from the hypothalamus until the metabolic rate decreases again.

The third thyroid hormone, calcitonin, targets bone tissue and therefore is especially important during childhood when bone growth is accelerated. Calcitonin inhibits resorption of calcium and phosphate by osteoclasts, thereby lowering the blood levels of these minerals and retaining them in bones. This one function of calcitonin has two important results: the maintenance of normal blood levels of calcium

and phosphate and the maintenance of a strong, stable bone matrix.

The stimulus for secretion of calcitonin is hypercalcemia (a high blood calcium level). When the blood calcium level rises, increased calcitonin ensures that no more will be removed from bones until need for blood calcium returns.

LEARNING TIP

An easy way to remember the function of calcitonin is to remember calciTONin TONes down serum calcium.

Parathyroid Glands

There are usually four parathyroid glands, two on the back of each lobe of the thyroid gland. The hormone they produce is called parathyroid hormone (PTH), which is an antagonist to calcitonin; it maintains normal blood levels of calcium and phosphate. Besides bone, the target organs of PTH are the small intestine and kidneys.

PTH increases the resorption of calcium and phosphate from the bones to the blood, which raises their blood levels. Absorption of calcium and phosphate from food in the small intestine is also increased by PTH through its action of activating vitamin D (calcitriol) in the kidneys. PTH also increases the resorption of calcium by the kidneys and the excretion of phosphate (more than is obtained from bones). Therefore, the overall effect of PTH is to raise the blood calcium level and lower the blood phosphate level.

Secretion of PTH is stimulated by hypocalcemia (a low blood calcium level) and is inhibited by hypercalcemia. In adults, PTH is probably the most important regulator of the blood calcium level. Calcium ions in the blood are essential for normal excitability of neurons and muscle cells and for the process of blood clotting.

Adrenal Glands

The two adrenal (also called suprarenal) glands are located one on top of each kidney. Each adrenal gland consists of an inner adrenal medulla and an outer adrenal cortex.

Adrenal Medulla

The cells of the adrenal medulla are called chromaffin cells. They secrete epinephrine and norepinephrine, which are collectively called catecholamines and are sympathomimetic (mimicking the sympathetic nervous system). Secretion of both hormones is stimulated by sympathetic impulses from the hypothalamus in stressful situations. The functions of the catecholamines mimic and prolong those of the sympathetic nervous system, which enable the individual to respond physiologically to stress situations.

Of the two hormones, epinephrine is secreted in larger amounts (approximately four times that of norepinephrine) and has many effects. It increases the heart rate and force of contraction, stimulates vasoconstriction in skin and most

viscera and vasodilation in skeletal muscles, dilates the bronchioles, decreases peristalsis, stimulates the liver to convert glycogen to glucose, increases the use of fats for energy, and increases the rate of cell respiration. The most significant function of norepinephrine is to cause vasoconstriction in the skin and most viscera, thereby raising blood pressure.

Adrenal Cortex

The adrenal cortex secretes three types of steroid hormones: mineralocorticoids, glucocorticoids, and sex hormones. The sex hormones are small amounts of male androgens and even smaller amounts of female estrogens. Their function is not known with certainty, although they may contribute to the growth spurt that often occurs just before puberty and to the libido (sex drive) in adult women.

LEARNING TIP

An easy way to remember the hormones of the adrenal cortex is to remember salt, sugar, and sex. Mineralocorticoids promote salt retention, glucocorticoids affect sugar (carbohydrate) metabolism, and androgens and estrogens are sex hormones.

Aldosterone is the most abundant of the mineralocorticoids, and its target organs are the kidneys. Aldosterone increases the reabsorption of sodium ions and the excretion of potassium ions by the kidney tubules. This means that sodium ions are returned to the blood and potassium ions are eliminated in urine. This function of aldosterone has important consequences. As sodium ions are reabsorbed, hydrogen ions may be excreted in exchange; this is one mechanism to prevent the accumulation of hydrogen ions that would lead to acidosis. Also, as sodium ions are reabsorbed, water and negative ions such as bicarbonate follow and are thus returned to the blood. Although the reabsorption of water is an indirect effect of aldosterone, it is important for the maintenance of normal blood volume and blood pressure.

Secretion of aldosterone may be stimulated in several ways: a low blood sodium level, a high blood potassium level, or loss of blood or dehydration that lowers blood pressure. Low blood pressure activates the renin-angiotensin mechanism of the kidneys, which culminates in the formation of angiotensin II. One function of angiotensin II is to increase secretion of aldosterone. The hormone called atrial natriuretic peptide (ANP), secreted by the atria of the heart when blood pressure or blood volume rises, seems to inhibit secretion of aldosterone (and renin) and thereby promotes elimination of sodium ions and water by the kidneys.

Cortisol is the most abundant of the glucocorticoids and has many target tissues. Cortisol stimulates gluconeogenesis (the conversion of triglycerides, lactic acid, and some amino

acids to glucose) in the liver. It also increases lipolysis and protein breakdown to liberate fatty acids and amino acids, respectively, for gluconeogenesis. The goal is to increase capabilities of energy production. By providing these secondary energy sources to most cells, cortisol ensures that whatever glucose is present will be available for the brain (the glucose-sparing effect).

Cortisol also has an anti-inflammatory effect because it blocks the effects of histamine and stabilizes the lysosomes in cells. Normal cortisol secretion seems to limit the inflammation process to what is useful for tissue repair and to prevent excessive tissue destruction. Excess cortisol has damaging effects, however: It raises blood glucose levels, decreases the immune response, and delays healing of damaged tissue.

The direct stimulus for cortisol secretion is ACTH from the anterior pituitary gland. Cortisol is also a “stress” hormone, and any type of physiological stress (injury, disease, malnutrition) stimulates the hypothalamus to secrete CRH. CRH increases the secretion of ACTH by the anterior pituitary, which increases cortisol secretion by the adrenal cortex.

Pancreas

The pancreas extends from the curve of the duodenum to the spleen. The endocrine portions of the pancreas are called islets of Langerhans (pancreatic islets); they contain alpha cells, which produce glucagon, and beta cells, which produce insulin. Delta cells in the islets secrete somatostatin, which inhibits secretion of both insulin and glucagon.

The functions of glucagon are all related to energy production. Glucagon stimulates the liver to catabolize glycogen

to glucose (glycogenolysis) and to increase gluconeogenesis to use fats and excess amino acids for energy production. The overall effect, therefore, is to raise the blood glucose level for cellular uptake and respiration.

The secretion of glucagon is stimulated by hypoglycemia, a low blood glucose level. Such a state may occur during physiological stress situations such as exercise or simply being between meals.

Insulin increases the transport of glucose from the blood into cells by increasing the permeability of cell membranes to glucose (brain and liver cells, however, are not dependent on insulin for glucose intake). Inside cells, glucose is broken down in cellular respiration to release energy. The liver and muscles are also stimulated by insulin to change glucose to glycogen (glycogenesis) to be stored for later use. Insulin also enables cells to take in fatty acids and amino acids to use in the synthesis of lipids and proteins (not energy production). Insulin, therefore, decreases the blood glucose level by increasing the use of glucose for energy, promoting the storage of excess glucose, and decreasing energy production from other food sources.

Secretion of insulin is stimulated by hyperglycemia, a high blood glucose level. This state occurs after meals, especially those high in carbohydrates. It should be apparent that insulin and glucagon function as antagonists and that normal secretion of both hormones ensures a blood glucose level that fluctuates within normal limits. Table 38.1 reviews endocrine hormone function.

Aging and the Endocrine System

Most of the endocrine glands decrease their secretions with age, but normal aging usually does not lead to serious hor-

TABLE 38.1 REVIEW OF ENDOCRINE FUNCTION

Hormone	Function(s)	Regulation of Secretion
<i>Hormones of the Posterior Pituitary Gland</i>		
<i>Oxytocin</i>	Promotes contraction of myometrium of uterus (labor) Promotes release of milk from mammary glands	Nerve impulses from hypothalamus, the result of stretching of cervix or stimulation of nipple Secretion from placenta at the end of gestation—stimulus unknown
<i>Antidiuretic hormone (ADH)</i>	Increases water reabsorption by the kidney tubules (water returns to the blood)	Decreased water content in the body (alcohol inhibits secretion)
<i>Hormones of the Anterior Pituitary Gland</i>		
<i>Growth hormone (GH)</i>	Increases rate of mitosis Increases amino acid transport into cells Increases rate of protein synthesis Increases use of fats for energy	GHRH (hypothalamus) stimulates secretion GHIH—somatostatin (hypothalamus) inhibits secretion
<i>Thyroid-stimulating hormone (TSH)</i>	Increases secretion of thyroxine and T ₃ by thyroid gland	TRH (hypothalamus)
<i>Adrenocorticotrophic hormone (ACTH)</i>	Increases secretion of cortisol by the adrenal cortex	CRH (hypothalamus)
<i>Prolactin</i>	Stimulates milk production by the mammary glands	PRH (hypothalamus) stimulates secretion PIH (hypothalamus) inhibits secretion
<i>Follicle-stimulating hormone (FSH)</i>	In women: Initiates growth of ova in ovarian follicles Increases secretion of estrogen by follicle cells	GnRH (hypothalamus) stimulates secretion Inhibin (ovaries or testes) inhibits secretion

Hormone	Function(s)	Regulation of Secretion
Hormones of the Anterior Pituitary Gland (Continued)		
<i>FSH (cont.)</i>	In men: Initiates sperm production in the testes	GnRH (hypothalamus)
<i>Luteinizing hormone (LH)</i>	In women: Causes ovulation Causes the ruptured ovarian follicle to become the corpus luteum Increases secretion of progesterone by the corpus luteum In men: Increases secretion of testosterone by the interstitial cells of the testes	GnRH (hypothalamus)
Hormones of the Thyroid Gland		
<i>Thyroxine and triiodothyronine (T₄ and T₃)</i>	Increase energy production from all food types Increase rate of protein synthesis	TSH (anterior pituitary)
<i>Calcitonin</i>	Decreases the reabsorption of calcium and phosphate from bones to blood	Hypercalcemia
Hormones of the Parathyroid Glands		
<i>Parathyroid hormone (PTH)</i>	Increases the reabsorption of calcium and phosphate from bone to blood Increases absorption of calcium and phosphate by the small intestine Increases the reabsorption of calcium and the excretion of phosphate by the kidneys; activates vitamin D	Hypocalcemia stimulates secretion. Hypercalcemia inhibits secretion.
Hormones of the Pancreas		
<i>Glucagon (alpha cells)</i>	Increases conversion of glycogen to glucose in the liver Increases the use of excess amino acids and fats for energy	Hypoglycemia
<i>Insulin (beta cells)</i>	Increases glucose transport into cells and the use of glucose for energy production Increases the conversion of excess glucose to glycogen in the liver and muscles Increases amino acid and fatty acid transport into cells and their use in synthesis reactions	Hyperglycemia
<i>Somatostatin (delta cells)</i>	Decreases secretion of insulin and glucagon. Slows absorption of nutrients.	Rising levels of insulin and glucagon
Hormones of the Adrenal Medulla		
<i>Norepinephrine</i>	Causes vasoconstriction in skin, viscera, and skeletal muscles	Sympathetic impulses from the hypothalamus in stress situations
<i>Epinephrine</i>	Increases heart rate and force of contraction Dilates bronchioles Decreases peristalsis Increases conversion of glycogen to glucose in the liver Causes vasodilation in skeletal muscles Causes vasoconstriction in skin and viscera Increases use of fats for energy Increases the rate of cell respiration	
Hormones of the Adrenal Cortex		
<i>Aldosterone</i>	Increases reabsorption of Na ⁺ ions by the kidneys to the blood Increases excretion of K ⁺ ions by the kidneys in urine	Low blood Na ⁺ level Low blood volume or blood pressure High blood K ⁺ level
<i>Cortisol</i>	Increases use of fats and excess amino acids for energy Increases gluconeogenesis Increases use of glucose Anti-inflammatory effect: stabilizes lysosomes and blocks the effects of histamine	ACTH (anterior pituitary) during physiological stress

Abbreviations: K⁺ = potassium; Na⁺ = sodium.

FIGURE 38.2 Effects of aging.

more deficiencies or illness (Fig. 38.2). Unless specific pathological conditions develop, the endocrine system usually continues to function adequately in old age.

NURSING ASSESSMENT

Health History

When performing a health history, a number of questions can be asked to determine whether an endocrine problem exists. Often, however, you might be aware of a history of an endocrine disorder, such as diabetes or hypothyroidism. When a disorder exists or is suspected, you can do a more focused assessment. Assessment of individual disorders is provided in Chapters 39 and 40. Table 38.2 offers general questions that can help you identify new problem areas. If the assessment reveals abnormalities, they should be reported to a registered nurse or physician.

NURSING CARE TIP

Some patients call diabetes mellitus “sugar.” So instead of asking if anyone in their family has diabetes, you may need to ask if anyone has “sugar.”

TABLE 38.2 SUBJECTIVE ASSESSMENT OF THE ENDOCRINE SYSTEM

Category	Questions to Ask	Rationale
Neuromuscular	Have you noticed muscle spasms or twitching?	These symptoms may be associated with excessive antidiuretic hormone secretion (SIADH) or calcium depletion resulting from hypoparathyroidism.
	Do you have numbness, tingling, or pain in your feet, legs, or hands?	These may be associated with neuropathy resulting from diabetes mellitus. Numbness and tingling may also indicate hypocalcemia related to hypoparathyroidism.
Nutrition/Fluid Balance	Have you gained or lost weight without trying?	Actual weight gain may be associated with hypothyroidism. Weight gain due to water retention may result from Cushing’s syndrome, or SIADH. Weight loss may result from uncontrolled diabetes or hyperthyroidism. Weight loss due to dehydration may be related to Addison’s disease.
	Have you noticed excessive thirst or urination?	Excessive thirst and urination are classic symptoms of diabetes mellitus and diabetes insipidus.
	Have you noticed a change in your energy level?	Lack of energy may be associated with uncontrolled diabetes, hypothyroidism, hyperthyroidism, Addison’s disease, or pituitary disorders.
Metabolic	Do you generally tolerate changes in environmental temperature?	Hypothyroidism can cause cold intolerance. Hyperthyroidism can cause heat intolerance.
Mood/Memory	Have you noticed a change in your mood or memory?	Mental function may be dull with hypothyroidism. Mood swings may occur with Cushing’s syndrome. Agitation or confusion may result from hypoglycemia in a person with diabetes.
Family History	Does anyone in your family have a thyroid problem, diabetes, or another endocrine disorder?	Some disorders are hereditary.

SIADH = syndrome of inappropriate antidiuretic hormone.

TABLE 38.3 ENDOCRINE-RELATED CAUSES OF ABNORMAL PHYSICAL ASSESSMENT FINDINGS

Category	Abnormal Assessment Finding	Possible Causes
Mood	Depressed mood or affect Nervousness Agitation	Hypothyroidism Hyperthyroidism, pheochromocytoma Low blood sugar
Nutrition/Fluid Balance	Weight gain Weight loss Poor skin turgor	Decreased metabolic rate in hypothyroidism, fluid excess Increased metabolic rate in hyperthyroidism; uncontrolled diabetes, dehydration Dehydration due to water loss in Addison's disease, diabetes mellitus, diabetes insipidus
Integumentary	Hyperpigmentation of skin Dry, scaly skin Dusky lower extremities with weak peripheral pulses	Addison's disease Hypothyroidism Circulatory changes in diabetes mellitus
Vital Signs	Change in pulse or temperature Elevated blood pressure	Elevated due to increased metabolic rate in hyperthyroidism Decreased due to slowed metabolic rate in hypothyroidism Increased catecholamine release in pheochromocytoma or fluid retention in Cushing's syndrome
Neuromuscular	Decreased blood pressure Tremor	Sodium and water loss in Addison's disease Hyperthyroidism, hypoglycemia, or pheochromocytoma
Head and Neck	Exophthalmos (bulging eyes) Fat pads on neck and shoulders ("buffalo hump"), round "moon" face Enlarged thyroid gland	Fat deposits and edema behind the eyes in Graves' disease Accumulation of fat in Cushing's syndrome Excessive stimulation by TSH in hypothyroidism or hyperthyroidism

Physical Assessment of the Patient with an Endocrine Disorder

Physical assessment starts with height, weight, and vital signs. Compare findings with the patient's baseline assessment if available. Table 38.3 includes common endocrine-related causes of physical assessment abnormalities.

Inspection

Observe the patient for mood and **affect** (emotional tone) throughout the physical assessment. Inspect the neck for thyroid enlargement. Look for eyes that bulge (**exophthalmos**). Note posture, body fat, and presence of tremor. Observe skin and hair texture and moisture. Note the presence of a moon-like face or "buffalo hump" on the upper back. Observe the lower extremities for skin and color changes that might indicate circulatory impairment. See Table 38.3 for rationales for these observations.

Palpation

The thyroid gland is the only palpable endocrine gland. The licensed practical nurse/licensed vocational nurse (LPN/LVN) may assist a physician or nurse practitioner to palpate the thyroid gland. The practitioner stands behind or in front of the seated patient and palpates the gland while the patient swallows a sip of water (Fig. 38.3). You can assist with positioning the patient, providing water, and instructing the

patient to take a sip of water and hold it in his or her mouth until told to swallow. The thyroid gland should never be palpated in a patient with uncontrolled hyperthyroidism because this can stimulate secretion of additional thyroid hormone.

Palpate all peripheral pulses. The posterior tibial and dorsalis pedis pulses may be diminished in patients with circulatory impairment. Palpate skin turgor by gently pinching

FIGURE 38.3 Thyroid palpation (From Dillon, P. M: *Nursing Health Assessment: A Critical Thinking Approach*, ed. 2. F.A. Davis, Philadelphia, 2007, with permission.)

exophthalmos: exo—outward + ophthalmos—eye

a small piece of skin. If a “tent” remains, the patient may be dehydrated as a result of water loss, as in ADH deficiency.

Auscultation and Percussion

Auscultation and percussion are not usually part of an endocrine assessment.

DIAGNOSTIC TESTS

Hormone Tests

Serum Hormone Levels

Many hormones can be measured from a simple blood specimen. This is useful in diagnosing hypofunctioning or hyperfunctioning gland states. See Table 38.4 for some commonly measured hormones.

Stimulation Tests

Stimulation tests may also help determine endocrine gland function. For this type of test, a substance is injected to attempt to stimulate a gland. The hormone secreted by that gland is then measured in the blood to determine how well it responded to the stimulation. For example, in a TRH stimulation test, TRH is injected. If the pituitary gland responds appropriately, TSH is secreted. If the thyroid gland responds appropriately to the TSH, T_3 and T_4 levels rise. Failure of the TRH to stimulate TSH and thyroid hormone indicates a pituitary or thyroid condition. Further studies might be done to determine the cause.

Suppression Tests

Suppression tests are the opposite of stimulating tests. For this type of test, a substance is injected that is expected to suppress a hormone’s release. For example, if dexametha-

TABLE 38.4 COMMON ENDOCRINE-RELATED LABORATORY TESTS

Test	Normal Values*	Significance
Thyroid Tests		
<i>Thyroid-stimulating hormone</i>	0.5–5.0 U/mL	↑ in primary hypothyroidism ↓ in primary hyperthyroidism
<i>Triiodothyronine (T_3)</i>	80–200 ng/100 mL	↓ in hypothyroidism ↑ in hyperthyroidism
<i>Thyroxine (T_4)</i>	4–12 μ g/100 mL	↓ in hypothyroidism ↑ in hyperthyroidism
Parathyroid Tests		
<i>Parathyroid hormone</i>	<25 pg/mL	↑ in primary hyperparathyroidism ↓ in primary hypoparathyroidism, parathyroid trauma during thyroid surgery
<i>Calcium</i>	8.5–10.5 mg/100 mL	↑ in some cancers, hyperparathyroidism ↓ in hypothyroidism
<i>Phosphorus</i>	2.4–4.7 mg/dL	↑ in hypoparathyroidism ↓ in hyperparathyroidism
Pituitary Tests		
<i>Growth hormone</i>	<5 ng/mL	↑ in acromegaly ↓ in small stature
<i>Antidiuretic hormone</i>	2.3–3.1 pg/mL	↑ in SIADH ↓ in diabetes insipidus
<i>Urine specific gravity</i>	1.010–1.025	↓ in diabetes insipidus
<i>Adrenocorticotropic hormone</i>	<120 pg/mL at 6–8 a.m.	↑ in Addison’s disease ↓ in Cushing’s syndrome, long-term corticosteroid therapy
Adrenal Tests		
<i>Cortisol</i>	5–25 μ g/100 mL	↑ in Cushing’s syndrome, stress ↓ in Addison’s disease, steroid withdrawal
<i>Vanillylmandelic acid (VMA; urine test)</i>	0.7–6.8 mg/24 h	↑ in pheochromocytoma
Pancreas Tests		
<i>Fasting plasma glucose (FPG)</i>	70–100 mg/dL	↑ in stress, Cushing’s syndrome FPG 101–125 = pre-diabetes FPG \geq 126 = diabetes mellitus
<i>Oral glucose tolerance test</i>	Blood glucose less than 140 mg/dL at 2 hours	↓ in hypoglycemia, Addison’s disease BG 140–199 at 2 hours = pre-diabetes BG \geq 200 at 2 hours = diabetes mellitus
<i>Glycosylated hemoglobin</i>	4%–7%	↑ in poor diabetes control

SIADH = syndrome of inappropriate antidiuretic hormone.

*All normal values are for a fasting test.

CRITICAL THINKING**Mrs. Hackworth**

■ Mrs. Hackworth is tired all the time, and the nurse practitioner orders a TSH level drawn. The result is higher than normal.

1. She asks, “If my thyroid level is high, then why am I so tired?” How should you respond?
2. After further testing, the NP places Mrs. Hackworth on levothyroxine (Synthroid) 50 µg daily. Her pharmacist supplies Synthroid 0.05 mg. Is her dose correct?

Suggested answers at end of chapter.

sone (a steroid hormone) is injected, cortisol release from the adrenal cortex is expected to be suppressed via a negative feedback mechanism. If the cortisol level is not suppressed, adrenal cortex dysfunction is suspected.

Urine Tests

Sometimes it is helpful to measure the amount of hormone or hormone by-product excreted in the urine during a 24-hour period. Examples are cortisol and vanillylmandelic acid, a product of catecholamine metabolism.

To collect a 24-hour urine specimen, you must obtain a special urine container from the laboratory. It is usually an opaque container that protects the specimen from light; it may have preservative in it. Check with the laboratory to find out whether the specimen needs to be kept on ice during the test and whether the patient needs to be on a special diet before or during the test. To keep a specimen on ice, fill a bath basin with ice and place the container in the basin. The ice must be refilled every few hours to keep the specimen cold. When initiating the test, ask the patient to urinate and discard the urine. The time of this first discarded voiding is considered the start of the test. Any urine collected from this time forward for 24 hours is saved. At the end of the 24-hour period, the patient is again asked to urinate, but this time the urine is saved. The entire collection is then labeled and sent to the laboratory. Instruct the patient how to do the test, place a sign on the toilet with the start and stop time of the test, and remind all staff to save the urine.

If the patient is incontinent or otherwise unable to participate in the test, a catheter may need to be inserted. If the patient already has an indwelling catheter, a new bag and tubing should be attached before the start of the test. The laboratory should be consulted to determine the need for a preservative or ice. Preservative can be added to the catheter bag if necessary. If ice is necessary, the bag should be kept in a basin of ice rather than hanging on the side of the bed.

CRITICAL THINKING**Mrs. Trombley**

■ Mrs. Trombley is having a 24-hour urine test done. You begin the test at 0600, and it progresses well until you learn that the nursing assistant helped her up to void in the toilet at noon, forgetting to save her urine.

1. What do you do?
2. How can you prevent this from happening again?
3. How would you document this incident?

Suggested answers at end of chapter.

If the specimen must be protected from light, the bag can be covered with dark plastic or foil.

Other Laboratory Tests

Some laboratory tests may indirectly reflect the function of an endocrine gland. For example, a serum calcium level helps indicate PTH or calcitonin secretion, and a blood glucose level reflects insulin secretion.

Nuclear Scanning

A thyroid scan may be done to determine the presence of tumors or nodules. For this test, a radioactive material is injected or radioactive iodine is taken orally. The material is taken up by the thyroid gland. After a specified time, the thyroid gland is scanned with a scintillation camera. The scan will show “hot spots,” which are nodules that are not malignant, or “cold spots” (areas that do not take up the radioactivity), which indicate malignancy. Cold spots can then be biopsied to confirm a diagnosis. Because such a small amount of radioactive material is used, there is no risk to the patient. The patient should be aware that the test takes approximately 30 minutes to complete.

Radiographic Tests

A computed tomographic (CT) scan or magnetic resonance imaging (MRI) may be done to locate a tumor or identify hypertrophy of a gland.

Ultrasound

Ultrasound may be done of the thyroid or parathyroid glands to determine if they are enlarged or to find masses.

Biopsy

Biopsy is done to obtain tissue to examine for possible cancerous cells. The thyroid gland can be biopsied either by needle aspiration under local anesthesia or using a surgical incision.

REVIEW QUESTIONS

- Which hormones are secreted by the posterior pituitary gland? Choose all that apply.
 - Antidiuretic hormone
 - Thyroid-stimulating hormone
 - Growth hormone
 - Luteinizing hormone
 - Oxytocin
 - Calcitonin
- What are the functions of T_4 and T_3 ?
 - Retention of salt and water
 - Maintenance of blood sugar
 - Maintenance of blood pressure
 - Regulation of energy production
- Which hormone maintains strong bones?
 - ADH
 - Insulin
 - Calcitonin
 - TRH
- The nurse is doing an admission assessment on a new resident to a nursing home. The patient's face and shoulders seem to have a lot of fat, but the patient's arms and legs are thin. Which of the following disorders might these findings relate to?
 - Cushing's syndrome
 - Diabetes insipidus
 - Diabetes mellitus
 - Pheochromocytoma
- When explaining a thyroid scan to a patient, which of the following statements is correct?
 - "You will take a special pill, and then an ultrasound will be taken of your neck."
 - "You will receive an injection of radioactive material, and then a special camera will take pictures of your thyroid gland."
 - "You will be placed into a special machine, and x-rays will be taken of your neck. It may be noisy."
 - "You will be given a special drink, and then magnetic energy is used to visualize the thyroid area."

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ **Mrs. Hackworth**

- "It's not your thyroid hormone that is high, it's your thyroid-stimulating hormone. That means your pituitary gland has to work extra hard to try to stimulate your thyroid gland."

$$\frac{50 \mu\text{g}}{1000 \mu\text{g}} \left| \frac{1 \text{ mg}}{1000 \mu\text{g}} \right. = 0.05 \text{ mg}$$

■ **Mrs. Trombley**

- The specimen must include all urine for a 24-hour period. Restart the test from noon.

- To prevent this from happening again, try placing an incontinence pad or other large item directly over the toilet as a reminder to the patient. Be sure there is a sign posted above the toilet or on the toilet handle, and communicate with the nursing assistants why the urine needs to be saved.
- "Patient voided in toilet at 1200. 24-hour urine test restarted; importance of saving urine explained to patient and staff. RN notified." Note that it is not appropriate to "blame" the nursing assistant for making a mistake.

QUESTIONS TO GUIDE YOUR READING

1. What are the disorders caused by variations in the hormones of the pituitary, thyroid, parathyroid, and adrenal glands?
2. How would you explain the pathophysiology of each of the endocrine disorders presented?
3. What are the etiologies, signs, and symptoms of each of the disorders?
4. What is current therapeutic treatment of each of the selected endocrine disorders?
5. What data would you collect when caring for patients with each of the endocrine disorders discussed?
6. What nursing care will you provide for patients with each of the disorders?
7. How will you know if your nursing interventions have been effective?

A variety of disorders can be found within the endocrine system. Although the causes vary, the pathophysiology usually involves either too little or too much hormone activity. Insufficient hormone activity may be the result of hypofunction of an endocrine gland or insensitivity of the target tissue to its hormone. Excessive hormone activity may be the result of a hyperactive gland, **ectopic** hormone production, or self-administration of too much replacement hormone (Table 39.1). If you can remember the function of each hormone in the body, understanding the problems involved with an altered amount of each hormone becomes easier.

Most endocrine disorders are either primary or secondary. A primary disorder is a problem within the gland that is out of balance. Secondary disorders are caused by problems outside the gland, such as an imbalance in a tropic hormone, certain drugs, trauma, surgery, or a problem in the feedback mechanism. For example, if the thyroid gland is diseased and causing hypothyroidism, it would be considered a primary problem. Sometimes hypothyroidism is caused by not enough thyroid-stimulating hormone from the pituitary gland, even though the thyroid gland is healthy. This would be considered a secondary problem.

LEARNING TIP

If you can remember what each hormone does in the body, it will be easier to remember what results from imbalances of that hormone. Most symptoms of hormone hyperactivity are the opposite of symptoms of that hormone's hypoactivity.

PITUITARY DISORDERS

Pituitary disorders often involve several hormone imbalances at once, caused by general hypopituitarism or hyperpituitarism. Problems involving all the pituitary hormones at once are rare. For simplicity, imbalances are considered separately here.

TABLE 39.1 CAUSES OF ENDOCRINE PROBLEMS

Insufficient Hormone Activity	Excess Hormone Activity
Gland hypofunction	Gland hyperfunction
Lack of tropic or stimulating hormone	Excess tropic or stimulating hormone
Target tissue insensitivity to hormone	Ectopic hormone production
	Self-administration of too much replacement hormone

ectopic: ec—away from normal + topic—place

TABLE 39.2 ANTIDIURETIC HORMONE DISORDERS SUMMARY

	Insufficient ADH	Excess ADH
Disorder	Diabetes insipidus	SIADH
Signs and Symptoms	Polyuria, polydipsia, hyponatremia, dehydration	Fluid retention, weight gain, hyponatremia
Diagnostic Tests	Urine specific gravity, urine and plasma osmolality	Serum and urine sodium and osmolality
Therapeutic Interventions	Synthetic ADH replacement	Treat cause
Priority Nursing Diagnoses	Risk for deficient fluid volume	Risk for excess fluid volume

Disorders Related to Antidiuretic Hormone Imbalance

Antidiuretic hormone (ADH; also called arginine vasopressin [AVP]) is synthesized in the hypothalamus and stored and secreted by the posterior pituitary gland. A decrease in ADH activity results in diabetes insipidus (DI). An increase in ADH activity is called syndrome of inappropriate antidiuretic hormone (SIADH). Table 39.2 compares DI and SIADH. Note how symptoms of too little ADH (water loss) are opposite from symptoms of too much ADH (water retention).

Diabetes Insipidus

PATHOPHYSIOLOGY. Diabetes insipidus is caused by a deficiency of ADH. Recall that ADH is responsible for reabsorption of water by the distal tubules and collecting ducts in the kidneys. If ADH is lacking, adequate reabsorption of water is prevented, leading to diuresis. In **nephrogenic** diabetes insipidus, there is enough ADH but the kidneys do not respond to it. Patients may urinate from 3 to 15 L per day. This leads to increased serum **osmolality** (concentrated blood) and dehydration. The increased osmolality and decreased blood pressure normally trigger ADH secretion, which causes water retention and dilutes the blood; in patients with DI, this does not occur. Increased osmolality also leads to extreme thirst, which usually causes the patient to drink enough fluids to maintain fluid balance. In an unconscious patient or a patient with a defective thirst mechanism, however, dehydration may quickly occur if the problem is not recognized and corrected. For more information, check out the Nephrogenic Diabetes Insipidus Foundation at www.ndif.org.

ETIOLOGY. The primary causes of diabetes insipidus are tumors or trauma to the pituitary gland. Surgery in the area of the pituitary and certain drugs, such as glucocorticoids or alcohol, may also cause DI. Occasionally, the cause is **psychogenic**, in which the patient drinks large quantities of

nephrogenic: nephro—kidney + genic—to produce

psychogenic: psycho—related to the mind + genic—to produce

water in the absence of true disease. Nephrogenic DI occurs mostly in males and may be inherited or acquired. It is diagnosed when the kidneys do not respond to ADH. It can be triggered by certain drugs or neoplasms or by damage to the kidneys from pyelonephritis, polycystic disease, or other causes.

SIGNS AND SYMPTOMS. The patient with DI urinates frequently (**polyuria**), and nighttime urination (**nocturia**) is present. This results in high serum osmolality and low urine osmolality. Urine specific gravity is decreased, making the urine diluted and light in color.

The patient experiences extreme thirst (**polydipsia**), and consumes large volumes of water. Often patients crave ice-cold water. If urine output exceeds fluid intake, dehydration occurs, with characteristic symptoms of hypotension, poor skin turgor, and weakness. **Hypovolemic** shock occurs if fluid balance is not restored. Dehydration and electrolyte imbalances result in a decrease in level of consciousness and death if the problem is not corrected.

The patient with DI may develop an enlarged bladder and kidney damage from constantly trying to “hold” too much urine.

DIAGNOSTIC TESTS. Diagnosis is based initially on a history of risk factors and reported symptoms. Urine specific gravity is less than 1.005 (normal: 1.010 to 1.025), and can be monitored by laboratory tests or by using reagent strips at the bedside. Plasma and urine osmolality are measured and compared to each other. The actual amount of sodium in the blood may be normal, but it appears elevated in relation to the decreased amount of water. A computed tomographic (CT) scanning or magnetic resonance imaging (MRI) may show a pituitary tumor.

A water-deprivation test may be done. For this test, the patient is deprived of water for up to 6 hours. Body weight and urine osmolality are tested hourly. If the urine continues to be diluted, even though the patient is not drinking and is losing weight as a result of volume depletion, DI is suspected. In the second stage of the test, the patient receives an injection of ADH, with a final urine test done 1 hour later. If the DI is nephrogenic, the kidneys do not respond to the injected ADH.

ADH levels can be measured in plasma or urine following administration of hypertonic saline or fluid restriction. The normal response would be elevated ADH; if it is not elevated, DI is suspected. The urine glucose level may also be checked to rule out diabetes mellitus.

THERAPEUTIC INTERVENTIONS. Hypotonic intravenous (IV) fluids such as 0.45% saline may be ordered to replace intravascular volume without adding excessive sodium. IV fluids are especially important if the patient is unable to take oral fluids.

polyuria: poly—much + uria—urine

nocturia: noct—night + uria—urine

polydipsia: poly—much + dipsia—thirst

hypovolemic: hypo—deficient + vol—volume + emic—blood

Medical treatment of DI involves replacement of ADH. In acute cases, vasopressin, a synthetic form of ADH, is given by the intravenous or subcutaneous route, along with intravenous fluid replacement. In patients who require long-term therapy, synthetic ADH (desmopressin, or DDAVP) in the form of a nasal spray is used, usually twice a day. Other drugs, such as chlorpropamide (Diabinese), help the kidneys respond better to ADH. Thiazide diuretics may decrease urine flow in the absence of ADH (even though they usually are used to increase urine output!). If a pituitary tumor is involved, treatment usually involves removal of the pituitary gland (**hypophysectomy**).

NURSING PROCESS FOR THE PATIENT WITH DIABETES INSIPIDUS. Assessment/Data Collection.

When doing a nursing assessment of a patient with DI, place special attention on fluid balance. Daily weights are the most reliable method for monitoring the amount of fluid that is being lost. Accurate intake and output measurement is also helpful. Skin turgor will be poor and mucous membranes will be dry and sticky if the patient is becoming dehydrated. Monitor skin integrity because dehydration increases risk of breakdown. Monitor vital signs for signs of shock. Use a reagent strip (dipstick) or urinometer to measure urine specific gravities. Monitor serum electrolytes and osmolality as ordered, and watch for changes in level of consciousness. Assess the patient’s understanding of his or her disease and treatment. Once treatment is initiated, continue to monitor fluid balance, being especially alert to signs of fluid overload.

Nursing Diagnosis, Planning, and Implementation. Deficient fluid volume related to failure of regulatory mechanisms

EXPECTED OUTCOME: Fluid balance will be maintained as evidenced by urine specific gravity between 1.010 and 1.025, skin turgor within normal limits, and stable daily weight.

- Monitor daily weight, I&O, vital signs, and urine specific gravity. *Decreased weight, output greater than intake, low blood pressure, elevated pulse rate, and high urine specific gravity may all indicate fluid deficit.*
- Provide free access to oral fluids if the DI is not psychogenic. If the patient’s thirst mechanism is not intact, give the patient fluids every hour. *Oral fluids are essential to replace the excess lost in diuresis. If the patient is alert with an intact thirst mechanism, the patient can usually manage this independently.*
- Encourage the patient to participate in maintaining intake and output records, monitoring weight, and checking urine specific gravity, if able. *This involves the patient and helps prepare him or her for self-monitoring at home.*
- Report a significant drop in blood pressure and a rising pulse to the registered nurse or physician *because these may be signs of hypovolemic shock.*

hypophysectomy: hypophysis—pituitary + ectomy—surgical removal

Risk for ineffective health maintenance related to deficient knowledge

EXPECTED OUTCOME: Patient will verbalize and demonstrate understanding of medication administration and self-monitoring of disease.

- Assess patient's understanding of his or her disease process and treatment. *Teaching should build on baseline knowledge.*
- Teach the patient about DI. *The patient will have to self-medicate and monitor his or her disease at home. Include:*
 - Basic pathophysiology of the disease
 - How to administer medications and monitor their effectiveness
 - How to measure urine specific gravity and the significance of results
 - Signs and symptoms of dehydration and fluid overload
- Stress the importance of monitoring daily weight: losses or gains of greater than 2 pounds in a day should be reported to the physician. *Weight loss or gain can indicate fluid imbalance and need for a change in medication regimen.*
- Advise the patient to wear identification, such as a medical alert bracelet, that identifies the disorder. *Faster treatment can be initiated if emergency personnel are aware of DI diagnosis.*

Evaluation. If treatment has been effective, signs of dehydration will be absent and weight and vital signs will be stable. The patient should be able to explain what is happening in the disease, symptoms to report, and demonstrate how to manage self-care.

Syndrome of Inappropriate Antidiuretic Hormone

PATHOPHYSIOLOGY. Syndrome of inappropriate antidiuretic hormone (SIADH) results from too much ADH in the body. This causes excess water to be reabsorbed by the kidney tubules and collecting ducts, leading to decreased urine output and fluid overload. As fluid builds up in the bloodstream, osmolality decreases and the blood becomes diluted. Normally, a decreased serum osmolality inhibits release of ADH. In SIADH, however, ADH continues to be released, adding to the fluid overload.

ETIOLOGY. Certain lung cancers, pancreatic cancer, or Hodgkin's disease may be ectopic sites of production of an ADH-like substance. Some drugs, such as tricyclic antidepressants and general anesthetics, may increase ADH secretion. Head trauma or surgery or a brain tumor affecting pituitary function may also cause SIADH. It may also be a complication of treatment of diabetes insipidus.

SIGNS AND SYMPTOMS. Symptoms of SIADH include symptoms of fluid overload, such as weight gain (usually without edema) and dilutional hyponatremia (Box 39.1 Manifestations of Dilutional Hyponatremia). The actual amount of sodium in the blood may be normal, but it

Box 39.1

Manifestations of Dilutional Hyponatremia

Bounding pulse
Elevated or normal blood pressure
Muscle weakness
Headache
Personality changes
Nausea
Diarrhea
Convulsions
Coma

appears low because of the diluting effect of the retained fluid. Serum osmolality is less than 275 mOsm/kg. The urine is concentrated because water is not being excreted. Muscle cramps and weakness may occur because of electrolyte imbalance. Because the osmolality of the blood is low, fluid may leak out of the vessels and cause brain swelling. If untreated, this results in lethargy, confusion, seizures, coma, and death.

DIAGNOSTIC TESTS. Serum and urine sodium levels and osmolality are measured. Serum ADH is high. Additional testing may be done to diagnose and locate an ADH-secreting tumor. Occasionally, a water load test may be done, which involves administering a specific amount of water, then measuring blood and urine sodium and osmolality hourly for 6 hours. The patient with SIADH retains the water instead of excreting it. This test can cause an unsafe fluid overload, so is not done unless necessary for diagnosis.

THERAPEUTIC INTERVENTIONS. Treatment is aimed at eliminating the cause. If a tumor is secreting ADH, surgical removal may be indicated. Symptoms may be alleviated by restricting fluids to 800 to 1000 mL per 24 hours. Hypertonic saline fluids may be administered intravenously, and oral salt may be encouraged to maintain the serum sodium level. If the cause is inoperable cancer, drugs such as furosemide (Lasix) and demeclocycline (Declomycin) may be used to block the action of ADH in the kidney.

LEARNING TIP

Remember “a pint’s a pound the world around.” So each time the patient gains 1 pound of fluid, it is equal to approximately 1 pint or 480 mL!

NURSING PROCESS FOR THE PATIENT WITH SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE. Assessment/Data Collection. Fluid overload with hyponatremia is the primary concern for the patient

with SIADH. To monitor fluid balance, assess vital signs, weight, intake and output, urine specific gravity, skin turgor, and edema. Auscultate lung sounds for crackles, a sign of fluid overload. Determine the patient's ability to maintain a fluid restriction. Assess level of consciousness and neuromuscular function. Monitor laboratory tests, including serum sodium level, as ordered by the physician. Assess the patient's understanding of the disease process and treatment.

Nursing Diagnosis, Planning, and Implementation. Excess fluid volume related to compromised regulatory mechanism

EXPECTED OUTCOME: Fluid balance will be maintained as evidenced by weight and serum sodium within normal limits, lungs clear.

- Monitor daily weight, I&O, vital signs, and urine specific gravity. *Increased weight, intake greater than output, elevated blood pressure, bounding pulse, and low urine specific gravity may all indicate fluid overload.*
- Maintain fluid restriction to reduce serum dilution and normalize serum sodium.
 - Fluids high in sodium, such as broth, cola, or tomato juice, may help correct dilutional hyponatremia.
- Promote comfort and choice during fluid restriction. *Fluid restrictions are not pleasant for patients, and measures to increase comfort can help increase compliance.*
 - Offer hard candy
 - Provide ice chips (counted as half the volume of fluid; that is, 100 mL of ice chips equal approximately 50 mL of water).
 - Allow the patient to participate in planning the types and times of fluid intake.
- Provide calibrated cups to help the patient maintain the restriction independently if able.
- Report a change in level of consciousness immediately, and monitor the patient for seizures. *These are signs of serious fluid imbalance.*

Risk for ineffective health maintenance related to knowledge deficit

EXPECTED OUTCOME: Patient will verbalize and demonstrate understanding of self-care.

- Assess patient's understanding of his or her disease process and treatment. *Teaching should build on baseline knowledge.*
- Explain the importance of maintaining the fluid restriction to the patient. *The patient must understand the fluid restriction to maintain it and manage it at home if it is to be continued.*
- Instruct the patient to report any weight gain greater than 2 pounds in 1 day, a change in urine output, or acute thirst. *These are signs of fluid overload or risk for overload.*

- Encourage use of medical alert bracelet or other identification *so emergency personnel will have information if needed.*

Evaluation. Weight should stabilize at the preillness level once treatment is begun. Serum sodium level should be within normal limits. Patients should be able to verbalize the cause of their symptoms and demonstrate self-care, including ability to maintain a fluid restriction if necessary.

CRITICAL THINKING

Mrs. Jackson

■ You are caring for Mrs. Jackson, a 78-year-old woman who has just returned to your unit following hip surgery. During the next 2 days, you notice that her weight increases from 118 to 124 pounds and she seems lethargic, but the nurse's report didn't indicate concern about it. You check her ankles and sacrum for edema but find none. In the afternoon, her son rushes out of the room and tells you she is becoming confused, adding that this is not like her at all.

1. What could be happening?
2. What assessment can you do to gather further data to support your suspicions?
3. What will you do?
4. Based on her weight gain, about how much water is she retaining?

Suggested answers at end of chapter.

Disorders Related to Growth Hormone Imbalance

Growth hormone (GH), also called somatotropin, is responsible for normal growth of bones, cartilage, and soft tissue. GH is synthesized and secreted by the anterior pituitary gland. An excess or deficiency of GH may be related to a more generalized problem with the pituitary gland. A deficit of GH results in dwarfism. Excess GH results in gigantism or acromegaly (Fig. 39.1).

Dwarfism

PATHOPHYSIOLOGY. Dwarfism, also called short stature, occurs when growth hormone is deficient in childhood. A deficiency of GH in adults does not affect growth.

ETIOLOGY. Growth hormone may be deficient as a result of a pituitary tumor or failure of the pituitary to develop. It may be the result of infection or other trauma to the pituitary gland. It may also be deficient in some cases of neglect or severe emotional stress, causing psychosocial dwarfism. Malnutrition is the most common cause worldwide. Sometimes the cause is not known (Box 39.2 Cultural Considerations).

FIGURE 39.1 Gigantism and dwarfism. (From Tamparo, CD, and Lewis, MA: *Diseases of the Human Body*, ed. 3. F.A. Davis, Philadelphia, 2000, p. 247, with permission.)

SIGNS AND SYMPTOMS. Children may grow to only 3 to 4 feet in height but have normal body proportions. Sexual maturation may be slowed, related to involvement of additional pituitary hormones. Dwarfism in children is sometimes accompanied by mental retardation. In adults, symptoms include weakness, hypoglycemia, sexual dysfunction, skin changes, and increased risk for cardiovascular and cerebrovascular disease. Headaches, mental slowness, and visual disturbances may also occur.

DIAGNOSTIC TESTS. Growth hormone levels in the blood are measured by a routine laboratory test. A growth hormone stimulation test may be done by measuring GH response to induced hypoglycemia. An MRI may help

Box 39.2

Cultural Considerations

Dwarfism, mostly related to a limited gene pool, often occurs among Amish communities. Ellis–van Creveld syndrome is prevalent among the Amish of Lancaster County, Pennsylvania. This syndrome is characterized by short stature and an extra digit on each hand, with some individuals having a congenital heart defect and nervous system involvement resulting in a degree of mental handicap.

determine the presence of a pituitary tumor; radiographic studies may be used to determine bone age.

THERAPEUTIC INTERVENTIONS. Treatment of dwarfism in a child is administration of growth hormone. In the past, GH was derived from human pituitary glands, so treatment was expensive. Now GH can be made in a laboratory using genetic engineering, and it is more readily available to those who need it. It is administered by injection. Surgery may be indicated if a tumor is the cause.

NURSING PROCESS FOR THE PATIENT WITH DWARFISM. Assessment/Data Collection. Assessment of the adult with dwarfism includes mental status, ability to cope with the effects of the disorder, and understanding of the treatment plan. Also assess for signs of cardiovascular disease and other complications of the disorder.

Nursing Diagnosis, Planning, and Implementation. Because the disorder in an adult has likely been present since childhood, most related problems will not be new to the patient. The priority for the nurse, then, is to approach the patient with respect while assessing current problems that may need attention.

Disturbed body image related to short stature

EXPECTED OUTCOME: Patient will express feelings of acceptance of self.

- Approach patient with an attitude of acceptance and caring to help develop trusting nurse-patient relationship.
- Provide an opportunity for patient to verbalize feelings. *Expressing feelings may help reduce anxiety.*
- Consult occupational therapist if necessary to provide techniques to assist patients to adapt to an environment that is geared toward people of average height.
- Provide information about support groups. *A support group can help the patient feel less alone.*

Evaluation. The goal has been achieved if the patient is able to express his or her feelings of acceptance of the disorder, and demonstrate adaptive techniques.

CRITICAL THINKING

Adoption

■ Three siblings were adopted to a loving home after having been in several foster homes. After a year in their new home, each child suddenly grew 6 to 8 inches. What do you think happened?

Suggested answer at end of chapter.

Acromegaly

Acromegaly is a rare excess of growth hormone that affects adults, usually in their 30s or 40s. If a GH excess occurs in children, the condition results in gigantism.

PATHOPHYSIOLOGY. Acromegaly occurs as a result of oversecretion of GH in an adult. Bones increase in size, leading to enlargement of facial features, hands, and feet. Long bones grow in width but not length because the epiphyseal disks are closed. Subcutaneous connective tissue increases, causing a fleshy appearance. Internal organs and glands enlarge. Impaired tolerance of carbohydrates leads to elevated blood glucose.

ETIOLOGY. Excess secretion of growth hormone can be caused by pituitary **hyperplasia**, a benign pituitary tumor, or excess of GH-releasing hormone due to hypothalamic dysfunction.

SIGNS AND SYMPTOMS. Often the first symptom noticed is a change in ring or shoe size. The nose, jaw, brow, hands, and feet enlarge (Fig. 39.2). The teeth may be displaced, causing difficulty chewing, or dentures may no longer fit. The tongue becomes thick, causing difficulty in speaking and swallowing (**dysphagia**). The patient may develop sleep apnea. Vertebral changes may lead to kyphosis. Visual disturbances may occur because of tumor pressure on the optic nerve. Headaches are a result of tumor pressure on the brain. Diabetes mellitus may develop because GH increases blood glucose and causes an increased workload for the pancreas. (See Chapter 40.) Osteoporosis and arthritis may occur. Erectile dysfunction may occur in men and **amenorrhea** in women. With treatment, soft tissues reduce in size, but bone growth is permanent.

DIAGNOSTIC TESTS. Serum growth hormone levels are measured, and radiographs show abnormal bone growth. Growth hormone may also be measured following a large dose of oral glucose. Normally, glucose suppresses GH release. If it continues to be released even after a glucose load, acromegaly is suspected. MRI is done to locate a pituitary tumor.

FIGURE 39.2 Patient with acromegaly. (From Martin, JB, Reichlin, S, and Brown, GM: *Clinical Neuroendocrinology*. F.A. Davis, Philadelphia, 1977, p. 353, with permission.)

hyperplasia: hyper—excessive + plasia—formation or deviation

dysphagia: dys—bad + phagia—swallowing

amenorrhea: a—not + men—month + orrhea—flow

THERAPEUTIC INTERVENTIONS. Treatment is aimed at the cause. Bromocriptine (Parlodel) or octreotide (Sandostatin) may decrease GH levels. Hypophysectomy or radiation may be indicated if a tumor is the cause. If the pituitary is removed, lifelong replacement of thyroid hormone, corticosteroids, and sex hormones is important to maintain homeostasis.

NURSING PROCESS FOR THE PATIENT WITH ACROMEGALY. Assessment/Data Collection. The nurse caring for the patient with acromegaly is concerned with the patient's response to the disease. Assess safety in relation to impaired eyesight, chewing, swallowing, and sleep apnea. Monitor serum glucose levels for onset of diabetes mellitus. Assess knowledge and acceptance of the disease. If hypophysectomy is planned, assess the patient for anxiety related to the surgery and perform a preoperative baseline neurological assessment.

Nursing Diagnosis, Planning, and Implementation.
Disturbed body image related to changes in appearance

EXPECTED OUTCOME: Patient will express feelings of acceptance of self.

- Approach patient with an attitude of acceptance and caring to help develop trusting nurse-patient relationship.
- Encourage the patient to be accepting of self because most changes will be permanent and require patient to become accustomed to a changed self-image.
- Provide information about support groups. A support group can help the patient feel less alone.

Risk for injury related to poor eyesight, sleep apnea, dysphagia

EXPECTED OUTCOME: Patient will not experience injury.

- Assess for increased risk of injury. An accurate assessment will guide interventions.
- Maintain safe, uncluttered environment to prevent injury from falls related to poor eyesight.
- Request swallowing evaluation from speech therapy if indicated. A speech therapist can diagnose swallowing problems and make recommendations.
- Observe for sleep apnea and discuss with physician if indicated. Sleep apnea, if present, will require sleep studies and treatment.

Additional nursing diagnoses are identified if diabetes mellitus or other problems exist.

Patient Education. Teach the patient and significant others about the disease and treatment. If the patient is having a hypophysectomy, be sure he or she understands that some symptoms will be relieved but that bone growth and visual changes may not reverse. Stress the need for lifelong hormone replacement after surgery. See section on care of the patient undergoing hypophysectomy later in this chapter.

Evaluation. The patient who is effectively treated will have some soft tissues return to normal size. The patient will be

safe and free from injury. The patient should be able to accurately describe self-care requirements.

Pituitary Tumors

Most tumors of the pituitary gland are benign adenomas. However, even benign tumors in the brain can cause many symptoms, including visual disturbances, symptoms of increased pressure in the brain, and symptoms related to hormone imbalances, as described earlier. Treatment for pituitary tumors is usually hypophysectomy (surgical removal of the pituitary gland). Radiation may also be used, either alone or as an adjunct to surgery.

Care of the Patient Undergoing Hypophysectomy

Removal of the pituitary gland is called hypophysectomy. Figure 39.3 shows the transsphenoidal approach to the gland. Some tumors may necessitate removal via a transfrontal craniotomy (entry through the frontal bone of the skull).

PREOPERATIVE CARE. Ensure that the patient understands the physician's explanation of surgery. Perform and document a baseline neurological assessment. Prepare the patient for what to expect following surgery. Instruct the patient to avoid any actions that increase pressure on the surgical site, such as coughing, sneezing, nose blowing, straining to move bowels, or bending from the waist. Because coughing can raise intracranial pressure and is therefore contraindicated, instruct the patient in deep breathing exercises or use of an incentive spirometer.

POSTOPERATIVE CARE. Perform routine neurological assessments to monitor for neurological damage. Also be sure to check urine for specific gravity because diabetes insipidus may occur following pituitary surgery. If a patient has had transsphenoidal surgery, he will have nasal packing and a “mustache dressing,” which is placed under the nose to collect drips. These are left in place and not removed unless ordered by the physician. Monitor the dressing for signs of

FIGURE 39.3 Transsphenoidal approach to pituitary gland for hypophysectomy.

cerebrospinal fluid (CSF) leakage. CSF contains glucose, so glucose testing strips can be used to determine if drainage is actually CSF or just nasal discharge. Remind the patient to avoid any actions that increase pressure on the surgical site. Obtain orders for stool softeners and antitussives as needed. Tooth brushing is avoided until the incision line is healed. The patient may use floss and mouth rinses. The patient is placed on hormone replacement therapy following hypophysectomy. Pituitary hormones are difficult to replace, so target hormones are generally given. These may include thyroid hormone, glucocorticoids, intranasal desmopressin, and sex hormones. Instruct the patient about how to administer the hormones, as well as side effects to report.

DISORDERS OF THE THYROID GLAND

Triiodothyronine (T_3) and thyroxine (T_4) are thyroid hormones secreted by the thyroid gland. These hormones may be collectively referred to as thyroid hormone (TH). Deficient secretion of TH results in hypothyroidism; excess TH results in hyperthyroidism. For more information on disorders of the thyroid gland, visit the American Thyroid Association at www.thyroid.org.

Hypothyroidism

Hypothyroidism occurs primarily in women 30 to 60 years old. If hypothyroidism occurs in an infant, the result is cretinism. Hypothyroidism that develops in an adult is called **myxedema**.

Pathophysiology

Primary hypothyroidism occurs when the thyroid gland fails to produce enough TH even though there is enough thyroid-stimulating hormone (TSH) being secreted by the pituitary gland. The pituitary responds to the low level of TH by producing more TSH. Secondary hypothyroidism is caused by low levels of TSH, which fail to stimulate release of TH. Tertiary hypothyroidism results from inadequate release of thyrotropin-releasing hormone (TRH), secreted by the hypothalamus. Most cases of hypothyroidism are primary (Table 39.3).

Because thyroid hormones are responsible for metabolism, low levels of these hormones result in a slowed metabolic rate, which causes many of the characteristic

TABLE 39.3 THYROID HORMONE ABNORMALITIES

	Hyperthyroidism	Hypothyroidism
Primary	TH↑ TSH↓	TH↓ TSH↑
Secondary (Pituitary Cause)	TH↑ TSH↑	TH↓ TSH↓

myxedema: myx—mucus + edema—swelling

symptoms of hypothyroidism. Other symptoms are related to myxedema, which refers to a nonpitting type of edema that occurs in connective tissues throughout the body.

Etiology

Primary hypothyroidism may be a result of a congenital defect, inflammation of the thyroid gland, or iodine deficiency. Hashimoto's thyroiditis is an **autoimmune** disorder that eventually destroys thyroid tissue, leading to hypothyroidism. Secondary or tertiary hypothyroidism may be caused by a pituitary or hypothalamic lesion or by postpartum pituitary necrosis, a rare disorder in which the pituitary is destroyed following pregnancy and delivery. Treatment of hyperthyroidism, whether with medication or thyroidectomy, can lead to secondary hypothyroidism. Peripheral resistance to TH may also occur.

Signs and Symptoms

Manifestations primarily are related to the reduced metabolic rate and include fatigue, weight gain, bradycardia, constipation, mental dullness, feeling cold, shortness of breath, decreased sweating, and dry skin and hair (Table 39.4). Heart failure may occur because of decreased pumping strength of the heart. Altered fat metabolism causes hyperlipidemia. Myxedema causes water retention, with puffiness in the face, eye area, and feet. Fluid may also accumulate around the heart, causing altered cardiac function. See Box 39.3 Patient Perspective.

Complications

If the metabolic rate drops so low that it becomes life threatening, the result is myxedema coma. This usually occurs in patients with longstanding, untreated hypothyroidism and can be triggered by stress, such as infection, trauma, or exposure to cold. The patient becomes hypothermic, with a temperature less than 95°F (35°C) and a decreased respiratory rate. Depressed mental function and lethargy may occur. Blood glucose drops. Cardiac output drops, which in turn can reduce perfusion of kidneys. Nonpitting edema of the hands and feet may develop. Death may occur as a result of respiratory failure. If you note changes in mental status or vital signs, the physician should be contacted immediately. Treatment of myxedema coma involves intubation and

autoimmune: auto—pertaining to self + immune—exempt

Box 39.3

Patient Perspective

Mary

When I turned 40-something, I began to notice a few changes in my body. I seemed to be easily fatigued, but I attributed that to moving our family across country and all the adjustments that needed to be made. I also noticed weight gain, most notably around my waist. Again, I thought, “well, I **am** 40-something,” but it seemed no matter how much I exercised and watched what I ate, I couldn't lose weight. Worse, I was gaining! One day a friend of mine pointed out that I always seemed tired. Each time she called to do something, my reply was always the same, “I'd love to, but not today, I am just so tired.”

Things started to get worse; I began losing hair by the handfuls each time I shampooed. It was so bad that every time I went to my hair stylist she had to reassure me that I wasn't going bald. However, my hair just didn't seem as full as it once did. I began to notice dry skin (I thought it was just our hard water) and constipation (I thought I had irritable bowel syndrome). Finally, I went to the doctor for a physical, including laboratory test, which included a TSH and free T₄. The diagnosis came back: I had hypothyroidism and was started on Synthroid. I noticed the effect on my energy almost immediately. Now I am able to exercise effectively. I have lost nearly all the weight I gained and my husband no longer complains about having to clean out the drain in our shower every time I wash my hair. I am thankful for the diagnosis and treatment because I feel like myself again.

mechanical ventilation. The patient is slowly rewarmed with blankets. Intravenous levothyroxine (Synthroid) is given, and any underlying cause is treated.

Diagnostic Tests

T₃ and T₄ levels are low, and TSH may be high or low, depending on the cause. If the pituitary is functioning normally, TSH is elevated in an attempt to stimulate an increase

TABLE 39.4 SYMPTOMS OF THYROID DISORDERS

	Hypothyroidism	Hyperthyroidism
Cardiovascular	Bradycardia, decreased cardiac output, cool skin, cold intolerance	Tachycardia, palpitations, increased cardiac output, warm skin, heat intolerance
Neurological	Lethargy, slowed movements, memory loss, confusion	Fatigue, restlessness, tremor, insomnia, emotional instability
Pulmonary	Dyspnea, hypoventilation	Dyspnea
Integumentary	Cool, dry skin; brittle, dry hair	Diaphoresis; warm, moist skin; fine, soft hair
Gastrointestinal	Decreased appetite, weight gain, constipation, increased serum lipid levels	Increased appetite, weight loss, frequent stools, decreased serum lipid levels
Reproductive	Decreased libido, erectile dysfunction	Decreased libido, erectile dysfunction, amenorrhea

in TH. Serum cholesterol and triglycerides are elevated. Antibodies are usually present in autoimmune disease.

Therapeutic Interventions

Primary hypothyroidism is easily treated with oral thyroid replacement hormone. Some patients still use TH from animal thyroids. Most patients now take synthetic thyroid hormone (levothyroxine). Doses are started low and are slowly increased to prevent symptoms of hyperthyroidism or cardiac complications.

Nursing Process for the Patient with Hypothyroidism

See Box 39.4 Nursing Care Plan for the Patient with Hypothyroidism.

Patient Education

Instruct the patient in the importance of consistent use of thyroid replacement medication and regular blood tests to monitor TSH. The patient needs to be aware that too much thyroid hormone will cause symptoms of hyperthyroidism. Such symptoms should be reported to the physician immediately. In addition, if the patient is experiencing mental status changes, discuss the need to avoid driving or operating machinery until symptoms are resolved.

CRITICAL THINKING

Mae

■ Mae is a 59-year-old woman who is tired all the time and has gained 16 pounds during the past year. Her physician does some blood tests and prescribes levothyroxine PO. Laboratory results show low T_3 and T_4 and elevated TSH.

1. Why is Mae's TSH elevated?
2. What will happen to Mae's caloric requirements as she begins treatment? Why?
3. Why should you teach Mae to check her pulse?

Suggested answers at end of chapter.

Hyperthyroidism

Hyperthyroidism is most often diagnosed in young women. Graves' disease, which is one cause of hyperthyroidism, is more common in young women. Multinodular goiter is more common in older women.

Pathophysiology

Hyperthyroidism results in excessive amounts of circulating thyroid hormone (thyrotoxicosis). Primary hyperthyroidism occurs when a problem within the thyroid gland causes excess hormone release. Secondary hyperthyroidism occurs because of excess TSH release from the pituitary, causing overstimulation of the thyroid gland; tertiary hyperthyroidism is caused by excess TRH from the hypothalamus. A high level of thyroid hormone increases the metabolic rate.

It is also believed to increase the number of beta-adrenergic receptor sites in the body, which enhances the activity of norepinephrine. The resulting fight-or-flight response is the cause of many of the symptoms of hyperthyroidism.

Etiology

A variety of disorders can cause hyperthyroidism. Graves' disease is the most common cause; it is thought to be an autoimmune disorder because thyroid-stimulating antibodies are present in the blood of affected patients.

Multinodular goiter, in which thyroid nodules secrete excess TH, is also sometimes associated with hyperthyroidism. A pituitary tumor may secrete excess TSH, which overstimulates the thyroid gland. A thyroid tumor may secrete TH. Patients taking thyroid hormone for hypothyroidism may take too much. Each of these problems can cause excess circulating TH and symptoms of hyperthyroidism.

Radiation exposure may predispose a patient to develop hyperthyroidism. Heredity may also play a role in autoimmune hyperthyroidism.

Signs and Symptoms

Many signs and symptoms are related to the hypermetabolic state, such as heat intolerance, increased appetite with weight loss, and increased frequency of bowel movements. Nervousness, tremor, tachycardia, and palpitations are caused by the increase in sympathetic nervous system activity, and may be more common in younger patients. Heart failure may occur because of tachycardia and the resulting inefficient pumping of the heart. See additional signs and symptoms in Table 39.4. If treatment is not begun, the patient may become manic or psychotic. Additional signs that occur only with Graves' disease include thickening of the skin on the anterior legs and exophthalmos (bulging of the eyes; Fig. 39.4) caused by swelling of the tissues behind

FIGURE 39.4 Exophthalmos caused by Graves' disease. (From Tamparo, CD, and Lewis, MA: *Diseases of the Human Body*, ed. 4. F.A. Davis, Philadelphia, 2005, p 339, with permission.)

Box 39.4 NURSING CARE PLAN for the Patient with Hypothyroidism

Nursing Diagnosis: Activity intolerance related to fatigue

Expected Outcomes (1) Patient reports lessening fatigue after treatment initiated. (2) Patient is able to carry out usual activities of daily living (ADLs).

Evaluation of Outcomes (1) Does patient report lessening fatigue? (2) Is patient able to carry out ADLs?

Interventions

Assist patient with self-care activities.

Allow for rest between activities.

Slowly increase patient's activities as medication begins to be effective.

Rationale

Patients with fatigue may have difficulty carrying out activities independently.

Rest periods will enable patient to conserve energy for activities.

As thyroid replacement therapy becomes effective, patient's fatigue will subside.

Evaluation

Are patient's self-care needs being met? Is assistance needed?

Does patient state rest is adequate?

Does patient tolerate increases in activity?

Geriatric

When getting elderly patients up, watch for orthostatic hypotension.

Orthostatic hypotension is common in elderly and may cause falls.

Does patient's blood pressure drop when changing positions?

Nursing Diagnosis: Constipation related to slowed gastrointestinal motility

Expected Outcomes (1) Soft, formed stool passed at preillness frequency. (2) Patient identifies measures to prevent constipation in future.

Evaluation of Outcomes (1) Are bowels moving according to patient's pre-illness pattern? (2) Does patient verbalize measures to prevent constipation?

Interventions

Monitor and record bowel movements.

Help patient follow usual pre-illness pattern (e.g., after morning coffee).

Increase fluids to eight 8-ounce glasses of water daily if cardiovascular status stable.

Add fiber to diet: fresh fruit, vegetables, bran.

Encourage regular ambulation.

Use bedside commode or bathroom rather than bedpan.

Obtain physician order for stool softener if needed.

If stool is impacted, break up stool digitally and gently remove.

Avoid use of enemas.

Rationale

A record helps determine if a problem exists.

A schedule allows bowel movement to occur before stool becomes hard and dry.

Adequate fluid intake helps prevent hard, dry stools.

Fiber helps increase the number of bowel movements.

Activity increases peristalsis.

The sitting position aids in evacuation.

Soft stools are passed more easily.

Breaking up stool eases evacuation.

Enemas can cause fluid and electrolyte imbalances and can damage mucosa.

Evaluation

Does record show a problem?

Is patient able to identify and implement usual self-care for bowels?

Does patient take adequate fluids?

Does patient tolerate fiber? Is it effective?

Is patient able to ambulate or engage in other activity?

Is sitting position effective?

Is stool softener needed? Effective?

Is stool impacted? Is digital disimpaction effective?

Does patient understand need to avoid enemas?

(Continued on following page)

Box 39.4 NURSING CARE PLAN for the Patient with Hypothyroidism (Continued)

Nursing Diagnosis: Impaired skin integrity related to dry skin, inactivity

Expected Outcomes (1) Skin is soft and moist. (2) Skin remains intact.

Evaluation of Outcomes Is skin soft, moist, and intact?

Interventions

Assess skin daily for breakdown.

Avoid use of soap on dry areas.
Try bath oil.

Use nondrying lotion following bath.

Encourage/assist with position changes at least every 2 hours.

Rationale

Skin lesions are more effectively treated when identified early.

Soap is drying to skin.

Lotion helps trap moisture in skin. Some lotions contain alcohol, however, which is drying.

Changing position enhances circulation to the skin, promoting healing and preventing breakdown.

Evaluation

Is breakdown present?

Does use of bath oil help?

Does patient state relief with use of lotion?

Does patient change position at least every 2 hours? Are pressure areas prevented?

Nursing Diagnosis: Imbalanced nutrition, more than requirements, related to decreased metabolic rate

Expected Outcomes (1) Patient will return to pre-illness weight. (2) Patient will verbalize understanding of dietary recommendations.

Evaluation of Outcomes (1) Is patient approaching pre-illness weight? (2) Is patient able to explain dietary recommendations and how they will be implemented?

Interventions

Weigh weekly and record.

Consult dietitian for therapeutic diet until hypothyroidism is controlled.

Encourage regular exercise within limits of fatigue.

Counsel patient that weight should normalize once hypothyroidism is controlled.

Allow patient to help determine acceptable diet modifications.

Rationale

Weekly weights record progress without the frustration of daily fluctuations.

The dietitian can provide food choices for gradual weight loss if necessary.

Exercise promotes weight control.

Thyroid replacement hormone increases the metabolic rate, allowing return to normal weight.

Geriatric

Older patients may have longstanding dietary habits that are hard to change.

Evaluation

Is patient losing or maintaining weight?

Does patient verbalize understanding of and ability to follow diet?

Does patient verbalize understanding of and ability to follow exercise plan?

Does patient verbalize understanding of instruction?

Is patient satisfied with weight loss plan?

the eyes. Other eye changes include photophobia and blurred or double vision.

Elderly patients may not exhibit the typical signs and symptoms of hyperthyroidism so be especially alert for this. These patients may present with heart failure, atrial fibrillation, fatigue, apathy, and depression.

Complications

THYROTOXIC CRISIS. Thyrotoxic crisis (also called thyroid storm) is a severe hyperthyroid state that can occur in hyperthyroid individuals who are untreated or who are experiencing another illness or stressor. It may also occur following thyroid surgery in patients who have been

inadequately prepared with antithyroid medication. Thyrotoxic crisis can result in death in as little as 2 hours if untreated. Symptoms include tachycardia, high fever, hypertension (with eventual heart failure and hypotension), dehydration, restlessness, and delirium or coma.

If thyrotoxic crisis occurs, treatment is first directed toward relieving the life-threatening symptoms. Acetaminophen is given for the fever. Aspirin is avoided because it binds with the same serum protein as T_4 , freeing additional T_4 into the circulation. Intravenous fluids and a cooling blanket may be ordered to cool the patient. A beta-adrenergic blocker, such as propranolol, is given for tachycardia. Oxygen is administered and the head of the bed is elevated because the high metabolic rate requires more oxygen. Once symptoms are controlled and the patient is safe, the underlying thyroid problem is treated.

HYPOTHYROIDISM. Another complication of hyperthyroidism can be hypothyroidism. This can occur as a result of long-term disease or as a result of treatment. Patients with a history of hyperthyroidism should be monitored for recurrent hyperthyroidism or the onset of hypothyroidism.

Diagnostic Tests

Serum levels of T_3 and T_4 are elevated. TSH is low in primary hyperthyroidism or high if the cause is pituitary. A thyroid scan can be done to locate a tumor. The thyroid gland may be enlarged; palpation of the thyroid in a patient suspected to be hyperthyroid should only be performed by a physician. TSI (thyroid-stimulating immunoglobulin) is present in Graves' disease. Rarely, a TRH stimulation test may be done.

Therapeutic Interventions

Several medications can be used to treat hyperthyroidism. Propylthiouracil (PTU) and methimazole (Tapazole) inhibit the synthesis of TH. Propranolol (Inderal) is a beta-blocking medication that relieves the sympathetic nervous system symptoms. Oral iodine suppresses the release of thyroid hormone.

Radioactive iodine (^{131}I or RAI) may be used to destroy a portion of the thyroid gland. The patient takes one oral dose of RAI. Dietary iodine normally goes to the thyroid gland, where it is used to make thyroid hormone. When RAI is given, the radioactivity destroys some of the cells that make thyroid hormone.

Sometimes medications alone control hyperthyroidism. If this does not occur, surgery is planned. If surgery is the treatment chosen, antithyroid medications are given to calm the thyroid before surgery. They help slow the heart rate and reduce other symptoms, making surgery safer. Iodine also reduces the vascularity of the thyroid gland, decreasing the risk of bleeding during surgery. Adequate preparation of the patient is important because a **euthyroid** state helps prevent a postoperative thyrotoxic crisis. Nursing care of the

patient undergoing a thyroidectomy is discussed later in this chapter.

Nursing Process for the Patient with Hyperthyroidism

ASSESSMENT/DATA COLLECTION. Monitor the patient with hyperthyroidism closely until normal thyroid activity is restored. Monitor vital signs and report any increases in pulse and blood pressure to the registered nurse or physician. Monitor lung sounds because crackles may indicate heart failure. Assess level of anxiety and ability to cope with symptoms. Monitor weight and bowel function. Assess eyes for risk for injury caused by exophthalmos, and note degree of muscle weakness. Never palpate the thyroid gland of a patient with hyperthyroidism because palpation may stimulate release of thyroid hormone and precipitate a thyrotoxic crisis.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Hyperthermia related to hypermetabolic state

EXPECTED OUTCOMES: Body temperature will be within normal limits.

- Monitor temperature. *Temperature may be elevated due to hypermetabolic state.*
- Administer acetaminophen as ordered *to reduce temperature.*
- Apply cooling blanket as ordered. *External cooling may be necessary if acetaminophen is not effective.*
- If a cooling blanket is necessary, set to one to two degrees below current temperature, and wrap extremities with towels *to prevent shivering, which can further increase temperature.*

Diarrhea related to increase in peristalsis

EXPECTED OUTCOMES: Patient will maintain fluid and electrolyte balance.

- Provide a low-fiber diet. *Fiber can increase peristalsis and stools.*
- Provide small frequent meals of bland foods (bananas, rice, applesauce) *that are less likely to worsen diarrhea.*
- Monitor electrolytes, especially sodium and potassium. *Diarrhea can cause electrolyte loss.*
- Monitor for dehydration. *Diarrhea causes fluid loss.*
- Keep skin clean and dry; apply barrier cream *to protect skin from injury from stool.*

Imbalanced nutrition, less than requirements, related to increased metabolism

EXPECTED OUTCOMES: The patient will maintain weight in proportion to height.

- Determine healthy weight for height, *so the expected outcome is realistic for the patient.*
- Monitor weight weekly *to make sure interventions are working.*
- Consult dietician for high-calorie diet with six meals *to meet caloric requirements.*

euthyroid: eu—normal, healthy + thyroid

Disturbed sleep pattern related to sympathetic stimulation

EXPECTED OUTCOMES: The patient will state feeling rested upon awakening.

- Provide a quiet, restful environment *to assist the patient to fall asleep.*
- Ask the patient if music or earplugs are desired *to mask environmental noise.*
- Administer propranolol or sedative as ordered *to reduce sympathetic stimulation and calm patient.*

Anxiety related to sympathetic stimulation

EXPECTED OUTCOMES: Patient will state anxiety is controlled.

- Provide the patient with accurate information about the disorder and treatment, and that proper treatment will correct symptoms. *Fear of the unknown can produce anxiety.*
- Administer propranolol or antianxiety agent as ordered *to reduce sympathetic stimulation and calm patient.*
- Offer massage, music, or other relaxation techniques preferred by the patient. *These may promote relaxation.*

Risk for injury related to hypermetabolic state and eye involvement

EXPECTED OUTCOMES: Patient will remain safe and without injury.

- Report changes in vital signs to the physician. *Prompt treatment can reduce complications.*
- Administer lubricating saline eyedrops as ordered *to protect eyes from drying.*
- Advise use of dark, tight fitting glasses *to protect eyes from light and injury.*
- Gently tape eyes shut with nonallergic tape for sleeping. *Exophthalmos may prevent the patient from fully closing the eyes.*
- Elevate the head of the bed *to reduce edema behind the eyes.*
- Provide a low-sodium diet. *This may decrease edema behind the eyes.*
- Teach patient to notify physician immediately if eye pain or vision changes occur. *These can be signs of pressure from edema on optic nerve, which can cause permanent damage if not corrected.*

PATIENT EDUCATION. Teach the patient about the disease and symptoms of hyperthyroidism or hypothyroidism to report. Also teach the patient how to take medications and the importance of routine follow-up laboratory testing.

EVALUATION. If the plan of care is effective, the patient will remain free from complications or injury. Eyes will be comfortable and free from injury. Body temperature will be kept within normal limits. Diarrhea will be controlled, and complications of diarrhea such as skin breakdown and

dehydration avoided. The patient's weight should remain stable. The patient should report that he or she is rested on awakening and that anxiety is controlled.

Care of the Patient Receiving Radioactive Iodine

If radioactive iodine is used, it is usually given orally in one dose. If the dose is high, such as for the patient with thyroid cancer, the patient is hospitalized. Patients receiving lower doses may be treated as outpatients. You should limit time spent with the patient and maintain a safe distance when providing direct care (see Chapter 10). Pregnant caregivers should avoid caring for patients receiving radioactive iodine. Urine, vomitus, and other body secretions are contaminated and should be disposed of according to hospital policy. Flush the toilet twice following disposal of contaminated material. The radiation safety officer and hospital policy should be consulted for specific precautions.

At home, the patient is instructed to avoid close contact with family members for about a week and to use careful hand washing after urinating. Oral contact with others should be avoided, and eating utensils should be washed thoroughly with soap and water. Hospital teaching protocols should be used for specific patient teaching. If the treatment is being administered for hyperthyroidism, inform the patient that symptoms will subside in about 6 to 8 weeks.

Side effects are rare, and may include a sore throat or nausea. Sore throat is easily treated with acetaminophen, and nausea can be reduced by taking the dose on an empty stomach. Encourage the patient to drink plenty of fluids to help remove the RAI from the body. In addition, the patient should be aware of symptoms of hypothyroidism to be reported because hypothyroidism may occur up to 15 years after the treatment.

Goiter

Pathophysiology and Etiology

Enlargement of the thyroid gland is called a goiter. The thyroid gland may enlarge in response to increased TSH levels. TSH is elevated in response to low TH, iodine deficiency, pregnancy, or viral, genetic, or other conditions. When a goiter is caused by iodine deficiency or other environmental factors, it is called an endemic goiter.

Some foods and medications are **goitrogens**. These substances interfere with the body's use of iodine and include such foods as turnips, cabbage, broccoli, horseradish, cauliflower, and carrots (Box 39.5 Nutrition Notes). Some **goitrogenic** medications include propylthiouracil, sulfonamides, lithium, and salicylates (aspirin).

A goiter may be associated with a hyperthyroid, hypothyroid, or euthyroid state. Goiter that occurs with hyperthyroidism is sometimes called a toxic goiter. Once the cause of the goiter is removed, the gland usually returns to normal size.

goitrogenic: goitro—goiter + genic—producing

**Box 39.5****Nutrition Notes****Relating Nutrition to Thyroid Disorders*****Iodine Deficiency***

Inland areas of all continents have iodine-poor soils. People in developing countries with only local food sources are still subject to endemic goiter; however, addition of iodine to table salt has significantly reduced the occurrence of endemic goiter in developed countries.

Vegetables in the cabbage family contain goitrogens, substances that block the body's absorption or utilization of iodine, but the risk is small. At higher risk of iodine deficiency are strict vegetarians who consume sea salt, which contains virtually no iodine, rather than iodized salt.

Iodine Excess

Saltwater fish, shellfish, and seaweed are naturally high in iodine so that iodine toxicity from seaweed has occurred in Japan. Excessive iodine can be manifested as either hyperthyroidism or hypothyroidism, sometimes producing "iodine goiter."

**FIGURE 39.5** Patient with goiter.**Signs and Symptoms**

The thyroid gland is enlarged, and swelling may be apparent at the base of the neck (Fig. 39.5). Alternatively, it may enlarge posteriorly, which can interfere with swallowing or breathing. The patient may have a full sensation in the neck. Symptoms of hypothyroidism or hyperthyroidism may be present.

Diagnostic Tests

A thyroid scan shows an enlarged thyroid gland. Serum T_3 and T_4 levels are measured to determine thyroid function. Additional diagnostic studies may be done to determine the cause or evaluate the size of the gland.

Therapeutic Interventions

Treatment is aimed at the cause. If goitrogens are suspected, the patient is given a list of foods to be avoided. If iodine deficiency is a problem, it is added to the diet with supplements or iodized salt. Hypothyroidism or hyperthyroidism is treated if indicated. Levothyroxine (Synthroid) may be given to reduce TSH levels via negative feedback. A thyroidectomy may be necessary if the gland is interfering with breathing or swallowing.

Nursing Care

Be careful to assess the effect of the goiter on breathing and swallowing. Stridor, a whistling sound, may be heard if the airway is obstructed. Stridor is an ominous sign and should be reported to the physician immediately. If the patient experiences difficulty swallowing, notify the physician and

collaborate with the dietitian to provide soft foods or liquid nutrition. A swallowing study might be ordered, which can assist a speech pathologist or other expert to make specific recommendations for safe swallowing.

Cancer of the Thyroid Gland

Although thyroid cancer is rare, it is the most common cancer of the endocrine system (Box 39.6 Cultural Considerations). Women are affected more often than men. Most tumors of the thyroid gland are not malignant.

Etiology

Thyroid hyperplasia may lead to thyroid cancer. Other causes include exposure to radiation, iodine deficiency, and prolonged exposure to goitrogens. Tendency to develop some forms of thyroid cancer is inherited.

Signs and Symptoms

A hard, painless nodule may be palpable on the thyroid gland. Difficulty breathing or swallowing or changes in the voice may occur if the tumor is near the esophagus and trachea. Most patients with cancer of the thyroid have normal TH levels.

Diagnostic Tests

A thyroid scan shows a "cold" nodule. This is because malignant tumors of the thyroid do not take up the radioactive iodine administered for the scan. A fine-needle aspiration biopsy confirms the diagnosis. A "hot" nodule indicates a benign tumor.

**Box 39.6****Cultural Considerations**

Because of the Chernobyl nuclear disaster in Russia in 1988, Russian immigrants are at exceptionally high risk for developing pituitary, thyroid, and parathyroid disorders and cancers. The proximity of Estonia, Latvia, Lithuania, Poland, and other Eastern European countries to Russia places immigrants and long-term visitors from these countries at risk also. The nurse needs to be alert for endocrine disorders among these populations and assist patients to arrange genetic counseling for those who desire it.

Therapeutic Interventions

A partial or total thyroidectomy may be done. Chemotherapy, radioactive iodine therapy, or external beam radiation may also be used, alone or following surgery.

Nursing Care

Nursing care is determined by the symptoms the patient is experiencing. See Chapter 10 for care of the patient with cancer.

Nursing Process for the Patient Undergoing Thyroidectomy

Patients may undergo thyroidectomy for cancer of the thyroid, hyperthyroidism, or a goiter that is causing dyspnea or dysphagia. See Chapter 11 for general care of a patient having surgery.

A total thyroidectomy is usually performed if cancer is present. After a total thyroidectomy, lifelong replacement hormone must be taken. A subtotal (partial) thyroidectomy may be done for hyperthyroidism, leaving a portion of the thyroid gland to secrete TH.

Preoperative Care

Before undergoing a thyroidectomy, the patient should be in a euthyroid state. This is accomplished with the use of antithyroid medication. Saturated solution of potassium iodide (SSKI) may also be administered to decrease the size and vascularity of the gland, reducing the risk of bleeding during surgery.

Do a baseline assessment of vital signs and voice quality, so you can compare findings postoperatively. Explain what the patient can expect before, during, and after surgery and clarify misconceptions. Preoperative teaching should include how to perform gentle range-of-motion exercises of the neck, how to support the neck during position changes, and how to use an incentive spirometer after surgery. See Chapter 11 for routine preoperative care.

Postoperative Care

ASSESSMENT/DATA COLLECTION. Monitor vital signs, oxygen saturation, drain (if present), and dressings every 15 minutes initially, progressing to every 4 hours, as ordered.

Decreased blood pressure with increased pulse should alert you to the possibility of shock related to blood loss. Tachycardia and fever, along with mental status changes, may indicate thyrotoxic crisis. Check the back of the neck for pooling of blood. Because of the location of the surgery, observe for signs of respiratory distress, including an increase in respiratory rate, dyspnea, or stridor. Ask the patient to speak to detect hoarseness of the voice, which may indicate trauma to the recurrent laryngeal nerve. Monitor the patient's serum calcium levels and watch for evidence of **tetany** (discussed later in this chapter). Report abnormal findings to the physician immediately.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Risk for ineffective airway clearance due to edema at surgical site

EXPECTED OUTCOMES: Patient will maintain a clear airway.

- Notify physician of respiratory distress immediately; keep a tracheostomy set at the bedside. *Although not common, a tracheostomy may be needed in an emergency if edema obstructs the airway.*
- Maintain patient in semi-Fowler's position to help reduce edema and promote comfort.
- Monitor neck dressing. *If the dressing seems to get tighter, it may be a sign that the patient's neck is swelling, which could impair the airway.*
- Use room humidifier or humidified oxygen to keep airways and secretions moist.
- Remind the patient to do coughing and deep breathing exercises every hour. *This keeps the airway clear of secretions.*
- Have suction equipment available in case patient is unable to cough up secretions effectively.
- Encourage the patient to use the incentive spirometer to assist with deep breathing.
- Assess the patient's swallowing and gag reflexes before offering clear liquids to guard against aspiration.

Risk for injury (tetany, thyrotoxic crisis) related to surgical procedure

EXPECTED OUTCOMES: Complications will be recognized and treated quickly.

- Monitor for numbness or tingling around the mouth or muscle spasms and report immediately if they occur. *These are symptoms of tetany that must be treated immediately. Tetany is most likely to occur 24 to 72 hours postoperatively.*
- Monitor vital signs frequently and report changes immediately. *Elevated vital signs may be signs of thyrotoxic crisis, which is most likely to occur up to 18 hours postoperatively.*

Pain related to surgical procedure

EXPECTED OUTCOMES: Patient will state that pain level is acceptable.

- Administer acetaminophen or opioids as ordered. Avoid aspirin products. *Aspirin binds to the same protein as thyroid hormone, and can precipitate a thyrotoxic crisis.*
- Use pillows or sandbags to support the patient's head. *Unexpected movement may be painful.*

Risk for ineffective health maintenance related to knowledge deficit

EXPECTED OUTCOMES: Patient will verbalize understanding of follow-up care. Patient's weight will stabilize at appropriate weight for height.

- Assist the patient with gentle range-of-motion exercises, avoiding hyperextension of the neck, which can cause strain on the incision line. *Avoidance of neck movement due to pain can result in contracture.*
- Consult dietitian to assist the patient with potential dietary changes needed following surgery. *With correction of metabolic alterations, dietary needs may be significantly altered.*
- Teach the patient the importance of follow-up care to avoid complications.
 - How to administer replacement hormone if indicated.
 - How to change the dressing and to report bleeding or signs of infection at the site.
 - Importance of immediately reporting unusual irritability, fever, or palpitations.
 - Importance of follow-up lab work for thyroid function.

EVALUATION. If the plan has been effective, complications caused by surgery will not occur or will be recognized and reported early. Pain will be prevented or controlled, and the patient will demonstrate understanding of dietary modifications and postoperative self-care.

Complications

THYROTOXIC CRISIS. Thyrotoxic crisis may result from manipulation of the thyroid gland during surgery, with the subsequent release of large amounts of thyroid hormone. This is a rare complication because the use of antithyroid drugs before surgery has become routine. For more information on thyrotoxic crisis, see the section on hyperthyroidism earlier in this chapter.

TETANY. Tetany is caused by low calcium levels and is characterized by tingling in the fingers and perioral area (around the mouth), muscle spasms, twitching, and cardiac dysrhythmias. Muscle spasms in the larynx can lead to respiratory obstruction. Watch carefully for symptoms of tetany and report them immediately if they occur because if the problem is not recognized quickly, death can result.

Tetany can occur if the parathyroid glands are accidentally removed during thyroid surgery. Because of the proximity of the parathyroid glands to the thyroid, it is sometimes difficult for the surgeon to avoid them. In the absence of

parathyroid hormone, serum calcium levels drop and tetany results. Intravenous calcium gluconate is given to treat acute tetany.

DISORDERS OF THE PARATHYROID GLANDS

Recall that the parathyroid glands secrete parathyroid hormone (PTH) in response to low serum calcium levels. PTH raises serum calcium levels by promoting calcium movement from bones to blood and by increasing absorption of dietary calcium. Decreased PTH activity is called hypoparathyroidism. Increased PTH activity is called hyperparathyroidism.

Hypoparathyroidism

Pathophysiology

A decrease in PTH causes a decrease in bone resorption of calcium, a decrease in calcium absorption by the GI tract, and decreased resorption in the kidneys. This means that calcium stays in bones instead of being moved into the blood, and more calcium is excreted from the body. The result is a decreased serum calcium level, called hypocalcemia. As calcium levels fall, phosphate levels rise.

Etiology

The most common causes of hypoparathyroidism are heredity and the accidental removal of the parathyroid glands during thyroidectomy. Because of the proximity of the glands to the thyroid, it is sometimes difficult to avoid removing them. Hypoparathyroidism also occurs following purposeful removal of the parathyroid glands for hyperparathyroidism or cancer. Another cause is hypomagnesemia, which impairs secretion of PTH. Hypomagnesemia can occur with chronic alcoholism or certain nutritional problems.

Signs and Symptoms

Calcium plays an important role in nerve cell stability. Hypocalcemia causes neuromuscular irritability. In acute cases, tetany may occur (see previous section on tetany), with numbness and tingling of the fingers and perioral area, muscle spasms, and twitching. (See Table 39.5.) Positive Chvostek's and Trousseau's signs are early indications of tetany. To check Chvostek's sign, tap on the patient's facial nerve just in front of the ear. Spasm of the face is a positive result, indicating hypocalcemia. To elicit Trousseau's sign, place a sphygmomanometer on the patient's arm and pump it to above the patient's systolic pressure. Spasm of the thumb and fingers occurs within 3 minutes if the patient has hypocalcemia. See Chapter 5 for pictures of these tests.

LEARNING TIP

To remember which test is which, remember **CH**vostek's sign is assessed near the **CH**eek.

TABLE 39.5 PARATHYROID DISORDERS SUMMARY

	Insufficient PTH	Excess PTH
Disorder	Hypoparathyroidism	Hyperparathyroidism
Signs and Symptoms	Hypocalcemia, neuromuscular irritability, tetany; positive Chvostek and Trousseau signs	Hypercalcemia, fatigue, pathological fractures
Diagnostic Tests	Serum PTH, calcium, and phosphate	Serum PTH, calcium, and phosphate
Therapeutic Management	Calcium replacement; high-calcium, low-phosphorus diet	Calcitonin, parathyroidectomy
Priority Nursing Diagnoses	Risk for injury related to tetany	Risk for injury related to bone demineralization

In chronic hypoparathyroidism, the patient is lethargic and experiences muscle spasms. Calcifications may occur in the eyes and brain, leading to psychosis. Cataracts can develop. Bone changes are evident on x-ray examination. Convulsions may occur. Death can result from laryngospasm if treatment is not provided.

Diagnostic Tests

Chvostek's and Trousseau's signs are present. Laboratory studies show decreased serum calcium and PTH levels and increased serum phosphate. Radiographs show bone changes.

Therapeutic Interventions

Acute cases of hypoparathyroidism are treated with intravenous calcium gluconate. Long-term treatment includes a high-calcium diet (Box 39.7 Dietary Sources of Calcium), with oral calcium and vitamin D supplements. Thiazide diuretics may also be used because they reduce the amount of calcium excreted in the urine. Magnesium is given if hypomagnesemia is present.

Nursing Process for the Patient with Hypoparathyroidism

ASSESSMENT/DATA COLLECTION. The patient at risk for hypoparathyroidism should be closely monitored for symptoms of tetany. If you suspect tetany, check for Chvostek's and Trousseau's signs. Monitor respirations closely for stridor, a sign of laryngospasm.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Risk for injury related to tetany

Box 39.7

Dietary Sources of Calcium

Milk
Cheeses
Yogurt
Sardines
Oysters
Salmon
Cauliflower
Green leafy vegetables

EXPECTED OUTCOME: The patient will remain free from injury; signs of tetany will be recognized and treated quickly.

- Monitor for signs of tetany and report immediately to RN or physician so treatment can be instituted quickly.
- Make sure a tracheostomy set, endotracheal tube, and intravenous calcium are available for emergency use if laryngospasm occurs.
- Consult a dietitian for high-calcium diet teaching. The patient may need a lifelong high-calcium diet.
- Teach the patient about the importance of diet and medication therapy, and follow-up laboratory testing. The patient needs to understand self-care for follow-up at home.

EVALUATION. Injury is prevented through early recognition and reporting of signs and symptoms of tetany. The patient should be able to describe correct treatment and self-care measures for home.

Hyperparathyroidism

Pathophysiology

Overactivity of one or more of the parathyroid glands causes an increase in PTH, with a subsequent increase in the serum calcium level (hypercalcemia). This is achieved through movement of calcium out of the bones and into the blood, absorption in the small intestine, and reabsorption by the kidneys. PTH also promotes phosphate excretion by the kidneys.

Etiology

Hyperparathyroidism is usually the result of hyperplasia or a benign tumor of the parathyroid glands, or it may be hereditary. Some cancers can also make a substance that mimics PTH and causes hypercalcemia. Secondary hyperparathyroidism occurs when the parathyroids secrete excessive PTH in response to low serum calcium levels. Serum calcium may be reduced in kidney disease because of the kidneys' failure to activate vitamin D, which is necessary for absorption of calcium in the small intestine.

Signs and Symptoms

Signs and symptoms of hyperparathyroidism are caused primarily by the increase in serum calcium level, although many patients are asymptomatic. Symptoms include fatigue,

depression, confusion, increased urination, anorexia, nausea, vomiting, kidney stones, and cardiac dysrhythmias. The increased serum calcium level also causes gastrin secretion, resulting in abdominal pain and peptic ulcers. Because calcium is being removed from bones, bone and joint pain and pathological fractures may occur. With severe hypercalcemia, the result may be coma and cardiac arrest.

Diagnostic Tests

Laboratory studies include serum calcium, phosphate, and PTH levels. Radiographs may show decreased bone density. Nuclear scanning may be used to help locate the parathyroid glands if surgical removal is planned.

Therapeutic Interventions

The patient is monitored for bone changes and decline in renal function. Hydration with intravenous normal saline lowers the calcium level by dilution. Furosemide (Lasix) is given to increase renal excretion of calcium. Alendronate (Fosamax) or calcitonin may be given to prevent calcium release from bones. Estrogen therapy might be used in women, although side effects must be considered.

If hypercalcemia is severe or if the patient is at risk for bone or kidney complications, surgery to remove the diseased parathyroid glands (parathyroidectomy) is performed. If possible, some parathyroid tissue is left intact to continue to secrete PTH.

Preoperative and postoperative care is similar to that of the patient undergoing thyroid surgery, with special attention paid to calcium and PTH levels. The patient will likely be on calcium and vitamin D supplements following surgery. A new procedure, called minimally invasive radio-guided parathyroidectomy, can be done under local anesthesia through a small incision.

Nursing Process for the Patient with Hyperparathyroidism

ASSESSMENT/DATA COLLECTION. Assess the patient for symptoms related to hypercalcemia, including muscle weakness, lethargy, bone pain, anorexia, nausea, vomiting, behavioral changes, and renal insufficiency. Monitor serum calcium levels as ordered.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Nursing diagnoses depend on assessment findings. Risk for injury usually takes priority.

Risk for injury (fracture, complications of hypercalcemia) related to calcium imbalance

EXPECTED OUTCOME: The patient remains free from injury.

- Monitor for and report signs or symptoms of calcium imbalance promptly. *Prompt treatment can prevent serious complications.*
- Encourage oral fluids to prevent dehydration and kidney stones and help excrete calcium.
- Encourage strengthening and weight-bearing exercises to help keep calcium in the bones.
- Provide a safe environment for ambulation; assist the patient with ambulation if necessary. *A fall could result in fracture if bones are demineralized.*

- Encourage smoking cessation. *Smoking causes bone loss.*
- Teach patient symptoms to report and use of long-term medications so patient can manage self-care at home.

EVALUATION. If the plan is effective, symptoms of hypercalcemia will be recognized and reported quickly, and complications and injury will be prevented.

DISORDERS OF THE ADRENAL GLANDS

Adrenal disorders may involve the adrenal medulla or the adrenal cortex. A rare tumor of the adrenal medulla, called a **pheochromocytoma**, causes hypersecretion of epinephrine and norepinephrine. Hyposecretion of epinephrine is rare and generally causes no symptoms. Hypersecretion of cortisol from the adrenal cortex results in Cushing's syndrome. Hypofunction of the adrenal cortex results in Addison's disease.

Pheochromocytoma

Pathophysiology

A pheochromocytoma is an uncommon tumor that arises from the chromaffin cells of the adrenal medulla. Occasionally, a pheochromocytoma occurs outside the adrenal gland. The tumor autonomously secretes catecholamines (epinephrine and norepinephrine) in excessive amounts. Ninety percent of pheochromocytomas are benign.

Etiology

The cause of pheochromocytoma is unknown. About 5% of cases are hereditary.

Signs and Symptoms

Because norepinephrine is the fight-or-flight hormone, patients with a pheochromocytoma have exaggerated fight-or-flight symptoms. These might be fairly constant, or occur in "attacks." Manifestations include hypertension, tachycardia (with heart rate greater than 100), palpitations, tremor, diaphoresis, feeling of apprehension, and severe pounding headache. Nausea and vomiting are occasionally present. Blood glucose may increase because catecholamines inhibit insulin release from the pancreas. Constipation may occur because catecholamines relax the bowel. The most prominent characteristic is intermittent unstable hypertension. Diastolic pressure may be greater than 115 mm Hg. If hypertension is uncontrolled, the patient is at risk for stroke, vision changes, and organ damage. It is estimated that about 0.1% of cases of hypertension are caused by a pheochromocytoma.

Diagnostic Tests

Patients with a suspected pheochromocytoma have a 24-hour urine test for metanephrines and vanillylmandelic acid

pheochromocytoma: pheo—dark + chromo—color + cyt—cell + oma—tumor

(VMA). These are endproducts of catecholamine metabolism. A blood test for metanephrines may also be done. The patient should avoid caffeine and medications for 2 days before and during the test. Check institution policy for other dietary restrictions. If results are elevated, a CT scan or MRI is done to locate the tumor.

Therapeutic Interventions

Treatment for pheochromocytoma is surgical removal of one or both adrenal glands. However, the patient must be stabilized before surgery. Alpha-blocking medications such as phenoxybenzamine (Dibenzylin) dilate blood vessels to control acute hypertension. Beta-blocking medication may be added to block beta-adrenergic receptors in the heart and lungs, reducing other fight-or-flight symptoms.

Nursing Process for the Patient with Pheochromocytoma

ASSESSMENT/DATA COLLECTION. Monitor vital signs frequently, and report elevations promptly.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Risk for injury related to hypertensive crisis

EXPECTED OUTCOME: Patient will be free from injury related to hypertension.

- Monitor vital signs and report elevated pulse and blood pressure promptly. *Prompt treatment helps prevent complications.*
- Approach the patient calmly and maintain a quiet environment. *Stress may precipitate a hypertensive episode.*
- Administer alpha and beta blockers as ordered to control symptoms.
- Teach the patient how the medications will reduce symptoms, and the importance of avoiding foods and beverages containing caffeine, *so the patient can participate in self-care.*
- If patient has surgery, continue careful monitoring *as manipulation of tumor can increase catecholamine release.*

EVALUATION. If interventions have been effective, the patient's vital signs will be within normal limits, and complications will be avoided.

Adrenocortical Insufficiency/ Addison's Disease

Adrenocortical insufficiency (AI) is the insufficient production of the hormones of the adrenal cortex. Primary AI is called Addison's disease.

Pathophysiology

Adrenal insufficiency is associated with reduced levels of cortisol, aldosterone, or both hormones. A deficiency in androgens may exist. In primary disease, ACTH levels from the pituitary may be elevated in an attempt to stimulate the adrenal cortex to synthesize more hormone. In secondary disease, deficient ACTH fails to stimulate adrenal steroid

synthesis. In most cases, the adrenal glands are atrophied, small, and misshapen and are unable to produce adequate amounts of hormone.

Etiology

Addison's disease is thought to be autoimmune; that is, the gland destroys itself in response to conditions such as tuberculosis, fungal infection, infection related to acquired immunodeficiency syndrome (AIDS), or metastatic cancer. It may also be associated with other autoimmune diseases, such as Hashimoto's thyroiditis. Adrenalectomy also results in adrenal insufficiency.

Secondary AI may be caused by dysfunction of the pituitary or hypothalamus. In addition, prolonged use of corticosteroid drugs may depress ACTH and corticotropin-releasing hormone production, which in turn reduces steroid hormone production. A patient receiving long-term corticosteroid therapy is particularly at risk for AI if the drugs are abruptly discontinued. Because the pituitary has been suppressed for a prolonged period, it may take up to a year before ACTH is produced normally again.

NURSING CARE TIP

Always slowly taper corticosteroid therapy to avoid adrenal crisis.

Signs and Symptoms

The most significant sign of Addison's disease is hypotension. This is related to the lack of aldosterone. Remember that aldosterone causes sodium and water retention in the kidney and potassium loss. If aldosterone is deficient, sodium and water are lost and hypotension and tachycardia result. Low cortisol levels cause hypoglycemia, weakness, fatigue, weight loss, confusion, and psychosis. In primary AI, increased ACTH may produce hyperpigmentation of the skin, causing the patient to have a tanned or bronze appearance. Anorexia, nausea, and vomiting may also occur, possibly as the result of electrolyte imbalances. Women may have decreased body hair because of low androgen levels.

Complications

If a patient is exposed to stress, such as infection, trauma, or psychological pressure, the body may be unable to respond normally with secretion of cortisol and an adrenal crisis can occur. Loss of large amounts of sodium and water and the resulting fluid volume deficit cause profound hypotension, dehydration, and tachycardia. Potassium retention can cause cardiac dysrhythmias. Hypoglycemia may be severe. Coma and death result if treatment is not initiated. Treatment of adrenal crisis involves rapidly restoring fluid volume and cortisol levels. Intravenous fluids (containing glucose) and large doses of glucocorticoids are administered. Electrolytes are replaced as needed. The cause of the crisis should be identified and treated.

Diagnostic Tests

Serum and urine cortisol levels are measured. Blood glucose is low. Blood urea nitrogen (BUN) and hematocrit levels may appear to be elevated because of dehydration. An ACTH stimulation test may help determine whether the adrenal glands are functioning. Serum sodium and potassium levels are monitored.

Therapeutic Interventions

Long-term treatment consists of replacement of glucocorticoids (hydrocortisone) and mineralocorticoids (fludrocortisone). Patients will need hormone replacement therapy for the rest of their lives. Hormones are given in divided doses, with two-thirds of the daily dose given in the morning and one-third in the evening to mimic the body's own diurnal rhythm. Remember that steroid hormones are our natural stress hormones and so are naturally elevated during times of stress. Therefore, during times of stress or illness, doses need to be increased to two to three times normal. The patient may also be placed on a high-sodium diet.

Nursing Process for the Patient with Addison's Disease

ASSESSMENT/DATA COLLECTION. The patient with Addison's disease should be assessed for understanding of and compliance with the treatment regimen. Monitor daily weights or intake and output to track fluid status. Monitor serum glucose levels and symptoms of hyperkalemia and hyponatremia. Report changes in mental status. If the patient is in crisis, monitor vital signs closely and report any signs of fluid volume deficit such as orthostatic hypotension or poor skin turgor to the physician immediately.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Risk for deficient fluid volume related to deficient adrenal cortical hormones

EXPECTED OUTCOME: Fluid volume will be stable as evidenced by stable weights and vital signs, and skin turgor within normal limits.

- Monitor fluid status and report changes promptly so treatment can be initiated.
- Administer steroid replacements as ordered to maintain fluid and electrolyte balance.

Risk for ineffective health maintenance related to deficient knowledge about self-care of Addison's disease

EXPECTED OUTCOME: The patient will verbalize understanding of self-monitoring and self-medication at home.

- Assess patient's understanding of his or her disease process and treatment. *Teaching should build on baseline knowledge.*
- Teach the patient the importance of hormone replacement. Doses are generally taken two-thirds in the morning and one-third in the evening. *The patient who does not secrete endogenous adrenocortical hormones must rely on replacements.*
- Help the patient identify the causes and symptoms of stress, and explain the need to increase medica-

tion dosage by two to three times during times of stress or illness according to the physician's instructions. *Since these hormones are normally increased during times of stress, it is important that the patient understand how to increase the dose during stress to prevent adrenal crisis.*

- Advise patient he or she may need to increase salt intake in hot weather *because of fluid and salt losses.*
- Recommend medical alert identification to the patient. *A patient in adrenal crisis may not be able to provide a medical history to emergency personnel, and identification can prevent delay of treatment.*
- If ordered by the physician, teach the patient and significant other how to use an emergency intramuscular hydrocortisone injection kit. *IM medication may be needed during stress or times when the patient is unable to take oral medications.*

EVALUATION. If nursing care is effective, the patient's fluid status will be stable, and the patient and family will be able to describe proper self-care of Addison's disease.

Cushing's Disease/Syndrome

Cushing's *disease* is characterized by excess cortisol secretion resulting from secretion of too much adrenocorticotropic hormone (ACTH) by the pituitary. Cushing's *syndrome* refers to symptoms of cortisol excess caused by other factors. See Table 39.6 for a comparison of adrenal insufficiency and Cushing's syndrome.

Pathophysiology

Recall that cortisol, aldosterone, and androgens are the three steroid hormones secreted by the adrenal cortex. Cortisol is essential for survival and is normally secreted in a diurnal rhythm, with levels increasing in the early morning. Secretion is increased during times of stress. In Cushing's syndrome, cortisol is hypersecreted without regard to stress or time of day. When levels of cortisol are very high, effects related to excess aldosterone and androgens are also seen.

LEARNING TIP

Remember from Chapter 38, an easy way to remember the hormones of the adrenal cortex is to think *salt, sugar, and sex*. Aldosterone promotes salt retention, cortisol affects sugar (carbohydrate) metabolism, and androgens are sex hormones.

Etiology

Cushing's disease is caused by the hypersecretion of ACTH by the pituitary. This is most often the result of a pituitary adenoma. Sometimes ACTH is produced by a tumor in the

TABLE 39.6 ADRENAL CORTEX HORMONE SUMMARY

	Hypofunction	Hyperfunction
Disorder	Adrenocortical insufficiency, Addison's disease	Cushing's syndrome
Signs and Symptoms	Sodium and water loss, hypotension, hypoglycemia, fatigue	Weight gain, sodium and water retention, hyperglycemia, buffalo hump, moon face
Diagnostic Tests	Serum and urine cortisol	Serum and urine cortisol
Therapeutic Management	Glucocorticoid and mineralocorticoid replacement	Alter steroid therapy schedule; surgery if tumor
Priority Nursing Diagnoses	Risk for fluid volume deficit	Risks for fluid volume excess, glucose intolerance, infection

lungs or other organs. The high levels of ACTH cause adrenal hyperplasia, which in turn increases production and release of cortisol.

The most common cause of Cushing's syndrome is prolonged use of glucocorticoid medication (e.g., prednisone) for chronic inflammatory disorders such as rheumatoid arthritis, chronic obstructive pulmonary disease, and Crohn's disease.

Signs and Symptoms

Most signs and symptoms of Cushing's syndrome are related to excess cortisol levels. Weight gain, truncal obesity with thin arms and legs, buffalo hump, and moon face result from deposits of adipose tissue at these sites (Fig. 39.6). Cortisol also causes insulin resistance and stimulates gluconeogenesis, which result in glucose intolerance. Some patients develop secondary diabetes mellitus. (See Chapter 40.) Muscle wasting and thin skin with purple striae occur as a result of cortisol's catabolic effect on tissues. Catabolic effects on bone lead to osteoporosis, pathological fractures, and back pain from compression fractures of the vertebrae. Because cortisol has anti-inflammatory and immunosuppressive actions, the patient is at risk for infection. Hyperpigmentation of the skin may occur. Approximately 50% of patients experience mental status changes from irritability to psychosis (sometimes referred to as steroid psychosis). Sodium and water retention are related to the mineralocorticoid effect. As sodium is retained, potassium is lost in the urine, causing hypokalemia. (See Chapter 5 to review these electrolyte imbalances.) Androgen effects include acne, growth of facial hair, and amenorrhea in women.

Diagnostic Tests

Suspicion of Cushing's disease or syndrome may initially be based on a cushingoid appearance. Plasma and urine cortisol and plasma ACTH are measured. A 24-hour urine test for cortisol may be collected. A dexamethasone suppression test may be done. Serum potassium is measured. Additional tests to locate the cause of excess endogenous cortisol may be done.

Therapeutic Interventions

If a pituitary or other ACTH-secreting tumor is present, surgical removal or radiation therapy to the pituitary may be employed. If the adrenals are the primary cause of the problem, radiation or removal of the adrenal gland or glands may

be performed. Drugs such as ketoconazole block production of adrenal steroids.

If the cause of Cushing's syndrome is administration of steroid medication, an every-other-day schedule or once-a-day dosing in the morning may reduce side effects. Usually steroids are prescribed as a last resort for chronic disorders that are unresponsive to other treatment. The patient and physician must weigh the risks and benefits of continuing the medication. The physician may order a high-

FIGURE 39.6 Physical manifestations seen in Cushing's syndrome.

potassium, low-sodium, high-protein diet. Potassium supplements may be ordered. If the patient has high blood sugar, appropriate therapy for diabetes should be instituted. (See Chapter 40.)

Nursing Process for the Patient With Cushing's Disease

ASSESSMENT/DATA COLLECTION. When caring for the patient with Cushing's disease or syndrome, assess the patient's drug history. Monitor vital signs and complications related to fluid and sodium excess. Auscultate the lungs for crackles, and assess extremities for edema. Assess skin integrity, and monitor capillary glucose as ordered by the physician. Watch for signs of infection.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Risk for excess fluid volume related to sodium and water retention

EXPECTED OUTCOME: Fluid volume will be stable as evidenced by stable daily weights.

- Monitor fluid status and report changes promptly so treatment can be initiated.

Risk for impaired skin integrity due to thin fragile skin

EXPECTED OUTCOME: The patient's skin will remain intact.

- Assist patient to change positions at least every 2 hours to prevent pressure ulcers.
- Observe skin and monitor for breakdown with every position change. *Early recognition and treatment of a problem can prevent further breakdown.*
- Use a lift sheet to move patient in bed to prevent friction and shear.
- Avoid harsh soaps and hot water. *These can dry skin and increase risk for injury.*
- Use moisturizing cream to keep skin from drying.
- Secure IVs and dressings without tape whenever possible. *Removal of tape can tear fragile skin.*
- Consider a specialty pressure-reducing mattress if the patient is very thin or unable to move to reduce risk of pressure ulcer.
- Consult dietitian if nutritional status is poor. *Poor nutrition further increases risk for skin breakdown and poor healing.*

Risk for infection related to immune suppression

EXPECTED OUTCOME: Patient will be infection-free as evidenced by WBC and temperature within normal limits.

- Use good hand washing technique before and after patient care. *Hand washing is important in reducing exposure to pathogens.*
- Instruct the patient in good hand washing, and in the importance of avoiding others who are ill. *The patient with an impaired immune system is more likely to contract illness from others.*
- Consult dietitian if nutritional status is poor. *Poor nutrition further impairs immune function.*

- Report signs or symptoms of infection promptly so treatment can be initiated.
- Encourage flu and pneumonia vaccinations to help prevent illness in event of exposure.

Risk for injury related to impaired glucose tolerance

EXPECTED OUTCOME: Blood glucose will remain within normal limits.

- If glucose intolerance occurs, be prepared to administer insulin because oral hypoglycemics are not usually effective.
- Refer the patient and family to diabetes education classes because diabetes is a complex disease that requires knowledge of self-care.
- See Chapter 40 for care of the patient with diabetes.

Disturbed body image related to cushingoid appearance

EXPECTED OUTCOME: Patient will express feelings of acceptance of self.

- Approach patient with an attitude of acceptance and caring to help develop trusting nurse-patient relationship.
- Provide an opportunity for patient to verbalize feelings. *Expressing feelings may help reduce anxiety.*

EVALUATION. If care has been effective, complications of fluid overload will be recognized and treated early. The patient will have intact skin and be free from signs of infection. The patient will demonstrate skill in self-care of diabetes if indicated, and will verbalize acceptance of self in spite of changes in appearance.

Nursing Care of the Patient Undergoing Adrenalectomy

Preoperative Care

Monitor the patient for electrolyte imbalance and hyperglycemia. Abnormalities must be corrected before surgery. To prevent adrenal crisis, glucocorticoids are administered because removal of the adrenals causes a sudden drop in adrenal hormones. Prepare the patient for adrenalectomy or hypophysectomy, depending on which surgery will be performed.

Postoperative Care

See care of the patient undergoing hypophysectomy earlier in this chapter. Following adrenalectomy, the patient receives routine postoperative care. In addition, the patient is closely monitored for changes in fluid and electrolyte balance and adrenal crisis. Patients who undergo bilateral adrenalectomy must take replacement glucocorticoid and mineralocorticoid hormones for the remainder of their life. If only one adrenal gland is removed, the remaining gland should eventually produce enough hormone to enable the patient to discontinue replacement hormone.

See Table 39.7 for a summary of endocrine disorders and Table 39.8 for a summary of medications used for endocrine disorders.

TABLE 39.7 SUMMARY OF ENDOCRINE DISORDERS

Hormone	Hypofunction	Hyperfunction
Antidiuretic hormone	Diabetes insipidus—water loss	SIADH—water retention
Growth hormone	Dwarfism—short stature	Acromegaly, gigantism—bone and tissue overgrowth
Thyroid hormone	Hypothyroidism—slow metabolism	Hyperthyroidism—increased metabolism
Epinephrine	Rare	Pheochromocytoma—hypertension
Parathyroid hormone	Hypoparathyroidism—low serum calcium, osteoporosis, tetany	Hyperparathyroidism—high calcium, weakness
Cortisol	Addison's disease—sodium and water loss	Cushing's syndrome—sodium and water retention, hyperglycemia; see text

TABLE 39.8 MEDICATIONS USED FOR ENDOCRINE DISORDERS

Medication Class	Examples/Action	Route	Side Effects	Nursing Implications
<i>Medications for ADH disorders</i>	Vasopressin (Pitressin): replaces ADH	IM, IV, SC	Water retention	Check daily weights and urine specific gravity.
	Desmopressin (DDAVP): replaces ADH	PS, IV, SC, Intranasal	Water loss, dehydration	
	Demeclocycline (Declomycin): reduces ADH release	PO	Photosensitivity, allergy, water loss	
<i>Medications for growth hormone disorders</i>	Bromocriptine (Parlodel): reduces growth hormone release	PO	Dizziness, hypotension, nausea	Do not give demeclocycline with dairy products or antacids. Monitor blood pressure, serum growth hormone.
	Octreotide (Sandostatin): suppresses growth hormone	SC, IM, IV	Uncommon: dizziness, nausea, constipation	Teach patient self-administration.
	Somatropin (Humatrope): replaces growth hormone	SC, IM	Insulin resistance, hypothyroidism	Monitor growth; teach patient self-administration.
<i>Medications for thyroid disorders</i>	Levothyroxine (Synthroid): replaces T ₃ and T ₄	PO, IM, IV	Tachycardia, insomnia, nervousness, weight loss	Monitor vital signs and thyroid laboratory results.
	Propylthiouracil (PTU): inhibits synthesis of thyroid hormones	PO	Nausea, vomiting, agranulocytosis	Monitor WBC and differential, thyroid function.
	Methimazole (Tapazole): inhibits synthesis of thyroid hormones	PO	Rash, agranulocytosis	
<i>Medications for parathyroid disorders</i>	Calcium gluconate: replaces calcium	PO, IV	Dysrhythmia, cardiac arrest, constipation	Monitor vital signs and ECG during IV therapy. Do not take PO calcium with other medications.
	Alendronate (Fosamax): inhibits resorption of bone; keeps calcium in bones	PO	Abdominal pain, constipation, diarrhea, nausea	Do not take with calcium supplements or caffeine.
<i>Medications for adrenal disorders</i>	Phenoxybenzamine (Dibenzylamine): blocks action of epinephrine at alpha receptors in pheochromocytoma	PO	Orthostatic hypotension	Monitor vital signs.
	Hydrocortisone: replaces cortisol in adrenal insufficiency	PO, IV	Cushing's effects	Teach patient to take with food and not to discontinue abruptly.
	Fludrocortisone (Florinef): replaces aldosterone in adrenal insufficiency	PO	Fluid retention, heart failure, hypokalemia	Monitor daily weights, vital signs, and serum potassium.

CRITICAL THINKING

Mrs. Tercini

■ Mrs. Tercini is a 62-year-old woman admitted to your unit in Addisonian crisis. She is lethargic, with a blood pressure of 86/58, pulse 112, and respirations 18. While interviewing her daughter, you learn that Mrs. Tercini has a history of Cushing's syndrome treated with bilateral adrenalectomy 25 years ago. She has been taking 150 µg fludrocortisone (Florinef) and 200 mg hydrocortisone daily ever since. Three days ago she developed the flu.

1. Why is an adrenalectomy done to treat Cushing's syndrome?
2. What is the most effective schedule for Mrs. Tercini's medication?
3. What precipitated this Addisonian crisis?
4. Why is Mrs. Tercini's blood pressure low?
5. How could this crisis have been prevented?
6. Fludrocortisone is available as 0.1-mg tablets. How many should you administer?

Suggested answers at end of chapter.

REVIEW QUESTIONS

1. Which disorder results from too much cortisol secretion in the body?
 - a. Addison's disease
 - b. Hypothyroidism
 - c. Cushing's disease
 - d. Pheochromocytoma
2. A patient with SIADH asks the nurse why he has gained 10 pounds. Which response is best?
 - a. "SIADH causes an increase in appetite. As soon as you are effectively treated, the weight should drop back to normal for you."
 - b. "You are retaining a lot of sodium and potassium, and that causes you to gain a lot of water weight."
 - c. "You have too much of a hormone in your system that causes you to retain water. The extra 10 pounds is likely water weight."
 - d. "Your kidneys are not working correctly, so they can't get rid of extra water from your system."
3. Which assessment finding should the nurse expect to see in the patient with uncontrolled diabetes insipidus? Choose all that apply.
 - a. Edema
 - b. Polyuria
 - c. Heat intolerance
 - d. Diarrhea
 - e. Polydipsia
 - f. Dehydration
4. Which of the following instructions should the nurse provide to the patient who is being discharged after a thyroidectomy?
 - a. "You must take your thyroid replacement every day just as the physician prescribes."
 - b. "You must weigh yourself daily and report any gain or loss of more than 1 pound."
 - c. "You will need to return to the physician's office for a weekly blood pressure check."
 - d. "You will need to restrict your sodium and potassium intake."
5. Which of the following nursing assessments is most important in the patient with hyperthyroidism and risk for thyrotoxic crisis?
 - a. Intake and output
 - b. Breath sounds
 - c. Bowel sounds
 - d. Vital signs
6. Which action by the nurse is most important following hypophysectomy?
 - a. Performing a routine neurological assessment
 - b. Encouraging the patient to cough and deep breathe
 - c. Monitoring for tracheal edema
 - d. Assisting with use of an incentive spirometer
7. Which of the following statements by the patient with hypothyroidism indicates to the nurse that the plan of care has been effective?
 - a. "I feel so much better now that my energy is returning."
 - b. "I'm really glad the diarrhea has stopped."
 - c. "I'm so glad I won't have to take medication for very long."
 - d. "My fingers aren't tingling any more."

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mrs. Jackson*

1. Her weight gain is most likely caused by fluid retention, which can be a result of heart failure or SIADH, among other things.
2. Assess edema, lung sounds, and vital signs. Check intake and output during the past 2 days. Monitor mental status and level of consciousness. Check recent lab work to see if her serum sodium is low. You also check a book on the unit and recall that anesthetics and morphine are possible causes of SIADH. Morphine can also cause confusion.
3. Notify the registered nurse of your findings and your suspicions. Be prepared to place Mrs. Jackson on a fluid restriction. Reassure her son that the physician is being notified of the changes he noted.
- 4.

$$\frac{6 \text{ pounds} \quad | \quad 480 \text{ mL}}{1 \text{ pound}} = 2880 \text{ mL or almost 3 liters}$$

■ *Adoption*

The children's growth hormone secretion was probably suppressed because of psychosocial stress. Once they felt secure in a loving environment, growth hormone levels returned to normal.

■ *Mae*

1. Mae's TSH is elevated because her pituitary gland is working overtime to try to stimulate the underactive thyroid gland.

2. Mae's metabolism has been slow, so she has been burning fewer calories. When she starts on thyroid replacement hormone, her metabolic rate will return to normal and she will need more calories. Intake of calories should be balanced with the possible need for weight loss.
3. If Mae receives too much thyroid hormone, she will have symptoms of hyperthyroidism, including an increased pulse rate. She should know how to check her pulse and to call her physician if it is elevated.

■ *Mrs. Tercini*

1. Cushing's syndrome is caused by too much cortisol. The adrenal cortex is responsible for secreting cortisol.
2. Mrs. Tercini should take two-thirds of her daily dose of hydrocortisone and fludrocortisone in the morning and one-third in the evening. This most closely mimics the body's natural corticosteroid secretion.
3. The flu probably triggered this crisis. Illness is a stressor, and normally the body secretes steroids during stress. Because Mrs. Tercini's body is unable to produce steroids, she experiences symptoms of hypoadrenalism during stressful times.
4. Mrs. Tercini's blood pressure is low because she has insufficient circulating mineralocorticoids. Without aldosterone, sodium and water are lost and blood pressure drops.
5. Mrs. Tercini should have taken extra medication when she became ill.

$$6. \quad \frac{150 \mu\text{g} \quad | \quad 1 \text{ mg} \quad | \quad 1 \text{ tab}}{1000 \mu\text{g} \quad | \quad 0.1 \text{ mg}} = 1.5 \text{ tablets}$$

11. What is reactive hypoglycemia? How is it diagnosed and treated?

DIABETES MELLITUS

Diabetes mellitus (be careful not to confuse this with diabetes insipidus) is a group of metabolic diseases in which defects in insulin secretion or action result in high blood sugar level (**hyperglycemia**). According to the latest Centers for Disease Control and Prevention (CDC) data, approximately 20.8 million people in the United States have diabetes mellitus, and 6.2 million of those do not know it. The direct and indirect cost (such as lost work time) of diabetes in the United States is about \$132 billion per year. The incidence of diabetes mellitus varies by race and ethnicity. In the United States, Hispanic, black, Native American, Alaska Native, and Asian American populations have a higher rate of diabetes than non-Hispanic white ethnic groups.¹

Diabetes is a serious disease that can cause complications such as blindness, kidney failure, heart attacks, and strokes. It is a leading cause of lower limb amputations in the United States. With good education and self-care, patients with diabetes can prevent or delay these complications and lead full, productive lives. A major role of the nurse is helping the patient learn to care for herself or himself effectively.

Pathophysiology

Body tissues, and the cells that compose them, use glucose for energy. Glucose is a simple sugar provided by the foods we eat. When carbohydrates are eaten they are digested into sugars, including glucose, which is then absorbed into the bloodstream. Carbohydrates provide most of the glucose used by the body; proteins and fats can indirectly provide smaller amounts of glucose. Glucose is able to enter the cells only with the help of insulin, a hormone produced by the beta cells in the islets of Langerhans of the pancreas (Fig. 40.1). When insulin comes in contact with the cell membrane, it combines with a receptor that allows activation of special glucose transporters in the membrane (Fig. 40.2). By helping glucose enter the body's cells, insulin lowers the glucose level in the blood. Insulin also helps the body store excess glucose in the liver in the form of glycogen.

Another hormone, glucagon, is produced by the alpha cells in the islets of Langerhans. Glucagon raises the blood glucose when needed by releasing the stored glucose from the liver and muscles. Insulin and glucagon work together to keep the blood glucose at a constant level.

Diabetes results from faulty production of insulin by the beta cells in the pancreas, or from inability of the body's cells to use insulin. When glucose is unable to enter body cells, it stays in the bloodstream; hyperglycemia results, and the cells are denied their energy source. Abnormal glucagon secretion may also play a role in type 2 diabetes.

diabetes mellitus: diabetes—passing through + mellitus—sweet
hyperglycemia: hyper—excessive + glyc—glucose + emia—in the blood

Types and Causes

Type 1 Diabetes Mellitus

Type 1 diabetes (formerly called juvenile diabetes mellitus, insulin-dependent diabetes mellitus, or IDDM) is caused by destruction of the beta cells in the islets of Langerhans of the pancreas. When the beta cells are destroyed, they are unable to produce insulin. Insulin must then be injected for the body to use food for energy. See Box 40.1 Patient Perspective for Dave's story about having type 1 diabetes. Only 5% to 10% of people with diabetes have type 1 diabetes.

It is believed that the pancreas may attack itself following certain viral infections or administration of certain drugs (this is called an autoimmune response). Almost 90% of patients newly diagnosed with type 1 diabetes have islet cell antibodies in their blood. These antibodies might be present for years before actual symptoms of diabetes develop. About 10% of people with type 1 diabetes cases also have a genetic predisposition to its development. The patient with type 1 diabetes is most often young and thin and is prone to develop **ketoacidosis** when blood glucose is elevated. (See Table 40.1 for a comparison of type 1 and type 2 diabetes.) Diabetic ketoacidosis is discussed later in this chapter. Research studies are ongoing to try to find ways to prevent type 1 diabetes once antibodies have been detected.

LATENT AUTOIMMUNE DIABETES OF ADULTHOOD (LADA)

This is a new type of type 1 diabetes that has recently been identified. Some patients who were initially diagnosed with type 2 diabetes were later found to have islet cell and insulin antibodies (which are usually associated with type 1), and their blood glucose levels were not controlled with oral medications. However, beta cell destruction tended to occur more slowly than with type 1 diabetes. This is possibly because of differences in the antibodies or the individual's response to the antibodies. Some experts distinguish patients with LADA as either thin or obese because the disorder has slightly different characteristics depending on the patient's body fat.

Type 2 Diabetes Mellitus

Ninety percent to 95% of people with diabetes have type 2 diabetes mellitus (formerly called adult-onset diabetes mellitus, non-insulin-dependent diabetes mellitus, or NIDDM). In type 2 diabetes mellitus, tissues are resistant to insulin. Insulin is still made by the pancreas, but in inadequate amounts. Sometimes the amount of insulin is normal or even high, but because the tissues are resistant to it, hyperglycemia results. Glucagon levels may be elevated.

Heredity is responsible for up to 90% of cases of type 2 diabetes. Obesity is also a major contributing factor. Often the patient with a new diagnosis of type 2 diabetes is obese, relates a family history of diabetes, and has had a recent life stressor such as the death of a family member, illness, or loss of a job.

ketoacidosis: keto—ketones + acid—acidic + osis—condition

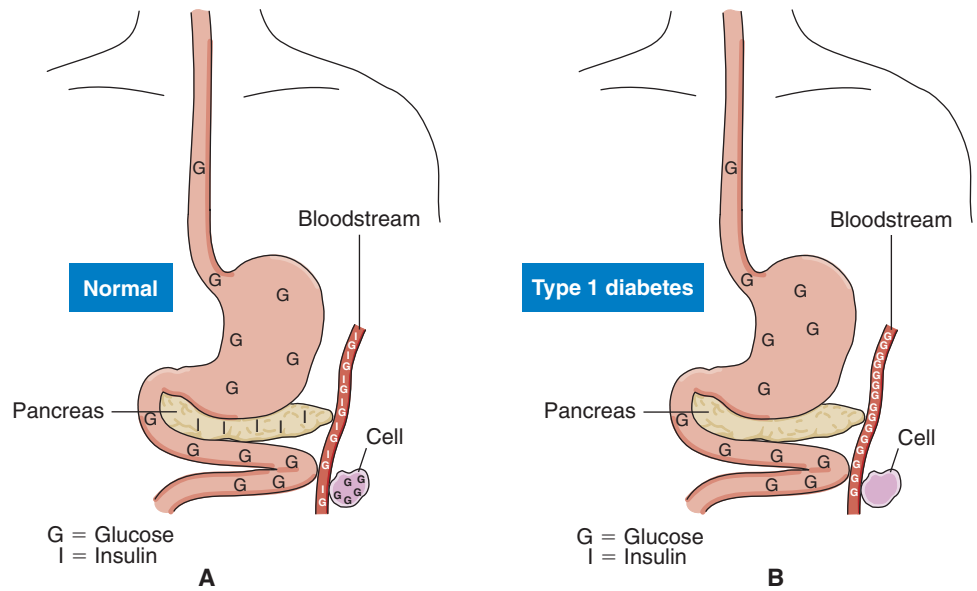

FIGURE 40.1 Maintenance of blood glucose levels. (A) Normal physiology: Foods (especially carbohydrates) are broken down into glucose, which is absorbed into the bloodstream for transport to the cells. Insulin, produced by the beta cells of the islets of Langerhans in the pancreas, is needed to “open the door” to the cells, allowing the glucose to enter. (B) In type 1 diabetes mellitus, the pancreas does not produce insulin. Because glucose is unable to enter the cells, it builds up in the bloodstream, causing hyperglycemia. (C) In type 2 diabetes mellitus, insulin production is reduced and/or cells are resistant to insulin. Less glucose enters the cell, and hyperglycemia results.

FIGURE 40.2 (A) Cell membrane in normal state, with insulin receptors and insulin to regulate glucose intake. (B) Cell membrane in type 1 diabetes: insulin not present, glucose remains outside of cell. (C) Cell membrane in type 2 diabetes: without insulin receptors, glucose remains outside cell (From Scanlon VC, Sanders T: *Essentials of Anatomy and Physiology*, ed 4. FA. Davis, 2003, Philadelphia, p 225, with permission.)

**Box 40.1****Patient Perspective****Dave**

I was diagnosed with type 1 diabetes mellitus at age 3 years. I remember being left in a children's ward of the hospital with the nuns (who were nurses) in their habits and looking into the parking lot as my parents got in the car and drove away. I remember the fear and horror of being left alone. Later, I remember my doctor teaching my mother and me about the diet and monitoring my urine for glucose and ketones. This was all we had in those days (the early 1960s). I was supposed to test my urine before meals and at bedtime, just like we monitor blood glucose today. Every time I saw my doctor he would review and change my treatment based on the results. Insulin then was extracted from pig and cow cadavers.

I remember my life being pretty normal except at holidays. When my brothers and sisters were getting Halloween candy and Christmas candy canes, I felt odd and left out. My mom was really tough and observant and I had to be sneaky to get away with stealing a treat or two left momentarily unobserved by those around me. I was thrilled when sugarless candy became available around age 10 or so and I could have my own candies to hoard for myself.

Hypoglycemic reactions were always a trauma-filled event at our house. They came at unexpected times, and my mom sometimes blamed herself. I can honestly say that my mom deserves more credit than I have ever given her for my good fortune with my diabetes. She did not have glucometers, glycohemoglobin tests, or even diabetes specialists and educators; she just had the desire of a mother who did everything she could to make sure I had and did everything right as far as she knew.

In my late teens I took everything my doctor and my mom had done for me and trashed them. I lived with reckless abandon: I did what I wanted, ate what I wanted, and didn't even think about the disease I lived with until I was about 30. I worked hard those years in construction, and

the physical activity probably delayed the complications that might otherwise have occurred.

At age 35, I began to experience the inevitable effects of long-term hyperglycemia. I developed diabetic retinopathy, the leading cause of adult-onset blindness in the United States. My vision was restored in my left eye with laser surgery. It would take another surgery (vitrectomy) to bring the vision in my right eye back to the 20/60 it is now from the 20/2000 it was before the surgery.

About that time I was referred to an endocrinologist who specialized in diabetes, and my treatment took a remarkable turn for the better. The endocrinologist began to aggressively change my medications, insulin regimen, exercise program, and diagnostic testing, all with the purpose of controlling blood glucose and preventing the onset and advancement of diabetic complications. This aggressive plan of action was taught to me by a registered nurse certified diabetes educator who worked with my doctor. I must also give enormous credit to the office staff nurses who were an integral part of the team, supporting me throughout the whole experience. The doctors and nurses made my education both understandable and pertinent. They basically put the ball in my court, and then it was up to me to take control of my own life. My wife was more than supportive throughout this time period too, and sacrificed much for the new array of medications and doctor's appointments that took a huge chunk out of our family finances.

I have mentioned briefly those involved in my life with diabetes. I take no credit for any of the results though; I believe it was God who made these choices available and miraculously reversed the effects of disease in my body. To the amazement of medical professionals, He continues to bless me with good health. It is because of all I have gone through with diabetes that I have recently completed my nursing degree and hope to become a diabetes educator myself.

TYPE 2 DIABETES IN YOUTH. More and more children and adolescents are developing type 2 diabetes, which in the past only occurred in adults. This is related to increasing obesity and decreasing activity levels in children today. Many experts are concerned about the growing number of obese children in the United States because of their increased risk for diabetes, heart disease, and other obesity-related problems.

Gestational Diabetes

Gestational diabetes mellitus (GDM) may develop during pregnancy, especially in women with risk factors for type 2 diabetes. The extra metabolic demands of pregnancy trigger

the onset of diabetes. Blood glucose usually returns to normal after delivery, but the mother has an increased risk for type 2 diabetes in the future. If the mother with GDM is overweight, she should be counseled that weight loss and exercise will decrease her risk of later developing diabetes. Mothers with GDM require specialized care and should be referred to an expert in this area.

Prediabetes

Prediabetes refers to blood glucose levels that are above normal but do not meet the criteria for diagnosing diabetes. Prediabetes usually occurs prior to the onset of type 2 diabetes. It is diagnosed by evaluating glucose tolerance or fast-

TABLE 40.1 COMPARISON OF TYPE 1 AND TYPE 2 DIABETES

	Type 1 (IDDM)	Type 2 (NIDDM)
Onset	Rapid	Slow
Age at onset	Usually <40	Usually >40
Risk factors	Virus, autoimmune response, heredity	Heredity, obesity
Usual body type	Lean	Obese
High blood glucose complication	Ketoacidosis	Hyperosmolar, Hyperglycemic, Nonketotic syndrome
Treatment	Diet, exercise; must have insulin to survive	Diet, exercise; may need oral hypoglycemics or insulin to control blood glucose level

ing glucose levels (see tests of diabetes below). Individuals with prediabetes may be able to prevent the onset of diabetes with weight loss and exercise.

Other Types of Diabetes

Secondary diabetes may develop as a result of another chronic illness that damages the islet cells, such as pancreatitis or cystic fibrosis. Prolonged use of some drugs, such as steroid hormones, phenytoin (Dilantin), thiazide diuretics, and thyroid hormone, may also impair insulin action and raise blood glucose. Maturity-onset diabetes of the young (MODY) is an inherited defect in insulin secretion that usually occurs in individuals under the age of 25. Less common causes include pancreatic trauma and other endocrine disorders.

Metabolic Syndrome

A newer finding is the link between diabetes and a condition called metabolic syndrome, sometimes called syndrome X. According to the American Heart Association and the National Heart, Lung, and Blood Institute, metabolic syndrome is diagnosed when at least three of the following criteria are met²:

- Elevated waist circumference (abdominal obesity)
- Triglyceride level of 150 mg/dL or higher
- High-density lipoprotein (HDL) (“good”) cholesterol lower than 40 mg/dL for men and lower than 50 mg/dL for women
- Blood pressure level of 130/85 mm Hg or higher
- Fasting glucose of 100 mg/dL or higher

Other risk factors include physical inactivity, aging, hormonal imbalance, and genetic predisposition. Hispanic Americans are at higher risk than Caucasians. A major factor is the growing obesity epidemic in the United States.

Any patient who fits this profile should be monitored closely for the onset of type 2 diabetes and heart disease. Patients should be counseled on the importance of a diet low in saturated fats and cholesterol, weight loss, physical activity, and control of blood pressure.

LEARNING TIP

Remember the classic symptoms of diabetes by the **3 Ps**: *polydipsia*, *polyuria*, and *polyphagia*.

Signs and Symptoms of Diabetes

Classic symptoms of diabetes mellitus include **polydipsia** (excessive thirst), **polyuria** (excessive urination), and **polyphagia** (excessive hunger). Because glucose is unable to enter the cells, the cells starve, causing hunger. The large amount of glucose in the blood causes an increase in serum concentration, or osmolality. The renal tubules are unable to reabsorb all the excess glucose that is filtered by the glomeruli, and **glycosuria** results. Large amounts of body water are required to excrete this glucose, causing polyuria, **nocturia**, and dehydration. The increased osmolality and dehydration cause polydipsia. High blood glucose may also cause fatigue, blurred vision, abdominal pain, and headaches. Ketones may build up in the blood and urine of patients with type 1 diabetes (ketoacidosis).

Diagnostic Tests

FASTING PLASMA GLUCOSE. Diagnosis of diabetes mellitus is based on plasma glucose levels measured by a laboratory. According to the American Diabetes Association,³ a normal plasma glucose level is less than 100 mg/dL, although different laboratories may have slightly different normal values. When the fasting plasma glucose (drawn after at least 8 hours without eating) is ≥ 126 mg/dL, diabetes is diagnosed. A second test may be required if the first test is not clearly diagnostic. If the fasting plasma glucose is between 100 and 125 mg/dL, the patient has impaired fasting glucose (IFG).

CASUAL PLASMA GLUCOSE. Sometimes it is not feasible to check a fasting plasma glucose. A casual plasma glucose (CPG) is checked without regard to the last meal. Diabetes is diagnosed if the CPG is ≥ 200 mg/dL, with symptoms of diabetes.

ORAL GLUCOSE TOLERANCE TEST. Another test to diagnose diabetes is the oral glucose tolerance test (OGTT). An OGTT measures blood glucose at intervals after the patient drinks a concentrated carbohydrate drink. Diabetes is

polydipsia: poly—many or much + dipsia—thirst

polyuria: poly—many or much + uria—urine

polyphagia: poly—many or much + phagia—to eat

glycosuria: glyc—glucose + uria—urine

nocturia: noc—by night + uria—urine

diagnosed when the blood glucose level is ≥ 200 mg/dL after 2 hours. A result between 140 and 199 mg/dL at 2 hours diagnoses impaired glucose tolerance (IGT).

GLYCOHEMOGLOBIN. The glycohemoglobin test (also called glycosylated hemoglobin, or HbA_{1c}) is used to gather baseline data and to monitor progress of diabetes control (not to diagnose diabetes). Glucose in the blood attaches to hemoglobin in the red blood cells. Red blood cells live about 3 months in the body. When the glucose that is attached to the hemoglobin is measured, it reflects the average blood glucose level for the previous 2 to 3 months. A normal HbA_{1c} is 4% to 6%. This is a helpful measurement when blood glucose levels fluctuate and a single measurement would be misleading. It also assists in determining the degree of effectiveness of a patient's treatment plan. Newer methods allow this test to be done in a physician's office while the patient waits. Glycohemoglobin testing might be inaccurate in some people, such as those with anemia. These individuals may have a glycated serum protein test, which is a similar test that indicates glucose levels over a period of 1 to 2 weeks instead of 3 months. See Table 40.2.

ADDITIONAL TESTS. Because diabetes affects so many body systems, additional tests recommended for baseline data include a lipid profile, serum creatinine and urine microalbumin levels to monitor kidney function, urinalysis, and electrocardiogram.

CRITICAL THINKING

Mr. McMillan

■ Mr. McMillan is a 50-year-old patient brought into the emergency department with extreme fatigue and dehydration. After the physician sees him, you ask Mr. McMillan some additional questions. Based on the patient's answers, you request that the physician add a glucose level to the laboratory tests ordered. The result is 1400 mg/dL.

1. What questions would you ask Mr. McMillan if you suspected diabetes?
2. Why was Mr. McMillan fatigued?
3. Why was he dehydrated?

Suggested answers at end of chapter.

Prevention

Although there is currently no known way to prevent type 1 diabetes, there are ways to prevent type 2 diabetes. Research studies have shown that patients at risk for diabetes, even those who already have IGT or IFG, can prevent or delay the onset of diabetes with weight loss and regular exercise. Losing as little as a 5% to 7% body weight through a half hour of exercise 5 days a week, and reducing fat and calories can reduce the risk of diabetes by 58%.⁴ Patients at risk should have their plasma glucose checked regularly.

TABLE 40.2 CORRELATION BETWEEN HbA_{1c} AND MEAN FASTING PLASMA GLUCOSE (FPG)²

HbA _{1c} (%)	FPG (mg/dL)

Therapeutic Interventions

The only cure for diabetes is a pancreas (or islet cell) transplant. However, diabetes can be controlled. Treatment begins with diet and exercise. Insulin is added in patients with type 1 diabetes and insulin or oral hypoglycemic medication as needed in those with type 2 diabetes. Blood glucose monitoring and education are also important to good diabetes control.

To monitor the effectiveness of treatment, patients should have regular health care follow-up visits. See Box 40.2 Summary of Diabetes Goals and Recommendations proposed by the American Diabetes Association for 2006.

Goals of Treatment

The American Diabetes Association recommends that patients maintain a **preprandial** (premeal) plasma glucose level of 90 to 130 mg/dL, peak **postprandial** glucose <180 mg/dL, and glycohemoglobin level of less than 7% to prevent or delay complications of diabetes. Because of the risk for cardiovascular disease, they also recommend maintaining blood pressure <130/80 mm Hg.³ The American Association of Clinical Endocrinologists recommends even stricter goals: preprandial plasma glucose of <110 mg/dL, 2-hour postprandial glucose <140 mg/dL, and HbA_{1c} $\leq 6.5\%$.⁵ All goals may be adjusted in individual circumstances. For example, the patient who does not feel symptoms of **hypoglycemia** might have a higher preprandial glucose goal to prevent undetected hypoglycemic episodes.

Medical Nutrition Therapy

The goal of medical nutrition therapy (MNT) is to achieve and maintain blood glucose and lipid levels as near to normal as possible to prevent long-term complications. For some, especially those with type 2 diabetes, weight loss and blood pressure control may be additional goals of nutrition therapy.

Because the patient with diabetes has a limited amount of insulin, either **endogenous** (from within the body) or

preprandial: pre—before + prandial—meal

postprandial: post—after + prandial—meal

hypoglycemia: hypo—deficient + glyco—glucose + emia—in the blood

endogenous: endo—within + genous—to produce

Box 40.2**Summary of Diabetes Goals and Recommendations**

Capillary plasma glucose should be measured at least three times a day for patients using multiple insulin injections. Blood pressure should be measured at every office visit. Target levels are:

- HbA_{1c} (every 3–6 months) <7%
 - Preprandial capillary glucose 90 to 130 mg/dL
 - Peak postprandial capillary glucose <180 mg/dL
 - Blood pressure <130/80 mm Hg
- Blood lipids should be measured at least yearly.

Target levels are:

- LDL <100 mg/dL
- Triglycerides <150 mg/dL
- HDL >40 mg/dL

Urine should be checked for microalbumin yearly.

Patient should receive:

- Yearly flu vaccine for all patients ≥6 months of age
- One lifetime pneumococcal vaccine for adults
- Aspirin therapy, 75–162 mg/day, if >21 years of age
- Statin therapy to achieve an LDL reduction of 30% to 40% regardless of baseline LDL levels if >40 years of age
- Smoking cessation counseling
- Yearly comprehensive foot examination
- Dilated comprehensive eye examination within 3 to 5 years of onset of type 1 diabetes, or at diagnosis of type 2 diabetes, and every year thereafter.

injected, it is important to eat an amount of food that will not exceed the insulin's ability to carry it into the cells. The meal plan should include consistent amounts of carbohydrates, proteins, and fats each day (Box 40.3 Nutrition Notes). Because carbohydrates contribute most to the blood glucose level, it is most important that carbohydrates are consistent from one day to the next. If a patient eats a small amount of carbohydrate one day and a large amount the next, the blood glucose will fluctuate, leading to complications. It is possible to relax nutrition restrictions somewhat if the patient is willing to test blood glucose frequently at home and adjust treatment accordingly. This requires in-depth instruction by a diabetes educator.

In the past, the commonly prescribed meal plan was the American Diabetes Association (ADA) diet, which was based on a basic meal plan with lists of amounts of foods that could be exchanged to vary the menu. The ADA no longer recommends a single meal plan, but rather advocates a complete assessment by a specially trained dietitian and

individualized nutrition therapy recommendations and teaching.

A variety of meal plans are available, as shown in Table 40.3. Because diabetes increases the risk of high serum cholesterol and triglycerides, all plans limit fat intake. Patients who use fat replacers (in foods such as fat-free baked goods or ice cream) should be aware that they still have food value and calories, so they cannot be considered “free” foods. Most plans also encourage the use of complex carbohydrates such as grains, pastas, vegetables, and fruits. Simple sugars, which may raise blood glucose more than complex carbohydrates (they have a higher *glycemic index*), are used less but are not prohibited as they were in the past. Sodium intake is limited in individuals with hypertension. Protein is limited in patients with any degree of kidney impairment. Any meal plan should be chosen to fit the patient's lifestyle and food preferences. Patient preferences based on ethnic background should also be considered (Box 40.4 Cultural Considerations).

The success of MNT is evaluated by monitoring glucose levels, HbA_{1c}, lipids, weight, blood pressure, and kidney function.

Exercise

Exercise is an important factor in controlling blood glucose and lipid levels. Exercise lowers blood glucose, both immediately and for approximately 24 hours after the exercise. Insulin is not needed for glucose to enter exercising muscle cells. Exercise also improves blood lipid levels and circulation, which is important for the person with diabetes, who already has an increased risk of cardiovascular disease. Patients are instructed to exercise on a regular basis, ideally 30 minutes on most days of the week, to keep blood glucose levels stable and promote health.

Some patients with complications of diabetes must be careful in their exercise choices. For example, a patient with **retinopathy** should not do anything that causes straining. (See Long-Term Complications later in this chapter.) A patient with **neuropathy** or foot problems should limit weight-bearing exercise. A physician or exercise physiologist should be consulted for an individualized exercise plan.

Persons with diabetes should always carry a quick source of sugar when exercising in case the blood glucose drops too low. Individuals on intermediate-acting insulin are taught to avoid exercising at the time of day when their blood glucose is at its lowest point (i.e., when insulin or medication is peaking) and to have a carbohydrate snack before exercising if blood glucose is less than 100 mg/dL. Exercising at similar times each day also helps prevent blood glucose fluctuations.

Patients should be cautioned to avoid exercise when their glucose level is higher than 250 mg/dL and ketones are present in the urine or if glucose is more than 300 mg/dL without ketones. This indicates that insufficient insulin is

retinopathy: retino—nervous tissue of the eye + pathy—illness

neuropathy: neuro—nervous system + pathy—illness

**Box 40.3****Nutrition Notes*****Individualizing Medical Nutrition Therapy in Diabetes Mellitus***

A certified diabetes educator can use many approaches in the nutritional management of diabetes. This permits a meal plan based on the patient's abilities and commitment. Several meal-planning approaches are described in Table 40.3 and commonly used ones are detailed below. The education of the patient with diabetes is a process that may take months, and should not be expected to be accomplished in a single visit or with a paper handout.

Overall goals and strategies differ for the type 1 and type 2 diabetics. In general, a patient with type 1 diabetes needs to prevent wide swings in blood glucose levels through careful timing of meals and snacks in relation to insulin therapy and activity. A patient with type 2 diabetes uses diet modifications to maintain near-normal glucose, blood pressure, and lipid levels and to lose weight as necessary.

Using MyPyramid

A basic educational tool, the MyPyramid, can be adapted for a first-level meal plan for the newly diagnosed person with diabetes. The physician or diabetes educator can select the kilocalorie level appropriate for the patient and common household measures are used as guidelines.

Using ADA Exchange Lists

A food guide called the *ADA Exchange Lists*, published jointly by the American Dietetic Association and the American Diabetes Association, is used by some patients with diabetes. This system is composed of six lists of foods plus a "free food" list. Foods in each list contain similar energy nutrients (carbohydrate, protein, and fat). For example, corn is on the starch list rather than the vegetable list because it is closer in composition to a slice of bread than to green beans. Individual food items within an exchange list are essentially equal to each other in nutrient composition and can thus be exchanged or "swapped" for each other. Exchanges were designed to be approximately equal in nutrients, not in volume; therefore, portion sizes vary widely. For instance, one fruit exchange is equal to $1\frac{1}{4}$ cup of whole strawberries but to only three dates. To correctly use this method of meal planning, patients must choose the prescribed number of items from each appropriate list: starch, fruit, milk, vegetable, meat, and fat.

A specific meal plan should be given to the patient with the exchange lists. A meal plan is a food guide that shows the number of choices or exchanges the patient should eat at each meal and snack. A meal plan based on exchange lists allows patients a variety of food choices yet requires minimal calculation. Even experienced users of the exchange list system should be advised to weigh or measure their portions several times per week to avoid portion inflation.

Using Carbohydrate Counting

Carbohydrate counting is a three-level approach to teaching meal planning that focuses on carbohydrates, but patients are told to eat about the same amount of protein each day and to choose low-fat foods. With this system, the patient keeps track of the units or exchanges of carbohydrates eaten throughout the day to keep carbohydrates and insulin balanced. Carbohydrate counting is based on classifying carbohydrates together, whether from starch, fruit, or milk. For example, one slice of whole wheat bread, one orange, and 8 oz of skim milk are each equivalent to one carbohydrate unit or exchange. This method offers more flexible food choices within a day's meal plan than the exchange list system and may achieve better control of blood glucose. Despite those advantages, however, carbohydrate counting may entail weighing and measuring food, keeping food records, monitoring blood sugar before and after eating, and controlling body weight. Mastery of level III of carbohydrate counting permits adjusting short-acting insulin dosage using insulin-to-carbohydrate ratios and is often a prerequisite for starting insulin pump therapy.

Using the Glycemic Index

All carbohydrates are not metabolized identically. Foods containing equal amounts of carbohydrate impact blood glucose levels differently. The glycemic index is a classification of foods according to the speed and degree of change in blood glucose levels. Compared with a standard of 100 for white bread, glucose has a glycemic index of 138, sucrose (table sugar) 83, and fructose 26. Baked russet potatoes and cornflakes have higher glycemic indices than sucrose, whereas sweet potatoes have a lower one. Because most meals contain a combination of nutrients, the glycemic index should not be a primary strategy but might be an adjunct to another meal planning system for highly motivated patients.

TABLE 40.3 MEAL-PLANNING APPROACHES FOR DIABETES

Approach	Comments	Availability
<i>Food Pyramid</i>	Initial phase of teaching Provides a basic foundation in normal nutrition. Does not emphasize meal consistency.	A colorful version is available from the National Dairy Council, 10255 West Higgins Road, Suite 900, Rosemont, IL 60018-4233 1-708-803-2000
<i>Dietary Guidelines</i>	Initial phase of teaching Provides a basic foundation in normal nutrition, 40 pages in length. Does not emphasize meal consistency.	United States Department of Agriculture Home & Garden Bulletin #232, Local Cooperative Extension Office
<i>The First Step in Diabetes</i>	Initial phase in teaching	The American Dietetic Association, 216 West Jackson Boulevard, Suite 800, Chicago, IL 60606-6995 1-800-366-1655
<i>Meal Planning</i>	Combines Food Pyramid and Dietary Guidelines, and provides information on meal consistency in a simplified format.	
<i>CHO Counting</i>	Progressive teaching tool that leads to maximum control of blood glucose and lipid levels. Decreased emphasis on balance and variety.	The American Dietetic Association, 216 West Jackson Boulevard, Suite 800, Chicago, IL 60606-6995 1-800-366-1655
<i>Month-O-Meals</i>	Each book contains 28 complete and interchangeable menus for breakfast, lunch, dinner, and snacks. Excellent approach for the patient who “just wants to be told what and when to eat.”	The American Dietetic Association, 216 West Jackson Boulevard, Suite 800, Chicago, IL 60606-6995 1-800-366-1655
<i>Exchange Lists of the American Dietetic and the American Diabetes Associations</i>	Allows the health-care educator to distribute all of the energy nutrients. More emphasis on the importance of eating a balanced diet than the CHO counting approach. Time consuming to learn and teach	The American Dietetic Association, 216 West Jackson Boulevard, Suite 800, Chicago, IL 60606-6995 1-800-366-1655

Source: Lutz, CA, and Przytulski, KR: Nutrition and Diet Therapy, ed. 4, F.A. Davis, Philadelphia, 2005.

available and glycogen may be released during exercise, further increasing the serum glucose.

Medication

INJECTED INSULIN. The individual with type 1 diabetes has no endogenous insulin and therefore must administer insulin daily. At this time, insulin cannot be taken by mouth because it is a protein and is therefore digested. Insulin is

generally given subcutaneously, although fast-acting insulin may be ordered via the intramuscular or intravenous route in urgent situations, or sometimes inhaled. There are several types of insulin and schedules by which it may be given. The type and schedule are determined by the physician, in collaboration with the patient, based on the patient's lifestyle and willingness to spend time on injections. In general, the more frequent the injections, the better the glucose control.

Insulin injections should be given in a different subcutaneous site each time to avoid injury to the tissues. A sample rotation chart is shown in Figure 40.3. Because each area absorbs insulin at a slightly different rate, it is advisable to use one area for a week, then move on to the next area. Within that area, each injection should be spaced at least 1 inch from the previous injection. Most experts recommend using primarily the torso (abdomen and buttocks) to provide more uniform absorption. Aspirating for blood before injection and rubbing the site following injection are not recommended with insulin injections.

Patients who desire tighter control of blood glucose levels and a more flexible lifestyle may choose to use an insulin pump (Fig. 40.4). This is a small device that delivers subcutaneous insulin continuously in small (basal) amounts. The patient can then add a bolus of insulin with the push of a button before meals or snacks. This provides insulin levels that are more normal, like a person without diabetes.

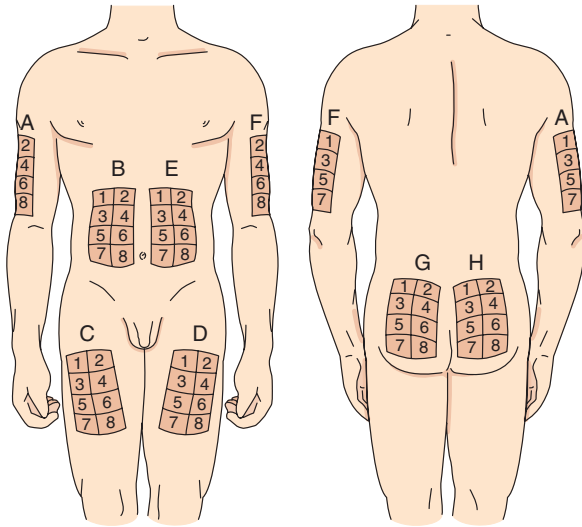

Box 40.4

Cultural Considerations

The diabetic diet for ethnic individuals may need a significant adjustment from the U.S. menu. An exchange list of foods for these patients will not be followed because their food choices are different. The patient may be labeled noncompliant, when in reality the health-care worker has been culturally insensitive.

The nurse can consult the American Diabetes Association in Washington, DC (1-800-342-2383) to obtain meal plans for ethnic individuals such as Asians, Hispanics, African Americans, and Native Americans. Some helpful web sites include www.diabetes.org/espanol and www.eatright.org.

Rotation sites for injection of insulin.

FIGURE 40.3 Sample insulin rotation chart.

Insulin is synthetically produced in a laboratory and is either identical to human insulin, or one or two amino acids different (called insulin analogs). In the past, insulin was derived from cows and pigs; this is no longer available in the United States, but may be available from other countries. Be careful to check the source when preparing insulin for injection (especially if you work in home care, where patients could purchase their insulin online from another country), because insulins from different sources may act slightly differently. Some individuals may be allergic to beef or pork preparations or may refuse them based on cultural practices.

Once insulin is injected, a period elapses before it begins to lower blood glucose. This time is called the *onset* of action. The *peak* action time occurs when the insulin is working at its hardest and the blood glucose is at its lowest point. It is during this peak time that the patient is most at risk for an episode of low blood glucose. *Duration* is the length of time the insulin works before it is used up. Onset, peak, and duration are determined by whether the insulin is short-, intermediate-, or long-acting (Table 40.4). It is important for the individual with diabetes and the nurse to

FIGURE 40.4 Patient wearing insulin pump.

be aware of the onset, peak, and duration of any insulin given. This assists in making decisions such as when to give insulin, when to exercise, and when to be alert to low blood glucose symptoms.

LEARNING TIP

The Evens-and-Odds Rule: to remember the onset, peak, and duration of intermediate-acting insulin, think *evens*—2, 12, and 24 hours. To remember short-acting insulin, think *odds*—1, 3, and 5 hours. These times are not exact, but they are a great memory booster when you need to think fast.

In the past, most patients with diabetes used an injection of intermediate-acting insulin before breakfast and possibly a second injection before supper. Many patients are now choosing to take more frequent injections of short-acting insulin before meals or a combination of short- and intermediate-acting or long-acting insulins to achieve better, “tighter” control. These patients are often taught to adjust their insulin dose based on blood glucose level and the amount of carbohydrates eaten. Tighter control can mean fewer complications in the long run.

One regimen that is becoming more common because it mimics normal insulin secretion is sometimes called

TABLE 40.4 ONSET, PEAK, AND DURATION OF INSULINS

Insulin Type	Example	Sample Brand Names	Onset	Peak	Duration
Very short acting	Insulin lispro,	Humalog	15–30 min	30–90 min	≤5 hr
	Insulin aspart	NovoLog	10–20 min	1–3 hr	3–5 hr
	Insulin human rDNA origin (for inhalation)	Exubera*			
Short acting	Regular	Humulin R, Novolin R	1/2–1 hr	2–5 hr	5–8 hr
Intermediate acting	NPH	Humulin N, Novolin N	1–2 hr	6–12 hr	18–26 hr
Long acting	Ultralente	Humulin U	4–6 hr	14–24 hr	26–36 hr
	Insulin glargine	Lantus AE	70 min	No peak	24 hr

Note: A variety of premixed formulas are also available.
 Note: All insulins listed are injected except Exubera.
 *Data for onset, peak, and duration not currently available.

“basal-bolus” insulin. This consists of an injection of a basal insulin once a day, often at bedtime, to provide a constant small amount of insulin in the bloodstream. Then an injection of very short-acting insulin is injected before meals to mimic the extra insulin that is secreted normally with meals.

When two insulins need to be given at the same time, they can often be mixed together to prevent having to give more than one injection. See Box 40.5 How to Mix Insulins in one syringe. Preset mixtures of intermediate- and short-acting insulins are available for patients who have difficulty learning to mix insulins.

LEARNING TIP

When mixing insulins, remember *clear to cloudy*. Always draw up the clear insulin first. This involves injecting air into the cloudy vial first. This is because if the clear is drawn up last, the vial may be contaminated by the cloudy insulin, altering the action of the clear insulin. If cloudy insulin is unknowingly contaminated by clear insulin, the clear will become cloudy and its effect will be diminished. Note: Lantus insulin cannot be mixed with other insulins.

Box 40.5

How to Mix Insulins

1. Assemble equipment: insulins, syringe (be sure it is large enough to hold the entire insulin dose), alcohol swab, physician's order.
 2. Check physician's order to confirm correct insulin types and doses of regular (clear) and an intermediate-acting (cloudy) insulin.
 3. Roll the bottle of cloudy insulin to mix. Do not shake, because this will cause bubbles.
 4. Wipe tops of both vials with alcohol swab.
 5. Draw up and inject an amount of air equal to the dose of intermediate-acting insulin into the cloudy vial. Remove syringe from vial.
 6. Draw up and inject an amount of air equal to the dose of short-acting insulin into the clear vial.
 7. Draw up the correct amount of clear insulin. Double-check amount with another nurse if this is the institution's policy.
 8. Remove the syringe and insert into the cloudy vial. Carefully draw up the correct amount of insulin. If too much insulin is accidentally drawn into the syringe, the syringe must be discarded and the process repeated. Double-check again with another nurse according to institution policy.
- NOTE: Some insulins cannot be mixed. Check a drug reference before mixing.

During times of stress or illness, some patients who usually take the same insulin doses every day are placed on “sliding-scale” insulin. This involves determining each dose of short-acting insulin based on blood glucose results, usually before meals and at bedtime. For example, a sliding-scale order might read, “For blood glucose <200, no insulin; 201 to 250, 2 units regular insulin; 251 to 300, 4 units regular insulin; 301 to 350, 6 units regular insulin; >350 call physician.”

INHALED INSULIN. A new short-acting human insulin that can be inhaled, Exubera, was approved by the Food and Drug Administration (FDA) in January 2006. Exubera is a dry powder insulin that can actually enter the circulation via the lungs faster than a subcutaneous injection. It can reduce lung function slightly, so patients must have pulmonary function tests before using it. It cannot be used by patients who smoke or who have quit smoking within the last 6 months. Some are concerned that patients may overuse inhaled insulin because it is easier to administer than injections, which will increase the risk of low blood glucose. It can be used alone or to supplement other treatment in type 2 diabetes, and may be used in conjunction with long-acting injected insulin in type 1 diabetes.

PROBLEMS WITH INSULIN THERAPY. Two problems that can occur with glucose control are the Somogyi effect and the dawn phenomenon. The Somogyi effect may be at fault when the patient's blood glucose seems to be rising in spite of increasing insulin doses. If insulin levels are too high, the blood glucose may drop too low, stimulating release of counterregulatory hormones (epinephrine, glucagon, corticosteroids, growth hormone) that then elevate the blood glucose. The low glucose levels often occur during the night, and the patient may report night sweats or morning headaches. The high morning glucose is then interpreted as hyperglycemia, and the insulin dose may be further increased, compounding the problem.

The dawn phenomenon is thought to occur because of the natural release of growth hormone and cortisol during the early morning hours. This causes hyperglycemia on arising in the morning.

CRITICAL THINKING

Mrs. Evans

■ Mrs. Evans is a 68-year-old woman with type 2 diabetes who resides in an assisted living facility. She is on 42 units of NPH insulin every morning.

1. If Mrs. Evans eats her breakfast at 8:00 every morning, when should she take her insulin?
2. At what time of day should she be alert for symptoms of low blood sugar?
3. What could happen if Mrs. Evans has a busy day and misses her lunch?

Suggested answers at end of chapter.

The patient might be asked to monitor blood sugar between 2 and 4 a.m. in addition to bedtime and morning testing to assess whether the Somogyi effect or the dawn phenomenon is occurring. Correction of the Somogyi effect involves reducing the insulin dose. The dawn phenomenon is treated with careful adjustment of meals and insulin; moving the evening insulin dose to bedtime may cause the insulin to peak when the blood glucose is highest.

ORAL HYPOGLYCEMIC MEDICATION. The patient with type 2 diabetes may be able to control blood glucose levels with medical nutrition therapy and exercise alone. Oral hypoglycemic medication or insulin may also be prescribed. Oral hypoglycemics are not insulin pills. Remember that if insulin is ingested, it is digested, because it is a protein. Because most oral hypoglycemic agents depend on at least a partially functioning pancreas, most are not useful for patients with type 1 diabetes. See Table 40.5 for a list of frequently used oral hypoglycemic agents.

Most insulins and oral hypoglycemics should be administered before meals (check individual drugs for specific timing). Care should be taken to prevent passage of more than 30 minutes between medication administration and the meal because this may result in a hypoglycemic episode.

If blood glucose levels are not controlled with oral hypoglycemic agents, insulin may be necessary for the person with type 2 diabetes. This does not mean the person has type 1 diabetes. Insulin may be necessary to control blood glucose, but it is not necessary to sustain life, as it is for the person with type 1 diabetes.

NEW DEVELOPMENTS IN DIABETES MEDICATION. Researchers are constantly looking for new medications that will help control blood glucose levels. One new medication is exenatide (Byetta), an injectable drug that was first isolated in the saliva of the Gila monster! It is an “incretin mimetic,” meaning it mimics natural incretins in the body. Incretins are hormones secreted by the gastrointestinal (GI)

TABLE 40.5 ORAL HYPOGLYCEMIC AGENTS

Medication Class/Action	Examples	Side Effects	Nursing Implications
Insulin Stimulators			
Sulfonylureas			
Stimulate insulin secretion by pancreas, increase insulin receptor sensitivity	Glipizide (Glucotrol) Glimepiride (Amaryl) Glyburide (Miconase, Diabeta)	Hypoglycemia, weight gain, possible increased risk of cardiovascular disease.	Monitor for hypoglycemia. Teach patient to avoid alcohol.
Meglitinides			
Stimulate insulin secretion by pancreas	Repaglinide (Prandin), nateglinide (Starlix)	Hypoglycemia, weight gain	Monitor for hypoglycemia. Dosed with meals to improve postprandial hyperglycemia; multiple dosing less convenient. Hold dose if patient skips meal.
Insulin Sensitizers			
Biguanide			
Decreases glucose production by liver; increases glucose uptake by muscle	Metformin (Glucophage)	Nausea, diarrhea, decreased appetite	Give with meals. May enhance weight loss. Withhold if patient is having tests involving contrast dye. Contraindicated in renal and hepatic disease and CHF. Notify physician of early symptoms of lactic acidosis: hyperventilation, myalgia, malaise.
Combination agents			
	Metformin/glyburide (Glucovance) Metformin/rosiglitazone (Avandamet)	See individual agents.	See individual agents.
Thiazolidinediones (glitazones)			
Reduces insulin resistance in muscles. Improves blood lipids; may lower blood pressure and improve cardiovascular risk.	Pioglitazone (Actos), rosiglitazone (Avandia)	Nausea, weight gain, and fluid retention	Give with meal. Works well with obese patients. Avoid with liver disease; monitor liver enzymes. May alter effectiveness of some birth control pills.
Absorption Delayers			
Alpha-glucosidase inhibitors (AGIs)			
Lower postprandial glucose by reducing rate of carbohydrate digestion and absorption.	Acarbose (Precose), miglitol (Glyset)	Flatulence, bloating	Give at start of each meal. No weight gain or hypoglycemia risk. Multiple dosing less convenient. If used in combination with another drug and hypoglycemia occurs, treat with milk or glucose tablets, not table sugar.

CHF = congestive heart failure.

tract that stimulate insulin release in response to nutrients in the intestine. Byetta works in conjunction with oral hypoglycemic agents, and stimulates insulin secretion, lowers production of glucagon, slows gastric emptying, and promotes weight loss.

Another new drug, pramlintide (Symlin), is an injectable agent that is used with insulin. It is a synthetic analog of amylin, a naturally occurring hormone that reduces glucose levels following meals. It may also promote weight loss in individuals who are overweight. Symlin carries with it an increased risk of hypoglycemia.

Self-Monitoring of Blood Glucose

The ability to test blood glucose levels at home has been a major advance in diabetes care. Blood glucose can be better controlled because of the availability of monitoring at any time, in any place. A variety of blood glucose monitors are on the market at a reasonable price (Fig. 40.5). Most of the cost involved in monitoring is in the test strips that must be used. Health insurance programs sometimes cover this cost.

Self-monitoring of blood glucose (SMBG) is generally done before meals and at bedtime by the individual on insulin who wishes to maintain tight control of blood glucose. Less frequent schedules may be prescribed for patients who are unable or unwilling to test four times a day or for patients not on insulin. Some may test before breakfast and supper, and some may vary testing times from day to day. Patients are also often recommended to periodically test 2 hours after meals. New noninvasive devices are being developed, such as a monitoring device that resembles a wrist watch. It is worn on the arm, and it checks glucose levels by extracting fluid from the arm every 20 minutes. An excellent test for long-term monitoring is the HbA_{1c} blood test, described earlier. It is usually done every 3 to 4 months.

The physician should be consulted for desirable blood glucose ranges because these may differ for each patient.

FIGURE 40.5 OneTouch Ultra glucose monitor. (Courtesy Life Scan.)

The American Diabetes Association recommends a preprandial goal of 90 to 130 mg/dL for most patients. Patients who are prone to insulin reactions (hypoglycemia) or small children or the elderly may have higher goal ranges, such as 100 to 150 mg/dL. Lower blood glucose levels for these populations could increase the risk of hypoglycemia.

Urine Glucose and Ketone Monitoring

Urine may also be tested for glucose and for ketones. Urine glucose testing was done routinely before the development of SMBG. A variety of dipsticks and tape products are available for urine testing. If glucose appears in the urine, the patient is warned that the blood glucose is elevated, but the actual level is unknown. Most people have glucose in their urine when their blood glucose is more than about 180 mg/dL. It is difficult to base treatment on urine glucose levels, and so routine urine testing for glucose is no longer recommended.

Urine should be tested for ketones during acute illness or stress, when blood glucose levels are consistently above 300 mg/dL, during pregnancy, or when symptoms of ketoacidosis are present. If ketones are present, the patient knows an insulin deficiency is present and should notify the physician. Patients with type 1 diabetes are most at risk for developing ketoacidosis; however, it is wise for the patient with type 2 diabetes to test for ketones if risk factors are present.

An important aspect of blood or urine monitoring is the interpretation of results. Monitoring is useless if the results are not used to improve blood glucose control. The patient should be instructed to keep a diary of blood glucose levels (Fig. 40.6). Some patients have computer software that graphs results. The patient may be taught by a diabetes educator to interpret the trends in the results, or the diary may be taken on a regular basis to the health-care provider for interpretation and adjustment of the treatment plan.

See Box 40.6 Diabetes Summary for diabetes symptoms, diagnosis, and treatment.

Transplant

If the patient is determined to be an appropriate candidate, a pancreas transplant may be considered. This is especially beneficial in the patient with kidney disease, who can receive both a kidney and pancreas transplant at the same time. Another promising treatment is the use of pancreatic islet cell transplant.

Acute Complications of Diabetes

The individual with diabetes is at risk for a variety of complications. Acute complications related to high and low blood glucose levels are treatable and can often be prevented with appropriate care.

Hyperglycemia

When calories eaten exceed insulin available or glucose used, high blood glucose (hyperglycemia) occurs. The most common cause of hyperglycemia is eating more than the meal plan prescribes. Another major cause is stress. Stress causes the release of counterregulatory hormones, including epinephrine, cortisol, growth hormone, and glucagon. These hormones all increase the blood glucose level. In a person

without diabetes, this is an adaptive function. However, the patient with diabetes is unable to compensate for the increased blood glucose with increased insulin secretion, and hyperglycemia occurs.

Patients must be able to recognize signs and symptoms of high blood glucose levels and know what to do if they occur (Table 40.6). For many patients, these are similar to the symptoms they experienced when they were first diagnosed with diabetes. Chronic high blood glucose levels can lead to long-term complications (discussed later in this chapter).

Hypoglycemia

Low blood glucose, or hypoglycemia, occurs when there is not enough glucose available in relation to circulating insulin. This is sometimes referred to as an insulin reaction. Hypoglycemia is usually defined as a blood glucose level below 50 mg/dL, although patients may feel symptoms at higher or lower levels. Occasionally, symptoms occur as a result of a rapid drop in blood glucose, even though the actual glucose level is normal or high. Causes of hypoglycemia may include skipping a meal, exercising more than usual, or accidentally administering too much insulin. An occasional hypoglycemic episode, treated promptly, should not lead to chronic complications. Repeated or extremely low blood glucose levels can cause neurological damage because there is not enough glucose for brain function. It is therefore important to teach patients how to prevent and treat low blood sugar (see Table 40.6).

Symptoms of low blood glucose include hunger, sweating, pallor, tremor, palpitations, and headache. These symptoms are caused by activation of the sympathetic nervous system. As hypoglycemia progresses, the brain is deprived

CRITICAL THINKING

Jeff

■ Jeff is a 16-year-old who is having trouble with repeated insulin reactions. He says he has not had this trouble before, and it is interfering with his new job. What questions might you ask as you do your assessment to help him figure out how to prevent future reactions?

Suggested answers at end of chapter.

of glucose and neurological symptoms such as irritability, confusion, seizures, and coma may occur.

If you find someone with symptoms of an altered blood glucose but are unable to identify whether it is high or low, do a blood glucose test. However, if the patient is exhibiting neurological symptoms, treat for low blood glucose immediately. The blood glucose may then be checked and further treatment provided as indicated.

To treat low blood glucose, administer a “fast sugar”—15 g of carbohydrate that will enter the bloodstream quickly. This may be 4 oz of orange juice, commercially available glucose tablets, or another quickly available source of sugar (Box 40.7 Fast Sugars). If the patient is not alert or is unable to safely swallow, subcutaneous glucagon can be given. If the patient is hospitalized, intravenous (IV) glucose can be administered by the RN. Recheck glucose in 15 minutes. If the blood glucose does not return to normal, repeat the procedure every 15 minutes until relief occurs. Do not overtreat hypoglycemia with too much sugar because this may cause

Box 40.6**Diabetes Summary**

Signs and Symptoms	Polyuria Polydipsia Polyphagia Fatigue Blurred vision Headache Abdominal pain
Diagnostic Tests	Fasting plasma glucose HbA _{1c} (glycosylated hemoglobin) Oral glucose tolerance test Additional testing for complications
Therapeutic Interventions	Diet Exercise Insulin Oral hypoglycemic medication Self-monitoring of blood glucose levels Education
Complications	Hypoglycemia, Hyperglycemia DKA, HHNKS
Priority Nursing Diagnoses	Risk for ineffective health maintenance, risk for imbalanced nutrition Risk for injury: complications

Miniature box of raisins
Commercial glucose tablets
6–8 Life Savers

hyperglycemia and rebound hypoglycemia. Many nurses added sugar to orange juice in the past; this is no longer recommended.

If the next meal is more than 1 hour away, follow the treatment with a protein and complex carbohydrate snack, such as crackers with cheese or peanut butter, or half of a sandwich. If symptoms worsen, call 911, or contact the physician for the hospitalized patient. Check hospital or agency policy for specific protocol for treating hypoglycemic episodes.

Some elderly patients with poor autonomic nervous system function or patients taking beta-adrenergic–blocking medication such as propranolol or atenolol (that block the sympathetic response) may not feel the symptoms of hypoglycemia. These patients should check glucose levels more frequently and keep the levels in a safe range to prevent hypoglycemic episodes.

Individuals with diabetes should be instructed to keep a fast sugar in their purse or pocket at all times. Fast sugars may also be stored in bedside tables, cars, and desks at work.

TABLE 40.6 COMPARISON OF HIGH AND LOW BLOOD GLUCOSE LEVELS

	Hyperglycemia	Hypoglycemia
Causes	Overeating Stress Illness Too little insulin or medication	Undereating, skipping a meal Too much insulin or medication Exercise
Symptoms	Polyuria Polydipsia Polyphagia Blurred vision Headache Lethargy Abdominal pain Ketonuria (if type I) Coma	Hunger Sweating Tremor Blurred vision Headache Irritability Confusion Seizures Coma
Treatment	Confirm hyperglycemia with glucose meter; if greater than 300 mg/dL, check urine for ketones and increase fluid intake. Assess cause of hyperglycemia, teach prevention. Return to prescribed treatment plan if applicable. Call physician for medication adjustment if indicated or if blood glucose is >200 mg/dL for 2 days. Call physician if patient is ill or vomiting.	Confirm hypoglycemia with glucose meter (if patient is not acutely ill). Administer 15 g fast-acting carbohydrate. Recheck glucose in 15 minutes; if still low, readminister carbohydrate. Continue cycle of checking glucose and administering fast sugar until hypoglycemia subsides; if symptoms worsen, call physician or emergency help. Glucagon subcutaneously or dextrose 50% IV may be administered if ordered. Assess cause of hypoglycemia, teach prevention.

Diabetic Ketoacidosis

PATHOPHYSIOLOGY. Diabetic ketoacidosis (DKA) occurs when blood glucose levels become very high and insulin is deficient. This most commonly occurs in individuals with type 1 diabetes. DKA is often the reason a person with undiagnosed type 1 diabetes first seeks help. It may also be the result of stress or illness in a person with previously diagnosed type 1 (or rarely, type 2) diabetes. When there is insufficient insulin to allow glucose into cells, the cells starve. The body then breaks down fat to be used for energy. The fat breakdown releases an acid substance called ketones. As ketones build up in the blood, ketoacidosis occurs.

The body attempts to compensate for acidosis by deepening respirations, thereby blowing off excess carbon dioxide. (See the section on metabolic acidosis in Chapter 5.) The deep, sighing respiratory pattern is called **Kussmaul's** respirations. The expired air has a fruity odor caused by the ketones and may be mistaken for alcohol. Some nurses have likened the odor to Juicy Fruit chewing gum.

With such high blood glucose and the accompanying polyuria, the body becomes dehydrated very quickly. Tachycardia, hypotension, and shock can result. Acidosis also causes potassium to leave the cells and accumulate in the blood (hyperkalemia). Potassium is then lost in large amounts in the urine. The combination of dehydration, potassium imbalance, and acidosis causes the patient to develop flulike symptoms, including abdominal pain and vomiting. The patient loses consciousness and death occurs if DKA is not treated. The mortality rate for DKA is about 5%.

THERAPEUTIC INTERVENTION. Treatment includes IV fluids, IV insulin, and blood glucose monitoring, often initially in an intensive care unit (ICU) setting. You can assist with monitoring hourly blood glucose levels and notify the RN or physician when the desired level is reached. Glucose should be added to the IV when the blood glucose drops to about 180 mg/dL to avoid hypoglycemia. Potassium should also be monitored closely, since it is essential to have normal levels for cardiac function. Arterial blood gases help monitor acidosis. The cause of the DKA should be identified and treated.

Prevention of ketoacidosis involves careful monitoring of blood glucose levels at home. If the blood glucose rises above 300 mg/dL, the patient should use a urine dipstick made to detect ketones. If ketones are present, the patient should drink water and recheck with the next urination. If ketones are still present, the physician should be notified. Patients should be instructed to never stop their insulin without a physician's supervision.

Hyperosmolar, Hyperglycemic, Nonketotic Syndrome

PATHOPHYSIOLOGY. Hyperosmolar, hyperglycemic, nonketotic (HHNK) syndrome occurs primarily in type 2 diabetes, when blood glucose levels are high as a result of stress or illness. Because the person with type 2 diabetes has some insulin production, cells do not starve and DKA

usually does not occur. HHNK occurs more often in the elderly.

As the blood glucose rises (hyperglycemic), polyuria causes profound dehydration, producing the hyperosmolar (concentrated) state. Blood glucose may rise as high as 1500 mg/dL, and electrolyte imbalances occur. Because ketoacidosis is not present, the patient may not feel as physically ill as the patient with DKA and may delay seeking treatment. Symptoms of HHNK develop slowly and include extreme thirst, lethargy, and mental confusion. Shock, coma, and death occur if HHNK is left untreated. The mortality rate for HHNK is between 10% and 20%.

THERAPEUTIC INTERVENTION. Treatment includes IV fluids and insulin, and glucose monitoring. Electrolytes are closely monitored. The cause of HHNK should be identified and treated. HHNK syndrome can be prevented with careful monitoring of glucose levels at home. Patients should be instructed to drink plenty of fluids if blood glucose levels are beginning to rise, especially in times of stress and illness. They should also know when to call their physician with high blood glucose results.

Long-Term Complications

Over time, chronic hyperglycemia causes a variety of serious complications in persons with diabetes. These involve the circulatory system, eyes, kidneys, skin, and nerves. Most of the complications involve either the large blood vessels in the body (macrovascular complications) or the tiny blood vessels, such as those in the eyes or kidneys (microvascular complications). The Diabetes Control and Complications Trial (DCCT), a large research study completed in 1993, showed that individuals with type 1 diabetes who maintain tight control of blood glucose experience fewer long-term complications than individuals who take traditional care of their diabetes.⁶ Similarly, the United Kingdom Prospective Diabetes Study (UKPDS), completed in 1998, showed that individuals with type 2 diabetes who maintain an HbA_{1c} below 7% can significantly reduce complications. In fact, for every percentage of decrease in HbA_{1c}, there were 25% fewer deaths from diabetes-related complications.⁷ Unfortunately, even tight control does not guarantee the prevention of all complications.

Macrovascular Complications

CIRCULATORY SYSTEM. Individuals with diabetes develop atherosclerosis and arteriosclerosis faster than the general population. They are more likely to have hypertension and elevated low-density lipoprotein (LDL) cholesterol and triglyceride levels. High blood glucose may also affect platelet function, leading to increased clotting. These problems lead to a higher incidence of strokes, heart attacks, and poor circulation in the feet and legs. The risk of cardiovascular disease and strokes is two to four times more common in persons with diabetes than in the general population.

Blood glucose and blood pressure control is vital to help prevent these deadly complications. Patients should

also avoid smoking, and maintain normal weight. Aspirin therapy to reduce platelet aggregation is recommended for patients older than 21 years of age with diabetes.

Microvascular Complications

EYES. Small blood vessels can become diseased, eventually leading to retinopathy in most patients with diabetes. Retinopathy involves damage to the tiny blood vessels that supply the eye. Small hemorrhages occur, which can cause blindness if not corrected. Twenty-three percent of all adults with diabetes report some vision impairment.⁸ Newer laser surgery techniques may help improve vision after hemorrhages occur. Diabetes is also associated with a high incidence of cataracts. Patients with diabetes should have a yearly dilated eye examination.

KIDNEYS. Nephropathy is caused by damage to the tiny blood vessels within the kidneys. Up to 40% of patients with diabetes develop some degree of nephropathy. Native Americans, Hispanics, and African Americans have the highest risk. A primary risk factor for diabetic nephropathy is poor control of blood glucose. If nephropathy occurs, the kidneys are unable to remove waste products and excess fluid from the blood. Diabetes is the leading cause of end-stage renal (kidney) disease (ESRD) in the United States. When the kidneys have lost most of their function, patients may have their blood cleansed artificially by either hemodialysis or peritoneal dialysis. (See Chapter 37.) The only cure for ESRD is a kidney transplant.

Patients should be taught the importance of blood glucose control to prevent or delay kidney disease. Angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB) medications have also been shown to slow the development of kidney problems in patients with diabetes. Patients who have both diabetes and hypertension should be placed on an ACEI or ARB. Routine urine tests are done to check for microalbuminuria (tiny amounts of protein in the urine) or microalbumin-to-creatinine ratios. If microalbuminuria occurs, a low-protein diet may help delay further development of nephropathy. A trained renal dietitian should work with the patient and physician in determining the best diet for the patient.

Nerves

Another complication of diabetes is neuropathy, which is damage to nerves as a result of chronic hyperglycemia. Neuropathy can cause numbness and pain in the extremities, erectile dysfunction (impotence) in males, sexual dysfunction in women, **gastroparesis** (delayed stomach emptying), and other problems. Unfortunately, pain caused by neuropathy is difficult to treat with traditional analgesics. Some antidepressant and anticonvulsant drugs may be helpful, and in some cases local injections of anesthetics may be used. A new drug, pregabalin (Lyrica), that reduces painful nerve impulses was recently approved by the FDA specifically for

nerve pain. Improved control of blood glucose levels may also help.

Infection

Persons with diabetes are prone to infection for several reasons. If injuries occur, healing may be slow because of impaired circulation. There may not be enough blood supply to heal the wound or fight an infection. For the same reason, it may be difficult for IV antibiotics to reach an infected site, and topical antibiotics may be preferable. In the presence of hyperglycemia, white blood cells become sluggish and ineffective, further reducing the body's ability to fight infection.

The incidence of periodontal (gum) disease, caused by bacteria in plaque, is also increased in individuals with diabetes. Patients must be taught to maintain good oral hygiene and make regular visits to the dentist.

Foot Complications

The combination of vascular disease, neuropathy, and risk for infection makes patients with diabetes prone to foot problems. Consider the patient who has no feeling in his or her feet because of neuropathy. If the patient steps on a tack, it may not be felt right away. Vascular disease will prevent a good blood supply from preventing infection and promoting healing. If infection sets in, it is slow to resolve and may progress to necrosis and gangrene. Pressure points on the feet may also break down (Fig. 40.7). One woman had a Bic pen in her shoe all day and did not realize it! Neuropathy can also lead to deformities of the feet, further increasing the risk for injuries.

For these reasons, diabetes is the leading cause of amputation of the lower extremities. Patients should be taught to protect their feet at all times by wearing well-fitting shoes and by washing, drying, and inspecting their feet daily (Box 40.8 Foot Care Tips). If any sores are noted, the patient should not delay in seeking treatment. During routine visits to the physician, the patient should be sure to remove shoes and socks so the feet can be thoroughly examined. The physician or diabetes specialist can test sensation in the feet with tiny filaments. Loss of protective sensation

FIGURE 40.7 Diabetic foot ulcer at site of amputated toe. (From Goldsmith, LA, Lazarus, GS, and Tharp, MD: *Adult and Pediatric Dermatology*. FA Davis, Philadelphia, 1997, p 438, with permission.)

nephropathy: nephro—of the kidney + pathy—illness

gastroparesis: gastro—stomach + paresis—partial paralysis

is an early risk factor for amputation, so any reduction in sensation is a warning sign that extra care must be taken. A podiatrist (foot doctor) can be consulted if problems occur. Specialized wound treatment centers have new healing techniques that have prevented many amputations (Box 40.9 Ethical Considerations).

CRITICAL THINKING

Mr. Jones

■ Mr. Jones is a 54-year-old banker with type 2 diabetes admitted to your unit with a tiny red area on his right heel. His admitting blood glucose is 360 mg/dL. The lesion is so small you wonder what the fuss is about. While doing his assessment, you find that he wore a new pair of shoes to work all day about a month ago and has been avoiding seeing his physician about the resulting red area. He is placed on IV antibiotics, and within 3 days the red area has broken open and has yellow drainage. He is sent home with topical antibiotics and crutches, to be followed by a visiting nurse. The wound takes 6 months to fully heal.

1. List three risk factors for foot problems.
2. Why did the sore take so long to heal?
3. Why do you think crutches are necessary?
4. Why might topical antibiotics work better than IV antibiotics?
5. The nurse documents the following description of Mr. Jones' wound: "Small red open area on heel, with yellow drainage on dressing." What is wrong with this charting? How can you improve it?

Suggested answers at end of chapter.

Box 40.8

Foot Care Tips

Wash and dry feet every day. Use warm (not hot) water to avoid burns.
 Apply lotion that does not contain alcohol, avoiding areas between toes.
 Inspect feet for sores or red areas daily (have a family member help if necessary).
 Report any abnormalities immediately.
 Wear leather shoes and cotton socks.
 Never go barefoot.
 Avoid garters and tight socks.
 Avoid crossing legs.
 Cut toenails to natural shape of nail—not into corners.
 See a podiatrist for calluses or problem toenails (avoid "bathroom surgery").
 Have feet checked at least once a year, preferably three to four times a year, for loss of sensation.

Box 40.9

Ethical Considerations

Refusal of treatment

Mr. Mann is 55 years old and has had diabetes for more than 20 years. He has not managed his diabetes well and has subsequently suffered many complications. Mr. Mann does not regularly test his blood sugar, so he does not always get the appropriate amount of insulin. In addition, he does not eat properly. He picks up fast food during his lunch break and he binges on various snack foods before he eats his dinner, or sometimes instead of eating his dinner.

Mr. Mann is not aware of the importance of taking care of himself to prevent long-term complications of diabetes. He is now seeking health care because of a neglected leg ulcer. He tried to treat it at home with over-the-counter remedies, but it did not improve, and it is now infected. Part of his foot is gangrenous and an amputation is recommended. The first time the surgery is mentioned, Mr. Mann becomes outraged and refuses to discuss it. He says he is "not going to leave this earth without all his parts." After further discussions with Mr. Mann, it is clear that he understands the consequences of his condition. He is more annoyed by the drainage from the ulcer than worried about the progressive gangrene. This is a complex case. Questions that should be asked may include:

- Does Mr. Mann *really* understand his current situation and likely consequences?
- Can Mr. Mann be treated without his permission?
- Should action be taken to have someone else named as Mr. Mann's guardian, despite his apparent competence?
- What would a "non compos mentis" (unconscious or incompetent) diagnosis mean for Mr. Mann's future care planning?
- Does disagreement with the medical establishment in itself denote incompetence?
- Does the level of risk if treatment is refused make any difference in the health professional's response?
- What if Mr. Mann's refusal is based on religious or cultural beliefs?
- Should his wishes be supported at all costs?
- What are the nurse's responsibilities?
- How does the application of ethical theory help to sort out the critical elements of this case?

Special Considerations for the Patient Undergoing Surgery

Surgery is a stressor. The counterregulatory hormones released during stress cause the blood glucose to rise, even if the patient has been fasting. High blood glucose levels interfere with immune function and healing, and can promote an

environment conducive to infection. Tight blood glucose control during hospitalization and surgery has been shown to significantly reduce complications. Check with the physician for changes in insulin orders. Often patients are placed on intravenous infusions of glucose and insulin during and immediately after surgery, in place of longer acting insulins. FPG levels should be maintained at less than 110 mg/dL at all times, and postprandial glucose should be less than 180 mg/dL.⁹ Monitor blood glucose levels every 2 to 4 hours or as ordered, and monitor carefully for signs and symptoms of hypoglycemia or hyperglycemia. If a patient uses a pump at home, check with a diabetes resource nurse and try to see that the patient can continue to use it during hospitalization.

Patients who were not previously on insulin may be placed on insulin during surgery and postoperatively. They can generally return to their presurgical treatment plan after the stress of surgery is past.

Nursing Process for the Patient with Diabetes Mellitus

Assessment/Data Collection

A complete history and physical assessment should be carried out because diabetes affects every body system. Some areas on which to focus are shown in Table 40.7. It is especially important to assess each patient's knowledge of diabetes and its care so that appropriate teaching can be done.

Nursing Diagnosis, Planning, and Implementation

Because diabetes affects so many different areas, nearly any nursing diagnosis may be appropriate. It is important to assess each patient as an individual and choose diagnoses based on assessment findings. A sample care plan is shown for a diagnosis of risk for ineffective health maintenance because patients with diabetes must learn to care for themselves to maintain their health (Box 40.10 Nursing Care Plan for the Patient with Diabetes Mellitus). The actual pres-

ence of the defining characteristics should be confirmed with the patient before choosing any nursing diagnosis. Once diagnoses have been identified, planning takes place. This should be done with the patient and family. Diabetes affects not only the person with the disease, but the entire family as well. The desired outcome for the plan of care is that the patient is knowledgeable about and able to care for his or her disease. Consult the dietitian, social worker, certified diabetes educator (CDE), home care nurse, outpatient education programs, and other resources as needed. (See Home Health Hints.)

Evaluation

The best indicator of the success of a care plan for diabetes is controlled blood glucose and glycohemoglobin levels. The patient should also be without symptoms of hypoglycemia or hyperglycemia and be able to state what to do if they do occur. Long-term complications should be minimized. Another important indicator is the patient's statement of satisfaction and comfort with the plan and his or her ability to carry it out on a daily basis.

Diabetes Self-Management Education

The individual with diabetes must receive diabetes self-management education (DSME) if at all possible. No amount of care from a physician or nurse can replace the self-care required of the person with diabetes. The involvement of family or significant others is also important for the success and well-being of the person with diabetes.

If the patient is hospitalized at diagnosis, the initial instruction is done in the hospital. However, with hospital stays becoming shorter, you must not waste any time. Begin assessing baseline knowledge and teaching as soon as the patient is feeling physically well enough to learn. Depending on your state nurse practice act, this is usually the responsibility of the primary or registered staff nurse, although aspects of the instruction may be delegated to the LPN/LVN. Some hospitals have a Certified Diabetes

Box 40.10 NURSING CARE PLAN for the Patient with Diabetes Mellitus

Nursing Diagnosis: Risk for ineffective health maintenance related to knowledge deficit in the patient with newly diagnosed diabetes mellitus

Expected Outcomes Blood glucose levels within parameters negotiated with health care provider. Patient states satisfaction with understanding of diabetes self-care.

Evaluation of Outcomes Are blood glucose levels within parameters negotiated? Does patient state satisfaction with understanding of diabetes self-care?

Interventions

Assess knowledge of diabetes self-care.

Assist patient to collaborate with health care provider to determine appropriate blood glucose levels and action to be taken if glucose levels are too high or too low.

Teach patient to assess glucose levels before meals and at bedtime or as ordered by health care provider. Ensure that patient knows how to obtain glucose monitor and instruction for home use.

Teach patient how to administer insulin or oral hypoglycemic agent. Ensure that meals are timed appropriately with medications. Replace any uneaten foods to prevent hypoglycemia.

Teach technique for administering insulin if indicated.

Observe for symptoms of hypoglycemia and hyperglycemia and treat as necessary. Teach causes, prevention, recognition, and treatment of hypoglycemia and hyperglycemia.

Consult with dietician for nutrition therapy instruction.

Consult with social worker or case manager as needed.

Rationale

Teaching should be initiated only if a knowledge deficit exists.

Appropriate blood glucose levels may be different for each patient. The patient should know what blood glucose levels require notification of the health care provider.

Good blood glucose control depends on knowledge of glucose levels and trends.

If most medications are taken without food to supply calories, hypoglycemia can occur. Check individual medication for specific instructions.

The patient and family should be familiar with the injection procedure.

If the patient has a good understanding of hypoglycemia and hyperglycemia, most episodes can be prevented. If hypoglycemia or hyperglycemia does occur, prompt treatment is essential to prevent complications.

The dietician is trained to provide in-depth meal plan instruction.

Some patients may not have the resources or support to carry out effective self-care.

Evaluation

Does patient exhibit knowledge of diabetes self-care?

Are blood glucose levels within parameters negotiated with health care provider?

Does patient state appropriate blood glucose levels and action to take if glucose is high or low?

Does patient demonstrate correct use of glucose monitor or state how monitor and instruction will be obtained?

Does patient state correct meal and medication schedule?

Does patient demonstrate correct injection technique?

Does patient state causes, prevention, symptoms, and treatment of hypoglycemia? Does patient carry fast sugar at all times?

Is patient able to state plan for obtaining appropriate meals?

Does patient state availability of adequate resources for self-care at home?

Interventions

Provide patient with information regarding comprehensive diabetes education. Remind patient that only survival skills have been taught during initial instruction. Assist patient to obtain medical alert card or tag that identifies diabetes.

Rationale

Instruction provided in the hospital usually is not comprehensive. Outpatient diabetes classes can provide additional self-care and health promotion information. If the patient is ever unresponsive for any reason, the health care provider would need to be aware of diabetes.

Evaluation

Does patient state plan for obtaining further diabetes education after discharge?

Does patient state plan to carry or wear identification at all times?

Geriatric

Assess ability to see and manipulate syringe, glucose monitor, and other equipment. Obtain assistive devices as needed.

The elderly patient may have poor eyesight or other sensory deficits.

Is patient able to manipulate equipment to safely care for self?

Educator (CDE) who provides classroom or bedside instruction. The dietitian should be contacted to provide nutrition instruction.

Most hospitals have policies or management plans describing the instruction to be provided by the nurse. Generally this encompasses “survival skills,” which include the basic information the patient needs initially to survive at home. Survival skills include medication administration, glucose monitoring, meal plan basics, and what to do if high or low blood glucose levels occur. A variety of helpful aids, such as pamphlets and videos, are available. Diabetes equipment suppliers provide kits that are full of samples and information. These are a significant help when you are teaching a patient. Also advise the patient to purchase a medical alert bracelet or necklace.

It is difficult to know how to operate and teach glucose monitoring with the variety of glucose monitors available. Many drugstores and medical supply stores not only sell the monitors but also provide training for the patient and family. You can obtain this information by calling local medical suppliers or by contacting the diabetes educator.

After discharge, the patient should be referred to outpatient diabetes classes for further instruction. If classes are unavailable or if the patient is unable to leave home, a referral to a visiting nurse should be given. It is usually advisable to have a nurse present for the patient’s first insulin injection at home. The ADA recommends that DSME include information about the following:

- Disease process and treatment options
- Nutrition therapy
- Importance of physical activity
- Medications
- SMBG (and urine ketone monitoring when appropriate)
- Preventing, detecting, and treating acute complications

- Preventing, detecting, and treating chronic complications
- Goal setting and problem solving
- Psychosocial adjustment to daily life
- Preconception, pregnancy, and gestational diabetes management¹⁰

Two websites that might be helpful to both you and your patients are www.diabetes.org and www.lifeclinic.com/focus/diabetes/resources.asp.

Because many people with diabetes are elderly, it is important to be aware of their special needs (Box 40.11 Gerontological Issues).

REACTIVE HYPOGLYCEMIA

Reactive hypoglycemia occurs when the blood glucose drops below a normal level, usually below 50 mg/dL. Hypoglycemia is most often a complication of diabetes treatment, but at times it may occur without the presence of diabetes. It may be a warning sign of impending diabetes.

**Box 40.11****Gerontological Issues**

Diabetes care can be a challenge for many older adults. Syringe magnifiers and talking glucose meters are available for those with impaired vision. Family members may be taught to draw up a week’s supply of insulin for the patient to store in the refrigerator. Home meal programs may help ensure an adequate diet. Older adults should also have an emergency call system in their home and regular contact with family members or other support people.

Pathophysiology

Low blood glucose may occur as an overreaction of the pancreas to eating. The pancreas senses a rising blood glucose and produces more insulin than is necessary for the use of that glucose. As a result, the blood glucose drops to below normal. Some experts believe that this is a rare condition and that many “hypoglycemic” episodes are due to activation of the sympathetic nervous system for other reasons, without true hypoglycemia.

Signs and Symptoms

Low blood glucose causes release of epinephrine, which in turn causes the blood glucose to rise. Epinephrine release causes a fight-or-flight reaction, which may produce shaking, sweating, and palpitations. Headache, chills, and confusion may also occur. Symptoms are the same as those described earlier related to hypoglycemia in diabetes.

Diagnosis

Diagnosis is often based on a 5-hour glucose tolerance test, with below-normal readings between 2 and 5 hours. However, with the availability of home glucose monitors, it is now preferable for patients to monitor blood glucose levels at home. Readings should be taken in the morning on arising, 2 hours after each meal, at bedtime, and during symptoms of hypoglycemia. These results may then be taken to the physician for interpretation.

Therapeutic Intervention

Treatment includes frequent small meals and avoidance of fasting. Simple sugars are avoided because they may aggravate symptoms. A high-protein, low-carbohydrate diet is stressed. See Table 40.8 for a sample diet.

TABLE 40.8 SAMPLE MEAL PLAN FOR HYPOGLYCEMIC DIET

Exchange Group	Sample Menu
Morning	
1 fruit	1/2 cup unsweetened orange juice
1 starch	3/4 cup whole-grain cereal
1 meat	1 oz low-fat cheese or meat
1/2 skim milk	1/2 cup skim milk
Free	Decaffeinated coffee
Mid-morning	
1 meat	1 tbsp peanut butter
1 starch	4 whole-grain crackers
Noon	
Chef salad:	
2–4 meat	2–4 oz lean meat
1 vegetable	Lettuce, tomatoes
1 fat	Dressing
1 fruit	1 small piece fresh fruit
1 skim milk	1 cup skim milk
1 starch	2 breadsticks (4 × 1/2 in)
Mid-afternoon	
1 meat	1 oz low-fat cheese
1 starch	4 whole-grain crackers
Evening	
2–4 meat	2–4 oz lean meat
1 starch	1/2 cup potato or pasta
1 vegetable	1/2 cup vegetable
1 fat	Lettuce salad with dressing
1 fruit	1 piece fresh fruit
Free	Decaffeinated coffee or tea
Bedtime	
1 starch and 1 meat	1/2 sandwich (1 slice whole-grain bread and 1 oz lean meat)
1 vegetable	Fresh vegetables
Free	Decaffeinated beverage

ETHICAL CONSIDERATIONS DISCUSSION

The principles of autonomy, nonmaleficence, and beneficence come into play in this case. Preservation of the patient’s autonomy regardless of personal feelings or even mounting evidence is paramount. The only exception is when the patient is not making decisions based on sound and accurate information (does he *really* know what to expect should he refuse treatment?), and secondly when the patient can be considered not of sound mind (*non compos mentis*). We all make decisions that may appear to others to be unwise, but it is a basic human right to make such decisions.

The principle of “do no harm” has significant application in this case. If the patient’s wishes are upheld, the respect for autonomy and choice means that the

patient’s integrity and humanity are intact, therefore no harm has been done. Conversely, should the patients’ wishes be overridden and he is forcibly subjected to treatment “for his own good,” then the patient was harmed at a fundamental level because there has been infringement of basic human rights. The role of the patient as an active participant in treatment planning must be protected. Doing good, like doing no harm, can also be applied. Should the patient’s choice be upheld, then the nurse is supporting the principle of beneficence. However, if the patient is forced to have the treatment against his will, the outcome for the patient’s foot may be good but his basic rights have been violated.

Home Health Hints

- Patients with newly diagnosed diabetes may be anxious and overwhelmed. Instruction may need to be repeated several times before they understand. Don't get discouraged; as patients adapt to new routines, they will become more involved and develop a better understanding of the education. Offer praise and positive reinforcement for all accomplishments.
- Some home glucose monitoring devices have a memory that the nurse can access on the visit. It gives the date, time, and blood glucose result. This is a good indication of compliance with self-monitoring performed by patient or caregiver.
- Assist your patients in obtaining the necessary supplies to manage their diabetes. Many medical supply companies can deliver these supplies to the home. Work with your agency to identify companies that are reliable in your area.
- Remember to call the patient the day before performing a venipuncture for a fasting blood sugar and remind him or her not to eat after midnight.
- Older patients tend to skip meals. Assist them to identify easy but nutritious meals, such as frozen dinners that are low in sodium, such as Healthy Choice products. Meals-on-Wheels is another option since they are able to deliver meals that are tailored to special diets.
- Prefilled syringes should be stored in the refrigerator flat or with needles pointing up. This prevents crystals from settling and clogging the needles.
- Patients can discard used syringes and needles in a hard plastic container such as a Clorox bottle with a screw top.
- If the patient has a visual or dexterity problem, suggest getting a syringe magnifier. A pharmacist or occupational therapist may be able to assist with obtaining one.
- Help the patient learn to use a mirror to look at the bottom of the feet or have a family member examine the patient's feet. The patient should remove shoes and socks at each physician visit for a thorough foot inspection. Catching a "red spot" early is the goal.
- Instruct the patient on the importance of wearing comfortable shoes. The patient should avoid sandals, high heels, flip flops, or ill-fitting shoes. If necessary, the physician can request a podiatry consult. The podiatrist can arrange for the patient to be measured and fitted with special shoes that properly fit his or her feet. Special shoes may be covered by Medicare.
- The patient should keep a pair of nonskid slippers at the bedside. If the patient needs to get up in the night to use the restroom, putting on secure slippers can help prevent the possibility of stepping on something and causing a foot injury.
- Due to decreased skin sensation in some persons with diabetes, hot water heaters should be set below 120°F (48.8°C).
- Even if patients have had diabetes for many years, observe them preparing and injecting their insulin. This provides an opportunity to praise good technique or correct bad habits.
- Diabetic patients with vision problems can become isolated and depressed. Assist your patient with obtaining vision aids that can help improve social outlets. Many communities have stores that specialize in low-vision products, such as a magnifier that attaches to a computer. This can help them gain some independence and facilitate communication with family and friends via email, or to join an online support group to share experiences and discuss feelings with others who have similar physical ailments.

REVIEW QUESTIONS

- Which of the following is the best definition of diabetes mellitus?
 - It is a group of metabolic diseases in which high blood glucose results from defective insulin secretion or action.
 - It is a disease that causes polyuria and polydipsia.
 - It is a disease characterized by macrovascular and microvascular complications.
 - It is a complex disease of protein and fat metabolism.
- Which of the following is a risk factor for type 2 diabetes mellitus?
 - Cardiovascular disease
 - Obesity
 - Age younger than 40 years
 - Virus exposure
- Diabetes is diagnosed when the fasting blood glucose is greater than ____.
- Which of the following symptoms is most commonly associated with hyperglycemia?
 - Tremor
 - Flank pain
 - Sweating
 - Polyuria

5. Protein in the urine is a sign of which long-term complication of diabetes?
 - a. Nephropathy
 - b. Neuropathy
 - c. Retinopathy
 - d. Gastroparesis
6. What is the best way for patients to avoid long-term complications of diabetes?
 - a. See the doctor for a complete check-up every 6 months.
 - b. Check feet daily.
 - c. Maintain blood sugar levels under 130 mg/dL.
 - d. Follow a strict 1500-calorie diet.
7. Which breakfast menu is most appropriate for a patient with diabetes?
 - a. Two eggs, two strips bacon, orange juice, coffee
 - b. Oatmeal with artificial sweetener, whole grain toast, tea
 - c. One half grapefruit, cranberry juice, bagel with sugar-free jelly
 - d. One slice whole grain toast with peanut butter, skim milk, orange juice
8. Place the steps for mixing insulin in correct sequential order.
 - a. Draw up cloudy insulin
 - b. Draw up clear insulin
 - c. Roll cloudy vial
 - d. Inject air into cloudy insulin
 - e. Inject air into clear insulin
 - f. Clean vial tops with alcohol
9. For which of the following blood glucose results would the nurse administer a fast sugar?
 - a. 48
 - b. 80
 - c. 126
 - d. 223
10. A patient who is preparing for surgery asks the nurse why his physician took him off his oral hypoglycemic and placed him on sliding scale insulin. Which response by the nurse is best?
 - a. "It helps us maintain better control of your blood sugar during surgery. You will most likely be back on your pills before you go home."
 - b. "The stress of surgery often exacerbates diabetes. We will teach you how to give insulin before you go home."
 - c. "Oral hypoglycemics are ineffective during times of stress. Insulin is the only way to keep your blood sugar under control."
 - d. "The oral agents must not be controlling your blood sugar any longer. I will check and see which insulin you will be going home with."
11. Which meal plan is best for the patient with reactive hypoglycemia?
 - a. High-carbohydrate meals
 - b. Small, frequent meals
 - c. Avoidance of fats and proteins
 - d. Three medium to large meals daily

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. McMillan*

1. “Have you been eating or drinking more than usual? Have you been urinating more than usual? Do you get up at night to urinate? Does anyone in your family have diabetes?”
2. Fatigue occurs because the glucose is unable to enter the cells without insulin, so they are starving.
3. Mr. McMillan is dehydrated because he is losing excessive amounts of urine as his kidneys lose excess glucose.

■ *Mrs. Evans*

1. Mrs. Evans should take her insulin no earlier than 7:30 a.m.
2. She should be alert for low blood sugar at midafternoon to just before supper. Although her insulin peaks between 1:30 and 7:30 p.m., her chances of having a hypoglycemic episode are slim once she has eaten her supper.
3. If she misses a meal, her blood sugar will drop further, increasing her risk of a hypoglycemic episode.

■ *Jeff*

What kind of new job is it? What schedule is he working? Is it more physically strenuous than his previous job? Does it interfere with his usual meal schedule? What other changes has he experienced in his life that may have affected his blood glucose?

■ *Mr. Jones*

1. Poor circulation, neuropathy, and slow wound healing place Mr. Jones at risk for problems.
2. Circulation to the foot may be poor, and white blood cells are sluggish if the blood glucose is high.
3. Any pressure on the foot while walking may further impair circulation. He should not bear weight on the affected foot.
4. If circulation to the area is poor, IV antibiotics may not reach the sore.
5. “Small red open area on right posterior heel, 1 cm × 1.5 cm, 2 mm deep, 2-cm area of yellow drainage on dressing.” In addition, many agencies are now taking instant photos of wounds to include in the chart. If no camera is available, a drawing of the size and shape is helpful.

QUESTIONS TO GUIDE YOUR READING

1. What is the normal anatomy of the reproductive system?
2. What are the normal functions of the reproductive system?
3. What data should you collect when caring for a patient with a disorder of the reproductive system?
4. Which diagnostic tests are commonly performed to diagnose disorders of the reproductive system?
5. What nursing care should you provide for patients undergoing each of the diagnostic tests?
6. Which therapeutic measures are commonly used for patients with disorders of the reproductive system?

REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY

The male and female reproductive systems produce gametes (sperm and egg cells [ova]) and facilitate the union of gametes in fertilization following sexual intercourse. Ideally, in women, the uterus provides the site for the developing embryo/fetus until birth.

Female Reproductive System

The female reproductive system consists of paired ovaries and fallopian tubes, a single uterus and vagina, and external genitalia (Fig. 41.1). The mammary glands may be considered accessory organs to the system.

Ovaries

The ovaries are a pair of oval structures, about 5 cm long and 2.5 cm wide, on either side of the uterus in the pelvic cavity (Fig. 41.2). The ovarian ligament extends from the medial side of the ovary to the uterine wall, and the broad ligament of the uterus is a fold of the peritoneum that also attaches to the ovaries. These ligaments help keep the ovaries in place.

The ovaries produce egg cells by the process of meiosis, more specifically called oogenesis, which begins at puberty and ends at **menopause**, usually occurring between the ages of 45 and 55. This process is cyclical in that usually one mature ovum is produced and released every 28 days and is under hormonal control (covered in the section on the

menopause: men—month + pause—stop

menstrual cycle). The follicles of the ovary produce the hormone estrogen and later, as the corpus luteum, secrete progesterone as well.

Fallopian Tubes

Each fallopian, or uterine, tube is about 13 cm long; the lateral end with its fringed-like fimbriae approach but do not touch the ovary, and the medial end attaches and opens into the uterus. The fallopian tube is lined with ciliated epithelium; in the wall is smooth muscle. The sweeping of the cilia and the peristaltic contractions of the smooth muscle usually ensure that the ovum (called “zygote” after fertilization), will reach the uterus. Fertilization usually takes place within the fallopian tube, and the zygote is swept into the uterus within 4 to 5 days.

Uterus

The uterus is a muscle which is about 8 cm long and 5 cm wide. It is superior to the urinary bladder and medial to the ovaries in the pelvic cavity. Ligaments help keep the uterus in place, tilted forward over the top of the bladder. During pregnancy the uterus increases greatly in size, and contains the placenta which nourishes the embryo (later called the fetus), and expels the infant near the end of gestation.

The fundus of the uterus is the upper portion above where the fallopian tubes enter laterally. The body is the large central portion. The cervix is the narrow, lower end, which opens into the vagina. The uterus is divided into three muscle layers. The outermost layer of the uterine wall is the perimetrium, a fold of the visceral peritoneum. The myometrium is the middle, smooth muscle layer. During

FIGURE 41.1 Female reproductive system in a midsagittal section. (From Scanlon, VC, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 3. FA. Davis, Philadelphia, 1999, p 446, with permission.)

FIGURE 41.2 Female reproductive system in an anterior view and a longitudinal section.

pregnancy these cells increase in size to accommodate the growing fetus, and during labor and delivery, oxytocin causes coordinated contractions of this middle layer to expel the fetus.

The lining of the uterus is called the endometrium, and is a highly vascular mucous membrane, part of which is lost and regenerated with each menstrual cycle. During pregnancy, the endometrium helps in forming the maternal side of the placenta.

Vagina

The vagina is a muscular tube about 7 to 9 cm long that extends from the cervix to the vaginal orifice in the perineum. It is between the urethra and the rectum. The functions of the vagina are to receive sperm from the penis during sexual intercourse, to serve as the exit for menstrual blood flow, and to serve as the birth canal at the end of pregnancy.

After puberty, the vaginal mucosa is relatively resistant to infection. The normal bacterial flora of the vagina creates an acidic pH, which retards microbial growth. Prior to puberty, the hymen, a fold of mucous membrane, provides mechanical protection.

External Genitals

Also called the vulva, the female external genital structures are the clitoris, mons pubis, labia majora and minora, and Bartholin's glands. The clitoris is a small mass of erectile tissue, approximately 6 mm long, anterior to the urethral orifice. Its function is sensory; it responds to sexual stimulation, and its vascular sinuses become filled with blood.

The mons pubis is a pad of fat over the pubic bones, covered with skin and pubic hair. Extending posteriorly from the mons are the lateral labia majora and the medial labia minora; these are paired folds of skin. The area between the labia minora is the vestibule; it contains the openings of the urethra and vagina. The labia cover these openings and prevent drying of their mucous membranes. Bartholin's glands, also called vestibular glands, are within the floor and at the base of the vestibule; their ducts open into the mucosa at the vaginal orifice. Their secretion keeps the mucosa moist and lubricates the vagina during sexual intercourse.

Mammary Glands

Enclosed within the breasts and surrounded by adipose tissue, the mammary glands produce milk after pregnancy. The milk enters the lactiferous ducts, which converge at the nipple. The skin around the nipple is a pigmented area called the areola. The formation of milk occurs secondary to hormonal influence. During pregnancy, high levels of estrogen and progesterone prepare the glands for milk production. Prolactin from the anterior pituitary causes the production of milk after pregnancy. The sucking of the infant on the nipple stimulates the release of oxytocin from the posterior pituitary gland, which in turn stimulates the release of milk as well as contraction of the uterine muscle.

The Menstrual Cycle

The menstrual cycle depends on follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary gland and estrogen and progesterone from the

ovaries. These hormones bring about changes in the ovaries and uterus. A cycle may be described in terms of three phases: menstrual phase, follicular phase, and luteal phase.

The menstrual phase involves the loss of the endometrium during menstruation, which may last 2 to 8 days, with an average duration of 3 to 6 days. At this time, secretion of FSH is increasing and several ovarian follicles, each with a potential ovum, begin to develop. Table 41.1 includes a summary of these hormones.

During the follicular phase, FSH stimulates growth of ovarian follicles and secretion of estrogen by the follicle cells. The secretion of LH also increases, but more slowly. FSH and estrogen promote the growth and maturation of the ovum, and estrogen stimulates the growth of blood vessels to regenerate the endometrium. This phase ends with ovulation, when a sharp increase in LH causes rupture of a mature ovarian follicle and an egg is released.

During the luteal phase, LH causes the ruptured follicle to become the corpus luteum, which begins to secrete progesterone in addition to estrogen. Progesterone stimulates further growth of blood vessels in the endometrium and promotes the storage of nutrients such as glycogen. As progesterone secretion increases, LH secretion decreases, and if the ovum is not fertilized, the secretion of progesterone also begins to decrease. Without progesterone, the endometrium cannot be maintained and begins to slough off in menstruation. FSH secretion begins to increase (as estrogen and progesterone decrease), and the cycle begins again. Although an average cycle is 28 days, cycles of 23 to 35 days may also be considered normal.

Male Reproductive System

The male reproductive system consists of the testes and a series of ducts and glands. Sperm are produced in the testes and are transported through the reproductive ducts: epididymis, ductus deferens, ejaculatory duct, and urethra (Fig. 41.3). The reproductive glands are the seminal vesicles,

prostate gland, and bulbourethral glands, all of which produce secretions that become part of semen.

Testes

The testes are located in the scrotum between the upper thighs, where the temperature is slightly lower than body temperature, which is necessary for the production of viable sperm. Each testis is about 5 cm long and 3 cm wide and contains the seminiferous tubules in which spermatogenesis (meiosis) takes place. In contrast to oogenesis, once started at puberty, spermatogenesis is a constant rather than cyclical process and usually continues throughout life. Also in the testes are specialized cells that produce the hormones testosterone and inhibin. Spermatogenesis is initiated by FSH from the anterior pituitary. LH from the anterior pituitary stimulates the secretion of testosterone, which contributes to the maturation of sperm. The secretion of inhibin is stimulated by testosterone; inhibin decreases the secretion of FSH, which helps keep the rate of spermatogenesis fairly constant. The functions of these hormones are summarized in Table 41.2.

The head of the sperm cell contains the 23 chromosomes, and has an acrosome on the tip that contains enzymes to digest the membrane of the egg cell during fertilization. Attached to the head is a midpiece with high numbers of mitochondria, and attached to the midpiece is a flagellum, which provides motility. Sperm from all the seminiferous tubules of a testis pass through tubules leading to the epididymis.

Epididymis, Ductus Deferens, and Ejaculatory Ducts

The epididymis is a tube about 4 to 6 meters long that is coiled on the posterior side of a testis. Smooth muscle within its wall propels sperm from the testes into the ductus deferens.

Also called the ductus deferens, the vas deferens extends from the epididymis in the scrotum to the ejaculatory

TABLE 41.1 HORMONES OF FEMALE REPRODUCTION

Hormone	Secreted By	Functions
<i>Follicle-stimulating hormone</i>	Anterior pituitary	Initiates development of ovarian follicles Stimulates secretion of estrogen by follicle cells
<i>Luteinizing hormone</i>	Anterior pituitary	Causes ovulation Converts ruptured ovarian follicle into corpus luteum Stimulates secretion of progesterone by corpus luteum
<i>Estrogen</i>	Ovary (follicle) Placenta	Promotes maturation of ovarian follicles Promotes growth of blood vessels in endometrium Initiates development of secondary sex characteristics
<i>Progesterone</i>	Ovary (corpus luteum) Placenta	Promotes growth of duct system of mammary glands Promotes further growth of blood vessels in endometrium Inhibits contractions of the myometrium during pregnancy
<i>Inhibin</i>	Ovary (corpus luteum)	Promotes growth of secretory cells of mammary glands
<i>Prolactin</i>	Anterior pituitary	Decreases secretion of FSH toward end of cycle Promotes production of milk after birth
<i>Oxytocin</i>	Posterior pituitary	Promotes release of milk

duct within the pelvic cavity. Exterior to the body, the vas deferens is contained within the spermatic cord, a connective tissue sheath. Testicular blood vessels and nerves share the spermatic cord; and the cord opens into the abdominopelvic wall at the inguinal canal. Within the pelvic cavity, the vas deferens loops over the ureter and extends down the posterior side of the urinary bladder to join the ejaculatory duct.

Each of the two ejaculatory ducts receives sperm from the ductus deferens and the secretion of the seminal vesicle on its own side. Both ejaculatory ducts empty into the urethra.

Seminal Vesicles, Prostate Gland, and Bulbourethral Glands

The paired seminal vesicles are posterior to the urinary bladder. Their secretion is alkaline and contains fructose, prostaglandins, and clotting proteins. The alkalinity neutralizes the urethra and the acidic environment of the female reproductive tract. The fructose is used for adenosine triphosphate (ATP) production, the prostaglandins enhance motility, and the clotting proteins coagulate the semen after

ejaculation. The duct of a seminal vesicle joins the ductus deferens on its side to form the ejaculatory duct.

The prostate is a muscular gland that surrounds the first 2 to 3 cm of the urethra as it emerges from the urinary bladder. The secretion of the prostate is alkaline and contributes to sperm motility. The smooth muscle of the prostate contracts during **ejaculation**, causing the expulsion of semen from the urethra.

The bulbourethral glands are located below the prostate gland and empty into the urethra. Their alkaline secretion coats the interior of the urethra just before ejaculation, which neutralizes any acidic urine that might be present.

The alkaline secretions of the male reproductive glands work to ensure that many sperm remain viable in the acidic environment of the vagina. The normal bacterial flora of the vagina create an acidic pH in the vaginal environment, but the pH of semen is about 7.4 and permits sperm to remain motile.

Urethra and Penis

The urethra is the last of the male reproductive ducts, and its longest portion is within the penis. The penis is an external

genital organ; its distal end is called the glans penis and when uncircumcised is covered with a fold of skin called the prepuce, or foreskin. Within the penis are three layers of erectile or cavernous tissue. Each consists of a framework of smooth muscle and connective tissue that contains blood sinuses, which are large, irregular vascular channels.

When blood flow through these sinuses is minimal, the penis is flaccid (soft). Sexual stimulation causes the arteries to the penis to dilate; the sinuses fill with blood, and the penis becomes erect and firm. This is brought about by parasympathetic impulses. The culmination of sexual stimulation is ejaculation, which is brought about by peristalsis of the reproductive ducts and contraction of the prostate gland.

Aging and the Reproductive System

For women, there is a definite end to reproductive capability; this is called menopause and is defined as having occurred when menses have ceased for 12 months. Menopause usually occurs between the ages of 45 and 55. Estrogen secretion decreases, and ovulation and menstrual cycles become irregular and finally cease. The decrease in estrogen has other effects as well. See Figure 41.4 for a mindmap on the effects of aging.

For most men, testosterone secretion continues throughout life, as does sperm production, although both diminish

with advancing age. Perhaps the most common reproductive problem for older men is enlargement of the prostate gland, called benign prostatic hyperplasia (see Figure 41.4).

FEMALE ASSESSMENT

Assessment of women's reproductive health can seem challenging because of the complex relationship of physical and psychosocial factors. Hormones not only affect a multitude of body functions, they also can influence moods and mental functioning. Reproduction involves not only physical processes, but also relationships, role identifications, and self-esteem issues.

Normal Function Baselines

Knowing about expected functioning of the reproductive system is the nurse's best preparation for nursing assessment. Regular, relatively pain-free shedding of an appropriate amount of the endometrial lining of the uterus is expected from puberty through midlife or later. Intercourse is normally expected to be free of pain and infection, to occur when desired by both partners, to be satisfying, and generally to result in pregnancy within a few months (unless precautions are taken). A pregnancy is expected to last approximately 40 weeks and to produce a healthy child. Physical and psychological sexual characteristics and function including **libido** are expected to be adequately maintained by hormones. Sexual functioning, desire, and fertility are expected to change throughout the process of aging. Although individuals may vary somewhat from these expected descriptions, these serve as a baseline for assessment of possible disorders. Chapter 42 further defines specific female reproductive system disorders.

Much of what happens in female reproductive system disorders occurs inside the body and may not show external signs. Skill in asking appropriate questions, documenting patient statements, and describing observations is essential. Descriptions of symptoms should be thorough and follow the WHAT'S UP? format described in Chapter 1. Short quotes of the patient's own words to describe change that you have noticed may add valuable information, but be careful to use critical thinking skills when interviewing and documenting rather than just quoting indiscriminately. Because many signs and symptoms of reproductive system disorders occur in a cyclic fashion, the patient may be asked to keep an accurate written record of occurrences, noting times and dates to identify patterns.

History

Subjective assessment of the female reproductive system includes general personal information as well as menstrual, obstetrical, gynecological, sexual, family, and psychosocial histories. See Table 41.3 for specific questions to ask.

FIGURE 41.4 Aging and the reproductive system. This concept map shows the effects the aging process has on the reproductive system.

libido: sexual desire

TABLE 41.3 SUBJECTIVE ASSESSMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Category	Questions to Ask During History Assessment	Rationale/Significance
<i>Personal History</i>	<ul style="list-style-type: none"> • Have you ever been diagnosed or treated for any health problems? • Have you had any recent weight changes? What type of change (if any)? • Are you experiencing pain? (Quality/quantity/character if patient reports pain). • Do you have any allergies? (Agent/type of reaction) • Are you using any medications? (Include prescription, over-the-counter and herbal remedies.) How much/how often do you take the medication? • Do you smoke, use caffeine, drink alcohol, or use recreational drugs? How much/how often? • Do you exercise? What type of exercise do you do? How often? • How many hours of sleep do you get in a 24-hour period of time? Do you feel you get enough rest? • Do you feel under stress? How do you deal with stress? • Have you been hit, kicked, slapped, or made to do anything sexually against your will since your last visit? 	<ul style="list-style-type: none"> • Data may reveal general state of health, knowledge/practice of health promotion behaviors, meaning of health, expectations related to care. • Weight changes may reflect physical or psychological pathology. • Subjective indication of pain may indicate a variety of disorders. • Allergy status should always be assessed to guide possible intervention should treatment be needed. • May lead to health issues not yet revealed. Medication use reflects meaning of health and pattern of health behaviors in many patients. Use of alternative treatments should be identified, and may guide possible interventions should treatment be needed. • Recreational behaviors may indicate risk of health disorders. Smoking increases risk of coagulation disorders with use of contraceptives containing estrogen. • Exercise is recognized as an activity that improves health status, in general, and for many disorders. • May indicate state of health or lead to discussion of social issues that lead to stress and, ultimately, physical disorders. • May indicate social issues that may lead to physical disorders. • Abuse screening should be considered during all primary care visits; may indicate need for intervention or guide care. • May reveal abnormalities of cycle and lead to a diagnosis of benign/malignant tumors, endometriosis, pregnancy, anemia, endocrine disorders.
<i>Menstrual History</i>	<ul style="list-style-type: none"> • At what age did you begin menstruating (menarche)? How often do you menstruate and how long do your periods last? How heavy is your flow? • At what age did you enter menopause (if applicable)? 	<ul style="list-style-type: none"> • May indicate health of reproductive system, knowledge/meaning of health maintenance practice, and risk for disease.
<i>Obstetric/ Gynecological History</i>	<ul style="list-style-type: none"> • How many pregnancies and deliveries have you had? Were your deliveries vaginal or cesarean section? Did you have any complications following your deliveries? • Have you had previous treatment/surgery on your reproductive organs? • Have you had any itching of your perineum or have you noted any vaginal discharge (describe)? • When was your last Pap/pelvic exam? What were the results? • Do you do BSE? How often? Have you noticed any breast changes? • Did you breastfeed? How long? 	<ul style="list-style-type: none"> • May indicate past health issues related to the reproductive organs and need for current evaluation related to issues. • Subjective report of itching or discharge may indicate disorder of inflammation or lead to diagnosis of sexually transmitted disease. • May reflect meaning of health and guide current care. • If changes have been noted by the patient, they should be evaluated by the primary care provider for the possible pathology. • Breastfeeding may offer some protection against breast cancer. If patient currently breastfeeding, may help guide care and diagnosis. • May indicate risk of sexually transmitted diseases, risk of unintended pregnancy, and indicate state of sexual satisfaction/intimacy. • Early onset of sexual activity increases risk of cervical cancer. • May reflect meaning of health, high-risk health behaviors, and risk for unintended pregnancy or sexually transmitted disease.
<i>Sexual History</i>	<ul style="list-style-type: none"> • Are you sexually active? How many partners do you have? Of what gender? Is your sexual activity satisfying? • When did you become sexually active? • What contraceptive method(s) do you use (if sexually active with a male)? How do you use them? 	<ul style="list-style-type: none"> • May indicate risk of sexually transmitted diseases, risk of unintended pregnancy, and indicate state of sexual satisfaction/intimacy. • Early onset of sexual activity increases risk of cervical cancer. • May reflect meaning of health, high-risk health behaviors, and risk for unintended pregnancy or sexually transmitted disease.

Category	Questions to Ask During History Assessment	Rationale/Significance
Sexual History (<i>Cont'd</i>)	<ul style="list-style-type: none"> • Have you ever been diagnosed with a sexually transmitted disease? When, what type, and how was it treated? That you are aware, was treatment successful? 	<ul style="list-style-type: none"> • May indicate high-risk sexual behavior patterns or potential for active disease and, therefore, indicate need for diagnostic testing and treatment.
Family History	<ul style="list-style-type: none"> • Do you have a family history of cardiovascular problems, cancer, osteoporosis, thyroid abnormalities? 	<ul style="list-style-type: none"> • May indicate underlying cause of or risk for sexual/physical abnormalities of the reproductive system.
Psychosocial History	<ul style="list-style-type: none"> • Are you married or in a significant relationship? Is the relationship satisfying? • Are you employed? Where? 	<ul style="list-style-type: none"> • Relevant to determine financial, social, and emotional support.

NURSING CARE TIP

It is helpful to have women retain a monthly calendar of their menstrual cycle, and bring it to any appointment during which discussion of the cycle may take place.

An obstetrical history includes number of pregnancies, pregnancy outcomes, and complications. These are generally documented using abbreviations of Latin words: G = number of pregnancies (from the Latin word **gravida**); P = births, whether alive or stillborn (regardless of number of fetuses) after 20 weeks' gestation (from the Latin word **para**); A = abortions, whether spontaneous or therapeutic (from the Latin word *abortus*; a spontaneous abortion is sometimes called a miscarriage). Roman numerals follow the letter to specify the number of each. For example, three pregnancies—twins, one single birth, and one spontaneous abortion—are recorded as GIII, PII, AI. This may also be written as G₃P₂A₁. Note, however, that some hospitals use different notation, further delineating history, such as number of premature or full-term births, number of living children, and number of therapeutic abortions. If you are uncertain of how to document, check your institutional history forms.

LEARNING TIP

Remember the word *gravida* by thinking of gravity and that a woman is generally heavier when pregnant.

You will also want to ask about any tests, surgeries, or treatments done on the reproductive organs and excretory system. Medications the patient is taking (for whatever reasons), height to weight ratio, and marked changes in weight may also provide significant data for diagnostic and care planning purposes concerning reproductive system disorders.

gravida: number of pregnancies

para: number of deliveries after 20 weeks' gestation

LEARNING TIP

There are many things to remember when asking health history questions. Making up an index card for your pocket or purchasing a prepared one from a medical bookstore can provide a handy reference.

Many nurses feel awkward asking reproductive history questions, and patients may also feel some uneasiness with this line of questioning. A matter-of-fact attitude, an assurance of confidentiality, and an adequate explanation about why the information is needed tend to encourage patient comfort and cooperation.

Breast Assessment

Palpation

Palpation is the most important assessment technique for breast examination because it can be used to identify alterations from normal consistency, to confirm the presence of lumps, and to locate areas of tenderness. Even mammograms are not sensitive enough to detect a small percentage of masses that can be felt by the patient or health-care provider.

Breast Self-Examination

Self-palpation during breast self-examination (BSE), if done regularly and thoroughly, may be even more sensitive than physician or nurse palpation because the patient becomes so familiar with her own breasts that she is more likely to notice subtle changes that an infrequently visited health practitioner might overlook. BSE is one of the most important health protection skills that nurses can teach to women. The few moments spent monthly on this activity may mean the difference between life and death or comfort and extreme suffering for women.

See Table 41.4 for additional objective assessments.

Patient Teaching

The examination procedure is simple. BSE should be done regularly once per month. A good time to perform BSE is 1 week following menses, when hormonal influence, which may result in edema and swelling of normal breast tissue

TABLE 41.4 OBJECTIVE ASSESSMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Category	Physical Assessment Findings	Possible Abnormal Findings/Causes
Clinical Breast Examination		
External Genitalia: Mons Pubis, Clitoris, Labia Majora/Minora, Bartholin's Glands Vagina	<ul style="list-style-type: none"> Observe and palpate for presence of swelling, lumps, skin changes, nipple exudate. Observe for color, symmetry, hair distribution, lesions, swelling or exudate. Observe for shape, bulges, color changes, lesions, exudate. 	<ul style="list-style-type: none"> Changes may indicate breast cancer, fibrocystic breast disease. Changes may indicate vulvular cancer, developmental abnormalities, infection, or injury. Changes may indicate infection, structural abnormalities, or injury.
Internal Genitalia: Uterus/cervix, fallopian tubes, ovaries (by trained personnel)	<ul style="list-style-type: none"> Palpate for tenderness, size, shape, mobility. Observe for color, lesions, exudate, bleeding. 	<ul style="list-style-type: none"> Changes may indicate infection, structural abnormalities, cervical cancer, polyps, endometriosis, fibroid/malignant tumors, pregnancy, or injury.
Perineum	<ul style="list-style-type: none"> Observe for lesions, shape. 	<ul style="list-style-type: none"> Abnormalities may indicate infection, structural abnormalities, or injury.
Anus	<ul style="list-style-type: none"> Observe for shape, color changes, lesions. 	<ul style="list-style-type: none"> Abnormalities can indicate hemorrhoids, or injury.
Inguinal Nodes	<ul style="list-style-type: none"> Palpate for swelling, tenderness. 	<ul style="list-style-type: none"> May indicate infectious process or regional malignancy.

structures, is at a minimum. For women who no longer have a regular menstrual period, any regular monthly schedule is fine. Although most women's breasts are not exactly the same size, marked differences between the breasts or a change in the size of one breast should be checked with a health-care provider. Puckering or dimpling of skin, asymmetrical movement, and different pointing position of the nipples should also be reported to a health-care provider. Whether the breasts are examined in parallel lines, a spiral formation, or a wedge pattern is probably insignificant. It is important, however, to encourage that the examination be methodical and cover all areas of the breast, the tail of Spence, and the axilla (Fig. 41.5).

PATIENT CARE TIP

Some women do BSE the day their telephone bill arrives each month because it is a dependable monthly reminder.

CRITICAL THINKING

Breast Health Education

■ Holly, age 24, states, "Why should I do breast exams at my age? I probably won't get breast cancer until I'm older, if I get it at all."

1. What should your response to Holly include?
2. Why would this be a good time to provide education about health maintenance?

Suggested answers at end of chapter.

FIGURE 41.5 Breast self-examination. (From Venes, DJ (ed): *Taber's Cyclopedic Medical Dictionary*, ed. 19. FA. Davis, Philadelphia, 2001, with permission.)

FIGURE 41.6 Diagnostic testing by ultrasound. (Modified from Cavanaugh, BM: *Nurse's Manual of Laboratory and Diagnostic Tests*, ed. 3. FA. Davis, Philadelphia, 1999, p 687, with permission.)

Diagnostic Tests of the Breasts

Ultrasound and Mammography

Further assessment of the breast may be done by other methods. Ultrasound examination is done by bouncing high-frequency sound waves off the tissues within the breast to determine the density of the tissues and to map the breast structures (Fig. 41.6). This is mainly useful for distinguishing fluid-filled (**cystic**) lumps from solid tumors but may also be used to guide a needle for fine-needle aspiration of cystic fluid or core needle biopsies.

Mammography is a radiographic (x-ray) examination of the breast. A special machine is used that spreads and flattens the breast tissue to a thin layer to more effectively show benign and malignant growths, which might be hidden by breast structures on typical chest examination (Fig. 41.7). Generally, at least two radiographs are taken of each breast, with the machine compressing the breast top to bottom and side to side to give comparison views of any lumps from more than one angle. If suspicious or unclear spots are seen, additional views may be taken. The American Cancer Society recommends from age 20 throughout life that women do monthly BSE, from ages 20 to 39 that they add a breast examination by a health professional every 3 years, and from age 40 that they have a yearly mammogram and breast examination by a health professional. Those who experience breast symptoms or have a strong family history of breast cancer may be advised to have more frequent examinations.

PATIENT TEACHING. Patients preparing for mammography should be advised to bathe and not to apply deodorant, powder, or any other substance to the upper body because these may cause false shadows on the test. They

cystic: baglike

mammography: mammo—breast + graphy—recording

FIGURE 41.7 Mammogram procedure. (Photo courtesy of Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

should be instructed that if a shadow is seen on a mammogram, further testing will be done to determine the reason for the shadow.

Thermography, Tomography, and Magnetic Resonance Imaging

There are several other less commonly used methods for diagnosis of breast disorders. Thermography is a method of mapping the breast using photographic paper, which records temperature variations throughout the tissue in different colors. Tomography takes very precise x-ray pictures of the breast, layer by layer, as it would look if it were in thin slices, and then stores these pictures in a computer. This allows for precise measurement of the position of tumors without the displacement caused by flattening the breast for a mammogram. Tomography, however, is much more expensive than mammography, so it is not a practical method to use for general screening of all women to detect possible breast cancers. Magnetic resonance imaging (MRI) uses radiofrequency radiation and magnetic fields to map the breast tissue. The equipment needed for this method is expensive, and it is unavailable in some areas.

PATIENT TEACHING. Ask patients preparing for MRI whether they have any metal inside their bodies, such as orthopedic wires, metal sutures, or artificial joint replacements, because heat is generated by the MRI and the procedure may be contraindicated.

Biopsy

If suspicious lesions are found in the breast by any of these assessment methods, the lesion may be again assessed using one of the other methods and then a biopsy performed to confirm the diagnosis. This procedure involves removing a small portion of tissue, fluid, or cells from the breast or

lymph nodes for microscopic examination. This may be done by surgically removing a portion of tissue or by aspirating fluid or cells through a needle that is placed into the lump or lesion. Needle biopsies are often done with local anesthetic and may take place in a clinic or physician's office. More extensive biopsies may require a general anesthetic. A frozen section examination may be done in the laboratory by moistening and rapidly freezing a section of tissue, slicing it very thinly, and immediately examining it by microscope. This allows for diagnosis to be made during the course of an operation, so that the patient is spared an additional later operation for removal of cancerous tissue.

NURSING CARE. As with any surgical intervention, be prepared to set out the sterile equipment and supplies needed for the procedure and ensure that a signed consent has been obtained after the risks and benefits of the procedure have been explained to the patient by the primary care provider. Following the biopsy, assess the patient for excessive bleeding and instruct about signs of impairment of healing processes. It is important that biopsy samples be clearly labeled, packaged appropriately for transport to laboratory facilities, and delivered promptly. Consult the laboratory for information about the transport container and whether a cell fixative is required in the container.

Assessment of the patient's psychological condition during breast diagnosis procedures is essential. Most women know someone who has had breast cancer. Although breast cancer screening procedures can seem routine to health-care workers, they may be a cause of much anxiety for patients and their families. An understanding and calm nurse who can explain the procedures can help the assessment phase to be less traumatic.

SAFETY TIP

Use at least two patient identifiers (neither to be the patient's location) whenever collecting laboratory samples or administering medications or blood products, and use two identifiers to label sample collection containers in the presence of the patient. 2006 National Patient Safety Goals from www.JCAHO.org.

Additional Diagnostic Tests of the Female Reproductive System

There are many tests to assess reproductive system function; this is presently an area of rapid change. The names of the individual procedures may also vary among institutions or according to particular methods used (e.g., a **salpingoscopy** is also called a fallopscopy, and a laparoscopy is the same as a peritoneoscopy). For this reason, this chapter is limited to general descriptions of categories of medical and surgical

assessment procedures rather than attempting to name all tests.

Hormonal Tests

Hormonal tests are commonly used to assess functioning of the endocrine system as it relates to reproduction. They may be used to measure potential fertility, to find reasons for abnormal menses, to assess hormone-producing tumors, and to determine whether treatments to adjust hormone levels have been effective. Several hormones may be assessed at any one time. Some hormonal tests are time specific, and the samples can be useless if not gathered within a certain time range.

NURSING CARE. Consult institution policy for specific instructions for each test. Explain the procedure to the patient and provide support. Women who are undergoing hormonal tests may feel embarrassed, worried about their femininity and potential fertility, and depressed because of repeated tests, often with little positive result. Some may fear loss of their spouse's love (and perhaps relationship) if they are diagnosed with alterations in hormonal levels or functioning leading to infertility.

Pelvic Examination

The pelvic examination allows visual inspection of the vagina and cervix, as well as sampling of mucus, discharge, cells, and exudates. Palpation of portions of the reproductive system and some treatments may also be done as part of the procedure (Fig. 41.8).

NURSING CARE. Be prepared to assist the health-care provider with the examination. Explain the procedure as you set out the supplies. Vaginal specula range from tiny virginal sizes to extra large. The appropriate size is related to the size and shape of the woman's (or child's) pelvis and whether she has had children or not. For a small child, a nasal speculum may be used. A clean basin of warm tap water to warm the speculum and a small amount of surgical lubricant should be placed near but not on the speculum (because some tests may be affected by water or lubricant). If reusable equipment is being used, be sure it has been sterilized between patients. Two clean gloves for the examiner should be placed nearby, and a light should be adjusted to illuminate the area. Other equipment may be set out according to the tests or treatments that will be carried out during the pelvic examination.

Instruct the patient to empty her bladder before the examination, change into a gown, and remove her underclothing. Instruct the patient to lie either on her back with her arms resting down at her sides (to aid relaxation of abdominal muscles) or in a side-lying position, according to the health-care provider's preference. Provide a sheet large enough so that there is plenty of room for her legs to spread while the sheet still covers the patient on both sides.

Bimanual Palpation

Because much of the reproductive system is not visible even with a speculum, **bimanual** palpation is often done during a

FIGURE 41.8 Pelvic exam with pap smear
(From Dillon, PM: *Nursing Health Assessment: A Critical Thinking Case Studies Approach*, ed. 2. FA. Davis, Philadelphia, 2007, with permission)

pelvic examination. One hand is placed on the abdomen and the other gloved hand is inserted deeply into the vagina. The uterus and **adnexa** are moved about between the two hands to feel the size, shape, and consistency of the uterus and adnexa and to check for any abnormal growths.

NURSING CARE. Explain the procedure and support the patient. Some women may be fearful, embarrassed, or tense and may find the procedure uncomfortable. Active relaxation strategies may decrease discomfort. See Box 41.1 Thoughts from a Sexual Assault Nurse Examiner for the experiences of a sexual assault nurse examiner.

Cytology

Cytology is the study of cells taken as tissue samples. There are several ways that cells from the reproductive system may be removed for microscopic examination. During a Pap smear, one or more small samples of cells are gently scraped away from the surface of the cervical canal using a small wooden spatula, tiny cylindrical brush, and/or long cotton-tipped applicator. They are then smeared or rolled onto microscopic slides and sprayed with a fixative to preserve them for viewing, or placed into a fixative solution for later preparation and viewing in a laboratory. Cells may also be collected by **conization**, which involves removing a small cone-shaped sample from the cervical canal, or by punch biopsy, which removes a small core of cells. Endometrial biopsy specimens are samples of cells taken from the lining of the uterus by scraping with a small spoon-shaped tool called a **curet**, which is inserted through the cervix. Small

adnexa: ad—together + nexa—to tie (usually refers to ovaries and tubes)

conization: coniz—cone-forming + ation—process

curet: scoop

CRITICAL THINKING

Reproductive Assessment

■ How might the age of the patient change your approach, plans, and teaching for patients who have disorders of the reproductive system? Consider your approach, plans, and teaching for each of the following scenarios.

1. A 2-year-old child is brought into the clinic by her mother because she has a foul-smelling discharge coming from her perineal area and a slight yellowish discharge from her vagina.
2. A 19-year-old woman comes to the doctor's office where you work for renewal of her yearly birth control pill prescription. Your employer enforces regular checks for cervical changes by renewing the prescription only after a Papanicolaou (Pap) smear is done. As you start setting out the Pap smear materials, your patient expresses some reluctance to have a Pap smear today because she is so sore already.
3. Your 56-year-old patient comes in to "get things checked out" because she hurts every time that she and her husband have intercourse.

Suggested answers at end of chapter.

biopsy specimens may also be taken by cutting or removing a suspicious lesion. Cells may be observed for changes indicative of hormonal secretion, cellular maturation, or abnormalities such as are seen with viral growths and cancerous or precancerous conditions.

NURSING CARE. Add appropriate sample collection materials and fixatives to the pelvic examination supplies

Box 41.1**Thoughts from a Sexual Assault Nurse Examiner (SANE)**

When patients come in to see me they are in crisis. They are unsure how or what to feel and whom to trust. They are very apprehensive. As patients give me the history of their assaults, they begin to trust me. They see someone who is interested in them and who believes them. By the time I actually start the head-to-toe physical examination, they know they are safe. Often when I am performing the physical examination, I start small talk and take an interest in their lives that has nothing to do with the assault. When they are discharged from my care, they are more animated, talkative, and sometimes smiling.

The patient I remember the most was a child whose father was molesting her when her mother went to work. She was about 6 years old. When she came to the hospital, she wasn't talking to anybody, let alone a nurse in a scary hospital at midnight. I spent 4 hours with this child. We colored, played, and talked about her brothers. By the end of the night, she allowed me to do an examination on her. And she trusted me enough to let the physician come in and look at her. Unfortunately, in her young life, she had a reason to be scared. Her life became much worse before it got better. Her father tried to kill her mother and himself as a result of this.

So many of us have grown up with pop culture television and we think of forensic examiners as profession-

als working with dead people. In fact, forensic nursing is caring for patients as it applies to the law. As a sexual assault nurse examiner, I care for those people who have experienced interpersonal violence. And in caring for this special population of patients, I care for them through the nursing process. I not only care for their physical trauma but also care for their spiritual needs; lastly, I collect evidence for the prosecution of a crime. I advocate for their safety needs, and help provide for their physical needs. I provide a bridge to the legal and mental health systems.

I began forensic nursing 8 years ago when the concept was still new. We were navigating uncharted waters and were unsure what the end result would bring. What we quickly learned is when you deliver good nursing care to patients, the end result can be a positive change in their lives, and that is the reward of the job: making a positive difference in patients' lives, giving them some tools to help in their recovery process. Having the patient and family look at you and say "thank you for helping me" is what we all went into nursing for.

Becoming a sexual assault nurse examiner has made me become a more empathic person, a more compassionate nurse, and a better citizen within my community.

according to the type of cytological examination being done. For a Pap smear, this may include one or two clear glass slides, fixative spray, cytobrush and/or wooden cervical spatula, and transport box for the slides. In some settings, or for larger cell samples in most settings, a sterile collection container which includes a preservative solution may be used. Consult the procedure manual or health-care provider concerning specific types of instruments to put out for biopsies and Pap smears. Cells die and degrade rapidly once removed from the patient, so they must be packaged securely for transport to laboratory facilities. Always label specimens carefully.

Prepare the patient by explaining the procedure and providing support. The woman may be fearful of cancer or other abnormality. Removal of the sample may cause pain, bleeding, swelling, or, later, inflammation, so the patient is monitored after the procedure and alerted to watch for and report these complications if they occur. Document the woman's status after the procedure on the chart and record that the sample was sent to the laboratory.

Swabs and Smears

Swabs and smears are done to determine which microorganisms are causing infection, and consequently which antibiotics should be used.

NURSING CARE. Add sample collection materials, including swabs, slides, and sterile saline in site-specific receptacles, and a gonorrhea/*Chlamydia* collection kit, to pelvic examination equipment if symptoms of vaginal infection are present. It is important to place samples of discharge or exudate into culture media that support growth. Clear media are required for some and charcoal media for others, so both types should be set out. Viral swabs require a special collection kit. *Chlamydia* samples are especially difficult to transport to laboratories, and special kits are available for this pathogen. Some microorganisms, such as yeasts and *Trichomonas*, can be identified well from smears on slides. Wet mounts are smears of discharge spread onto a slide. These must be taken to the microscope immediately after they are obtained. Sodium chloride and potassium hydroxide are dropped onto individual wet mount slides before they dry to aid in identification of some microorganisms. Support the patient, who may be anxious about possible sexually transmitted diseases and effects on relationships.

Sonography

Ultrasound assessment (also called sonography) may be done to determine size, shape, development, and density of structures associated with the female reproductive system,

as well as fetal measurements and some types of prenatal diagnoses. This procedure is especially useful for differentiating cysts from solid tumors, as well as locating ectopic pregnancies and intrauterine devices. Ultrasound may also be used to guide needles for obtaining samples of fluid or cells. Either external or vaginal transducers may be used to send and receive the signals for this procedure. Vaginal transducers are placed in a plastic sheath before insertion into the vagina. A full bladder may be required for some ultrasound tests.

NURSING CARE. Explain the procedure and support the patient. The pressure of the transducer on the skin or in the vagina may be painful if the adjacent structures are inflamed or swollen, or if the bladder is very full.

Radiographic Procedures

Several radiographic procedures may be used for diagnosis of reproductive system problems. Computed tomographic (CT) scanning and MRI are used to locate tumors of the reproductive system. Structures of the female reproductive system may also be outlined by taking x-ray pictures of cavities that have been filled with a radiopaque substance. During a **hysterosalpingogram**, dye is injected into the uterus until it comes out the ends of the fallopian tubes. This test is useful for identifying congenital abnormalities in the shape or structure of the uterus and blockages of the fallopian tubes.

NURSING CARE. Prepare the patient for this test according to the x-ray department policy and the physician's orders (they may include a laxative, suppository, or enema). Ensure that the patient understands the procedure and that appropriate consents are signed as required. Ask about allergies to iodine or shellfish because contrast media may contain iodine. Notify the charge nurse immediately if the

hysterosalpingogram: hystero—womb + salpingo—tube + gram—record

patient reports an allergy. After the procedure, assess for nausea, light-headedness, and signs of allergic reaction and promote comfort, as some cramping may occur. Discharge teaching should include signs of infection and advice that the x-ray dye may stain clothing. Provide a perineal pad following the procedure and advise the patient to wear a perineal pad until any vaginal drainage stops.

Endoscopic Examinations

Several types of endoscopic examinations are done to visually inspect internal areas to diagnose (and sometimes treat) reproductive system disorders. The names of the tests vary according to the area inspected, but all these generally make use of a fiberoptic light and lens system, which is inserted through a tube called a cannula into a small incision. A laparoscopy is done to view the abdominal cavity and is useful for identifying problems such as endometriosis (Fig. 41.9). A salpingoscopy is performed to see the inside of the fallopian tubes and a **hysteroscopy** to see the inside of the uterus. A binocular microscope is used with an endoscope that is introduced into the vagina to closely study lesions of the cervix during a **colposcopy**. During **culdoscopy**, an endoscope is introduced into the vagina and through a small incision in the vagina into the cul-de-sac of Douglas, a cavity behind the uterus, in order to observe for abnormalities in this region (Fig. 41.10).

NURSING CARE. Preoperatively the patient is prepared for an endoscopic examination according to institutional protocol. This generally involves asking the patient whether she has fasted as instructed, assessing vital signs, recording the time of last voiding, helping the patient into the operating room gown, and obtaining a signature on the consent form. General anesthesia may be given for some endoscopic procedures. Explain what to expect and provide

hysteroscopy: hystero—womb + scopy—looking

colposcopy: colpo—vagina + scopy—looking

culdoscopy: culdo—cul de sac + scopy—looking

FIGURE 41.9 Laparoscopy. (Modified from Cavanaugh, *BM: Nurse's Manual of Laboratory and Diagnostic Tests*, ed. 3. F.A. Davis, Philadelphia, 1999, p 571, with permission.)

FIGURE 41.10 Culdoscopy. (Modified from Cavanaugh, BM: *Nurse's Manual of Laboratory and Diagnostic Tests*, ed. 3. FA. Davis, Philadelphia, 1999, p 566, with permission.)

support for the woman. The patient may be anxious about possible disorders.

Postoperatively, provide comfort measures. These procedures produce almost no blood loss. The woman may experience pain in the neck, shoulders, and upper back if carbon dioxide (CO₂) gas was pumped into the body compartment being examined. Called **insufflation**, this is done to increase the distance between structures, so that it is easier for the physician to see and diagnose possible disorders. The CO₂ remaining after completion of the examination travels to the highest level of the body before being absorbed, so lying flat for a few hours after the examination may decrease discomfort. If incisions were made through the abdominal wall for insertion of the endoscope and for insufflation, these are tiny and a Band-Aid or small dressing is applied.

PATIENT TEACHING. Advise the patient to observe the sites for redness, bleeding, or any drainage, seeking evaluation by the physician promptly if these should occur or otherwise approximately 1 week later for suture removal (according to physician preference). If the endoscopic procedure was done transvaginally, provide a perineal pad following the procedure and advise the patient to wear a perineal pad until the drainage stops. Also instruct the patient to report any bright bleeding after the operative day, and to report any fever or foul-smelling discharge.

Further detail about some specific forms of the tests that have been described in this chapter are included with the disorders to which they apply in Chapters 42 and 43. Also see Table 41.5.

MALE ASSESSMENT

As with the female reproductive system, the male reproductive system is a complex interaction of both physical and psychosocial factors. Unlike women, however, men

may find it much more difficult in our society to talk about or admit to having problems related to reproductive health. From toilet training through adulthood, men are expected to have behaviors associated with maleness. Unfortunately, by the time some boys reach manhood, their male identity may be defined by the successful functioning of their sex organs.

One of the important first steps in obtaining a male reproductive assessment is to provide a comfortable, non-judgmental, confidential atmosphere for discussion. This means you must first be knowledgeable and comfortable with sexual issues. Nurses do not hesitate to ask female patients about their menstrual history and should be equally comfortable in asking men about their **erection** or ejaculation history. Be open and straightforward with all questions and answers. It may be necessary at times to use more commonly expressed sexual words instead of medical terminology. You will discover that many men do not know the function of their prostate gland or the difference between ejaculation and **orgasm**. Use the assessment as an opportunity to teach men the facts about their own sexual functioning.

History

There are some basic questions to ask a male patient during a reproductive assessment (Table 41.6). Additional questions related to sexual function include the following:

1. “Are you having any problems getting or keeping an acceptable erection?” Additional questions might be whether the patient can have an erection anytime (with or without a sex partner); if erection problems occur when he is under stress or taking medication; or if he is involved in substance abuse. “Do you have erections first thing in the morning or during sleep?” If the patient is able to get an erection, is it straight and firm enough for penetration? Does the erection last long enough for him to reach orgasm?
2. “Are you able to ejaculate during orgasm? Do you have any painful sensations related to the experience? Does any fluid come out during the ejaculation process, and if so, is it a small, moderate, or large amount, and is it clear, cloudy, or brown in color?” The amount and color may depend on whether the patient has had recent sexual activity or genitourinary surgery or may indicate a congenital anomaly or infection.
3. For patients younger than 40 years old: “Do you practice monthly testicular self-examinations?” Men younger than age 40 should be encouraged to perform monthly testicular examinations as a cancer prevention measure.
4. For patients older than 40 years: “When was the last time you had a prostate examination?” A digital rectal examination (DRE) should be a regular part of a man’s routine physical after age 41. Prostate cancer is treatable when detected early.

As mentioned earlier, a professional, matter-of-fact attitude, along with an explanation as to why the questions

TABLE 41.5 DIAGNOSTIC PROCEDURES FOR THE FEMALE REPRODUCTIVE SYSTEM

Procedure	Definition/Normal Finding	Significance of Abnormal Findings	Nursing Management
<i>Noninvasive</i>			
<i>Breast Self-Examination (BSE)/Clinical Breast Examination (CBE)</i>	Assessment of breast tissue by patient (BSE) or health-care provider (CBE) through inspection and palpation	Abnormal physical exam may indicate pathology and indicates need for further assessment.	Educate about appropriate technique and witness a return demonstration of BSE. Education about BSE may be demonstrated during CBE.
<i>Ultrasound/Sonography</i>	High-frequency sound waves bounce off tissue to map tissue structure and determine tissue density. Also may be used to guide biopsy procedure.	May help to determine abnormal lesions, abnormalities of tissue structure, or presence of abnormal fluid volume	Follow institutional guidelines for patient preparation and support which may be determined by testing goals.
<i>Mammography X-ray</i>	Radiographic examination of tissue. X-ray may be used with dye contrast injected into body before procedure.	May help to determine abnormal lesions or abnormalities of normal tissue structure	Educate patient not to apply lotions/powders to skin over area to be tested by mammogram. If dye is used, inquire about past allergic reaction to dye and/or watch for allergic response after procedure.
<i>Thermography/Computed Tomography (CT)/Magnetic Resonance Imaging (MRI)</i>	Precise pictures of tissue using temperature (thermography), x-ray (computed tomography), or radiofrequency (MRI)	May help to determine abnormal lesions or abnormalities of normal tissue structure	Ask patient about presence of metal or wire inside their bodies before MRI as the procedure may then be contraindicated.
<i>Hormonal Tests</i>	Assessment of endocrine function related to reproduction	Abnormal hormone levels may reflect fertility potential, find reasons for abnormal menses, assess for hormone-producing tumors, or evaluate if adjustment of hormone levels have been effective.	Explain procedure to patient and provide support.
<i>Invasive</i>			
<i>Pelvic Examination/Bimanual Examination</i>	Inspection and palpation of external/internal reproductive organs by health-care provider	Abnormal physical examination may detect pathology or may indicate need for further testing.	Consult institutional policies for specific instructions for each test. Explain procedure to patient and provide support.
<i>Biopsy/Cytology/Swabs/Smears</i>	Obtainment of body cells/tissue through aspiration or excision, or swabbing/scrapping of tissue/exudate	May diagnose pathology or infection	Consult institutional policies for specific instructions for each test. Explain procedure to patient and provide support.
<i>Endoscopy/Laparoscopy</i>	Use of fiberoptic light and lens system to inspect internal structures	May help to determine abnormal lesions or abnormalities of normal tissue structure. Biopsies may be taken of tissue during procedure.	Explain procedure to patient and provide support. Observe for postprocedure complications.

are necessary, can put both you and the patient at ease during the assessment.

Physical Examination

The physical examination is generally performed by a physician or practitioner trained in physical assessments. The examination begins with the patient's general appearance. He is observed for male patterns of hair growth on the head, face, chest, arms, and legs. Normal male pubic hair pattern is in an upside-down triangular shape, with hair growth up toward the umbilicus. The patient's height and muscle mass are noted. Men are commonly taller than 5 feet, 6 inches tall, weigh more than 135 pounds, and have shoulders that are broader than their hips. The presence of excess breast tissue

may indicate **gynecomastia**, an excess of female hormones. Abnormal findings in either hair patterns or muscle mass often indicate a hormone imbalance.

The penis, scrotum, and testes (testicles) are examined by observation and palpation. On observation, the penis is normally flaccid (soft) and hanging straight down. The size can vary greatly and should not be a concern unless it is unusually small (microphallus) or edematous. The left testis generally hangs slightly lower in the scrotum than the right.

The penis is examined for warts, sores (evidence of sexually transmitted diseases), swelling, curves, or lumps

gynecomastia: gynec—female + mastia—breast

TABLE 41.6 SUBJECTIVE ASSESSMENT OF THE MALE REPRODUCTIVE SYSTEM AND SEXUAL HEALTH

Category	Questions to Ask During History Assessment	Rationale/Significance
<i>Medication</i>	Are you using any medications? (Include prescription, over-the-counter, and herbal remedies.) How much/how often? (For medications that affect sexual desire, erection, or ejaculation, refer to Chapter 43.)	Loss of sexual desire, erection, ejaculation, orgasm, or fertility can occur as a result of some medication use.
<i>Family History</i>	Do you have a family history of genetically transmitted diseases (e.g., heart problems, hypertension, diabetes)? Did your mother use DES during pregnancy?	These conditions put one at high risk for circulation problems that interfere with erections, congenital anomalies of reproductive organs.
<i>Personal Habits and Health Promotion Behaviors</i>	Do you smoke, use caffeine, drink alcohol, use recreational drugs, or use steroids? How much/how often? Do you use hot tubs, engage in long-distance drives, or ride a bike? How much/how often? Do you use contraceptives? What type of contraceptives do you use? How do you use them? Do you do TSE? Have you noticed any changes in your testicles or other reproductive organs?	These habits may lead to decreased blood flow to penis, loss of erection; decreased testosterone (male hormone) interferes with erection and fertility; excessive heat decreases sperm production. Data will reveal knowledge/practice of health promotive behaviors, meaning of health, as well as history of changes/abnormalities.
<i>Personal Health History</i>	Did you have mumps during adolescence, or have you recently had an infection or fever?	Some infectious processes may lead to decreased sperm production.
<i>Mental Health</i>	Are you experiencing stress? How do you deal with stress? Are you having problems with a sexual partner? Have you ever or are you experiencing performance anxiety or depression?	Decreased sexual desire and ability to have an erection may result from mental and/or emotional issues.
<i>Circulatory/Respiratory</i>	Have you ever been diagnosed with or treated for heart problems/surgery, high blood pressure, sickle cell disease, lung disease, or sleep apnea?	Decreased circulation can lead to inability to have usable erection; decreased respiratory function can result in activity intolerance, loss of erection, congenital anomalies of reproductive organs.
<i>Gastrointestinal</i>	Have you ever been diagnosed/treated for liver infection/disease or bowel problems?	Liver infections/disease can lead to decreased testosterone and increased estrogen production, loss of erection; gastrointestinal/bowel problems can lead to pain, loss of desire; surgery may result in loss of blood or nerve flow.
<i>Musculoskeletal</i>	Do you have painful joints, pelvic/lower back pain, or nerve damage?	Pain, loss of desire; limited movement/positions, loss of erection, ejaculation, and orgasm may result from musculoskeletal problems.
<i>Neurological</i>	Have you ever experienced a stroke or suffered from multiple sclerosis or Parkinson's disease?	Limited movement/positions, loss of sensations, loss of control can result from neurological problems.
<i>Metabolic/Endocrine</i>	Have you ever suffered from diabetes, obesity, or thyroid problems?	Diabetes mellitus can result in circulation problems, retrograde ejaculation, nerve damage; obesity can result in decreased male hormones, excess female hormones.
<i>Genitourinary</i>	Have you ever been diagnosed with a congenital deformity of the penis/testicles, suffered from prostate problems, or experienced erection/ejaculation problems? Have you ever been diagnosed with a sexually transmitted disease? When, what type, and how was it treated? That you are aware, was treatment successful? Do you have any lesions, pain, discharge, swelling of the reproductive organs? Have you noticed any abnormalities/changes in size, shape, color of your external reproductive organs? (Describe).	Difficulty with penetration, erection problems, retrograde ejaculation, infertility may be associated with genitourinary abnormalities. Lesions, pain, discharge, swelling, or other abnormalities of the external reproductive organs may indicate infection, structural abnormalities such as varicocele, or other disease processes such as cancer.
<i>Sexual Practices</i>	Are you sexually active? How many partners do you have? Of what gender? How often do you have intercourse (including positions, timing with female ovulation cycle if heterosexual)? Is the amount/type of sexual activity satisfying? Do you masturbate, or use lubricants?	Some sexual practices can lead to a decrease in quality and quantity of sperm that reach the female egg.

DES = diethylstilbestrol.

along the shaft. The examiner also makes sure the urethral opening is at the tip of the penis and not on the underside of the shaft (**hypospadias**) or on the dorsum of the shaft (**epispadias**). If the man is not **circumcised**, the foreskin should be pulled back carefully and the glans inspected for signs of inflammation or foul-smelling discharge. The practitioner should be sure to replace the foreskin in the forward position after the examination is completed.

The scrotum and testes are carefully examined and palpated. Both testes should be present and a normal size (approximately 2 cm × 4 cm). The testes are egg shaped and should feel smooth and rubbery when lightly palpated between the thumb and fingers. The epididymis can be felt along the top edge and posterior section of each testis. The testes and scrotum are palpated for any lumps, cysts, or tumors. If a fluid-filled mass (**hydrocele**) is found, further evaluation should be done. A simple noninvasive test called **transillumination** is used to determine if the mass is fluid filled or solid. With the room lights out, a flashlight is held behind the scrotum. If the mass is fluid, a red glow appears; if it is solid, it appears opaque. Each spermatic cord (made up of veins, arteries, lymphatics, nerves, and the vas deferens) is palpated and should feel firm and threadlike. If

hypospadias: hypo—under + spadias

epispadias: epi—upon + spadias

circumcised: circum—around + cised—cut

hydrocele: hydro—water + cele—hernia

transillumination: trans—across + illumin—light + ation—process

a condition called a **varicocele** is present, the area feels like a bag of worms. A varicocele, which is swelling of the veins of the spermatic cord, is one of the most common problems associated with male infertility.

The male patient is also examined for inguinal hernias by pressing up through the scrotum into each of the inguinal rings while asking him to cough or bear down. Each side is examined separately while he is in the standing position. A hernia feels like a pulsation against the examining fingertips.

A digital rectal examination may be done by an experienced practitioner. During DRE, the prostate gland is palpated by inserting a gloved, lubricated finger into the rectum while the man is in a knee-to-chest position. The entire posterior lobe of the gland can be felt this way. The gland should feel slightly firm and without any lumps. If the prostate gland feels very hard or soft, enlarged, or contains any lumps, a rectal ultrasound with needle biopsy is often ordered. A swollen, painful prostate generally indicates that an infection is present. Remind all men older than age 40 that unless they have had a complete removal of the prostate gland, they still need a DRE performed every year. Many men are under the impression that any prostate surgery means the gland has been completely removed. When simple surgery is performed, prostate tissue is left in the body and will begin to regrow over time. This prostatic tissue can become cancerous and needs to be monitored with a yearly DRE.

See Table 41.7 for a summary of objective assessments of the male reproductive system.

varicocele

TABLE 41.7 OBJECTIVE ASSESSMENT OF THE MALE REPRODUCTIVE SYSTEM

Category	Physical Assessment Findings	Possible Abnormal Findings/Causes
Clinical Breast Examination	<ul style="list-style-type: none"> Observe and palpate for presence of swelling, lumps, skin changes, nipple exudates. 	<ul style="list-style-type: none"> Changes may indicate breast cancer, though rare in males.
Glans of Penis	<ul style="list-style-type: none"> Observe for lesions, exudate, tenderness. Observe for placement of the urethra. If foreskin is present, attempt to reduce to observe for lesions, exudate, inflammation. 	<ul style="list-style-type: none"> Lesions, exudate, tenderness can indicate presence of infective or disease process, injury. Epispadias/hypospadias may be noted when observing for placement of the urethra.
Shaft of Penis	<ul style="list-style-type: none"> Observe for lesions, tenderness, shape. 	<ul style="list-style-type: none"> Lesions, exudate, tenderness can indicate presence of infectious or disease process, injury. Irregularity of shape may indicate structural abnormalities/diseases.
Scrotum	<ul style="list-style-type: none"> Visualize and palpate for swelling, pain, lesions. 	<ul style="list-style-type: none"> Inguinal herniation may be noted. Swelling may occur with heart or renal failure, local inflammation, injury.
Testes	<ul style="list-style-type: none"> Palpate for descent, pain, lesions, size, shape, consistency. Palpate for lesions/swelling of epididymitis. 	<ul style="list-style-type: none"> Absence of palpated testes may indicate non-descent. Testicular lesion can indicate testicular cancer. Swelling, pain can indicate infectious process.
Spermatic Cord	<ul style="list-style-type: none"> Palpate for swelling, size, consistency, pain 	<ul style="list-style-type: none"> Presence of swelling, pain can indicate infection or varicocele. Bulge, pain may indicate inguinal hernia.
Inguinal Ring (by trained personnel)	<ul style="list-style-type: none"> Palpate for bulge, pain. 	
Inguinal Lymph Nodes	<ul style="list-style-type: none"> Palpate for swelling, pain. 	<ul style="list-style-type: none"> Swelling, pain may indicate infectious process or regional malignancy.
Digital Rectal Exam: DRE (by trained personnel)	<ul style="list-style-type: none"> Observe external rectum for lesions, exudate. Palpate for pain, swelling, penile exudate. 	<ul style="list-style-type: none"> Pain, swelling, exudate may indicate benign changes, infectious process, cancer, or injury.

Testicular Self-Examination

All men after puberty should do monthly testicular self-examination (TSE) to detect any tumors or other changes in the scrotum. See Box 41.2 Guidelines for Monthly Testicular Self-Examination for instructions that can be used to teach a man how to examine his testicles. Also see Figure 41.11.

CRITICAL THINKING

Testicular Evaluation

■ Tony is a 20-year-old who complains of a “bump” on his right testicle. He comes into the health clinic and asks if he can take any medication for his “disease.”

1. What would be the best action?
2. What should your health assessment include?

Suggested answers at end of chapter.

Breast Self-Examination

Although breast cancer in men is rare, it can occur. Men, like women, should perform monthly breast self-examination.

Diagnostic Tests of the Male Reproductive System

Ultrasound

An ultrasound may be done to diagnose or evaluate a variety of male reproductive or genitourinary problems. A transrectal ultrasound may be done to diagnose prostate cancer. For this procedure, a rectal probe transducer is inserted into the rectum and sound waves are used to evaluate the prostate gland. An enema may be ordered before the procedure. No special aftercare is necessary.

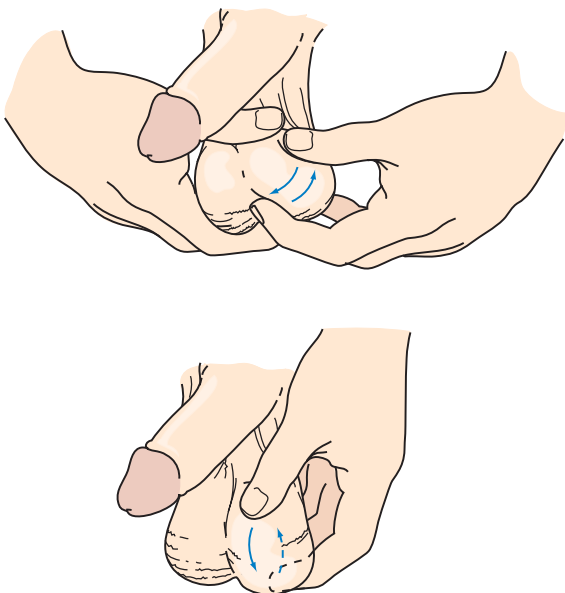

FIGURE 41.11 Testicular self-examination.

Box 41.2

Guidelines for Monthly Testicular Self-Examination

The examination is easiest during or right after a warm shower or bath, when the scrotum is relaxed and the testicles are hanging low. Choose 1 day a month to always do the examination.

1. Raise the penis up out of the way and look for any difference in size or shape of each side of the scrotum (sac). The left side usually hangs a little lower than the right.
2. Using both hands; hold the scrotum in the palms. Begin, one at a time, to gently roll each testicle between the thumb and first three fingers, feeling for any lumps or hard spots.
3. Identify the parts. The testicles should feel round, smooth, and egg shaped. The epididymis along the top and back side should feel soft and a little bit tender. The spermatic cord is a tube that runs from the epididymis and usually feels firm, smooth, and movable.
4. See your doctor immediately if you feel any lumps or unusual changes.

Pelvic or scrotal ultrasound helps evaluate and locate masses. Ultrasound may also be done to guide a needle during a fine-needle biopsy.

Cystourethroscopy

Cystourethroscopy may be done to evaluate the degree of obstruction by an enlarged prostate gland. For this procedure, a Foley catheter is inserted and a dye is injected into the bladder. Radiographs are taken with the dye in the bladder and while voiding after the catheter has been removed.

NURSING CARE. The procedure is explained to the patient, and possible allergic reaction to dyes is assessed and communicated to the physician as necessary. The patient is instructed to void before the procedure. A sedative or analgesic may be ordered to help the patient relax during the procedure.

After the procedure, intake and output are measured for 24 hours and alteration from the patient’s normal pattern or absence of urination are reported to the physician. Fluids are encouraged to promote excretion of the dye.

Laboratory Tests

PROSTATE-SPECIFIC ANTIGEN. The normal value of prostate-specific antigen (PSA) is less than 4 ng/L. PSA is a glycoprotein produced by prostate cells. An elevated level indicates prostatic hypertrophy or cancer.

PROSTATIC ACID PHOSPHATASE. Normal value of prostatic acid phosphatase (PAP) is less than 3 ng/mL. PAP

is an enzyme that normally affects metabolism of prostate cancer cells. An elevated level indicates prostate cancer.

OTHER TESTS. If prostate cancer is suspected or diagnosed, additional tests may be done. Acid phosphatase may be elevated in metastatic prostate cancer. Alkaline phosphatase and serum calcium levels may be elevated if metastasis to the bone has occurred. See Table 41.8 for a summary of diagnostic procedures.

Tests for Infertility

Various hormone levels may be measured, including FSH, LH, testosterone, and adrenocorticotrophic hormone (ACTH) to help determine causes of infertility in male patients.

Semen analysis may be done to provide information about causes of infertility or to evaluate whether a vasc-

tomy has been effective. Semen may be analyzed for sperm count, motility, and shape. Other tests determine whether the semen contains adequate nutrients to support sperm, whether antibodies to the sperm are present, and the ability of the sperm to penetrate an ovum.

NURSING CARE. The patient is instructed to refrain from ejaculation for 3 days before collecting the semen sample to avoid altering findings. Generally, specimens are collected on three separate occasions over a period of 4 to 6 days. Masturbation and ejaculation directly into a sterile container are recommended to avoid loss of semen. Condoms and lubricants should be avoided. The sample should be taken to the laboratory within 1 hour of collection. Additional tests of the male reproductive system are discussed in Chapter 43.

TABLE 41.8 DIAGNOSTIC PROCEDURES FOR THE MALE REPRODUCTIVE SYSTEM

Procedure	Definition/Normal Finding	Significance of Abnormal Findings	Nursing Management
		<i>Noninvasive</i>	
<i>Testicular Self-Examination (TSE)</i>	Palpation of testes by patient.	Abnormalities may indicate pathology and require further evaluation.	Instruct patient on appropriate technique and witness a return demonstration.
<i>Ultrasound</i>	High-frequency sound waves bounce off tissue to map tissue structure and determine tissue density. Also may be used to guide biopsy procedure.	May help to determine abnormal lesions, abnormalities of tissue structure, or presence of abnormal fluid volume.	Follow institutional guidelines for patient preparation and support which may be determined by testing goals.
<i>Hormonal Tests/Antigen Level Testing</i>	Blood test to measure hormone or antigen levels.	Abnormal hormone levels may reflect fertility potential. Abnormal antigen levels may indicate pathology.	Consult institutional policies for specific instructions for each test. Explain procedure to patient and provide support.
		<i>Invasive</i>	
<i>Digital Rectal Examination</i>	Palpation of internal reproductive organs, especially prostate gland, through rectum.	Abnormal physical exam may indicate pathology and indicates need for further testing.	Educate patient about procedure and provide support.
<i>Cystourethroscopy</i>	Insertion of a Foley catheter and dye into the bladder to evaluate for obstruction (usually an enlarged prostate) by radiography.	Obstruction may cause difficulty with urination.	Educate patient about the procedure and postprocedure care. Instruct patient to void before procedure. Measure intake and output for 24 hours following the procedure. Observe for allergic reaction.

REVIEW QUESTIONS

- Which male reproductive duct carries sperm into the abdominal cavity?
 - Urethra
 - Epididymis
 - Ductus deferens
 - Ejaculatory duct
- Which of the following is the usual site of fertilization?
 - Ovary
 - Uterus
 - Vagina
 - Fallopian tube
- Which procedure is most helpful in distinguishing a fluid-filled mass from a solid mass of the breast?
 - BSE
 - Mammogram

- c. Clinical breast examination
 - d. Ultrasound
4. Which of the following items should be placed out in preparation for a Pap smear? Choose all responses that are correct.
 - a. 50-mL syringe
 - b. Vaginal speculum
 - c. Lubricant
 - d. Clean gloves
 - e. Slides and fixative spray
 - f. Normal saline
 5. When obtaining the history of a 17-year-old male during a sports physical, what important screening practice should be discussed?
 - a. Yearly DRE
 - b. Monthly TSE
 - c. Yearly PSA
 - d. Bimonthly bimanual examination
 6. A patient has just had a laparoscopy to investigate the causes of her infertility. Why should the nurse instruct her to lie flat in the bed for a few hours?
 - a. She could rupture her abdominal incision.
 - b. Her blood pressure will be extremely low because of blood loss.
 - c. The carbon dioxide left over from the test will travel upward and cause pain.
 - d. Her uterus needs to be at the same level as her heart to prevent excessive swelling.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Breast Health Education*

1. The answer should include basic breast health statistics, risks, as well as proper assessment practice and techniques as discussed in this chapter. Technique should be demonstrated and a return demonstration received during the visit. The patient should also verbalize understanding of risks related to breast health and proper BSE technique to verify teaching was effective.
2. Questions about breast health and self-assessment practices provide an opportunity for the nurse to educate a patient about health facts and technique. Patient questions can also be a cue to patient readiness and willingness to learn.

■ *Reproductive Assessment*

1. Calm fears. Explain simply. Allow the parent to stay with the child if appropriate. Consider whether the child has possibly been abused. (If so, evidence needs to be collected and a report filed with the appropriate child protection authorities.) Place a nasal speculum out for examination. Place a forceps out for removal of a possible foreign body (not uncommon at this age). Teach that this is a normal part of the body that is to be protected and taken care of.
2. Assess knowledge and maturity. Set out supplies for a Pap smear and for swabs and smears. Teach while getting supplies ready. Explain that vaginal soreness generally needs to be treated and that the doctor must know more about the problem to do so effectively. Explain that inflammations can interfere with Pap smear results, so it may have to be repeated later after treatment. Explain culture and sensitivity testing. Teach about risk reduction and inform that oral contraceptives do not offer a barrier.

3. Try to put the woman at ease through general conversation. Set out supplies for a Pap smear (if needed) and for swabs and smears. Teach while getting supplies ready. Discuss aging and the effects of decreased estrogen in general and specifically on vaginal tissues. Inform that there are several ways to deal with the problems resulting from decreased estrogen, such as oral hormonal replacements, water-soluble vaginal lubricants, vaginal creams, estrogen patches, and estrogen receptor modulator medication.

■ *Testicular Evaluation*

1. Palpable scrotal changes can be present from a variety of reproductive and/or genitourinary abnormalities. Before Tony's question can be answered, a complete history needs to be obtained and a clinical exam of the genitalia performed.
2. The history should explore:
 - If TSEs are regularly performed and if changes have been noted.
 - If Tony is sexually active and has, recently or in the past, been knowingly exposed to a sexually transmitted disease.
 - If there has been pain associated with the "bump" or exudate noted from the penis.

The assessment should include:

- Visual inspection of the size, shape, symmetry and color of the scrotum and its contents.
- Palpation to assess for abnormalities and pain.
- Cultures to rule out sexually transmitted diseases.
- An inguinal exam to rule out herniation.

Ultimately, based on this complaint, a testicular tumor should be ruled out.

Nursing Care of Women with Reproductive System Disorders

DEBRA PERRY-PHILO AND

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of each of the disorders of the female reproductive system?
2. What are the etiologies, signs, and symptoms of each of the disorders?
3. What care would you provide for patients undergoing tests for each of the disorders?
4. What is current therapeutic management for each of the disorders?
5. What data should you collect when caring for patients with disorders of the female reproductive system?
6. What nursing care will you provide for patients with each of the covered disorders?
7. How will you know if your nursing interventions have been effective?
8. How do different forms of contraceptives available vary in effectiveness?

Reproductive system disorders can be frightening, irritating, frustrating, embarrassing, and in some cases fatal. They involve not just body parts but also roles, relationships, and sense of identity and purpose in life. Nurses can play an important role in helping women with these disorders. Women's health is an area where much research is being done. The Nurses' Health Study, conducted at Harvard Medical School, is a large ongoing study on many topics related to women's health. You can learn about it at www.nurseshealthstudy.org.

BREAST DISORDERS

Benign Breast Disorders

Much has been done in recent years to educate the general public concerning breast cancer. It is the most commonly diagnosed cancer in women.¹ Heightened awareness of the risks of breast cancer, however, sometimes results in excessive anxiety among women with benign breast conditions. The following section covers benign, or noncancerous, breast disorders.

Cyclic Breast Discomfort

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. The most common breast symptoms result from cyclic variations in hormone levels. Swelling, tenderness, and sometimes pain (**mastalgia**) can be related to hormone-mediated changes within the breast tissues that prepare them for their potential role of breastfeeding.

TREATMENT. If persistent or severe, these symptoms may be treated with oral contraceptives that modify hormone levels or nonsteroidal anti-inflammatory drugs (NSAIDs) to control pain. Explaining that cyclic discomfort is temporary and not from a disease process helps to allay fears.

Fibrocystic Breast Disease

Fibrocystic breast disease is common in women between the ages of 30 and 50. Many refer to it as simply “fibrocystic breast changes.”

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Overresponsiveness of cells in the breasts to hormonal stimulation (especially estrogen) may cause long-term changes resulting in replacement of normal tissue with fibrous tissue, **ectasia** (overdevelopment) of cells, and blockage of ducts so that cysts form around trapped fluid. This makes the breasts feel somewhat hard and lumpy, and sometimes painful. These changes often occur during the reproductive years, and can respond to hormonal variations during the menstrual cycle. It usually subsides with menopause.

DIAGNOSIS AND TREATMENT. Fibrocystic breast changes can be identified on palpation. A mammogram or

ultrasound may be done to assist in diagnosis. Needle or excisional biopsy may be done to rule out malignancy. Treatment for fibrocystic breast changes is based on patient symptoms. Often, no treatment is necessary. Analgesics, primarily NSAIDs, may be needed for discomfort. Herbal remedies, such as evening primrose oil, or supplemental vitamin therapy may offer symptomatic relief, but these therapies remain controversial. Limitation of dietary fat and caffeine and addition of oral contraceptive use may be helpful to control hormonal changes that result in discomfort.

Although **fibrocystic** changes are not cancerous, more frequent mammography or ultrasound may be advised as fibrocystic changes may make it more difficult to feel early cancerous lumps during breast self-examination (BSE). Some types of breast cysts are associated with a higher cancer risk. Needle aspiration may be used to treat cystic lesions.

Mastitis

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Breast infection with inflammation (**mastitis**) occurs as a result of injury and introduction of bacteria into the breast. This condition most commonly occurs while breastfeeding. The breast becomes swollen, hot, red, and painful and may form an abscess.

TREATMENT. Mastitis may be treated either with antibiotics or by incision and drainage (I&D) of the abscessed area. NSAIDs, warm packs, and breast supports are often used to control pain and swelling.

NURSING CARE AND TEACHING. You may assist with an I&D by setting out the equipment: a wrapped sterile sharp-pointed scalpel blade, a blade handle, clean gloves, and dressing materials. A dressing may be applied over the I&D site to absorb drainage.

Patient teaching should include instructions to wash hands carefully to prevent the spread of infection. If the patient is breastfeeding, it is often continued to promote drainage of the breast, mother/infant bonding, and infant nutrition. The infant is often already colonized with the bacteria so further exposure is not thought to be detrimental.

NURSING CARE TIP

If a mother is breastfeeding, frequent changes in feeding positions as well as exercising good hygiene techniques, such as hand washing when handling the breasts, may help to prevent mastitis.

Malignant Breast Disorders

Etiology

Research has identified factors that increase the risk of development of breast cancer: increasing age, personal or family

mastalgia: mast—breast + algia—pain

ectasia: extension

fibrocystic: fibro—fibrous + cystic—saclike

mastitis: mast—breast + itis—inflammation

history of breast cancer, high-fat diet, high alcohol intake, treatment with estrogens (especially when used without progestins), early menarche, late menopause, no pregnancy or late first pregnancy, no breastfeeding, or breastfeeding for a short period of time following delivery.

Prevention

Exercising moderation in fat and alcohol consumption, using nonhormonal methods of birth control, and managing menopausal symptoms can reduce risk of breast cancer. However, there are many factors that cannot be controlled, so the importance of early detection cannot be overemphasized. Recent research has discovered genes (BRCA1 and BRCA2) that are linked with susceptibility to breast cancer. These findings offer the possibility of very early identification of women at the most risk of developing breast cancer (and also ovarian cancer for those with BRCA1). They can then be monitored closely for any changes and receive early treatment if cancer develops.

Diagnostic Tests

Breast self-examination and clinical breast examinations are important parts of identification of cancer. Cancerous growths tend to be harder, less mobile, less painful, more irregularly shaped, and have less clearly defined borders than benign growths. The prognosis is good for women who have breast cancers removed in the early stages but gets worse when treatment begins during the later stages of the disease process. Teaching and encouraging the regular use of BSE and appropriate use of mammography can save lives. Refer to Chapter 41 for more about BSE and for explanations about diagnostic tests used to assist in determining whether tumors of the breast are malignant.

Staging

The spread (metastasis) of cancerous cells from the primary site to other areas of the body by way of the blood or lymph is denoted by staging classifications. (See Chapter 10.) The lower numbers indicate less cancer spread.

Therapeutic Interventions and Complications

There are five main treatment options for breast cancer: radiation therapy, chemotherapy, hormonal therapy, modification of biological response, and surgery. These options may be used separately or in combination depending on the condition of the patient and the stage of the disease.

The possibility of metastases necessitates drastic treatment of the whole body in many cases to prevent secondary cancer growth at other sites. Both radiation and chemotherapy generally combat cancer by destroying rapidly reproducing cells. These treatments are effective against cancer but also tend to destroy normal body cells that reproduce rapidly, such as hair and the cells lining the mouth, vagina, and gastrointestinal tract. Interventions to help preserve these tissues and maintain nutrition can be helpful (see Chapter 10).

Hormonal therapy may be undertaken to deprive cancer cells of hormones that stimulate their growth. Because

breast cancer cells are often estrogen sensitive, this may be accomplished by decreasing circulating estrogen levels with drugs or by blocking the use of estrogen by cancer cells as occurs with use of the drug tamoxifen citrate. Interference with estrogen levels, however, may produce menopausal symptoms and increase the risk of osteoporosis and heart disease.

Substances that modify the body's biological responses may be given to intensify positive responses of the body (e.g., stimulate the immune system) or to decrease negative body responses. Some examples of biological response modifiers are interferons, tumor necrosis factor, interleukins, and various experimental immunotherapy formulations. This is an area of much research and is likely to expand greatly during the next few years.

Breast surgeries to remove cancerous tissue can be disfiguring and have profound effects on the patient's self-concept. The amount of tissue removed varies depending on the size, nature, and invasiveness of the cancer. A lumpectomy removes just the tumor and a margin around it. A **mastectomy** may be partial (removing only part of the breast), simple (removing breast tissue of one or both breasts), or radical (removing breast tissue, underlying muscle, and surrounding lymph nodes). Recently, surgical practice has shifted from mainly radical mastectomies to more breast-conserving surgeries with the addition of radiation therapy, and result in similar survival rates being demonstrated.

Nursing Care

See Box 42.1 Nursing Care Plan for Care of the Patient Undergoing a Mastectomy.

Alternative therapies are also available for many cancers. See Chapter 4 for information about helping patients evaluate alternative and complementary therapies. The American Cancer Society and cancer treatment centers also have people who can answer questions about experimental and alternative therapies and discuss research findings. For more information about breast cancer, visit the American Cancer Society at www.cancer.org.

(Text continued on page 904)

CRITICAL THINKING

Julie

■ Julie, age 32, reports pain and grapelike “lumps” in her breasts.

1. What questions would you ask to further assess the complaint?
2. What diagnostic tests would you expect to be suggested (if any)?
3. What treatment options might be used?

Suggested answers at end of chapter.

mastectomy: mast—breast + ec—away + tomy—cutting

BOX 42.1 NURSING CARE PLAN for the Patient Undergoing a Mastectomy

Nursing Diagnosis: Risk for anxiety related to uncertainty about diagnosis, prognosis, and treatments

Expected Outcomes Patient will verbalize and demonstrate a decrease in anxiety.

Evaluation of Outcomes (1) Does the patient report a decrease in anxiety following education and explanation of the procedure? (2) Do patient's vital signs, verbal, and nonverbal behavior suggest a decrease in anxiety?

Interventions

Assess vital signs and observe verbal and nonverbal behavior.

Assess patient's current knowledge of the procedure and level of anxiety related to the procedure.

Teach patient what to expect about the surgical experience based on patient's understanding, concerns, and willingness to learn.

Support the physician's explanations, answer questions, and refer to knowledgeable sources.

Rationale

An increase in blood pressure, pulse and respirations as well as observation of mild to severe agitation may reflect an anxiety state.

Knowledge dispels unreasonable fears and helps patient to prepare to cope with stressors.

Evaluation

Are the patient's vital signs within normal range for the patient? Is verbal and nonverbal behavior consistent with an anxiety state?

Does patient express satisfaction with amount and type of information?

Does patient evidence adequate understanding of the procedure as well as understanding of what to expect afterward?

Nursing Diagnosis: Risk for ineffective breathing pattern related to pain with chest movement

Expected Outcomes Effective breathing pattern with clearance of mucus from air passages

Evaluation of Outcomes (1) Are respirations regular, easy, and unlabored? (2) Is respiratory rate and oxygen saturation within a normal range for the patient? (3) Are lung sounds clear?

Interventions

Assess patient's vital signs, oxygen saturation, pain level, and lung sounds.

Medicate to relieve pain as necessary.

Encourage deep breathing and coughing each hour.

Encourage use of an incentive spirometer each hour when awake.

Rationale

A change in vital signs, a decrease in oxygen saturation, an unacceptable pain level as defined by the patient, and unclear lung sounds may reflect an ineffective breathing pattern related to pain.

Pain may inhibit deep breathing efforts.

This helps to loosen secretions and to prevent atelectasis, pneumonia, and inadequate oxygenation of tissues.

To encourage deep breathing

Evaluation

Are the patient's vital signs and oxygen saturation within normal range for the patient?

Does patient report pain at an acceptable level?

Are lung sounds clear?

Does patient evidence pain or guarding during chest movement?

Does chest sound clear?

Are skin color and oxygen saturation adequate?

Does patient use spirometer correctly?

Nursing Diagnosis: Risk for ineffective tissue perfusion and integrity related to damage to blood and lymph vessels and tension at surgical incision site

Expected Outcomes Incision will heal by primary intention without excessive bleeding or swelling.

Evaluation of Outcomes Are vital signs within normal range for the patient?
Is dressing dry and intact?

Are edges of the incision well approximated, with scant bleeding/serous drainage, and mild edema/erythema?
Is range of motion appropriate to post-operative time period?

Interventions

Monitor vital signs, oxygen saturation, and peripheral vascular status according to hospital policy and as necessary.

Avoid use of the affected arm for blood pressure, venipunctures, and injections.

Check for bleeding, amount and color of drainage if a drain device is used, and swelling.

Measure circumference of arms daily and compare.

Elevate affected arm if swelling occurs.

Place items where patient may easily reach them.

Encourage reasonable exercise of the affected arm following post-mastectomy exercises that are approved by the institution.

Provide education for the patient related to post-operative self-care and signs and symptoms of ineffective healing.

Rationale

Vital signs, oxygen saturation, and peripheral vascular signs reflect circulatory status.

Restrictive and invasive procedures might further compromise tissue integrity of the affected arm.

Excessive bleeding and swelling may further compromise tissue perfusion.

Swelling causes an increase in circumference.

Gravity aids fluid return to the heart.

Excessive movement of the arm may exert tension on incision and increase bleeding.

Reasonable exercise promotes circulation, preserves muscle and joint function, and increases self-care ability.

Early assessment and intervention help prevent the development of serious complications.

Evaluation

Are vital signs stable and within normal range?
Is dressing dry?

Is arm protected?

Does incisional area look swollen, smooth, or shiny? Are drainage amount and color appropriate?
Is affected arm larger than unaffected arm?
Does elevation prevent swelling?

Can patient reach items without abducting the arm over 90 degrees?
Is patient moving the arm appropriately and gradually increasing range of motion and self-care ability?

Does patient demonstrate and verbalize understanding related to appropriate post-operative self-care?

Nursing Diagnosis: Risk for ineffective coping related to cancer threat and body image disturbance

Expected Outcomes Patient verbalizes ability to cope; seeks help and support appropriately.

Evaluation of Outcomes (1) Does patient take interest in care of condition? (2) Does patient ask appropriate questions related to care and verbalize appropriate concerns?

Interventions

Maintain an open and trusting therapeutic relationship.

Allow grieving to take place.

Encourage patient to express feelings and concerns.

Encourage active problem solving.

Help patient remember previous successes in coping and strategies used.

Refer to appropriate agencies for further support as needed (e.g., American Cancer Society, Reach for Recovery, local support groups,

Rationale

Effective communication is based on trust.

Loss of a breast disturbs many aspects of body image, and cancer threatens one's sense of security and reasonableness of life.

Active problem solving promotes self-efficacy and combats depression.

Memory of prior success can encourage hope for future success.

Social support can assist individuals to meet their needs while developing effective coping skills and strategies.

Evaluation

Is patient talking about concerns?

Is patient willing able to talk about loss?

How are family members interacting with patient?
How is patient responding to family members and friends?
Is patient planning for the future?
Is patient taking an active interest in her personal appearance?
Does patient have sufficient coping skills or supports available to promote healthy living?

Breast Modification Surgeries

Mammoplasty is surgical modification of the breast. This may be done to restore a normal shape after removal of cancerous tissues. Many women, however, undergo mammoplasty electively to reduce or increase the size or to improve the shape of their breasts. Because nurses are very aware of the dangers involved with surgery, psychosocial issues may seem to be a trivial reason to voluntarily assume such risks to life and health. However, body image is an important component of quality of life. Patients' informed decisions should be respected if they choose this surgery. It is essential that you present a caring and nonjudgmental attitude.

Breast Reduction and Mastopexy

Generally, in breast reduction operations the nipple is separated from the surrounding tissue except for a small section with the blood vessels and nerves that supply it (Fig. 42.1). A large wedge of tissue is removed from the bottom of the breast, the edges are sewn together, and the nipple is reimplanted in a higher position. This not only decreases the overall size of the breast, which may help with back, neck,

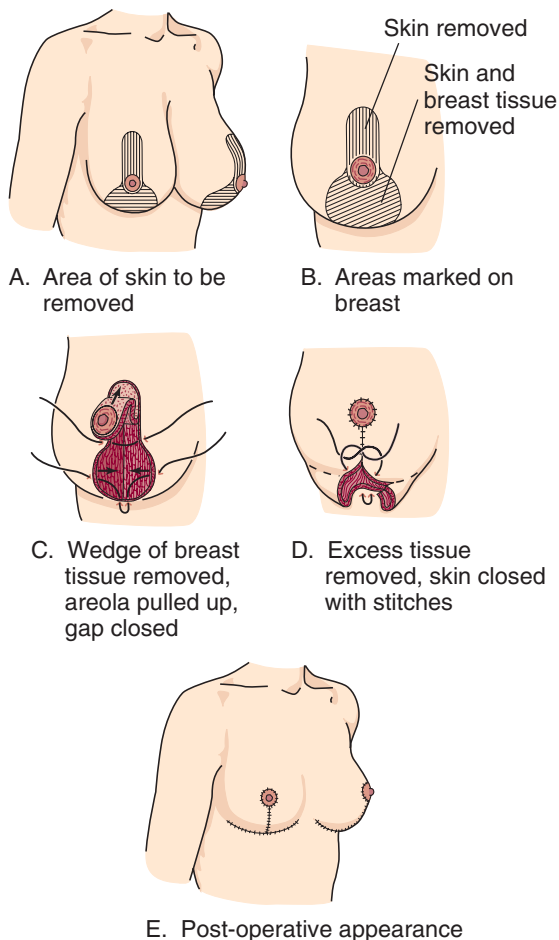

FIGURE 42.1 Breast reduction. (Modified from Love, SM: Dr. Susan Love's Breast Book, ed. 3. Perseus Publishing, Cambridge, MA, 2000; used with permission.)

mammoplasty: mamm(o)—breast + plasty—to mold

and head pain, it also corrects excessive sagging—a common problem for women with large breasts.

A **mastopexy** involves the removal of some skin and fat with subsequent resuturing so that the breast tissues are held higher on the chest to correct sagging breasts. This procedure usually does not remove as much tissue as a breast reduction.

Augmentation and Reconstruction Mammoplasty

Augmentation is a surgery to increase the size of the breasts. An implant—either a bag containing saline solution or silicone gel or a transplanted portion of the patient's own body tissues from another area—is inserted through an incision and positioned either under or over the pectoral muscles (Fig. 42.2).

For reconstructive mammoplasty, use of the patient's own tissues is generally safer than use of artificial implants because no foreign material is introduced into the body. For situations in which significant amounts of tissue are needed for reconstruction, a portion of tissue may be moved from one area of the body to another as a **pedicle** graft. Pedicle literally means “little foot” because the graft remains attached to a stalk (containing the blood vessels and nerves) somewhat resembling a little leg with a foot (the graft) attached. Figure 42.3 shows two options for mastectomy graft repair—using the latissimus dorsi muscle and overlying tissue on the side of the chest or using the rectus abdominis muscle of the abdomen with its overlying tissue. For both these procedures, a portion of muscle is separated from its usual attachment. Tissues overlying a part of the muscle are excised and left attached to the muscle. This segment of

FIGURE 42.2 Breast implants. (A) Implant over muscle. (B) Implant under muscle. (Modified from Love, SM: Dr. Susan Love's Breast Book, ed. 3. Perseus Publishing, Cambridge, MA, 2000; used with permission.)

pedicle: ped—foot + icle—little

FIGURE 42.3 Mastectomy reconstruction. (Modified from Love, SM: *Dr. Susan Love's Breast Book*, ed. 3. Perseus Publishing, Cambridge, MA, 2000; used with permission.)

tissue is then pulled under the skin and superficial layers to an incision at the mastectomy site. There it is brought to the surface and attached to reconstruct a breast shape. Tissue from the buttock area or the abdomen may also be grafted onto a mastectomy site without a pedicle.

Complications

Any of these surgeries may be complicated by infection or impaired healing. The use of silicone implants has been less than satisfactory for many women. Some women have experienced hardening of breast tissues and others have developed serious autoimmune disease problems after receiving silicone gel implants. Although actual etiologies of all the problems are uncertain, many surgeries have been undertaken recently to remove silicone implants, and saline implants are now used more often.

Nursing Care and Teaching

Carefully assess the healing process when changing dressings and explain to the patient how to assess healing, as not all tissues successfully attach at the new site. Failure of attachment can require surgical revision. Signs of poor attachment include unnatural color of the incision, graft, or surrounding tissues; swelling; drainage; gaping of incision

Box 42.2

Breast Disorders Summary

Signs and Symptoms

Swelling, tenderness, pain, redness
Palpable lumps
Leakage of fluid/blood from nipple
Changes in contour of skin of breast/nipple

Diagnostic Tests and Findings

BSE/CBE
Culture and sensitivity
Mammography/ultrasound
Excisional/fine-needle biopsy

Therapeutic Interventions

NSAIDs
Caffeine avoidance
Hormone therapy
Anti-infectives if infection present
Incision and drainage if abscessed area
Lumpectomy/mastectomy/breast reconstruction
Chemotherapy/radiation
Biological response modifiers

Complications

Hormone therapy may cause menopausal symptoms.
Breast surgery may have profound negative effect on patient's self-concept.

Priority Nursing Diagnoses

Acute pain r/t distention of the breast
Fear r/t diagnosis of breast lesion and possible cancer
Deficient knowledge r/t health status and treatment

BSE = breast self-examination; CBE = clinical breast examination; NSAIDs = nonsteroidal anti-inflammatory drugs; r/t = related to.

lines; and sloughing of the graft or edges of the site. See Box 42.2 for a Breast Disorders Summary.

MENSTRUAL DISORDERS

Flow and Cycle Disorders

Pathophysiology, Etiologies, and Signs and Symptoms

There are many types of menstrual abnormalities (Table 42.1). Causes can include stress, pregnancy, hormonal imbalances, metabolic imbalances (such as obesity, anorexia nervosa, and loss of too much body fat through excessive exercise), tumors (both benign and malignant), infections, organ diseases (such as liver, kidney, or thyroid disease), blood or bone marrow abnormalities, and the presence of foreign bodies in the uterus (such as intrauterine devices).

TABLE 42.1 MENSTRUAL FLOW DISORDERS

Disorder	Description
<i>Amenorrhea</i>	Menses absent for more than 6 months or three of previous cycles Called primary amenorrhea when menarche has not occurred by age 17 Called secondary amenorrhea when menses are absent after menarche
<i>Oligomenorrhea</i>	Menstrual cycles of more than 35 days
<i>Hypomenorrhea</i>	Less than the expected amount of menstrual bleeding
<i>Menorrhagia</i>	Passing more than 80 mL of blood per menses
<i>Hypermenorrhea</i>	Menses lasting longer than 7 days
<i>Polymenorrhea (also called Metrorrhagia)</i>	Menses more frequently than 21-day intervals
<i>Menometrorrhagia (also called Metro-menorrhagia)</i>	Overly long, heavy, and irregular menses

Menstrual abnormalities can be distressing and can result in anemia, persistent fatigue, and sexual dysfunction. Establishment of a comfortable and open professional relationship is essential for communication about such concerns.

Diagnostic Tests

Appropriate testing to determine the cause of menstrual abnormalities can involve a thorough medical history and physical examination. Papanicolaou (Pap) smear, cervical and vaginal cultures, laparoscopy, ultrasound, pregnancy testing, urine testing, and extensive blood testing may be done to screen for any of the disorders that may influence the menstrual cycle and flow. Generally, health-care providers initially test to rule out the most likely causes and then begin to test for more obscure disorders until the cause of the disorder is identified. For example, reproductive hormone levels are likely to be tested before kidney or liver function, unless the latter disorders are evident in the initial history and physical examination.

Therapeutic Interventions

Medical treatment of menstrual disorders generally involves manipulation of hormone levels. Surgical treatment of menstrual disorders can involve **dilation and curettage** (D&C), **laser ablation** of endometrial tissue, and **hysterectomy**. During D&C the cervix is first dilated (opened wider) and then a curet—a sharp, spoonlike instrument—is inserted through the cervix and used to scoop out the inner lining of the uterus. Laser ablation involves targeted burning of

dilation and curettage: dilat(e)—to widen + ation—the process of + curet—scoop + tage—doing

laser ablation: laser—light amplification by stimulated emission of radiation + ab—away + lat—to carry + ion—the process

hysterectomy: hyster—womb + ec—away + tomy—cutting

endometrial tissue so that scar tissue that does not bleed forms. Hysterectomy (removal of the uterus), a last-resort treatment, is described later in this chapter.

Nursing Care and Teaching

Estimation of the amount of blood lost during menses may be difficult because pad counts can vary widely depending on the frequency of pad changes and the portion of the pad that contains blood. The only accurate way to estimate menstrual flow is by weighing the pads (sealed in a biohazard bag) and then subtracting the weight of the original pads. A 1-g increase in pad weight equals approximately 1 mL of blood loss. You can document what the patient says for blood loss, but be sure to quote it and in parentheses place “patient estimate” after the quote.

Dysmenorrhea

Pathophysiology, Etiologies, and Signs and Symptoms

Painful menstruation, or **dysmenorrhea**, is a common problem in women, although few find it to be incapacitating. Primary dysmenorrhea is not pathological and is thought to be caused mainly by the action of endogenous prostaglandins, which stimulate uterine contractions producing cramping pain. Secondary dysmenorrhea occurs after normal menses, without discomfort, and may be caused by some pathological condition such as endometriosis, pelvic infection, **retroversion** of the uterus, fibroid tumors, or reproductive disorders caused by other body system pathology.

Diagnostic Tests

Hormonal tests such as estrogen and progesterone levels may be required for primary dysmenorrhea, but laparoscopic examination, biopsies, cultures, and various other reproductive function tests (explained later in the chapter) may be required for investigation of secondary dysmenorrhea.

Therapeutic Interventions

Primary dysmenorrhea may be treated with drugs that inhibit prostaglandin synthesis, such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Correction of secondary causes of dysmenorrhea may include such measures as hormonal adjustment, usually with oral contraceptives or hormone replacement therapy (HRT), dilation and curettage, or other surgical or medical intervention based on the primary cause.

Nursing Care and Teaching

Several nonprescription preparations are available for treatment of dysmenorrhea, but patients should be advised to read the labels carefully because aspirin and NSAIDs (the main component of many of the drugs) may be bought less expensively. Other added drugs in these compounds, such as diuretics, may not be necessary. If dysmenorrhea is related to uterine retroversion, assuming a knee-to-chest position may relieve the discomfort. Sudden development of dys-

dysmenorrhea: dys—painful + men(o)—month + rhea—flow
retroversion: retro—back + version—turning

menorrhagia in a woman with no previous menstrual discomfort should always be investigated.

Premenstrual Syndrome

Pathophysiology, Etiologies, and Signs and Symptoms

Premenstrual syndrome (PMS) is a recurrent problem for many women and may involve water retention; headaches; discomfort of joints, muscles, and breasts; changes in affect, concentration, and coordination; and sensory changes. Few women find PMS serious enough to interfere with work or relationships. The impact of ovarian hormones, aldosterone, and neurotransmitters such as monoamine oxidase and serotonin on PMS is not well understood, and further research is needed.

Therapeutic Interventions

A variety of drugs have been given to combat PMS with varying degrees of success. Some commonly used PMS medications include drugs that affect prostaglandin production, hormonal balance, and neurotransmitter production and reuptake, as well as diuretics and supplements of calcium, magnesium, vitamin E, and vitamin B₆. Patients should be warned, however, that dosages of vitamins should not be increased without professional advice because vitamins are medications (as well as nutrients) and high doses of some vitamins can lead to physiological damage.

Nursing Care and Teaching

Being understanding and nonjudgmental is especially important. Some women who suffer from severe PMS may have been treated as if they are psychologically unbalanced because of the interaction of hormones and neurotransmitters and because of outdated ideas concerning PMS. You can help by providing educational materials on lifestyle measures, such as restriction of alcohol, caffeine, nicotine, salt, and simple sugars; participation in regular exercise; and development of stress management skills that can help women who have a tendency to experience PMS.

Endometriosis

Pathophysiology, Etiologies, and Signs and Symptoms

Endometriosis is a condition in which functioning endometrial tissue is located outside the uterus (Fig. 42.4). Several theories have been proposed to explain development of endometriosis, including faulty developmental differentiation of cells, transport of endometrial cells via blood and lymph to other parts of the body, and **retrograde** menstruation—a backward leakage of blood and tissue out through the fallopian tubes during the menstrual period.

Endometriotic cells grow in areas of sufficient blood supply, extending into other tissues such as intestinal walls, ovaries, and other abdominal structures. On a cyclic basis, mediated by ovarian hormones, these cells build up and slough just as they would in the uterus, but the sloughing

FIGURE 42.4 Possible sites of endometriosis.

and bleeding occur in the enclosed abdominal cavity or into the tissues that they have invaded. The build-up of the blood and cells can result in pain, swelling, damage to abdominal organs and structures, scar tissue development, and infertility.

Therapeutic Interventions

Surgical intervention may be required, especially if scar tissue develops into tight bands, which can cause strangulation of sections of bowel or ureters. Reduction of estrogen and prevention of ovulation either with medications or by surgical removal of the ovaries can be very effective but result in infertility and menopausal symptoms. Analgesics may be required.

Nursing Care and Teaching

The severity and persistence of the pain of endometriosis may lead to overuse of pain medication, so it is important to teach patients alternative pain relief strategies such as relaxation exercises and application of heat to the abdomen or back.

Menopause

Pathophysiology and Signs and Symptoms

Menopause is the permanent cessation of menstrual cycles resulting from decreased hormone production. This is a natural part of aging, but it is placed within this section because several related uncomfortable symptoms and conditions can occur. The climacteric (perimenopause) is the period of gradual decline in hormone production before the permanent end of menses and may last from months to several years. **Perimenopausal** physical symptoms vary widely and may include erratic menses, atrophy of urogenital tissues with a marked decrease in the amount of natural lubrication, a pH shift toward alkalinity (encouraging yeast overgrowth), and vasomotor instability (resulting in hot flashes and night sweats).

Estrogen protects women against several disease processes; the risk of heart disease and osteoporosis increases with declining estrogen production. Mental changes may also occur because of the complex interplay of reproductive hormones and neurotransmitters. It is important to acknowledge mental symptoms such as irritability,

retrograde: retro—backward + grade—step

perimenopausal: peri—around + men(o)—month + pausal—stopping

CRITICAL THINKING

Lola

■ Lola, age 53, has been experiencing menopausal “hot flashes” during the afternoons as she works in her office.

1. What treatments can you suggest to help with her symptoms?
2. If she considers HRT, what information do you need to share with her?

Suggested answers at end of chapter.

anxiety, insomnia, memory problems, and mild depression as a normal, temporary result of hormonal changes, so that perimenopausal women do not doubt their sanity.

Therapeutic Interventions

Hormone replacement therapy (HRT) is a controversial treatment for perimenopausal symptoms. Medications such as conjugated estrogens (Premarin), estradiol, and medroxyprogesterone acetate (Provera) may be prescribed. The National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health conducted a major research project to study the risks and benefits of combined estrogen and progestin therapy for healthy women. However, the project was halted in July 2002, 3 years early, because of very worrisome results. Positive findings with HRT included a one-third reduction in hip fractures, a 24% reduction in total fractures, and a 37% decrease in colorectal cancer. Disturbing findings included a 26% increase in breast cancer, a 41% increase in strokes, a 29% increase in heart attacks, doubling of venous thromboembolism rates, and an overall 22% increase in cardiovascular disease. It is uncertain what to make of these data because there was no differ-

ence in total mortality when comparing women treated with HRT and those given a placebo. Long-term results will continue to be examined, but for now, the risks of HRT have been deemed too great to continue the study.² The NHLBI continues to research these issues. Stay updated on the latest findings at http://www.nhlbi.nih.gov/whi/whi_faq.htm.

Dietary changes with the inclusion of **phytoestrogens**, which are present in foods/herbs such as soy, tofu, flax seeds, black cohosh, and dong quai, may provide the benefits of estrogen replacement without necessitating the inclusion of HRT. Women should discuss food and herb supplements with their primary care providers before using them.

Prevention of osteoporosis begins in early adulthood. Fair-skinned, Caucasian women are at greatest risk for bone loss. Throughout life, adequate intake of calcium and vitamin D (preferably from foods) and regular weight-bearing exercise help to maximize bone mass. At menopause, some women may receive HRT or intensive treatment with bone-building medications to retard bone loss. See Table 42.2 for a summary of medications used for hormonal problems.

Complications

It is important to note that resumption of vaginal bleeding after menstruation has finally ceased can be a sign of endometrial cell disorder caused by either benign changes, such as polyps, or malignant changes of internal reproductive organs. Bleeding that occurs following previous cessation should always be investigated.

Nursing Care and Teaching

Patients who are perimenopausal often ask nurses about how to cope effectively with symptoms. Planning ahead for hot flashes by dressing in clothing that may be removed or applied in layers makes adjustment easier. Not allowing hot flashes to interrupt activities is an important strategy, as is

phytoestrogens: phyto—plant + estrogens—hormones

TABLE 42.2 MEDICATIONS FOR DISORDERS RELATED TO HORMONAL ALTERATIONS (BREAST DISORDERS, MENSTRUAL DISORDERS, MENOPAUSE)

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Oral Contraceptives/ HRT Interfere with gonadotropin-releasing hormone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) release; maintain stable hormonal levels, relax uterus, limit endometrial proliferation, promote vasomotor stability, prevent bone loss	Combination: Progesterone and Estrogen Norethindrone/levonorgestral/medroxyprogesterone and ethinyl estradiol/conjugated estrogens (Ortho-Novum, Alesse, Prempro)	PO	Hypertension, breakthrough bleeding, amenorrhea, headache, increased risk of gallbladder/liver disease and thromboembolic disorders secondary to hypercoagulation, glucose intolerance, decreased breast milk production, depression	Educate patient regarding use and side effects. Include education about the “ACHES” side effects presented later in this chapter, as they may indicate presence of serious, detrimental body system involvement.

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
	Estrogen Only Conjugated estrogens (Premarin)	PO		
	Progesterone Only Norethindrone/ medroxyprogesterone (Micronor, Provera)	PO		
NSAIDs Inhibit prostaglandin synthesis, therefore interrupt pain receptors and produce anti-inflammatory effect	Ibuprofen (Motrin, Nuprin, Advil)	PO	Peptic ulcer or GI perforations, GI bleeding, bleeding tendency, rash, pruritus, liver/renal dysfunction	Avoid with aspirin allergy; administer with milk or food, caution about side effects, use during pregnancy, or using when on anticoagulant therapy.
	Naproxen (Aleve)	PO		
	Ketoprofen (Orudis)	PO		
Antineoplastic Medications Acts as estrogen antagonist to inhibit growth of estrogen-dependent tumors	Tamoxifen citrate (Novo-Tamoxifen)	PO	Vasomotor changes, menstrual changes, increased vaginal discharge, endometrial hyperplasia/polyps, rash, bone pain, retinopathy (with high doses)	Report vaginal bleeding, leg cramps, shortness of breath, weakness. Promote use of non-hormonal contraceptives when using medication.

engaging in satisfying and calming activities that contribute to a sense of serenity. Treatment of vaginal symptoms with a water-soluble moisture restorer or lubricant or with an estrogen cream (following prescription directions) can help. Eating a healthy diet that is light in caffeine, sugar, and alcohol can help women better control their bodies and minds. Looking forward to new challenges rather than toward the past may help to counteract depressive tendencies occurring with hormonal changes. It is important to remind perimenopausal women that they may still be fertile after several months of **amenorrhea**. To prevent conception, they need to continue to practice birth control until they receive confirmation from their primary care provider that menopause is complete.

See Box 42.3 for a summary of menstrual disorders.

IRRITATIONS AND INFLAMMATIONS OF THE VAGINA AND VULVA

Several causative agents can irritate the vulva and the vagina. Signs and symptoms are often similar, but there are some differences in the discharge produced in response to the disorders. See Table 42.3 for common vaginal irritations and inflammations that are not generally sexually transmitted. See Chapter 44 for information on sexually transmitted diseases.

Pathophysiology, Etiologies, and Signs and Symptoms

The normal vaginal environment is a balanced ecosystem with a pH of less than 4.2 as a result of lactic acid and hydrogen peroxide production by cells in the vagina. This acidic pH protects against the growth of many pathogenic microorganisms. A variety of normal resident microorganisms coexist relatively harmoniously unless the ecological balance is destroyed. Candidiasis, bacterial **vaginosis**, and **cytolytic** vaginitis are all instances of overgrowth of normally present, nonpathogenic microorganisms. Trichomoniasis also is included here because it can be transmitted nonsexually (on fomites, such as toilet seats), as well as sexually, and it grows well when the vaginal environment is disturbed.

Several conditions can predispose patients to an overgrowth of resident microbes: poor nutrition (especially diets high in simple sugars), inconsistent control of blood glucose levels in patients with diabetes, stress, pregnancy, marked hormonal fluctuations, pH changes, prolonged overheating of the genital area with little aeration (as happens with sitting still for long periods in overly restrictive clothing), and changes in the balance of vaginal flora types because of antibiotic treatment or douching. Patients who have a compromised immune system may experience frequent overgrowth of resident microbes, and, conversely, vaginal infections can make women more susceptible to

amenorrhea: a—without + men(o)—month + rhea—flow

vaginosis: vagin—vagina + osis—condition

Box 42.3

Menstrual Disorders Summary

Signs and Symptoms	Increase/decrease in menstrual flow Increased pain with menses or generalized abdominal pain Structural change of the internal reproductive organs Fluid retention Headaches Breast pain/lesions/swelling Mood changes
Diagnostic Tests and Findings	Hormone levels Pregnancy test Pap smear Cervical/vaginal cultures Urine testing Ultrasound Laparoscopy Biopsy
Therapeutic Interventions	Medication to stabilize hormone levels NSAIDs D&C, laser ablation, hysterectomy Treatment of underlying causes Vitamin/mineral supplements Diuretics/SSRIs/dietary changes (PMS)
Priority Nursing Diagnoses	Deficient fluid volume r/t increased bleeding Pain r/t cramping Sexual dysfunction r/t menstrual disorders

D&C = dilation and curettage; NSAIDs = nonsteroidal anti-inflammatory drugs; r/t = related to; SSRIs = serotonin reuptake inhibitors.

infection with sexually transmitted diseases, such as gonorrhea and human immunodeficiency virus (HIV). Frequent and persistent yeast infections may be one sign of HIV. Vaginosis (overgrowth) and vaginitis (inflammation) can sometimes produce irritation and inflammation in the male sexual partner as well and may lead to urethritis, **balanitis**, excoriation, and sores on the penis. A variety of anti-infective medications are used for these disorders (Table 42.4). If the male partner is not also treated, he may reactivate the problem for the woman. Therefore, several types of medication come in “partner packs” for both partners to use.

balanitis: balan—acorn (shape of glans penis) + itis—
inflammation

Nursing Care and Teaching of the Patient Undergoing Diagnostic Testing

The patient may feel embarrassed to speak about what is bothering her. A safe question to begin with for most patients is, “Hello. What can I write on your chart as the reason for your visit today?” If embarrassment is evident, a comment that you need to know a bit about what materials to put out for examination purposes often defuses an uncomfortable situation. As you set up materials for a pelvic examination, swabs, and cultures, you can explain that some information is needed to determine how to treat the problem. (See Chapter 41.) Often this is a good time to ask about the discharge and other signs and symptoms using the WHAT’S UP? format. (See Chapter 1.) Allow the patient privacy while she changes into a gown. Return to the room if requested as a chaperone, assistant, and support for the woman. NOTE: If any wet mount slides are made, these must be taken to the laboratory immediately while still wet. Use standard precautions to transport samples. Although swabs may be taken for culture, the health-care provider may prescribe medication before the results of the swabs return because such irritations are so uncomfortable.

SAFETY TIP

Use at least two patient identifiers (neither to be the patient’s location) whenever collecting laboratory samples or administering medications or blood products, and use two identifiers to label sample collection containers in the presence of the patient (2006 National Patient Safety Goals from www.JCAHO.org).

Nursing Care and Teaching of the Patient Undergoing Treatment

Vaginal inflammations and infections may require oral medication or local application of medication either in cream, suppository, or medicated douche form. Depending on the practice standards in the area, the nurse may apply this for patients who are unable to do this for themselves or may teach patients to self-administer. Anatomically, the vagina slopes back toward the sacrum for approximately the length of an adult finger (although it can stretch longer). Application is easiest when the patient is lying down ready to sleep because vaginal medications tend to run out when the patient stands or sits. Medicated douches may be administered with the patient sitting on a bedpan with the bed in semi-Fowler’s position or, if self-administered, while sitting on a toilet. Most vaginal medications come with an applicator that either injects a dose of creamy medication or pushes a firmer, shaped dose of medication off the end of the tube when the plunger is depressed. Consult instructions supplied with the medication. Patients should be instructed to use all the medication as prescribed and to wear an absorbent pad to prevent possible staining of clothing.

TABLE 42.3 COMMON VAGINAL IRRITATIONS AND INFLAMMATIONS

Disorder and Etiology	Signs and Symptoms	Discharge/ Examination	Diagnostic Tests	Usual Treatment
Candidiasis: <i>Candida albicans</i> , <i>glabrata</i> , or <i>tropicalis</i> overgrowth	Burning, itching, redness of vulva; burning on urination	White, cottage cheese appearance	Wet mount slides (yeasts look like tiny, budding tree branches); may be cultured	Antifungals (drugs mostly ending in <i>-azole</i>)
Bacterial vaginosis: <i>Gardnerella vaginalis</i> , <i>Mycoplasma</i> , or anaerobe overgrowth	None or vulvar or vaginal irritation	White or gray, homogeneous, foul-smelling discharge; pH higher than 4.5	Wet mount slides show “clue cells” or release fishy odor when potassium hydroxide is applied	Drugs such as metronidazole or clindamycin
Trichomoniasis: <i>Trichomonas vaginalis</i> (may be transmitted by inanimate objects or sexually)	Itching, irritation, foul odor, redness, dysuria	Discharge may be frothy; pH higher than 4.5; “strawberry cervix” resulting from petechiae	Wet mount slides treated with normal saline show motile cells with flagella (like tiny whips); may also be cultured	Metronidazole, 2-g single dose
Cytolytic vaginosis: Lactobacilli overgrowth, stress, some medications	Burning, irritation, pain with intercourse	Nonodorous, thick, white, pasty, or dry and flaking	Lower than normal pH as tested with pH indicator tape (or litmus strip); may be cultured	Depends on cause; alkaline douches may be prescribed
Contact vulvo vaginitis: contact with allergens or irritating chemicals such as contraceptive creams or bubble baths	Itching, burning, redness	Generally no change from normal discharge, though may be increased	History and physical information, recent contact with chemicals	Avoidance of the offending substance; warm sitz baths or application of hydrocortisone cream
Atrophic vaginitis: estrogen levels too low to support estrogen-sensitive vaginal tissues	Vulvovaginal irritation, less lubrication, dyspareunia, increased tendency for resident microbe overgrowth	May have little or increased discharge; discharge may be watery, yellow, or green; may be blood-tinged	Maturation index may be determined during Pap test to identify atrophic cellular changes, but diagnosis is usually by history and physical information only	HRT (oral, patch, or vulvovaginal cream) or water-soluble lubricant replacing vaginal lubricants

TABLE 42.4 MEDICATIONS FOR IRRITATIONS AND INFLAMMATIONS OF THE VAGINA AND VULVA

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antibiotics Inhibit bacterial protein synthesis	Clindamycin (Cleocin)	Intravaginal	Candidiasis, pruritus, rash, hypersensitivity, abdominal pain Overgrowth of other infectious organisms	Education on correct use; use as directed even if symptoms cease. Report change in symptoms.
Antifungals Believed to bind to sterol in fungal cell membrane, thereby altering cell permeability	Fluconazole (Diflucan) Miconazole (Monistat) Terconazole (Terazol) Clotrimazole (Gyne-Lotrimin)	PO Topical to external genitalia; intravaginal	Pruritus, rash, hypersensitivity, abdominal pain	Education on correct use; use as directed even if symptoms cease. Report side effects.
Antiprotozoal Enters cells of microorganisms that contain nitroreductase, interferes with DNA synthesis and causes cell death	Metronidazole (Flagyl)	PO	Dizziness, weakness, insomnia, abdominal cramping, anorexia, nausea/diarrhea/emetesis, vaginal dryness, overgrowth of other infectious organisms	Teach patient to avoid alcohol use while on medication and for 48 hours after completion. Use medication as directed, even if symptoms cease. Take with meals. Treat partner.

TOXIC SHOCK SYNDROME

Pathophysiology, Etiologies, and Signs and Symptoms

Toxic shock syndrome (TSS), first identified in 1978, is primarily associated with superabsorbent tampon use during menstruation but can also occur with use of nasal packings, or in other individuals with no specific risk factors. It is a severe systemic infection with strains of *Staphylococcus aureus*, which produce an epidermal toxin. The effect of the toxin on the liver, kidneys, and circulatory system makes this a life-threatening condition. A streptococcal infection can cause a similar syndrome.

Individuals with TSS may experience a sudden high fever with sore throat, headache, dizziness, confusion, redness of the palms and soles of the feet, skin rashes, blisters, and petechiae followed by peeling of the skin. Muscle weakness, muscle pain, and gastrointestinal upset also have been reported. Signs and symptoms such as these should be reported to the health-care provider immediately.

Prevention

Tampon makers have removed the highly absorbent fibers that were most often associated with the syndrome from their product lines, and TSS is now rare. Women can also reduce their risk of developing TSS by substituting sanitary pads for tampons at least part of the time (nighttime use may work well); changing tampons every 4 hours; washing hands carefully before inserting anything into the vagina; not leaving female barrier contraceptives in place for longer than needed; and not using tampons or female barrier contraceptives in the first 12 weeks after giving birth.

Nursing Care and Teaching

All menstruating women should be taught measures to prevent TSS. They should also be taught to recognize symptoms of TSS because early identification and treatment can save lives.

DISORDERS RELATED TO THE DEVELOPMENT OF THE GENITAL ORGANS

Pathophysiology, Etiologies, and Signs and Symptoms

Several types of congenital malformations of the reproductive organs may affect the health of female patients. Genetic or environmental factors during pregnancy may cause these, and they may require medical or surgical treatment at some point in life. **Agenesis** of structures means that they never

developed. **Hypoplasia** of reproductive tract portions means that they are underdeveloped. **Imperforate** means that expected openings do not exist. Blind pouches exist where cavities should meet but do not. The uterus can form in several different configurations, including a double uterus.

Many malformations are discovered during childhood or early adolescence, but some are identified when patients seek medical help because of dysmenorrhea, **dyspareunia** (pain with intercourse), infertility, repeated spontaneous abortions (miscarriages), or preterm labor when pregnant.

Diagnostic Tests

Procedures such as ultrasonography, hysterosalpingography, computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic examinations may be used to determine the type and extent of developmental defects.

Therapeutic Interventions

Some defects can be repaired surgically, but others cannot. Depending on the type and location of the defect, surgeries may be done by endoscopy or by surgical incision. Absence of hormone-producing tissue may be overcome by hormone supplements.

Nursing Care and Teaching

Patients who have these problems may struggle with self-esteem issues, such as feeling that they are somehow incomplete or have been cheated of something they desire. You can show that you are willing to listen if and when the patient wishes to talk while allowing her as much privacy as she desires.

Displacement Disorders

Pathophysiology, Etiologies, and Signs and Symptoms

The pelvic organs are suspended within the pelvis by ligaments and supported by muscles and fascia. The pubococcygeal muscle runs from the pubis to the coccyx and supplies support from below. Pregnancies (especially those producing large babies) and rapid or traumatic deliveries may result in stretching and injury of the supporting structures, which can cause displacement of the uterus, vagina, bladder, or bowel from its normal position. The observation that some children have defective muscular support of the pelvic organs and that prolapse is more prevalent in some families seems to suggest that congenital defects and genetic inheritance may also influence displacement disorders even without pregnancy. Scarring from sexually transmitted diseases also may cause some displacement of the pelvic organs. Aging generally increases the problem because the effects of gravity over time contribute to stretching, and lower estrogen levels weaken estrogen-dependent supportive tissues. Chronic

hypoplasia: hypo—little + plasia—shape (or form)

imperforate: im—not + perforate—pierced

dyspareunia: dys—painful or abnormal + pareunia—mating

agenesis: a—without + genesis—production

constipation, obesity, and lack of exercise also worsen these problems.

Therapeutic Interventions

A pessary is a supportive (usually ring-shaped) device that is placed in the proximal end of the vagina to help support the pelvic organs. These are usually removed daily at bedtime for cleaning, but some types are designed to remain in the vagina for months at a time. When pessary use is begun, it is important that the woman return to the physician for a recheck after an initial period of use to determine whether the pessary is causing pressure damage to tissues. Because the pessary is a foreign object in the vagina, increased vaginal discharge may be expected. Discharge should not be pink, bloody, or purulent.

Nursing Care and Teaching

Teach patients to eat a healthy diet to avoid obesity and constipation and how to do Kegel exercises to keep the pubococcygeal muscle strong to support the organs in the pelvic cavity. There are several variations of such exercises. The important idea is that the appropriate muscles are exercised adequately to strengthen and build up the ability to control muscle contractions.

1. To find the pubococcygeal muscle, tighten while urinating so that the flow of urine stops.
2. Squeeze the muscle that stopped urinary flow tightly, holding for 10 seconds, and totally relaxing the muscle afterward. Repeat 15 times per day.
3. Practice controlling the muscle by contracting and relaxing it to move the pelvic floor upward and downward very slowly. Thinking of an elevator helps some women. Repeat this 15 times per day.

NURSING CARE TIP

Teach patients to do Kegel exercises while waiting in lines to use otherwise wasted time to promote their health. Another suggestion is to plan specific times of day or activities that would include Kegel exercises, such as while in a car or working at a computer.

These exercises can be done anywhere and are not apparent to anyone watching.

Cystocele

Pathophysiology, Etiologies, and Signs and Symptoms

Cystocele occurs when the bladder sags into the vaginal space because of inadequate support (Fig. 42.5). A feeling of pelvic pressure and stress incontinence are common with this condition.

Therapeutic Interventions

Kegel exercises or the use of a pessary may help. If these measures are ineffective, anterior **colporrhaphy**, which is a surgical repair of the anterior portion of the vagina, may be necessary to correct this problem. Another possible surgical treatment involves resuspending the bladder.

cystocele: cysto—bag (bladder) + cele—hernia

colporrhaphy: colpo—vagina + rrhaphy—suture

FIGURE 42.5 (A) Cystocele. (B) Rectocele.

Rectocele

Pathophysiology, Etiologies, and Signs and Symptoms

Rectocele occurs when a portion of the rectum sags into the vagina because of inadequate support (see Fig. 42.5). A feeling of pelvic pressure, as well as fecal incontinence, constipation, and hemorrhoids, may result.

Therapeutic Interventions

Kegel exercises may help strengthen the supporting muscles. The patient should maintain bowel regularity with a high-fiber diet to avoid further discomfort and sagging from bowel overdistention. Posterior colporrhaphy may be necessary to correct this problem.

Uterine Position Disorders

Pathophysiology, Etiologies, and Signs and Symptoms

The most common variations in position of the uterus are **anteversion**, **anteflexion**, **retroversion**, and **retroflexion** (Fig. 42.6). In anteversion, the uterus lies too far forward, and in retroversion, it lies too far backward. In anteflexion,

the upper portion of the uterus bends forward, and in retroflexion, it bends backward.

Symptoms that may result from these uterine displacements include painful menstruation and intercourse, infertility, and repeated spontaneous abortion.

Therapeutic Interventions

A pessary may correct some positional problems. If infertility or recurrent spontaneous abortion is involved or the condition is very painful, surgery to correct the condition may be undertaken.

Uterine Prolapse

Pathophysiology, Etiologies, and Signs and Symptoms

Uterine prolapse occurs when the uterus sags into the vagina (Fig. 42.7). The amount of sagging can vary and may increase over time as a result of the effects of gravity, poor pelvic support, and excessive lifting or straining. In first-degree prolapse, less than half the uterus sags into the vagina. In second-degree prolapse, the entire uterus sags into the vagina. In third-degree prolapse, the uterus sags outside the body.

Uterine prolapse can be very uncomfortable, resulting in back pain, pelvic pain, pain with intercourse (or inability to have intercourse), urinary incontinence, constipation, and the development of hemorrhoids. The pressure on the uterus also may compromise circulation, resulting in tissue necrosis. Vaginal vault prolapse may also occur in

rectocele: recto—rectum + cele—hernia
anteversion: ante—front + version—turning
anteflexion: ante—front + flexion—bending
retroflexion: retro—back + flexion—bending

FIGURE 42.6 Uterine positions. (A) Anteversion. (B) Anteflexion. (C) Retroversion. (D) Retroflexion.

FIGURE 42.7 Uterine prolapse. (A) Normal uterus. (B) First-degree prolapse: Descent within the vagina. (C) Second-degree prolapse. (D) Third-degree prolapse: The vagina is completely everted.

women who have had a hysterectomy, so that the vagina turns inside out and sags downward with similar signs and symptoms. This condition generally requires surgical resuspension.

Therapeutic Interventions

Some of the more minor uterine displacements may be treated with use of a pessary. Kegel exercises may be more effective in prevention of uterine prolapse than in treatment because, once the tissues become stretched sufficiently for the uterus to sag into the vagina, the continued weight of the uterus prevents adequate contraction of the muscles. Surgery may be done to correct this problem. Although the uterus may be resuspended by shortening the muscles and fascia, hysterectomy is the more common treatment unless further childbearing is desired.

See Box 42.4 for a summary of structural disorders.

FERTILITY DISORDERS

Infertility is a complicated problem that must be considered according to the causative factors. Some couples with infertility may have multiple reproductive problems. Both male and female partners should be examined. (See Chapter 43 for greater detail on male reproductive system disorders.) Often the woman sees the health-care provider first and may be given a specimen container and advised to give the container to her partner for provision of a semen sample for

analysis. See Table 42.5 for a summary of fertility disorders and diagnostic tests.

Nursing Care and Teaching of the Patient Undergoing Fertility Testing

An understanding attitude is very important because infertility can be a cause of low self-esteem, as well as relationship problems. Patients who have been undergoing diagnostic testing or treatment for infertility can become very discouraged with the process and the expense, especially if it has been ineffective. Having to plan your sexual activity around a health-care provider's directions can compromise feelings of spontaneity, enjoyment, and privacy. Extensive questioning by nurses can aggravate the situation, but avoiding conversation may convey a lack of caring. A friendly, "Which test shall I help you get ready for today?" may well be enough to get the needed information. Many women undergoing infertility testing are very well informed about the test they will be having and can tell you so that you know which equipment to set out.

On the first infertility investigation visit, the nurse may teach or give a handout to the patient about keeping a precise record of her oral temperatures with a basal thermometer each morning on awakening, before any other activity. The first day of her menses is day 1 on the temperature chart. Changing levels of hormones result in slight temperature changes, which can be used to identify when ovulation seems to be occurring and when particular hormone levels

Box 42.4**Structural Disorders of the Genital Organs Summary**

Signs and Symptoms	Pain with menses or sexual intercourse Infertility Spontaneous abortion or preterm labor Prolapse of uterus, bladder, or rectum into vagina or outside of body
Diagnostic Tests and Findings	Physical examination Ultrasound Hysterosalpingography CT or MRI scan Endoscopy
Therapeutic Interventions	Kegel exercises Surgery Hormone supplements
Priority Nursing Diagnoses	Acute/chronic pain r/t structural abnormality/surgery Urinary incontinence or constipation r/t structural abnormalities Sexual dysfunction r/t disturbance in self-concept Grief r/t absence/loss of reproductive status

CT = computed tomography; MRI = magnetic resonance imaging.

should be tested. Because many factors may influence temperature and cycles, explain that it may take a few months of recording to clearly identify her own pattern.

You may assist with office procedures such as endometrial biopsy, which may be done during a pelvic examination 2 or 3 days before menses is expected. A pregnancy test should be done before this procedure to avoid interfering with a pregnancy. Consult your procedure manual, laboratory manual, or health-care provider for what materials to set up. The woman may receive pain medication and paracervical block anesthesia for the procedure. Assess pulse and blood pressure. A vasovagal reaction treatment kit containing epinephrine (or atropine, according to the health-care provider's choice), a tourniquet, and a syringe should be kept handy for injection if a vasovagal reflex occurs during the procedure. Vasovagal reflex is a reflex stimulation of the vagal nerve that can happen when the cervix, larynx, or trachea is manipulated and results in slowing of the heart rate and decreased cardiac output, so that the blood pressure drops markedly.

Therapeutic Interventions

Treatment of infertility is designed to ensure that an adequate amount of sperm and an ovum can be in close proximity in the most conducive environment for fertilization.

Removal of barriers such as scar tissue may require surgery. Depending on the results of blood tests and the **postcoital** test (described in Table 42.5), adjustments of environmental factors may involve such actions as sperm washing to avoid destructive antigen-antibody responses, changing the pH of the seminal fluid to encourage sperm motility, treating the female partner to prevent substances in her genital tract fluids from disabling the sperm, or adjusting her hormone levels. The number of sperm or ova available may be increased through use of such fertility drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and change periodically as a result of ongoing research. In-depth coverage of these treatments is beyond the scope of this book.

Various methods may be used to bring the gametes into close proximity. If the problem involves inability to get the sperm close enough to the ovum (as may happen with ejaculatory problems), the physician may place a semen sample from the male partner closer to the ovum via a small catheter. **In vitro fertilization (IVF)** involves bringing ova and sperm together outside the bodies of the participants. Ova may be harvested using a long needle or an endoscope after hormonal preparation of the woman. Sperm may be obtained through masturbation; intercourse with a nonlubricated, nonspermicidal condom; or electrical stimulation of ejaculation for patients with spinal cord injuries.

For those whose sperm is unable to successfully penetrate the ovum, procedures involving gamete micromanipulation may be done. Under a microscope, an ovum from the female partner is partially opened by removing a portion of the outer covering to facilitate sperm penetration, or sperm may be injected into the ovum. This fertilized ovum is then reinserted into the woman's body.

When measures to improve the chances of conception using the partners' own gametes are unsuccessful, gametes from donors may be utilized. Artificial insemination by injecting another man's sperm into the genital tract of the female patient is the simplest of the donor procedures. Ova also may be harvested from a donor woman and used for in vitro fertilization using the male partner's sperm if possible. Both these procedures allow for genetic inheritance from one member of the couple. If genetic inheritance is not possible or desirable (as with familial disease carriers), both donor sperm and ova may be used for in vitro fertilization to be transferred into the female patient. Surrogacy is a situation in which an embryo from one couple is placed into a "host" mother for growth of a baby for the couple, and is a topic of much ethical debate.

Nursing Care and Teaching of the Patient Undergoing Treatment

Patients who are undergoing infertility treatment may experience many upsetting and distressing feelings. Feelings of inadequacy, frustration, depression, and anger are common.

postcoital: post—after + coital—pertaining to intercourse

in vitro fertilization: in—inside + vitro—glass + fertiliz—fruitful + ation—process

TABLE 42.5 FERTILITY DISORDERS

Disorder	Pathophysiology/Etiology	Diagnostic Tests
Male	Possible anatomic abnormalities, hormonal factors, genetic defects, inflammatory conditions, immune system disorders, difficulties with sexual function or technique, psychological factors, or exogenous influences such as drug use, radiation or chemical exposure, trauma, and excessive testicular temperatures (as may occur with prolonged hot tub use or too-tight clothing)	Semen analysis of number, condition, and movement of the sperm and composition of seminal fluid using various tests
Female: Ovulation	Possible anatomic and physiological abnormalities of ovaries; hormonal balance problems related to hypothalamus, thyroid, or adrenal glands; or polycystic ovary syndrome	Basal body temperature charting, midluteal serum progesterone blood levels, luteinizing hormone levels, blood or urine testing, ultrasound monitoring of a follicle for evidence of release of ovum, endometrial biopsy, observation of male hair distribution, and other hormone testing as indicated
Tubal	Possible obstruction of the fallopian tubes resulting from anatomic variations, scarring, or adhesions; prior surgeries; and inflammatory processes involving other abdominal tissues	Hysterosalpingography (described in Chapter 41), laparoscopy
Uterine	Possible abnormalities in shape or blockages within the uterus (rare cause of infertility but a potential cause of pregnancy loss before maturity), menstrual disorders involving the endometrium	Hysteroscopy (described in Chapter 41), removal of tissue samples using curet or endoscope
Other Sources of Infertility	Possible reproductive environmental factors such as destructive antigen-antibody responses, inappropriate pH of seminal fluid for maximal sperm motility, or substances in female partner's genital tract fluids that disable sperm	Postcoital test: couple is advised to have intercourse when luteinizing hormone and estrogen levels are high, then a specimen of cervical mucus is taken from the woman 2–12 hours later for analysis of reproductive environment

If the infertility was caused by something the patient perceives as avoidable, such as sexually transmitted disease, guilt feelings may add to the psychological discomfort. Any or all of the previously described tests may be completed and some repeated many times without success in identification of underlying etiology for infertility, and may result in repeated disappointments. Some patients cling to the hope that new tests and treatments are being developed that may help them, whereas others feel that they are being used as a “guinea pig” for development of new strategies. The beginning of menses may signal a time of mourning for these couples. Depression may result after failed IVF attempts. Strained relationships may develop between marriage partners, especially if there is disagreement about the value of testing or the importance of having children.

Usually more than the desired number of embryos is implanted because it is expected that not all will survive and because this is more cost effective with less physical risk for the mother. However, this requires heart-wrenching decisions of whether to “reduce” (abort) extra pregnancies or to risk having more than the desired number of children at once as a result of the fertility treatments.

Offer a listening ear while being careful not to give advice about treatment modalities. There are many ongoing debates among researchers and practitioners as to the value of particular procedures; consequently, strategies may vary widely from one health-care provider to another. Encourage open communication among the patient, the health-care

provider, and the patient's significant other, and encourage decision making that is informed and based on the patient's values.

Many varieties of assistive reproductive technology are available, and the number is increasing with research. Most of the procedures are called by acronyms (names developed by using first letters of each descriptor). For example, *GIFT* means “gamete intrafallopian transfer” (gametes are placed together in the fallopian tube with the hope that fertilization will occur). *ZIFT* means “zygote intrafallopian transfer” (fertilization of gametes occurs outside of the body; the conceptus is then placed into a woman's fallopian tube to make the journey to the uterus). Acronyms can be a useful shortcut but can be confusing. Most nurses probably do not need to know all acronyms of infertility treatments unless they work in a gynecologist's office or infertility clinic. Knowing that words in all capital letters are generally acronyms helps understanding of many procedures.

REPRODUCTIVE LIFE PLANNING

Reproductive life planning is a more comprehensive term than *contraception* and implies reasoned decisions related to pregnancy timing and whether or not to have children. Nurses can contribute to the overall health and quality of life for women and families by assisting them to find the information they need to make wise choices.

There are many different types of birth control available and several additional types are in developmental and testing stages. General categories of agents are discussed in this chapter. General knowledge of how the different types of contraceptives work can assist the nurse in answering patients' questions or helping patients find additional information. This section is not intended to be a substitute for discussion with the health-care provider or for information supplied with individual products.

No numerical statements of effectiveness are included here because several different sets of statistics are currently in use. It seems likely that as products improve, hormone dosages are changed, or more data come in from users, the numbers will be adjusted. Methods are introduced in the order of general effectiveness from most to least effective (with the exception that experimental methods are discussed at the end regardless of their efficacy). Consult your clinic or health-care provider for an approved, current comparison list of methods for distribution.

For some patients, the distinction of whether the birth control method actually prevents conception or only interferes with implantation or maintenance of a pregnancy is an important factor in their decision. If a patient believes life begins at conception, any action other than prevention of conception would be considered equivalent to abortion.

Oral Contraceptives

Oral **contraceptive** medications are among the most widely used forms of birth control in North America. Most contain an estrogen and a progestin in combination, although some (minipills) contain only a progestin. Some work to prevent conception by inhibiting ovulation or changing the environment of the reproductive tract so that activity of the sperm is inhibited. Others do not prevent conception but make implantation less likely and hasten the breakdown of the corpus luteum so that pregnancy-sustaining hormones are not produced. Many of the adverse effects that occurred in the past have been overcome by adjustment of dosage levels.

Oral contraceptives may also be used in some instances to regulate irregular menses to decrease dysmenorrhea, or to decrease the symptoms associated with endometriosis or cyclic breast changes. There is much debate about whether hormonal contraceptive agents may offer some protection against some sexually transmitted diseases (STDs) based on lower statistical rates of STDs among oral contraceptive users. However, cellular changes of the cervix seen with hormonal contraceptive use actually tend to be associated with higher rates of some sexually transmitted diseases.³ Unless some specific mechanism of prevention is demonstrated by research, it seems irresponsible to suggest that oral contraceptives alone offer protection against anything other than pregnancy. Therefore, women should still be advised about the risks of contracting sexually transmitted diseases while taking an oral contraceptive.

Advantages, Disadvantages, Side Effects, and Risks

Oral contraceptives are very effective. Improvement of dysmenorrhea, endometriosis, increased regularity of menses, and decrease in menstrual flow may occur; however, some women experience menstrual changes such as amenorrhea, irregular or prolonged menses, and intermenstrual spotting. They require a great deal of commitment because irregular use decreases effectiveness. To encourage regular use, oral contraceptives are generally dispensed in containers labeled with the days of the week, and some companies include unmedicated pills in the package to be taken during the time of hormone cessation for menses, so that the woman only has to remember to take a daily pill, not specific to her cycle.

Some women experience side effects such as acne, fluid retention, headaches, breast swelling and discomfort, mid cycle bleeding, and sometimes depression. Use of an oral contraceptive also has some risks. Higher rates of blood clot formation, strokes, high blood pressure, heart attacks, and worsening of diabetes are rare occurrences with some hormonal contraceptives and are generally related to preexistent disease entities. Women who smoke or have diabetes, high blood pressure, heart disease, or a history of thrombophlebitis should receive counseling about the risks of oral contraceptives and education about alternative methods of contraception.

Oral contraceptives decrease the risk of endometrial and ovarian cancer, but there is debate about risk of breast cancer, and cervical **dysplasia** (cell changes that may become cancerous) sometimes occurs among oral contraceptive users. Women should definitely be advised to have regular annual (or more frequent if abnormalities develop) Pap smears while taking oral contraceptives.

Many medications can alter the effectiveness of oral contraceptives, and women should be warned always to alert health-care providers and pharmacists that they are on an oral contraceptive whenever a new medication is to be started or a regular medication is discontinued. Use of hormonal contraceptives increases the risk of vitamin B deficiencies, so a healthy diet with good sources of B vitamins is advisable.

LEARNING TIP

Side effects of oral contraceptives can be serious. Teach your patient to watch for "ACHES," and to contact her primary care provider immediately if they occur. ACHES stands for:

- Abdominal pain*
- Chest pain*
- Headache*
- Eye pain*
- Severe leg pain*

contraceptive: contra—against + ceptive—taking in (conceiving)

dysplasia: dys—painful or abnormal + plasia—shape or form

Contraceptive Implants

Contraceptive implants are small permeable tubes surgically implanted through a small incision under the skin; they slowly release medication for long-term contraception. Implants have been used with varying success. Currently, none is being used due to the unreliability of effectiveness and complications related to use. However, the use of a single tube is being considered. An implant containing norgestrel acetate (Uniplant) implanted under the skin of the upper arm or in the gluteal region has been tested in clinical trials and has been found to be effective for 1 year. It will likely be available in the near future.

Depot Medications

Medroxyprogesterone acetate (Depo-Provera) is a contraceptive agent available in a slow-release (depot) form that can be injected intramuscularly. Medication is continuously released for 3 months.

Advantages, Disadvantages, Side Effects, and Risks

The main advantage of depot medications is that the woman does not have to remember to take medication daily. Disadvantages are that the medication is not immediately effective, so another method is necessary for the first 2 weeks after the initial injection, and that fertility may not return for several months to 1 year after cessation of injections.

Alterations in menstrual flow, especially amenorrhea, are the most commonly noted side effects. Weight gain of 5 to 10 pounds is also common, which can lead to discontinuation of use. Other side effects and risks are similar to those encountered with oral contraceptives that contain progesterone only.

Estrogen-Progestogen Contraceptive Ring

A newer method is an estrogen-progestogen contraceptive ring (NuvaRing). It works in much the same manner as other hormonal contraceptives by slowly releasing hormones. The user inserts the ring into the vagina around the cervix, similar to a diaphragm. The ring is left in place for 3 weeks and then removed for 1 week in order for menses to occur.

Advantages, Disadvantages, Side Effects, and Risks

Not having to remember daily medication can be an advantage to the contraceptive ring, but failing to remove it at the right time may disrupt the regularity of the menstrual cycles. With consistent use, it is very effective in preventing pregnancy. Since it does not provide a barrier over the cervix, there is less risk of infection than with a diaphragm or cervical cap. A common side effect is an increase in normal vaginal discharge. Other side effects and risks are similar to other low-dose hormonal contraceptives.

Transdermal Contraceptive Patch

A transdermal patch is now available that contains norelgestromin and ethinyl estradiol (Ortho Evra). This patch is

placed on the abdomen, upper arm, or buttock following a menstrual period and left in place for 1 week. A new patch is placed on the body each week for 3 weeks. After 3 weeks, the patch is removed and not replaced for 1 week in order for menses to occur.

Advantages, Disadvantages, Side Effects, and Risks

The contraceptive patch has been found to be similar to oral contraceptives in effectiveness, side effects, and risks, without having to remember to take a pill each day. Bathing, swimming, and other activities can continue as the patch will remain where placed.

Barrier Methods

Barrier methods of birth control are less effective in preventing pregnancy than most of the previously mentioned methods when used alone. Barriers are intended to prevent sperm from reaching the ovum. There are several forms of barrier contraceptives. Used in combination, effectiveness of barrier methods and spermicidal preparations come close to that of oral contraceptives. Spermicidal preparations may be purchased without a prescription.

Condoms

Condoms are to be used once and then discarded into an appropriate waste receptacle. They should be stored in a cool, dry place before use and should not be stored tightly pressed because heat and continued pressure can weaken them. Storage in a wallet or glove compartment is not advisable. Petroleum-based substances, such as Vaseline, can also weaken condoms, so use of water-soluble lubricants (preferably spermicides) should be advised.

ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS OF MALE CONDOMS.

Male condoms have long been used for contraception because they are a relatively inexpensive, totally reversible method that men can control at the time of intercourse. They provide some barrier protection against transmission of sexually transmitted disease organisms as well. An electron microscopic study of a sample of nonlubricated latex condoms, however, found that the majority of those viewed had surface abnormalities, including cracking and melted areas. Patients should be informed that barrier methods can reduce risk but do not absolutely prevent transmission of STDs, especially in areas of contact not covered by the barrier. The main disadvantages of condom use are interruption of foreplay for application, decreased sensation, and the possibility of slippage or breakage during intercourse. These disadvantages may be overcome by incorporating application of the condom by the female partner as a part of foreplay; using thinner, lubricated, or textured condoms to increase sensation; using the correct size condom with a reservoir or applied with approximately half an inch at the tip of the condom loose enough to serve as a reservoir for the semen (Fig. 42.8); and removal from the vagina before relaxation of the erection.

FIGURE 42.8 Correct application of a condom.

ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS OF FEMALE CONDOMS. Female condoms are a more recent innovation that allows female initiation of contraception, as well as some barrier protection against infection with sexually transmitted diseases. Coverage of the labia by the condom may provide more of a barrier than male condoms (Fig. 42.9). Disadvantages are greater expense than male condoms, decreased sensation, the necessity to apply before intercourse, and the possibility of flaws in the condom material.

Diaphragms and Cervical Caps

Diaphragms and cervical caps work in the same manner by blocking the entry of sperm through the cervix (Fig. 42.10). The barrier effect is enhanced by simultaneous use of a spermicide. Application of a spermicide to the edges of each device, and placement of a small amount in their cups before use, increases effectiveness.

ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS. These methods are relatively inexpensive, are female initiated, and work without systemic medication. Diaphragms and cervical caps require initial fitting and a prescription to buy them, may need to be refitted after childbirth and the loss or gain of weight, and can last for years. These devices should be replaced periodically as the manufacturer recommends or whenever there is any evidence of hardening, cracking, or thin spots. They need to be washed with soap and water, dried, and stored in a case away from heat and sunlight between uses.

Women and their partners may experience irritation or allergic reaction to the spermicide or the contraceptive device material, which would require changing birth control methods. All these methods require that the device be inserted before intercourse and left in place for several hours after intercourse. (See package insert for recommendations.)

FIGURE 42.9 Female condom application. (A) Inner ring is squeezed for insertion. (B) Sheath is inserted similar to a tampon. (C) Inner ring is pushed up as far as it can go with index finger. (D) Condom in place.

An increase in incidence of urinary tract infection has been reported with use of the diaphragm, and risk of toxic shock syndrome increases with prolonged uninterrupted use of cervical barriers. Adequate fluid intake, voiding shortly after intercourse, and removal of the device when 8 hours have passed since intercourse all help to prevent these potential problems. If urinary tract infections are recurrent using the diaphragm, changing to a cervical cap may decrease the

FIGURE 42.10 Contraceptive diaphragm.

occurrence because there is less pressure against the bladder through the anterior vagina.

Spermicides

Spermicidal agents may be used alone, although use in combination with a barrier method is much more effective. They come in a variety of forms, such as creams, gels, foams, and suppositories, which kill or disable sperm so that fertilization does not occur.

Advantages, Disadvantages, Side Effects, and Risks

Spermicidal preparations are relatively inexpensive and can be male or female initiated. They do not produce systemic effects, and no hormones are involved. They are less effective alone than with the previously described methods. Spermicides require application before each act of intercourse and are considered by some patients to be somewhat messy. Many contain the same ingredient—nonoxynol 9. If genital irritation or a rash occurs with a spermicide, the patient should read labels carefully to avoid future contact with the same ingredient.

Intrauterine Devices

The presence of a foreign object in the uterus is thought to alter the environment, so that implantation is less likely to occur. Intrauterine devices (IUDs) are generally made from a form of plastic and may contain copper wire or a supply of a progestin that is slowly released into the system to further alter the uterine environment, so that fertilization or implantation is hindered.

Advantages, Disadvantages, Side Effects, and Risks

The main advantage of an IUD is continued contraception without the necessity of remembering to take medication and without the side effects associated with medications. The

disadvantages are changes in menstrual bleeding (especially increases in bleeding), cramping, and increased risk of pelvic inflammatory disease (PID). Rarely, an IUD has caused a uterine perforation. IUDs are contraindicated for women who have never been pregnant, those with uterine abnormalities, those with PID, and those who have a history of anemia or heavy menstrual flow. Expulsion or displacement of the IUD can occur, so women should be taught to feel for the presence of the external string before intercourse.

Insertion Procedure

Insertion of an IUD is generally done as a physician's office procedure with a nurse assisting. Usually this is done during the first 7 days of the menstrual cycle because the cervix is generally slightly dilated at this time. If you are assisting with this procedure, you will need to put out a vasovagal reaction treatment kit, an IUD insertion kit containing one or more uterine "sounds," a tenaculum (a special long forceps) for grasping the cervix, and the IUD package. The IUD is generally inserted into the vagina through a tube that comes packaged with the IUD, which temporarily holds the IUD flat or folded so that it requires less room for insertion. When the IUD is pushed out the end of the tube, it springs into a shape that helps to keep it inside the uterus. One potential danger associated with IUD insertion is vasovagal reflex stimulation (previously described in association with endometrial biopsy). Periodically assess pulse or blood pressure during the procedure and notify the health-care provider of slowing of the heart rate or a decrease in blood pressure.

Natural Family Planning

Periodic abstinence, or natural family planning, is less effective than the previously described methods. It is a method by which couples control their fertility by restricting intercourse to "safe periods" in which risk of conception is low. Many signs may be assessed to determine "safe" days, including temperature changes, cervical consistency and mucus changes, calendar timing, and awareness of symptoms of fertility.

Slight body temperature changes can indicate ovulation. During the first half of the menstrual cycle, the temperature remains low, with a marked drop just before ovulation occurs. With ovulation the temperature rises and stays higher for the last half of the cycle. Women who use this assessment method should use a basal body temperature thermometer when they awaken, before doing anything else, and record it on a chart.

Cervical consistency and mucus changes may also help pinpoint ovulation. As hormone levels change, the consistency of cervical mucus changes. As ovulation approaches, there is an increase in the amount of mucus and the mucus becomes more clear, thin, slippery, and stretchable than at other times of the month. Around the time of ovulation the cervix becomes softer to touch and more open than at other times of the cycle.

Following the calendar can work fairly well if a woman's menstrual periods are regular, but becoming aware of her pattern may take time. Symptoms such as breast ten-

derness and mid cycle discomfort (mittelschmerz) may also help identify ovulation. Users of this method should be advised to abstain for approximately 3 days before ovulation and 3 to 4 days after because the sperm and ovum can survive for a long period in the female genital tract.

Advantages and Disadvantages

The advantages of this method are that it requires no expense or medication, and it is the only birth control method presently approved by the Catholic Church. The disadvantages are that it requires the cooperation of both partners and may interfere with spontaneity of sexual expression. It is generally not very effective as a means of birth control. It may be difficult to be accurate about ovulation times because infectious and inflammatory processes may affect temperature readings, infections and feminine hygiene products may affect cervical mucus, and irregularity of flow and symptoms may make prediction difficult.

Less Effective Methods

Coitus Interruptus

Coitus interruptus involves removal of the penis from the vagina before ejaculation occurs.

ADVANTAGES, DISADVANTAGES, AND RISKS.

Although this method requires no expense or preparation, it is not very effective. Excellent control of ejaculation is required, and even the small amount of sperm that may be present in preejaculatory fluid may result in pregnancy.

Postcoital Douching

The intended purpose of postcoital douching is to wash sperm out of the reproductive tract or to kill or immobilize sperm that the douche solution contacts.

ADVANTAGES, DISADVANTAGES, AND RISKS. This is relatively inexpensive and female initiated, but it is not very effective. Sperm move very rapidly once deposited, and douching may actually push the sperm upward.

Breastfeeding

Breastfeeding is sometimes used as a method of birth control because the high blood levels of prolactin that occur with breastfeeding may suppress ovulation.

ADVANTAGES, DISADVANTAGES, AND RISKS. This method costs nothing but is not very effective. Prolactin levels can vary widely, and ovulation may resume at any time without any noticeable signs, resulting in pregnancy before even experiencing a menstrual period after the previous birth.

Ongoing Research: Future Possibilities for Contraceptive Choices

Many researchers have tried to develop effective and reversible male contraceptives. A plant called *Tripterygium*, used in Chinese herbal medicine, when taken orally yields substances that can limit numbers and mobility of sperm, but it also has active ingredients that suppress immunity somewhat, so further investigation is necessary. Reversible

injection procedures to block the seminal vas deferens are also being investigated, as are reversible injection procedures to block the fallopian tubes. Reversible birth control vaccines are also being investigated for both men and women with the goal of causing an immune response to occur at some vital point in the process of conception.

Some questions related to contraceptive vaccines include the unknown long-term repercussions of stimulating the body to respond with immunity to itself and whether governments could use vaccines as a means to control populations without their consent. Another frightening possibility is that with further removal of the threat of pregnancy, even fewer people would use barrier methods and STDs would increase even more dramatically.

CRITICAL THINKING

Jessica

■ You have just observed a patient who looks to be about 13 years old announce loudly at the clinic reception desk that she is “ready to be a responsible adult” and would like some birth control.

1. What information needs to be gathered from her?
2. What do you think she needs to know?
3. How can contraceptive teaching capitalize on her desire to be a responsible adult?

Suggested answers at end of chapter.

Sterilization

Actions

Permanent sterilization can be accomplished by either interrupting the fallopian tubes or vas deferens (vasectomy) (Fig. 42.11) or by removing the uterus and suturing the proximal end of the vagina closed. Tubal interruption may be done by tying a suture or placing a ring or clip around each fallopian tube, by coagulating a section of the tubes, or by surgically removing a portion of the tube and suturing the ends. These procedures are usually done by laparoscope in an outpatient setting, as an additional procedure performed during a cesarean section, or within a few days following a vaginal delivery. A new nonsurgical procedure (Essure) uses an endoscope to implant a tiny insert into each fallopian tube to block patency.

Advantages, Disadvantages, Side Effects, and Risks

Although this method is not absolutely certain to be permanent, the failure rate is low and has been decreasing recently with newer surgical methods. Reversal is sometimes requested at a later time to reestablish fertility. This requires microsurgery with anesthesia and has a poor success rate.

Patient Teaching

Patients should be advised by their surgeon about the complications of the surgery and of reversal before they

FIGURE 42.11 Vasectomy and reversal.

sign a consent form for sterilization. If any uncertainty about the surgery is evident, the physician should be notified promptly.

PREGNANCY TERMINATION

Termination of pregnancy (abortion) is a difficult topic. Discussions about it are often highly charged with emotion. Both pro-life and pro-choice advocates argue on the basis of human rights—the former based on supposed rights of the fetus and the latter on supposed rights of the mother—because of the humanity of each party. There are very few people on either side of the philosophical argument, however, who would describe abortion as a healthy medical intervention. Most agree that abortion is a problematic solution to a difficult situation. There are instances in which carrying a pregnancy to term threatens the life of the mother. There are also many more instances in which a pregnancy is inconvenient or undesired.

Therapeutic Abortion for Ectopic Pregnancy

An ectopic pregnancy is the implantation of a fertilized ovum in an area other than the uterus. It may occur because of an abnormally shaped uterus or fallopian tubes that are obstructed as a result of abnormal development, scarring from STDs or other inflammatory processes, or for unknown reasons. This is a life-threatening situation for the mother, and currently abortion is the only treatment.

Therapeutic Abortion for Prenatal Abnormalities

Development of a variety of prenatal testing methods has introduced the possibility of knowing many things about a baby before birth. Prenatal testing may be done using ultra-

sound, samples of fluid taken from the amniotic sac or the placental villi, or blood samples from the mother. From these tests, several genetic diseases and congenital deformities can be identified. After anomalies are diagnosed, some patients choose to abort the baby. This is a very difficult decision to consider even in instances in which the baby has a fatal defect that will not allow it to live outside the uterus. It is important to provide information about alternatives to abortion and possible treatments for their child when a patient has a serious prenatal diagnosis. No one should feel pressured to make the decision quickly to abort, but legal requirements and increasing risk for the mother may limit the time to decide. Abortion because of fetal abnormality may result in much grieving and guilt for the patient and her family.

Methods of Abortion

Several methods are available. The method is determined primarily by the length of the gestation and the goal of inflicting as little trauma to the mother's reproductive system as possible while still inducing pregnancy loss. Periods for the different abortion methods and the allowable reasons for legal abortion vary according to the laws of the state, province, or country.

Chemical Agents

The “morning after pill,” or emergency contraceptive treatment, consists of postcoital administration of sufficient estrogen or an estrogen/progestin combination to cause sudden sloughing of the endometrial lining of the uterus, preventing implantation of a possibly fertilized ovum. For this to be effective, the initial dose is generally given within 72 hours of intercourse. This treatment is used in case of unex-

pected unprotected sexual intercourse (as with sexual assault) or unexpected risk of conception (as with condom failure). Nausea and cramping may accompany the shedding of the uterine lining, and an antiemetic may be taken to manage nausea. No advance planning before intercourse is required, so this can be abused as a casual form of birth control. These patients may need education about appropriate birth control methods.

Another example of postcoital contraception is the drug RU-486, which is a progestin antagonist. It prevents the binding of progestins at their receptors, resulting in a chemically induced abortion up to the 10th week of pregnancy. Nausea and cramping may accompany expulsion of uterine contents. There is much debate about whether RU-486 should be used at all or only within specific guidelines. The United States Food and Drug Administration approved RU-486 in 2000 in an accelerated drug-approval process, but legislative bills have been introduced and reintroduced to stipulate regulations for health-care providers prescribing RU-486. Undoubtedly RU-486, as well as methotrexate (a cancer medication) and misoprostol (a medication to prevent stomach ulcers), all of which can stimulate abortion, will continue to be the subject of much debate.

Abortion Methods for Early Pregnancy

Early in a pregnancy (during approximately the first 13 weeks) there are three primary means of pregnancy termination—menstrual extraction, vacuum aspiration, and D&C. Menstrual extraction is removal of the endometrial lining by manual suction and can be done during the first 7 weeks following the last menstrual period (LMP). This can be done without anesthesia and without cervical dilation by inserting a small cannula into the cervix and aspirating with a large syringe. Vacuum aspiration is a similar process that is used from confirmation of pregnancy through the first 13 weeks. It requires cervical dilation and is generally done with local anesthesia. The patient returns home 1 to 4 hours after the procedure. D&C may also be used during the first 13 weeks. In this procedure, the cervix is dilated and the uterine contents are scooped away with a curet rather than being removed by suction.

Abortion Methods for Later Pregnancy

During the second trimester, the fetus is much larger, so more dilation is required. A dilation and evacuation (D&E) may be performed in much the same manner as a D&C. Generally, dried laminaria (a type of seaweed) or some other absorbent substance is placed inside the cervical canal. This absorbs fluid and swells, thus gradually dilating the cervix. Prostaglandin may be administered either by suppository into the vagina or by injection into the amniotic sac; this usually induces uterine contractions and results in delivery a few hours later. Unfortunately, a live fetus too premature to survive may be born by this method and continue to breathe for a time until death.

An induction with either a saline or urea injection may be used for pregnancies beyond 16 weeks. A portion of amniotic fluid is removed and replaced with concentrated

saline or urea solution, which kills the fetus and stimulates contractions. Sometimes saline and prostaglandins are used in combination to terminate a pregnancy.

Hysterotomy involves removal of the uterine contents through an abdominal incision in the same manner as a cesarean section. This procedure is rarely done for pregnancy termination.

Risks and Complications

Abortion involves risks. Some are the same risks inherent in childbirth, such as possible hemorrhage or introduction of infection, but there are additional risks related to interruption of natural processes and the aggressiveness with which the products of conception are removed during abortion. During an uncomplicated childbirth, the uterine lining is not scraped or forcefully emptied by suction. Natural hormonal preparation for term childbirth contributes to uterine contraction after the birth, which decreases blood loss, but no such preparation occurs for abortion. Artificial dilation of the cervix may cause injury, as may introduction of the instruments used for abortion. Injured tissues are more likely to become sites for growth of microorganisms than are intact tissues. Finally, the possibility of infertility as a result of complications related to abortion, although relatively uncommon, is a risk.

Some possible physical complications following therapeutic abortion are injuries to the uterus or cervix, excessive bleeding, infection, retention of some products of conception, and possible failure of abortion. Rarely, second-trimester abortions can be complicated by amniotic fluid embolism, in which amniotic fluid is absorbed into the uterine circulation because of disruption of placental attachments with instruments. Amniotic fluid in the mother's circulatory system can result in circulatory collapse and disseminated intravascular coagulation (DIC). DIC is a serious derangement of the body's blood clotting controls and, although rare, can be fatal. Clotting mechanisms are overstimulated, so that the blood begins to form clots in vessels all over the body. In response to this hypercoagulation, fibrinolytic mechanisms are overstimulated and the patient may suffer severe and widespread bleeding. Treatment of this disorder is difficult because the normal mechanisms for both sides of this clotting/clot dissolving equation are hypersensitive.

Nursing Care and Teaching

Aftercare is very important. Abortion patients rarely stay overnight, and complications may occur after they are discharged. They should be carefully assessed after the procedure for signs of bleeding. Instruct that bleeding should not exceed that of a heavy period, that the passage of clots larger than a quarter may be a sign of complications, and that the discharge should not become foul smelling. Patients should be given a phone number (available 24 hours per day, 7 days per week) to call if fever, chills, excessive bleeding, or foul-smelling discharge occur. The patient should be advised to abstain from sexual intercourse for the time specified by

hysterotomy: hystero—womb + tomy—cutting

the health-care provider (usually about 3 weeks). A grief response may occur after a pregnancy termination, even if the baby was definitely unwanted and the patient does not have strong beliefs against abortion. There is much debate about frequency of postabortion syndrome or whether such a condition exists. However, loss and trauma have occurred in any case, and reorganization of the self takes time. Availability of psychological counseling for women after abortion is very important. Women should be given a number to call if they experience psychological discomforts. The need for birth control should be assessed.

Ethical Issues

Ethically an individual nurse should not be required to assist in any treatment that demands that he or she act in a way that contradicts personal moral beliefs. This would violate the nurse's rights. However, there is also an ethical duty to provide care to patients for whom the nurse is responsible. Therefore, it is wise for nurses who have moral objections to abortion to carefully choose their work setting. For example, choosing to work in day surgery in a hospital that performs

abortions and refusing to care for abortion patients is not a legitimate option. One way that nurses can positively influence the abortion situation is by teaching about family planning, which may lower the number of requests for abortions. Another way might be to become involved with agencies that help pregnant women to have viable alternatives to abortion. See Box 42.5 Ethical Considerations.

TUMORS OF THE REPRODUCTIVE SYSTEM

Benign Growths

Fibroid Tumors

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Fibroid tumors, or **leiomyomas** (plural form is leiomyomata), are benign tumors made up of endometrial cells that have implanted on or within the walls of the uterus. These can grow very large and may cause pain or menstrual

leiomyoma: leio—smooth + myom(a)—fibroid

Box 42.5

Ethical Considerations

Abortion

The famous case of *Roe vs Wade* (1973) changed the legal status of therapeutic abortion in the United States but added a great deal of confusion to its ethical and moral status. A careful reading of the *Roe vs Wade* decision reveals that the court made no decision about the ethics or morality of elective (therapeutic) abortion. Rather, the court said that according to the U.S. Constitution, all people, including women, have a right to determine what they can do with their bodies (*right to self-determination*) and a right to privacy. Therefore, during the first trimester a woman and her physician may decide to terminate a pregnancy without interference from the state. During the second trimester, the state may regulate the circumstances under which an abortion may occur to protect the woman's health. Once the fetus is viable, the state may also prohibit abortion. Although a woman may have a right to obtain an abortion, there is not a right to require the death of the fetus should a viable fetus be identified after the abortion procedure. Pro-choice groups put the right to self-determination and privacy central to their concerns. Pro-life groups generally believe that abortion is fundamentally killing and therefore wrong.

One of the central issues in the debate is the status of the fetus. Is the fetus considered a person with individual rights separate from those of the woman who is pregnant? Another central question is when does human life begin? Is abortion at any stage of pregnancy morally acceptable? Each fertilized egg contains the essential genetic material

for the development of a unique individual. However, many fertilized eggs never successfully implant in the uterus in the natural process of conception. Does such a factor make the timing of the procedure a critical element? Related to this problem is the status of frozen embryos created through in vitro fertilization. They too contain the essential, unique genetic material for the development of a human person. If every embryo should be respected as potential human life, what moral obligation do we have toward those embryos? What about those embryos left in freezers unclaimed? Should we implant them into childless women? Should we use cells that are otherwise scheduled to be destroyed in order to treat disease or further the understanding of genetic disorders?

The issues around abortion are huge, and there are no easy suggested answers. There are many resources that can provide information and guidance to the public about the variables. However, health-care workers are not only members of the public, they are the people on the front line interacting and serving women who are having these procedures. Anyone who decides to work in an establishment like an abortion clinic or a unit where terminations occur is expected to be fully prepared to participate in treatments and procedures. The fundamental question of if this procedure is right or wrong, for whatever reason, has no bearing in such a facility. The staff must be comfortable in their belief that the service they are providing is congruent with their internal and professional value set.

disorders, exert pressure on the bladder or bowel, cause necrosis because of pressure on the blood supply to tissues, and interfere with fertility.

THERAPEUTIC INTERVENTIONS. Because fibroids are estrogen sensitive, medical treatment may involve hormone suppression. Surgical treatment may involve **myomectomy** or hysterectomy. Myomectomy is removal of only the fibroid tumor and may be chosen to preserve fertility. Myomectomy may be done surgically through an abdominal or vaginal incision or with a laser introduced through a laparoscope. Hysterectomy may be necessary for very large fibroids or those that cause severe bleeding or discomfort.

Polyyps

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Polyyps are generally benign growths that grow inside the uterus or on the cervix and may bleed after intercourse or between menstrual cycles. These are generally teardrop shaped and are attached by a stalk. Polyyps develop most often after the age of 42.

THERAPEUTIC INTERVENTIONS. Polyyps are generally removed vaginally or transcervically by separating the stalk from the uterus and then stopping the bleeding by use of chemical, electrical, or laser **cautery**. Removal of polyyps in the vagina may be done without anesthetic in a physician's office. Removal of polyyps transcervically requires cervical dilation and is more likely to be done in a hospital with anesthesia.

Reproductive System Cysts

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Several types of cysts may affect women's health. Cysts of the ovaries may develop associated with incomplete ovulation, **hypertrophy** of the corpus luteum after ovulation, or inflammation of the ovary. Most ovarian cysts eventually will shrink spontaneously and merely cause discomfort for a time. Chocolate cysts are formed when endometrial cells bleed into an enclosed space, as occurs with endometriosis. These are called chocolate cysts because they are filled with old blood that has become chocolate colored. Cystadenomas are benign growths that can sometimes undergo cellular transformation and become cancerous. Any pelvic mass in a postmenopausal woman has a high potential for malignancy and should be investigated.

THERAPEUTIC INTERVENTIONS. Most cysts are not surgically removed, but excessive size, interference with fertility, and high cancer potential may make needle drainage, biopsy, laparoscopic surgery, or **laparotomy** advisable. If cysts are painful, application of heat to the abdomen or back may help promote comfort.

myomectomy: myom(a)—fibroid + ec—away + tomy—cutting

cautery: branding iron

hypertrophy: hyper—too much + trophy—nourishment
(growth)

laparotomy: laparo(o)—abdominal wall + tomy—cutting

Polycystic Ovary Syndrome

PATHOPHYSIOLOGY AND ETIOLOGY. Polycystic ovary syndrome (PCOS) is a complex abnormality of endocrine balance of unknown etiology. Multiple cysts on the ovaries are a sign that was discovered early and for which the disease was named, but they are not present in all cases. There seem to be strong genetic links with such family history as too much or too little hair (especially for women), severe acne, diabetes, irregular menses, and infertility. Many of the symptoms of PCOS are a result of excessive levels of insulin in the blood because of insulin resistance. Excess insulin in turn stimulates secretion of androgens.

SIGNS AND SYMPTOMS. Women with PCOS often present with infertility, obesity, and menstrual disturbances. They may also exhibit masculinization because of the excess androgen secretion. They have a higher risk for diabetes mellitus, elevated blood pressure, coronary artery disease, and endometrial cancer.

DIAGNOSTIC TESTS. Diagnostic tests may include blood tests to rule out other causes of endocrine abnormality, tests to determine whether ovulation is occurring (such as mid luteal progesterone levels and basal body temperature graphing), endometrial biopsies to determine the level of proliferation and to check for endometrial cancer, and blood tests to determine lipid levels and glucose tolerance.

THERAPEUTIC INTERVENTIONS. Medical treatments may involve blood pressure medications, lipid control medications, and oral hypoglycemics. Diet and exercise may be recommended for weight reduction, control of lipid levels, and cardiac health. Oral contraceptives may be used to normalize hormone levels and protect the endometrium for those not desiring to conceive. Ovulation-inducing medication may be used for those women who desire to conceive. If masculinization is a problem, antiandrogen medications may be prescribed. In severe cases, gonadotropin-releasing hormone (GnRH) agonists may be used to produce medical suppression of the ovaries, with results similar to removal of the ovaries. This is followed 6 months later with an estrogen/progestin combination to protect the bones from development of osteoporosis.

Bartholin's Cysts

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Bartholin's cysts are actually infected or obstructed Bartholin's glands at either side of the vaginal opening. Excessive swelling of Bartholin's glands results in pain with sitting and with intercourse.

THERAPEUTIC INTERVENTIONS. Incision and drainage may alleviate the discomfort. If Bartholin's cyst formation occurs often, **marsupialization**—the surgical formation of a

marsupialization: marsupial—pouch + ization—process of
making

pouch around an opening made into a gland to facilitate drainage—may be necessary. Sitz baths may be ordered to cleanse the area and to promote comfort and healing.

Dermoid Cysts

PATHOPHYSIOLOGY, ETIOLOGIES, SIGNS AND SYMPTOMS. Rarely, for unknown reasons, a **dermoid** cyst (also called a cystic **teratoma**) may develop from a germinal cell of an ovary. This cell divides and differentiates into various tissue types such as skin, teeth, bones, hair, and even extremities in a disordered arrangement. This type of cyst may grow quite large and may occur on both ovaries at the same time.

THERAPEUTIC INTERVENTIONS. Dermoid cysts are removed by laparoscopy or laparotomy. If the cyst contains glandular tissue that is secreting hormones, adjustment of hormone levels to normal may take some time. Although most teratomas are benign, some are malignant, especially in postmenopausal women, so a biopsy is generally done on the tissue.

NURSING CARE AND TEACHING. Growth of a dermoid can be a frightening experience for a woman. Reassurance that this is merely a disordered group of cells identical to the other cells in her body, rather than a monster or deformed baby, is important.

Malignant Disorders

It is sometimes difficult to distinguish benign growths from malignant growths without biopsy results, and some benign growths can become cancerous. Malignancies can occur in all parts of the reproductive system and can occur at all ages. Although reproductive system cancers are more common in older age groups, ovarian tumors can occur even in young children. Both male and female children of women who were given diethylstilbestrol (DES) in the past to prevent premature delivery in high-risk pregnancies have experienced a high incidence of developmental defects and cancers of the reproductive organs.

Many different types of genital cancer are possible, and discussion of every type in detail is beyond the focus of this book. This section presents a general overview of the most common cancers. Cancerous changes often can be observed or noticed, and if investigated and treated early enough, cure is often complete.

LEARNING TIP

Three C changes that may indicate cancer are changes in color, contour, and consistency of a tissue.

dermoid: derm—skin + oid—form

teratoma: terat—monster + oma—growth

Vulvar Cancer

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Although vulvar cancer is not common, alertness to changes in visible parts of the reproductive system such as the vulva can result in early diagnosis, requirement of less drastic treatment, and end with more positive results. Persistent itching of the vulva or appearance of white or red patches, rough areas, skin ulcers, or wartlike growths on the vulva should not be ignored; these can be signs of precancerous or cancerous changes. Risk factors for development of vulvar cancer are an STD of any type, precancerous or cancerous changes of the anus or any of the genitalia, immune system depression, and smoking.

DIAGNOSTIC TESTS. Regular Pap smears and physical examinations can identify lesions. Biopsy of suspicious lesions is necessary to diagnose vulvar cancer.

THERAPEUTIC INTERVENTIONS. If discovered early, vulvar cancer may be treated with removal or destruction of cancerous cells. If not diagnosed early, it may require surgical removal of the entire vulva and associated lymph nodes (a radical vulvectomy) with subsequent skin grafting from other areas of the body for repair.

Cervical Cancer

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Changes in the cells of the cervix (called cervical intraepithelial neoplasia [CIN]) can progress to cervical cancer. Dysplastic cells (those with dysplasia) are generally less differentiated or less ordered than expected for their cell type.

Some identified risk factors for development of cervical cancer include starting sexual activity at an early age, having multiple sexual partners, having several pregnancies, smoking, and being infected with human papillomavirus or herpes simplex virus type II (HSV-II). Use of oral contraceptives for several years may also increase a woman's risk of developing cervical cancer, although part of the difference in incidence may be because women using oral contraceptives may not be using barrier protection against STDs. Although some women experience slight spotting or a serosanguineous discharge with cervical cancer, many are asymptomatic until the cancer is widespread.

DIAGNOSTIC TESTS. Pap smears are the best method of screening for cervical cancer presently available, but some work is being done on self-tests that women can collect. A Pap smear determines the degree of cellular change, or dysplasia. Ranking systems vary, but Pap smear results are usually presented in categories that range from no atypical cells seen to invasive cancer evident (0 to IV). This procedure has significantly reduced the incidence of invasive cervical cancer over the years since its introduction because cellular changes can be identified early enough for treatment before the cells become cancerous. Schiller's test may be done if a patient has an abnormal Pap smear. This involves painting the cervix with iodine. Dysplastic cells stain differently than normal ones. Biopsy is done to confirm

a cancer diagnosis. Recommendations for frequency of screening vary, but most recommend that Pap smears begin at either age 21 or with the start of sexual activity and be done yearly unless abnormalities develop. After a period of normal Pap smears, some health-care providers advocate longer intervals for low-risk people.

THERAPEUTIC INTERVENTIONS. Treatments for pre-invasive neoplasia include **cryotherapy** (freezing), laser therapy (burning), and surgical removal of the involved area with a loop excision instrument or by conization (Fig. 42.12). All these procedures are done through the vagina, so there are no external incisions. After any of these treatments the patient is advised not to douche, use tampons, or have intercourse for approximately 2 weeks to allow for healing to take place. She should be advised to report immediately if fever, bloody vaginal discharge, or foul-smelling vaginal discharge occurs. For invasive cancers, hysterectomy, radiation implant, or chemotherapy may be done.

Endometrial Cancer

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Endometrial cancer is the most common type of uterine cancer. Most develop in response to relative estrogen excess. Abrupt changes in bleeding patterns, especially bleeding in a menopausal woman, may indicate endometrial cancer development. Estrogen excess can develop for many reasons. Estrogen levels fluctuate widely in the perimenopausal period. Obesity results in increased estrogen production that is not balanced by progestins. Estrogen replacement therapy for menopausal symptoms without the addition of progestins also has been associated with an increase in endometrial cancer, but addition of a progestin may decrease the risk of endometrial cancer to

less than that of untreated women. Whether alcohol consumption increases the risk of endometrial cancer by interfering with estrogen metabolism is still a matter of debate. Some endometrial cancer, however, is unexplained by any presently known risk factors.

DIAGNOSTIC TESTS. Diagnosis is generally done by endometrial biopsy, but MRI may be used to evaluate invasiveness and involvement of lymph nodes.

THERAPEUTIC INTERVENTIONS. Depending on the stage of endometrial cancer and metastasis, treatment with hysterectomy, radiation, or chemotherapy may be used.

Ovarian Cancer

PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS. Ovarian cancer is an especially insidious killer because cellular changes in the ovaries often are asymptomatic until the cancer is quite advanced. Little is known about what prompts these cells to undergo malignant changes. Risk factors are not definitely identified, but some proposed factors include low fertility and number of children, late menopause, a family history of reproductive or colon cancers, and a diet rich in animal fats. Use of hormonal contraception may help prevent this because it results in less ovulation during the woman's lifetime.

DIAGNOSTIC TESTS. Identification of abnormal growths on the ovaries may begin with bimanual examination, so it is important for women, especially in the older age groups, to continue to have regular pelvic examinations even if they are not sexually active and even if they have had a hysterectomy. Various blood tests measuring tumor marker substances, ultrasonography, CT scanning, and MRI may also be used to assist in diagnosis.

THERAPEUTIC INTERVENTIONS. Treatment may involve surgical removal of the ovaries by laparoscopy or

cryotherapy: cryo—cold + therapy—treatment

FIGURE 42.12 Conization

laparotomy. Sometimes the ovaries are removed to prevent the disease in women who have a high familial risk. Radiation and combination chemotherapy may also be used.

Nursing Care and Teaching of Patients with Malignant Disorders

Radiation therapy for cancers of the reproductive system may involve the placement of radioactive implants into the patient's body for 24 to 72 hours. Avoid prolonged contact with the patient and perform care with as much of the patient's body between you and the implant as possible (e.g., for cervical implants, stand at the head of the bed rather than at the foot). Prevent inappropriate radiation of the patient's other body parts by such actions as maintaining patency of a urinary catheter to avoid unnecessary exposure of the bladder. Follow institutional guidelines for radiation precautions. Do not give care to patients with radioactive implants if you are pregnant. A foul-smelling vaginal discharge is expected after radiation by implant because of tissue destruction caused by the radiation; document the amount and character of the discharge. Chemotherapy treatments often cause severe nausea, as well as anorexia and sores of the mouth, vagina, and anus. See Chapter 10 for care of patients receiving chemotherapy.

See Box 42.6 for a summary of tumors of the reproductive system.

GYNECOLOGICAL SURGERY

Endoscopic Surgeries

Many of the surgeries performed on the reproductive system may be done using an endoscope. The scopes used contain not only magnifying lenses and a light source but may also include tiny tools for performing surgery, for removal of small areas of diseased tissue and samples, for suction, and for cauterization of bleeding vessels. Because endoscopic surgeries require tiny incisions (usually less than 1 inch long), there is less tissue disruption and very little bleeding when compared with traditional surgical techniques. Smaller incisions also present less risk of infection than traditional methods, and recuperation is generally more rapid with fewer complications. Overall the danger to the patient is generally low for endoscopic surgeries; however, not all surgical situations may be satisfactorily handled in this way. The size of the cannula restricts the size of tissues that can be removed, unless they can be divided into smaller sections and then pulled out through the cannula. If affected areas are widespread, the scope may not be able to reach all sites. Traditional surgery still may have to be done when endoscopic surgery has been ineffective, and this can be frustrating to patients. However, information gained through the prior endoscopic surgery may decrease the time required for the traditional surgery.

Laparoscopies are the most common type of endoscopic surgical procedure employed for women's reproductive system surgeries. This method can be used for access to the abdominal cavity and the anterior portions of the repro-

Box 42.6

Tumors of the Reproductive System Summary

Signs and Symptoms	Menstrual pain/dysfunction Infertility Incontinence Constipation Vaginal bleeding Abdominal/perineal pain/swelling Androgen characteristics Obesity Diabetes Coronary artery disease
Diagnostic Tests and Findings	Physical examination Laparoscopy Ultrasound CT or MRI scan Biopsy Alteration in hormone levels
Therapeutic Interventions	Surgery Chemical/electrical/laser cauterization Oral contraceptives and medications Incision/drainage/marsupialization
Priority Nursing Diagnoses	Acute/chronic pain r/t lesion/surgery. Urinary incontinence or constipation r/t lesion/surgery. Impaired body image r/t body structure abnormality. Sexual dysfunction r/t disturbance in self-concept. Grief r/t absence/loss of reproductive status.

CT = computed tomography; MRI = magnetic resonance imaging; r/t = related to.

ductive organs. Tubal ligations, tubal repairs, removal of ectopic pregnancy implantations, removal of small tumors, removal of endometriotic sections of tissue, and aspiration of fluid-filled cysts can all be done by this method.

Culdoscopies may be done to access the area at the back of the uterus. A **culdotomy**, which is an incision into the upper posterior portion of the vagina, is necessary to insert the cannula. A **culdocentesis**, which is the removal of fluid from the cul-de-sac of Douglas, may be done during a culdoscopy. Aftercare is much the same as for laparoscopy, although the patient should be informed that a small amount of vaginal spotting may be expected from the incision but heavy, purulent, or foul-smelling discharge could indicate infection. (See Chapter 41.)

culdotomy: culdo—cul-de-sac + tomy—cutting

culdocentesis: culdo—cul-de-sac + centesis—puncturing

Colposcopies are generally used to screen, diagnose, or treat problems of the cervix. The binocular microscope attached to the scope cannula, which is introduced into the vagina, allows the physician to examine dysplastic cells while they are still in their normal place and to treat cervical dysplasia as previously described. Hysteroscopy may be used to treat problems within the uterus. Removal of polyps and other growths, modification of congenital malformations such as septa (walls of tissue where there should be none), and laser ablation of endometrial tissue may all be done during hysteroscopy. The endoscope may be inserted further into the fallopian tubes to perform a salpingoscopy, allowing surgical or laser opening of blocked tubes.

Nursing Care and Teaching

Postoperative care involves careful assessment for signs of possible excessive internal bleeding, including checks of vital signs, skin color and temperature, and pain. Measures to reduce the discomfort produced by residual carbon dioxide from insufflation may include instruction to lie flat for a few hours, massaging of the back and shoulders, and administration of pain medication. Instruction about possible danger signs, any medications, and when and where to go for suture removal complete the discharge teaching.

Hysterectomy

Removal of the uterus (hysterectomy) may be done for a variety of reasons, including abnormally heavy or painful menstruation, large fibroids or other benign tumors, severe uterine prolapse, and cancer of the uterus. It should not be

done merely as a sterilization procedure because the risks involved in hysterectomy surgery are much greater than risks associated with tubal ligation. The surgery is usually performed through an abdominal incision, but it may be done vaginally in some cases. The vagina is left intact except for suturing of the proximal end, which had been attached to the uterus, forming a blind pouch. Although less vaginal lubrication is present after hysterectomy, nerve routes are maintained and satisfactory sexual intercourse is expected to continue.

The uterus alone may be removed, and in some cases the tubes and ovaries may also be removed—a procedure called total abdominal hysterectomy with **bilateral salpingo-oophorectomy** (TAH-BSO), or **panhysterectomy**. If the ovaries are removed, the woman undergoes immediate menopause and may suffer from symptoms associated with menopause, including the increased risks of cardiovascular disease and osteoporosis. Because removal of the ovaries is usually done because of the presence of estrogen-dependent cancer, estrogen replacement is not usually feasible in these cases, and extra care, comfort, and explanation from nurses are necessary. See Box 42.7 Nursing Care Plan for the Patient Undergoing Hysterectomy. In addition to the nursing diagnoses covered, also assess for anxiety related to surgery and resulting body image changes and for ineffective coping.

bilateral salpingo-oophorectomy: salpingo—tubal + oophor—ovary + ec—from + tomy—cutting

panhysterectomy: pan—all + hyster—uterus + ec—from + tomy—cutting

BOX 42.7 NURSING CARE PLAN for the Patient Undergoing Hysterectomy

Nursing Diagnosis: Risk for ineffective tissue perfusion related to surgical incision and removal of the uterus (and possibly the ovaries)

Expected Outcomes Incision(s) will heal by primary intention without excessive bleeding.

Evaluation of Outcomes (1) Are vital signs within normal range for patient? (2) Is dressing dry and intact and/or does perineal pad show <3cm stain every hour? (3) Are edges of the incision well approximated, with scant bleeding/serous drainage, and mild edema/erythema (if applicable)?

Interventions

Monitor vital signs and oxygen saturation according to hospital policy and as necessary.

Check for bleeding or other discharge on perineal pad and on abdominal dressing (if applicable).

Assess wound healing (if applicable) twice a day (bid) and report any evidence of infection or inadequate healing promptly.

Rationale

Vital signs and oxygen saturation reflect tissue perfusion status.

Excessive bleeding may compromise tissue perfusion and slow healing. Vaginal discharge gives clues to healing of incision at the proximal end of the vagina.

Early treatment of inadequate wound healing decreases postoperative complications.

Evaluation

Are vital signs stable and within normal range?

Is pad or dressing dry? Is discharge foul smelling?

Is incisional area swollen, reddened, or draining purulent material?

Nursing Diagnosis: Risk for impaired urinary elimination related to manipulation of the bladder and ureters during surgery, anticholinergic drugs, fluid intake changes, and fear of pain

Expected Outcomes Patient will have urinary output 30 mL/hr or more without difficulty.

Evaluation of Outcomes (1) Is patient able to void and effectively empty bladder when voiding?
(2) Is patient voiding at least 30 mL per hour?

Interventions

Assess urinary output after surgery. Report if less than 30 mL/hr or unable to void.

Assess bladder fullness using Doppler monitoring or scratch test (listening with a stethoscope, lightly scratch abdomen as you move downward from xiphoid until you hear change in sound indicating top of the bladder).

Medicate for pain on a fixed schedule for operative day and first postoperative day (unless patient declines pain medication).

Rationale

Inadequate urinary output can be an evidence of dehydration, low glomerular perfusion, kidney dysfunction, damage to ureter, or urinary retention.

Urinary retention can cause damage to kidneys, ureters, and bladder.

Scratch test and Doppler monitoring cause less discomfort and pressure to an abdominal incision area.

Maintenance of a consistent blood level of medication in the immediate postoperative period provides relief of pain and promotes voiding without fear of discomfort.

Evaluation

Is output adequate?
Is patient able to void without discomfort?

Does patient feel she is emptying fully when voiding?

Does Doppler indicate residual urine after voiding?
Where is level of sound change with scratch test?

Does patient state that she is comfortable?

Nursing Diagnosis: Risk for constipation and gas related to manipulation of the bowel during surgery, opioid analgesics and anticholinergic drugs, diet changes, less exercise than usual, and fear of pain when passing stool

Expected Outcomes Patient will pass soft formed stool without excessive gas discomfort by third postoperative day.

Evaluation of Outcomes (1) Are bowel sounds active in all four quadrants? (2) Is patient passing gas without difficulty? (3) Is patient able to have a formed bowel movement within 3 days of surgery?

Interventions

Assess for active bowel sounds in all four abdominal quadrants before giving anything orally.

Encourage high fluid intake, and graduate diet toward a high-fiber, regular diet as soon as patient is able to tolerate it (or doctor's orders prescribe).

Encourage adequate exercise.

Assess quantity and quality of pain. Control pain with analgesics, especially before administering suppository or enema.

Give stool softeners, laxatives, suppositories, or enemas as ordered (check bowel protocol or standing orders).

Rationale

Manipulation of the bowel during surgery or anesthetics and other medications may interfere with bowel function.

Adequate fluid and fiber in the diet softens the stool for easy passage.

Reasonable exercise promotes peristalsis and relieves gas discomfort.

The presence of pain may inhibit defecation.

Soft stool is easier to pass.

Evaluation

Are bowel sounds sluggish, active, or hyperactive?

Are bowel sounds present in all four quadrants?

Is patient drinking well?

Is patient ready for more normal foods, as well as liquids?

Has patient dangled at bedside the day of surgery and then walked increasing amounts each day following?

Is patient passing intestinal gas without difficulty?

Does patient express satisfaction with pain control and report pain at an acceptable level?

Has patient passed soft formed stool by the third day after surgery?

REVIEW QUESTIONS

1. A breastfeeding patient says “My doctor said I have mastalgia. What does that mean?” Which response by the nurse is best?
 - a. “That means you may have an infection in your breasts.”
 - b. “Mastalgia is just the normal discomfort that is associated with breastfeeding.”
 - c. “The word mastalgia just means breast pain; it can occur with monthly cycles of hormone levels.”
 - d. “Mastalgia is the medical term for fibrocystic breast disease. It is important to have it treated promptly.”
2. Which response by the nurse is most appropriate when a 60-year-old woman who has been menopausal for several years relates that she has begun having vaginal bleeding again?
 - a. “Ignore it—it is perfectly normal.”
 - b. “Try taking some ibuprofen. That may reduce the bleeding.”
 - c. “You should see a doctor to have that checked as soon as possible.”
 - d. “Give it time—bleeding after menopause usually goes away within a month.”
3. During an endometrial biopsy, for which of the following signs and symptoms of vasovagal response should the nurse observe?
 - a. Pain in the chest and abdomen
 - b. Cramping and diaphoresis
 - c. High blood pressure and tachycardia
 - d. Bradycardia and falling blood pressure
4. Which of the following medications can be used to treat vasovagal response during gynecologic procedures?
 - a. Atropine
 - b. Morphine
 - c. Epinephrine
 - d. Norepinephrine
5. The nurse is discharging a patient with endometriosis from an office visit. She says her medication helps but does not relieve all her discomfort. What other measures can the nurse recommend?
 - a. “Check with the health food store. There are several herbal remedies that can be very effective.”
 - b. “Try using the relaxation exercises you learned in your childbirth classes. A warm compress to your abdomen might also help.”
 - c. “You can double up on your pain medication on occasion, but you shouldn’t do it on a regular basis.”
 - d. “If the medications aren’t effective, then it is time to talk to the doctor about a hysterectomy.”
6. The nurse enters the room of a patient who is 1 day post left-sided mastectomy and notes a phlebotomist taking blood from her left antecubital space. What should the nurse do first?
 - a. Nothing; the nurse is not the phlebotomist’s supervisor.
 - b. Nothing; blood pressures should be avoided in the affected arm, but blood draws are safe.
 - c. Stop the phlebotomist and point out that needlesticks must be avoided in the affected arm.
 - d. Notify the physician.
7. Following a panhysterectomy, what should the nurse teach the patient to expect?
 - a. Heavy bleeding for a week
 - b. Symptoms of menopause
 - c. Painful intercourse for approximately 6 months
 - d. Monthly cramping but no menstrual flow
8. A patient who has just returned from an abdominal panhysterectomy is at risk for impaired urinary elimination. At least how many mL should be in her catheter bag 8 hours post operatively? _____
9. Which of the following is the least effective form of contraception?
 - a. Douching
 - b. Condom with spermicide
 - c. Diaphragm with spermicide
 - d. Oral contraceptive medication

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Julie*

1. Questions to further assess Julie's complaint should include: Do you do BSEs? Has there been a change in the characteristics of the "bumps"? Are the pain and lumps related to your menstrual cycle? Are the lumps mobile or fixed? Have you noticed any skin or nipple changes of your breasts? Have you noticed any leakage of fluid or blood from your breasts? Are you breastfeeding or have you recently delivered an infant? Have you had a fever?
2. A possible screening mammogram may be considered, realizing that breast tissue is dense at this age and a mammogram is not as accurate as it will be after about age 40. Diagnostic tests may include breast ultrasound and needle/excisional biopsy.
3. Treatment options will be based on the etiology. Treatment for fibrocystic breast changes may include oral contraceptives and dietary changes, including limiting fat and caffeine. Treatment for mastitis (unlikely, but a possible diagnosis based on complaint) may include antibiotics, warm compresses, breast supports, or excision. Treatment for breast cancer may include lumpectomy, mastectomy, chemotherapy, radiation, as well as reconstruction at some point.

■ *Lola*

1. Interventions that may help control Lola's discomfort related to hot flashes include possible inclusion of HRT therapy, inclusion of phytoestrogens into her diet, limiting caffeinated foods or beverages, dressing in layers so that some may be removed as needed, and lowering the thermostat as needed.
2. Information that should be shared with Lola concerning HRT therapy should include the risks as well

as benefits according to most recent studies. Risks include increased risk of stroke, cardiovascular disease, breast cancer, and thromboembolism. Benefits include symptomatic relief and decreased risk of complications from osteoporosis.

■ *Jessica*

1. Some important information from Jessica would include her true age (laws vary concerning birth control for minors), her intentions, her family situation, whether she is already sexually active, and what information she wants.
2. She needs to know that being sexually active involves more risks than just pregnancy. Discussion of STDs is vital. Discussion of violence, potential for abuse, long-term effects, and psychological suffering, which may accompany early sexual activity, may also be important. The choices of birth control should be explained, including the risks, effectiveness, disadvantages, and advantages of each method.
3. Although focusing on her desire to be a responsible adult is an admirable attitude, potential scenarios can be presented for her "responsible" consideration, such as the following: What would she do if contraceptive failure resulted in a pregnancy? How would she feel if she contracted an incurable or permanently damaging sexually transmitted disease that she might pass on to someone else? How would she react now to being "dumped" by someone she cares for who is less responsible and mature? Asking about her goals and plans in life may be significant. Counseling that evidences concern for the individual at this stage may do a lot to postpone sexual activity until the patient is more mature. It is important for her to realize that choosing to delay sexual activity at this time may be the most responsible and health-promoting life decision she can make.

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiologies associated with male genitourinary and reproductive disorders?
2. What are the etiologies, signs and symptoms, and treatments of prostate disorders?
3. What nursing care will you provide for patients with male genitourinary or reproductive disorders?
4. What are disorders of the testes and penis, and how do they impact sexual function?
5. What are some physical and emotional causes of erectile dysfunction?
6. What is the nurse's role in helping men cope with the loss of sexual function?
7. Which disorders of the male reproductive system interfere with fertility?
8. What are the treatment options for male infertility?

Problems affecting the male genitals and urinary system are generally difficult areas for both the patient and the nurse to deal with because of the sexual nature of the male anatomy. It is important to realize that sexuality is a natural part of each of us as human beings and should not be avoided when we provide care to patients. Very often the nurse is in an ideal position to provide important sexual health-care teaching to patients. If the patient is approached in a confident, confidential manner, it can be a positive learning experience for both the patient and the nurse.

PROSTATE DISORDERS

The prostate gland sits at the base of the bladder and wraps around the upper part of the male urethra like a doughnut. The primary purpose of the prostate is to provide alkaline secretions to semen and to aid in ejaculation. The prostate does not contain any hormones; however, many men fear that prostate problems and treatment will cause problems with their erections or their “nature” (sexual activities).

Prostatitis

Pathophysiology

Prostatitis, or inflammation of the prostate gland, can occur any time after puberty. The problem may be chronic or a single, acute episode. The inflammation causes the prostate gland to swell, resulting in pain, especially when standing. It eventually may lead to difficulty in passing urine as a result of an inward squeezing of the urethra that causes a mild obstruction.

Etiology

There are three basic types of prostatitis: acute bacterial, chronic bacterial, and nonbacterial. Bacterial prostatitis is most common in older men. It results in edema and inflammation of all or part of the prostate gland.

The bacteria primarily responsible for the infection are gram-negative organisms such as *Escherichia coli*; however, gram-positive and gonococcal bacteria may also play a part. The prostate gland may become infected by the following:

- Bacteria ascending the urethra
- Infected urine refluxing from the bladder into the prostatic ducts
- Bacteria in the blood or lymph supply to the gland
- Surgical instrumentation or other forms of urethral trauma.

Prevention

Ways to avert prostatitis are regular and complete emptying of the bladder to prevent urinary tract infection (UTI), avoiding excess alcohol (more than 2 to 3 oz per day—alcohol is a bladder irritant), and avoiding certain high-risk sexual practices. Avoiding contamination of the urinary tract and factors that produce congestion of the prostate gland are the best preventive measures.

prostatitis: prostat—prostate gland + itis—inflammation

Signs and Symptoms

The most common symptoms are the same ones that occur with any UTI: complaints of urgency, frequency, hesitancy, and dysuria. Because of the location and role of the prostate gland, the patient may complain of low back, perineal, and postejaculation pain; he may also have a fever and chills.

Complications

One complication of acute bacterial prostatitis is urinary retention. If the prostate is extremely swollen, it prevents complete bladder emptying. For most men, the most troublesome complication may be a temporary problem with erections. Ascending infections, prostatic abscess, **epididymitis**, and prostatic calculi (stones) are some of the more serious and rare complications of prostatitis.

Diagnostic Tests

The first test performed is a careful, gentle, digital rectal examination (DRE) of the prostate. The prostate gland is examined by the health-care provider by insertion of a gloved finger into the rectum. The examiner may find a warm, irregular, swollen, painful prostate gland. A urine culture generally is positive for bacteria. The examiner may also gently massage the prostate gland and order an expressed prostate secretion (EPS) test that reveals bacteria and a large number of white blood cells.

Therapeutic Interventions

Acute bacterial prostatitis is usually treated medically with antibiotic therapy. The preferred treatment is trimethoprim and sulfamethoxazole (Bactrim) for 30 days. Other antibiotics, including the fluoroquinolones (ciprofloxacin, ofloxacin), may be used for chronic prostatitis (Table 43.1).

Other forms of treatment may include anti-inflammatory agents, stool softeners, warm sitz baths, prostatic massage, and diet changes such as decreasing spicy foods and alcohol. Patients should also avoid alpha-adrenergic agonist medications, which can cause urinary retention. In some cases, prostate surgery is necessary to remove the obstruction.

Nursing Process for the Patient with Prostatitis

ASSESSMENT/DATA COLLECTION. Begin the assessment by asking the patient to describe signs and symptoms that indicate evidence of a UTI, such as sudden fever, chills, and complaints of urgency, frequency, hesitancy, dysuria, and nocturia. In addition, the patient may have complaints of pain in the lower back, in the perineum, or after ejaculating. Ask the patient if he has ever had a UTI or prostate infection in the past. Care must be taken to assess urinary retention resulting from obstruction. Obtain a urine culture and assist with collection of the EPS specimen, if requested, as part of the patient assessment.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. The nursing diagnoses and interventions for patients with prostatitis may include:

(Text continued on page 938)

epididymitis: epi—upon + didym—testis + itis—inflammation

TABLE 43.1 MEDICATIONS USED FOR DISORDERS OF THE MALE REPRODUCTIVE ORGANS

Medication Class	Medication/Action	Route	Side Effects	Nursing Implications
Medications Used for Infections <i>Antibiotics</i>	Sulfonamides: Trimethoprim/ sulfamethoxazole (Bactrim; Septra) <i>Block bacterial synthesis of essential nucleic acids</i>	PO or IV	GI upset Anorexia Rash Urticaria Photosensitivity CNS disturbance Crystals in urine	Instruct patient to maintain hydration; take medication on empty stomach with 8 oz water. Avoid unnecessary sunlight.
	Fluoroquinolones: Ofloxacin (Floxin) Levofloxacin (Levaquin) <i>Inhibit cell wall synthesis</i>	PO or IV	GI upset Dizziness Headache CNS disturbances Flatulence Rash Photosensitivity Rare but serious: Tendon rupture	Do not administer with antacids. Caution with other medication use; renal, hepatic or CNS disorders.
Medications Used for Cancer of the Male Reproductive System: Testosterone-Suppressing/Blocking Agents	Leuprolide (Lupron) <i>Initially stimulates then inhibits follicle-stimulating and follicle-luteinizing hormones (FSH and LH) to suppress testosterone</i>	SQ or IM	GI upset Insomnia Sexual dysfunction Tremor Bone pain Constipation Gynecomastia CNS disturbance Photosensitivity Serious: Elevated liver enzymes Arrhythmias MI	Store drug at room temperature and protect from light. Instruct patient that signs and symptoms may increase initially. Monitor for side effects.
	Goserelin (Zoladex) Analogue to luteinizing-releasing hormone; works on pituitary to decrease follicle-stimulating hormone to decrease sex hormones	Implanted	GI upset CNS disturbance Bone pain Sexual dysfunction Skin disorders Gynecomastia Serious: Arrhythmias Hypertension Urinary obstruction Spinal cord compression	Inject into upper abdominal wall. Do not aspirate syringe. Educate patient medication may increase testosterone initially, thus increase incidence of signs and symptoms.
	Flutamide (Eulexin) <i>Inhibits androgen uptake and/or binding in tissues</i>	PO	GI upset Fatigue Sexual dysfunction Incontinence Constipation Rash Photosensitivity Gynecomastia Serious: Hypertension Hepatotoxicity Blood dyscrasias	Instruct patient that urine color changes to amber/yellow-green; avoid excess exposure to sun; promptly report side effects. Monitor hepatic function tests.
	Diethylstilbestrol (DES) (estrogen preparation) <i>Decreases FSH and LH to decrease testosterone</i>	PO or IV	GI upset CNS disturbance Visual disturbance Serious: Seizures Hypertension Thromboembolism*	Give with or after meals. Use cautiously with other disease processes or with conditions that lead to prolonged immobilization.

Medication Class	Medication/Action	Route	Side Effects	Nursing Implications
Medications Commonly Used for BPH				
Alpha-Adrenergic Antagonists and Alpha-Reductase Inhibitors	Tamsulosin (Flomax) Terazosin (Hytrin) Alfuzosin (Uroxatral) Doxazosin (Cardura) Alpha-adrenergic antagonists Relax smooth muscle; produce vasodilation	PO	GI upset Dry mouth CNS disturbance Visual disturbance Palpitations Urinary urgency Sexual dysfunction Serious: Profound hypotension	Warn patient dizziness may occur with onset of use; report side effects. Monitor blood pressure/pulse. Do not crush or chew tablets. Caution with driving or use of heavy machinery.
	Finasteride (Proscar) Dutasteride (Avodart) <i>Alpha-reductase inhibitors. Inhibit enzyme responsible for formation of potent androgen from testosterone</i>	PO	Sexual dysfunction Gynecomastia Decreased volume of ejaculation	Do not chew or crush tablets. Baseline PSA and DRE before use. Instruct patient on side effects. Caution with liver dysfunction.
Medications Commonly Used for Erectile Dysfunction				
Vasodilators, Smooth Muscle Relaxers, Hormone Replacement	Sildenafil (Viagra) Tadalafil (Cialis) Vardenafil (Levitra) <i>Relax smooth muscle; produce vasodilation</i>	PO	GI upset Dizziness Headache Visual disturbance Flushing Rash Rare but serious: Prolonged erection Arrhythmias MI Stroke	Take about 1 hr before sexual activity (may be taken 0.5–4 hr before). Assess cardiovascular status before use; may be contraindicated. Avoid use when taking nitroglycerin preparations.
	Alprostadil (Caverject injection or Muse suppository) Prostaglandin E1 <i>Relax smooth muscle; produce vasodilation</i>	Intracavernosal injection or intraurethral suppository	Flulike symptoms Diarrhea Penile pain/fibrosis Urethral burning/bleeding Prolonged erection CNS disturbance Flushing Serious: Hypotension Seizures Heart rate disturbance	Monitor vital signs. Inform patient erection should occur in 2–5 min and not last for >4 hr. Instruct patient to report side effects immediately.
	Yohimbine <i>Herbal vasodilator</i>	PO	GI upset Tremors CNS disturbance Insomnia Tachycardia Serious: Hypertension OR severe hypotension Arrhythmias Cardiac failure	Assess for other medical conditions before use. Monitor blood pressure, renal and hepatic function.
	Testosterone transdermal (Testoderm, Androderm)	Transdermal patch	Gynecomastia Acne Nausea	Rule out cancer before use. Monitor hepatic function. Instruct patient to report side effects, prolonged erection, difficulty urinating.
	Testosterone cypionate (Depotestosterone injection) <i>Testosterone replacements; produce androgen effects</i>	IM	Insomnia Edema Male pattern baldness Itching Erythema Skin irritation Bladder irritability	

CNS = central nervous system; DRE = digital rectal examination; GI = gastrointestinal; MI = myocardial infarction; PSA = prostate-specific antigen.
 *NOTE: This medication promotes profound defects of the reproductive organs in offspring when taken by pregnant women. Even though this discussion is related to male disorders, it is prudent to acknowledge this fact at this time.

Impaired urinary elimination related to obstruction

EXPECTED OUTCOME: Patient will be able to void with urinary residual <25% of bladder capacity.

- If suspicion of urinary retention is present, determine urinary residual volume by catheterizing patient or obtaining a bladder ultrasound immediately after voiding. *Incomplete emptying of the bladder may lead to increased discomfort or ascending infection.*
- Have the patient complete a bladder log including patterns of elimination and urine loss, as well as volume/type of fluid consumed for 3 to 7 days. *This will provide for an objective verification of intake and output volumes and aid in determination of urinary retention.*
- Educate patient about avoidance of risk factors for urinary retention (e.g., alpha-adrenergic agonists, overfilling of the bladder). *These are modifiable variables that may limit retention of urine.*

Ineffective health maintenance: knowledge deficit related to cause, treatment, and prevention of prostatitis

EXPECTED OUTCOME: Patient will verbalize understanding of disorder and meet goals for health plan.

- Determine patient's current knowledge and understanding about cause and treatment of prostatitis. *This will allow for additional and/or correct information to be provided about the disorder for appropriate understanding.*
- Provide patient with additional and/or correct information about the cause and treatment of prostatitis. *This will allow the patient to have a full understanding of the etiology and care related to the disorder and increase likelihood of patient compliance.*
- Include patient's partner in care. *Some treatment options may also include treatment of the partner (e.g., sexually transmitted diseases such as gonorrhea, chlamydia, or trichomoniasis; see Chapter 44).*
- Encourage use of antibiotics as directed, and advise to take medication until finished *in order to best treat infection and prevent development of antibiotic-resistant bacteria.*

Impaired comfort related to swelling and irritation of the prostate gland

EXPECTED OUTCOME: Patient will state that comfort is at an acceptable level.

- Use a culturally appropriate pain scale to help patient identify comfort level. *This will aid in understanding comfort level as defined by the patient and aid in guiding appropriate interventions.*
- Encourage appropriate use of anti-inflammatory medication as ordered. *This will decrease inflammation and promote comfort.*
- Encourage use of comfort measures such as warm

sitz baths or prostatic massage, as needed, *to decrease swelling and promote comfort.*

- Consult physician about need for stool softeners. *Firm stool will further irritate the prostate during defecation and increase discomfort.*

Anxiety related to sexual concerns

EXPECTED OUTCOME: Patient will identify presence of anxiety and verbalize concerns about sexuality.

- Identify source of concern related to sexual activity and meaning assigned to disorder as described by the patient. *This will help in guiding interventions that are appropriate for the patient related to etiology of concern.*
- Explore coping skills previously used by the patient to relieve anxiety, reinforce these skills, and explore other outlets for stress. *Coping mechanisms that have been helpful in the past may aid patient in dealing with current stressors that result in anxiety.*
- Encourage the patient to discuss possible complications and questions about sexual practices with his health-care provider. *In some cases, sexual intercourse is encouraged as a means of relieving prostatic congestion; in other situations, it may be contraindicated.*

EVALUATION. A clean urine culture with complete disappearance of signs and symptoms of prostatitis is the desired outcome. Maintaining an acceptable comfort level, understanding the cause and treatment plan, and verbalizing concerns related to the disorder are also desired throughout the care process. Prevention of chronic prostatitis can generally be achieved with patient education.

PATIENT EDUCATION. Teach the patient the causes, prevention, and treatment of prostatitis. Include risk factors such as the use of indwelling urinary catheters, poor hygiene or risky sexual practices, excessive intake of bladder irritants such as alcohol, ignoring signs and symptoms of UTIs, and poor compliance with the antibiotic treatment plan.

Encourage the patient to wash his hands and sitz bath equipment before and after each treatment. Fluids such as water and cranberry juice should be encouraged up to 2500 to 3000 mL per day unless contraindicated by heart failure or other chronic illness. Bladder irritants in the form of caffeine products (e.g., coffee, tea, cola, and chocolate), citrus juices, and alcohol should be taken in very limited amounts. Encourage the patient to empty his bladder every 2 to 3 hours even if he does not feel the urge to urinate.

Benign Prostatic Hyperplasia

Enlargement of the prostate gland is a normal process in older men. It begins at about age 50 and happens in 75% of men older than age 70. Benign prostatic hyperplasia (BPH) is a nonmalignant growth of the prostate that gradually causes urinary obstruction. According to current studies,

BPH does not increase a man's risk of developing cancer of the prostate.

Pathophysiology

There is a slow increase in the number of cells in the prostate gland, generally the results of aging and the male hormone dihydrotestosterone. As the size of the prostate gland increases, it begins to compress or squeeze the urethra shut. The narrowing of the urethra means the bladder must work harder to expel the urine. More effort and a longer time is required to empty the bladder. Eventually the narrowing causes an obstruction and may lead to urinary retention or eventually distention of the kidney with urine (hydronephrosis).

It is the location of the enlargement, not the amount, that causes the problem. A small growth in the prostate gland closest to the urethra may cause more problems with urination than a growth the size of an orange in the outer portion of the gland.

Etiology

There is no known cause of BPH other than normal aging. Some men think they may have caused the problem by certain sexual practices; however, there is no scientific proof at this time. Some factors that are being investigated in research studies are high-fat diet, ethnic background, and lifestyle issues.

Prevention

Because there is no known cause, there is no proven method to prevent enlargement of the prostate gland. There are many new treatments that are aimed at slowing down the enlargement process. One such treatment that is being researched is the herbal supplement saw palmetto.

Signs and Symptoms

Symptoms of BPH are usually identified in two ways; they are either problems related to obstruction or problems related to irritation. Symptoms related to obstruction include decrease in the size or force of the urinary stream, difficulty in starting a stream, dribbling after urination is thought to be completed, urinary retention, and a feeling that the bladder is not empty. The patient may also experience overflow incontinence or an interrupted stream, where the urine stops mid stream and then starts again.

Symptoms related to irritation include nocturia, dysuria, and urgency. A prostatic symptom index score sheet has been developed, and health-care providers are asking their older patients the questions as a way of assessing the seriousness of their symptoms and determining treatment options.

Complications

When BPH is untreated and obstruction is prolonged, serious complications may occur. Urine that sits in the bladder for too long can back up into the kidneys and cause hydronephrosis, renal insufficiency, or **urosepsis**; it can also

damage the bladder walls, leading to bladder dysfunction, recurrent UTIs, or calculi (stones).

Diagnostic Tests

The first step is a medical history, including specific questions about the patient's symptoms. A DRE of the prostate is then conducted by the health-care provider to assess for enlargement and whether the gland is hard, lumpy, or "boggy." Primary tests include urinalysis and blood work. BUN (blood urea nitrogen), serum creatinine, and prostate-specific antigen (PSA) levels may be elevated. Secondary tests include **urodynamic** flow studies which may show a decreased urine flow rate. Transrectal ultrasound of the prostate and cystoscopy may reflect structural abnormalities.

Therapeutic Interventions

If the patient has no symptoms or only mild ones, the most current medical approach is "watchful waiting." The health-care provider watches for any increase in symptoms or signs that the urethra is becoming obstructed. Treatment of symptoms may include use of a catheter (indwelling or intermittent), encouraging oral fluids, and antibiotics for UTI.

Conservative medical treatment includes the use of medication to either relax the smooth muscles of the prostate and bladder neck or block the male hormone to prevent or shrink tissue growth. Alpha-adrenergic antagonists are medications that relax the smooth muscles, such as tamsulosin (Flomax), terazosin (Hytrin), and doxazosin (Cardura). These medications are also used to treat high blood pressure, so patients need to work closely with their health-care providers to avoid overdose or the negative side effects of postural hypotension (see Table 43.1).

The most commonly used medications to block the action of the male hormone in the prostate gland are finasteride (Proscar) and dutasteride (Avodart). All these medications must be taken on a long-term, continuous basis to achieve results. Conservative measures are used initially unless there are recurring infections, repeated gross hematuria, bladder or kidney damage, evidence of cancer, or unsatisfactory lifestyle changes.

Nonsurgical invasive treatments, some of which are experimental, are available in some areas of the country in addition to surgical options. These include the transurethral microwave antenna (TUMA), which involves heat applied directly to the gland, and may inhibit growth, and the prostatic balloon, which dilates the urethra by stretching or compressing urethral tissue. Prostatic stents may be used to open the passageway for urine to flow more freely.

Surgical Treatment

TRANSURETHRAL RESECTION OF THE PROSTATE.

During the past 50 years, transurethral resection of the prostate (TURP) has been the surgical treatment used most often to relieve obstruction caused by an enlarged prostate (Fig. 43.1). Several other transurethral options also exist. Transurethral incision of the prostate (TUIP) uses surgical

urosepsis: uro—urine + sepsis—systemic infection

urodynamic: uro—urine + dynamic—force

FIGURE 43.1 Transurethral resection of the prostate.

incisions into the gland to relieve obstruction. Transurethral ultrasound-guided laser-induced prostatectomy (TULIP) uses laser to relieve obstruction.

For TURP, the patient is anesthetized and the surgery is performed using an instrument called a resectoscope. The resectoscope is inserted into the urethra and the prostate gland is “chipped” away a piece at a time. Special surgical instruments are now being used that “vaporize” or “microwave” the pieces and cut down on the amount of bleeding during surgery. During routine TURP, the “chips” are flushed out using an irrigating solution and are sent to the laboratory to be analyzed for possible evidence of cancer. The prostate gland is not completely removed but peeled away like the rind of an orange. The prostatic tissue that is left eventually grows back and can cause obstruction again at a later time. Patients need to be reminded to continue having yearly prostate examinations.

As the tissue is removed during TURP, bleeding occurs. A Foley catheter is left in place with 30 to 60 mL of sterile water inflating the balloon. The balloon is overfilled and may be secured tightly to the leg or abdomen to **tamp-ponade** (compress) the prostate area and stop the bleeding. Irrigation solution generally flows continuously (Fig. 43.2); manual irrigation may be done for the first 24 hours to help maintain catheter patency by removing clots and chips. The health-care provider will remove the Foley catheter after the danger of hemorrhage has passed.

You may need to save “serial urines” after the Foley catheter has been removed. To do this, each time the patient urinates, save some of the urine in a transparent cup, and make sure to line up the cups in order (usually on a shelf in the bathroom). This way you or the physician can see whether the urine is becoming progressively less bloody and clearer with each void.

Complications associated with prostate surgery depend on the type and extent of the procedure performed. The main

FIGURE 43.2 Bladder irrigation.

medical complications include clot formation, bladder spasms, and infection. Less common complications may be urinary incontinence, hemorrhage, and erectile dysfunction (Box 43.1 Nursing Care Plan for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia).

Retrograde ejaculation is a common side effect of prostate surgery. When any of the prostate gland is removed, there is a decrease in the amount of semen produced and a part of the ejaculatory ducts may be removed. The result is that less semen is pushed outside the body, and instead it “falls back” into the bladder. This causes no harm; the semen is simply passed during the next urination.

It is important to understand that erection, ejaculation, and orgasm are all separate actions. Erection means the penis becomes hard, ejaculation is the release of semen, and orgasm is felt as pulsations along the urethra. Unless additional problems are present, the patient continues to have erections and orgasmic sensations but decreased or no ejaculation.

RADICAL PROSTATECTOMY. When the prostate gland is very large, is causing obstruction, or is cancerous, a radical **prostatectomy** is performed to remove the entire prostate gland.

retrograde: retro—backward + grade—step

prostatectomy: prostat—prostate gland + ectomy—excision

Open Prostatectomy. Several approaches may be taken during traditional radical surgery (Fig. 43.3). In the **suprapubic** approach, an incision is made through the lower abdomen into the bladder. The gland is removed, and the urethra is reattached to the bladder. The retropubic approach is similar except there is no incision into the bladder. A perineal prostatectomy involves making an incision between the scrotum and anus and removing the gland. This procedure is rarely done because of the increased risk of contamination of the incision (close to the rectum), and risk of urinary incontinence, erectile dysfunction, or injury to the rectum.

An open prostatectomy means a longer hospital stay compared with other BPH surgeries. A suprapubic catheter and care for an abdominal incision increase the length of stay and the risk for complications. Follow-up home care for

wound dressing changes and catheter care is an important aspect of nursing interventions for these patients.

Minimally Invasive Prostatectomy. Newer techniques use laparoscopy and even tiny robot arms to perform radical prostatectomy through five small “porthole” incisions in the abdomen. The surgeon makes all the decisions about the surgery while guiding the robotic arms. The robotic arms allow more precision and maneuverability, especially in small areas. Because robotic surgery is so much less invasive, studies are showing better results with less post-operative bleeding and incontinence and shorter hospital stays.

Nursing Process for the Patient with BPH and TURP

ASSESSMENT/DATA COLLECTION. Begin by asking the patient if he has ever had treatment or surgery for

suprapubic: supra—above + pubic—pubic bone

(Text continued on page 944)

Box 43.1 NURSING CARE PLAN for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia

Nursing Diagnosis: Risk for injury (bleeding) related to surgical intervention

Expected Outcomes Urine will become progressively more clear, with no abnormally heavy bleeding.

Evaluation of Outcomes (1) Is urine clearing? (2) Is bleeding reported promptly?

Interventions

Closely monitor urinary output in terms of amount, color, and presence of clots at least every hour for the first 24 to 48 hr postoperatively. Monitor serial urines.

Explain to patient that some bloody urine is normal after a TURP, as long as it does not suddenly get much worse. Also explain that a little blood mixed with irrigating fluid in a Foley bag may look worse than it actually is.

Encourage patient to drink up to 2500 mL per day (unless contraindicated by other medical conditions) of water, noncitrus juices, and other noncaffeinated, nonalcoholic beverages.

Teach patient to avoid constipation (stool softener, fluids, prune juice) and heavy lifting.

Advise patient to lie down if urine becomes bright red or has large clots.

Teach patient to avoid aspirin and NSAIDs until risk of bleeding is over.

Rationale

Careful monitoring and reporting of changes can help prevent major complications.

Seeing the catheter bag filled with bloody drainage may be upsetting to a patient or his family.

Increasing urine flow can help flush blood from bladder.

These can increase pressure in the abdomen and cause bleeding.

Activity can increase bleeding.

Aspirin and NSAIDs reduce platelet function and increase risk of bleeding.

Evaluation

Is urine becoming progressively less bloody and more clear with each void?

Is patient aware of what to expect in Foley bag?

Is patient drinking adequate amounts?

Does patient verbalize understanding of instructions?

Does patient reduce activity if bleeding increases?

Does patient verbalize understanding?

(Continued on following page)

Box 43.1 NURSING CARE PLAN for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia (*Continued*)

Nursing Diagnosis: Acute pain related to bladder spasms, obstruction, or surgical process

Expected Outcomes (1) Patient states pain has decreased to acceptable level. (2) Patient identifies at least two comfort measures.

Evaluation of Outcomes (1) Does patient state that pain is decreased to acceptable level? (2) Is patient able to identify at least two measures that will help relieve pain?

Interventions

Monitor pain every 2 to 4 hr for first 48 hr and within 30 min of any intervention using a culturally specific scale.

Monitor for signs of pain related to bladder spasms, obstruction, or surgical process, such as facial grimaces, irrigation solution that does not flow into bladder, urinating around catheter, multiple clots.

Give prescribed medication (analgesics, antispasmodics such as B&O suppository) and monitor response.

Irrigate catheter as ordered.

Educate regarding and support use of nonpharmacologic methods to control pain such as relaxation and deep breathing techniques.

Rationale

A pain scale is a more accurate measure of pain.

Relief of mechanical cause of pain promotes comfort, rest, and healing.

Medications relieve symptoms.

Removal of clots reduces spasms and pain.

Relaxation calms spasms and relieves pain. Nonpharmacologic measures should be used with, not in place of, medication.

Evaluation

Does patient verbalize pain as increasing or decreasing on the scale?

Is patient free from signs of pain related to bladder spasms, obstruction, or surgical process?

Does patient state relief when medications are given?

Does irrigating solution go in and out easily?

Are clots being removed?
Is patient able to relax?

Nursing Diagnosis: Urge urinary incontinence related to poor sphincter control

Expected Outcomes (1) Patient identifies at least two methods to achieve dryness. (2) Patient verbalizes satisfactory control of dribbling.

Evaluation of Outcomes (1) Does patient identify ways to prevent incontinence? Do they help? (2) Does patient verbalize satisfaction with outcome?

Interventions

Teach Kegel (pelvic floor) exercises (see Chapter 42)—to be practiced every time patient urinates and throughout the day.

Discuss use of condom catheter or penile pads.

Instruct patient to continue drinking 2000 to 4000 mL of noncaffeinated, nonalcoholic beverages each day.

Encourage patient to discuss long-term (>6 months) incontinence problems with physician. National incontinence support groups are available.

Rationale

Strengthens muscle tone to hold urine after catheter is removed.

Specific urine control devices are available for men.

Adequate nonirritating fluid intake is important for healing and preventing UTI.

Patient may need to learn self-catheterization or try medication.

Evaluation

Is patient able to start and stop urine stream?

Does patient indicate an informed choice of incontinence products?

Does patient drink adequate fluids even though he dribbles?

Does patient verbalize understanding of what to do if incontinence continues?

Nursing Diagnosis: Ineffective therapeutic regimen management related to lack of knowledge of postoperative restrictions and care

Expected Outcomes (1) Patient avoids activities that increase intra-abdominal pressure resulting in excessive bleeding. (2) Patient verbalizes understanding of how to prevent postoperative infection.

Evaluation of Outcomes (1) Does patient verbalize understanding of how to prevent bleeding? (2) Is infection prevented?

Interventions

Teach patient to avoid lifting heavy objects (>10 lb), stair climbing, driving, strenuous exercise, constipation, straining during bowel movements, and sexual activities until approved by physician (about 6 weeks).

Instruct patient on proper catheter care using verbal, written, and demonstration techniques (some patients are sent home before catheter is removed). Include the following information:

- Keep catheter bag secured to abdomen or thigh and below bladder.
- Wash catheter/meatal junction with soap and water once daily.
- Use clean technique to change from leg bag to night drainage bag.
- Report signs and symptoms of UTI to physician immediately.
- Encourage oral fluids.

Teach all patients to report bleeding that is not stopped with resting, fever, swelling, or difficulty urinating to physician promptly.

Rationale

Heavy lifting or straining can disrupt the healing process and result in tissue damage or excess bleeding.

Urinary tract infections are extremely dangerous and can cause death following genitourinary surgery in an elderly patient.

These are signs of complications that may require prompt intervention.

Evaluation

Does patient verbalize understanding of reasons for limitation of heavy lifting and straining?

Can patient give a return demonstration of proper catheter care? Is patient free from signs and symptoms of infection?

Does patient verbalize understanding of signs and symptoms to report?

Nursing Diagnosis: Anxiety related to concerns over loss of sexual functioning following prostate surgery

Expected Outcomes (1) Patient verbalizes normal sexual changes that happen after prostate surgery. (2) Patient identifies support systems if needed.

Evaluation of Outcomes Is patient able to verbalize understanding of expected body function following prostate surgery?

Interventions

Explain to patient that he will probably have retrograde ejaculation into bladder after surgery. It is not harmful and semen will come out when he urinates.

Instruct patient to talk with urologist if erection problems occur.

Rationale

Removal of the prostate gland often results in retrograde ejaculation.

Urologists who specialize in treatment of erectile dysfunction can be helpful.

Evaluation

Does patient understand what will happen when he ejaculates?

Is patient aware of local support services?

B&O = belladonna and opium; NSAIDs = nonsteroidal anti-inflammatory drugs; TURP = transurethral resection of the prostate; UTI = urinary tract infection.

FIGURE 43.3 (A) Suprapubic prostatectomy. (B) Retropubic prostatectomy. (C) Perineal prostatectomy.

prostate trouble. Assess amount and type of fluid intake per day and whether the patient has noticed any of the symptoms of BPH. Monitor output, and, if he is not catheterized, assure that urine retention is being managed appropriately.

NURSING DIAGNOSES, PLANNING, AND INTERVENTIONS. Nursing diagnoses for patients with mild or no symptoms are directed at knowledge deficits related to prevention of UTIs, knowing when to report an increase in symptoms to the health-care provider, and taking medication exactly as the health-care provider orders. Instruct patients to report changes in urinary output or difficulty voiding. Advise the patient to keep a log book of intake and output and difficulty voiding. Assure that patients scheduled for prostate surgery understand what to expect after surgery.

For nursing care of the patient following TURP see Box 43.1 Nursing Care Plan for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia. In addition, each patient experiences individual responses and needs. Care plans must be individualized, keeping in mind that the majority of these patients are elderly and have secondary medical problems such as cardiovascular disease.

EVALUATION. A patient should be discharged home with a minimum of bladder discomfort, light pink to clear urine, no evidence of UTI, and knowledge related to self-care at home. Home care nursing may be required if the patient lives alone or does not have the capacity to provide for meals, toileting, or transportation for the follow-up visit. See Box 43.2 Benign Prostatic Hyperplasia Summary.

Cancer of the Prostate

Cancer of the prostate is the second most common cause of cancer death in American men older than 60 years of age. The incidence of prostate cancer has been on the rise for many years, and just recently has begun to drop slightly. The

CRITICAL THINKING

Mr. Atkinson

■ Mr. Atkinson is a 68-year-old African American farmer with an enlarged prostate. He lives on a 75-acre farm with his wife and one son. He is scheduled for a TURP in 6 weeks.

1. Mr. Atkinson is currently taking terazosin (Hytrin), and his physician wants him to increase his dose from 2 mg to 5 mg q hr until surgery. He has a bottle at home of 2-mg tablets. How should you instruct him to take his medication? What side effect should he be advised to watch for?
2. What postoperative instructions should he be given in light of his occupation?
3. What should you tell him if he asks about how the surgery will affect his “nature” (sexual activities)?

Suggested answers at end of chapter.

cause for this is unknown. Most prostate cancers are very slow growing and often do not cause a major threat to health or life.

Pathophysiology

Prostate cancer depends on testosterone to grow. The cancer cells are usually slow growing and begin in the posterior (back) or lateral (side) part of the gland. The cancer spreads by one of three routes. If it spreads by local invasion, it will move into the bladder, seminal vesicles, or peritoneum. The cancer may also spread through the lymph system to the pelvic nodes and may travel as far as the supraclavicular nodes. The third route is through the vascular system to bone, lung, and liver. Prostate cancer is staged or graded based on the growth or spread.

Box 43.2**Benign Prostatic Hyperplasia (BPH) Summary****Signs and Symptoms**

- **Related to Obstruction:** Decrease in size/force of stream, difficulty in starting stream, dribbling, interrupted stream, urinary retention, overflow incontinence
- **Related to Irritation:** Nocturia, dysuria, urgency

Diagnostic Tests

- **Primary:** Urinalysis, BUN, serum creatinine, prostate-specific antigen (PSA)
- **Secondary:** Urodynamic flow studies, transrectal ultrasound, cystoscopy

Therapeutic Interventions

- **Conservative:** Alpha-blockers, testosterone blockers
- **Nonsurgical:** Transurethral microwave antenna (TUMA), prostatic balloon, prostatic stents
- **Transurethral:** Transurethral incision of the prostate (TUIP), transurethral ultrasound-guided laser-induced prostatectomy (TULIP), transurethral resection of the prostate (TURP)
- **Radical Prostatectomy:** Suprapubic, retropubic, perineal, laparoscopic, or robotic resection

Complications

- Ascending or localized infection
- Injury to surrounding tissues during surgery
- Impaired sexual function related to tissue injury

Priority Nursing Diagnoses

- Impaired urinary elimination related to obstruction
- Ineffective health maintenance: knowledge deficit related to causes, treatment, and prevention of BPH
- Pain (acute or chronic) related to urine retention, bladder spasms, surgery

Etiology

Age is the primary risk factor. Prostate cancer is found most often in men older than age 65 and is rare in men younger than age 40. Other risk factors are higher levels of testosterone, high-fat diet, and immediate family history.

Prostate cancer rates are highest in African American men and lowest in American Indian and Native Alaskan men.¹ Occupational exposure to cadmium (e.g., welding, electroplating, alkaline battery manufacturing) has been identified as an added risk factor.

Signs and Symptoms

Symptoms are rare in the early stage of prostate cancer. Later stages include symptoms of urinary obstruction, hematuria, and urinary retention. In the advanced (metastatic) stage, symptoms may be bone pain in the back or hip, anemia, weakness, weight loss, and overall tiredness.

Complications

Early complications of prostate cancer are related to bladder problems, such as difficulty in urinating, and bladder or kidney infection. As the cancer metastasizes, the patient may develop problems such as pain, bone fractures, weight loss, and depression; eventually death may occur if treatment is not successful.

Diagnostic Tests

A routine DRE of the prostate is the first test; often the examiner finds a hard lump or hardened lobe. Blood tests

looking for high levels of prostate-specific antigen (PSA) or prostatic acid phosphatase (PAP) are done. When there is a palpable tumor, the health-care provider may order a transrectal ultrasound and biopsy to help confirm the diagnosis. Bone scans and other tests may be ordered to determine if the cancer has spread outside the prostate gland.

Therapeutic Interventions

Prostate cancer in the early stages may be treated with testosterone-suppressing medications, such as leuprolide (Lupron) or goserelin (Zoladex); surgery, such as TURP or radical prostatectomy; or a combination of medication and radiation therapy. In later stages, the treatment is usually a radical prostatectomy, radiation therapy, or implantation of radioactive “seeds” into the prostate (brachytherapy). Metastatic prostate cancer treatment involves relief of symptoms or blocking testosterone by bilateral **orchiectomy**, estrogen therapy (diethylstilbestrol [DES]), administration of antiandrogen (flutamide [Eulexin]), or use of agents such as leuprolide and goserelin. Sometimes chemotherapy is used to help relieve symptoms from the cancer spread.

Brachytherapy, external-beam radiation therapy, and radical prostatectomy combinations are showing favorable results in the treatment of advanced cancer. Gene therapy, vaccine, and immune-based interventions are the latest medical treatment options under investigation in the war against

orchiectomy: orchi—testes + ectomy—excision

prostate cancer. Nontraditional prostate cancer prevention using vitamin E and selenium continue to be investigated.

RADICAL PROSTATECTOMY. The radical prostatectomy procedure is generally reserved for patients with cancer of the prostate or when the gland is too large to resect using the TURP method.

The patient returns from surgery with a large indwelling catheter in the urethra and may also have a suprapubic catheter. Often there is a Penrose or sump drain in place to remove fluids from the abdominal cavity and allow the wound to heal from the inside outward. Special care must be taken to keep the incision and drain sites clean and dry. Dressings should be changed according to institution policy using sterile technique.

There are more complications associated with radical prostatectomy than any other treatment option. The major complications are hemorrhage, infection, loss of urinary control, and erectile dysfunction.

Patient Education

All men older than age 40 should be encouraged to have a yearly DRE of the prostate. Prevention and early detection are the best ways to fight prostate cancer.

PENILE DISORDERS

Problems of the penis, aside from sexually transmitted diseases, are fairly rare but may cause great concern and worry for the patient. Most men have difficulty seeking help for a “private” problem. It is important to be sensitive when assessing or providing care for these patients.

Peyronie’s Disease

Peyronie’s disease often gives the penis a curved or crooked look when it is erect. Fibrous bands or plaques form mainly on the dorsal (top) part of the layer of tissue that surrounds one of the corpora cavernosa of the penis. The plaque may be caused by injury or inflammation of the penile tissue, or it may come and go spontaneously. If the plaque is thick enough, it can cause curvature, painful erection, difficulty in vaginal penetration, and erectile dysfunction. When conservative treatments such as vitamin E, steroids, or ultrasound do not work, surgery may be needed to remove the plaque. Patients need to be reassured that the problem is not life threatening and can be treated.

Priapism

Priapism is a painful erection that lasts too long. Anytime an erection lasts for longer than 4 to 6 hours it can become a medical emergency. The small veins in the corpora cavernosa spasm, so the blood cannot drain back out of the penis as it should. When the blood cannot drain, the tissue of the

penis does not get oxygen and there can be permanent tissue damage. There may be a complete loss of erection ability after the priapism episode. Prolonged priapism can also prevent the patient from passing urine, which can lead to painful bladder and kidney problems. Some causes of priapism are prolonged sexual activity, sickle cell anemia, leukemia, widespread cancer, spinal cord injury or tumors, and use of medication or recreational drugs such as crack cocaine. Treatment in the emergency department may include ice packs, sedatives, analgesics, injection of medications directly into the penis to relax the vein spasms, needle aspiration, and irrigation of the corpora. If all else fails, surgery is done to drain the blood out of the penis.

Phimosis and Paraphimosis

Phimosis is the term used to describe a condition in which the foreskin of an uncircumcised male becomes so tight it is difficult or impossible to pull back away from the head of the penis. It may make it impossible to clean the area underneath. Smegma, a cottage cheese–like secretion made by the glands of the foreskin, becomes trapped under the foreskin and is an excellent place for the growth of bacterial and yeast infections. Treatment usually begins with antibiotics and warm soaks to the area. The physician may then cut a small slit in the foreskin to relieve the pressure and treat the infection. A full circumcision may be recommended if the problem continues or if a condom catheter is necessary for urine drainage. Phimosis is generally prevented by teaching uncircumcised males to pull the foreskin back carefully, wash with mild soap and water daily, and replace the foreskin to its normal position.

Paraphimosis occurs when the uncircumcised foreskin is pulled back, during intercourse or bathing, and not immediately replaced in a forward position. This causes constriction of the dorsal veins, which leads to edema and pain. Moderate to severe paraphimosis is a medical emergency and requires immediate care by a physician. The longer the problem continues, the greater the risk of circulation problems and possible gangrene. Again, prevention through daily cleaning and replacing the foreskin in its normal place is important.

Cancer of the Penis

Cancer of the penis has been found in men who were not circumcised as babies or have acquired the human papillomavirus (HPV). The tumor looks like a small, round, raised wart. It is one form of cancer that may be spread to the sex partner. Several research studies have found a link between cancer of the penis and cancer of the uterine cervix. Cancer of the penis may be treated with minor surgery such as a circumcision or laser removal of the growth. If the cancer has spread, the treatment may mean cutting away part or all of

phimosis: phimo—muzzling + osis—condition

paraphimosis: para—abnormal + phimo—muzzling + osis—condition

priapism: priap—phallus + ism—condition of

the penis, radiation, or chemotherapy. Finding and treating any wartlike tumor in its earliest stages is an important part of patient education.

TESTICULAR DISORDERS

Cryptorchidism

Cryptorchidism (undescended testes) is a congenital condition in which a baby boy is born with one or both of his testes not in the scrotum. The testes normally drop down (descend) into the scrotum in the last 1 to 2 months before the boy is born. Many times the testes descend into the scrotum on their own by 2 years of age. If they do not descend by the age of 2, surgery should be done to correct the problem. Testes that are not brought down into the scrotum decrease a man's chances of producing a child, usually because excessive body heat damages sperm production in the testes. Studies have shown that the chances of testicular cancer are also higher if the condition is not corrected before the child reaches his teen years. If normal male sex characteristics do not develop during puberty because the testosterone level is too low, extra testosterone medication may be given. Testosterone can be administered in the form of a daily pill, by long-term injection, or by patch.

Hydrocele

A **hydrocele** is a collection of fluid in the scrotal sac. Hydroceles are not dangerous and generally do not cause any pain. The cause is not known, and it can happen at any point during the lifetime. No treatment is necessary unless the hydrocele is so large that it causes discomfort or embarrassment or is a threat to the blood supply to the testes. If treatment is needed, the health-care provider aspirates, or surgically drains, the fluid.

Varicocele

A varicocele is a condition sometimes called varicose veins of the scrotum. The main blood supply to the testes travels along the spermatic cord. The veins become dilated, and when the man is standing, the area in the scrotum begins to feel like a “bag of worms.” The patient may complain of a pulling sensation, a dull ache, or scrotal pain. The sensations are most often felt when standing up. Most varicoceles occur on the left side because of the way the scrotal vein enters at a sharp angle from the left renal vein.

A varicocele is often not discovered until a couple tries to have a baby and is unable to conceive. It is believed that the varicose veins may increase the temperature of the testes and cause damage to the sperm. The most successful treatment is surgical repair of the varicose veins.

cryptorchidism: crypt—hidden + orchid—testis + ism—condition

hydrocele: hydro—water + cele—swelling

Epididymitis

The epididymis is a small tube along the back of the testes where sperm is matured for its last 10 to 12 days before it is ready to be ejaculated. Epididymitis is inflammation or infection of the epididymis that may be caused by bacteria, viruses, parasites, chemicals, or trauma. Epididymitis may be facilitated by sexual or nonsexual contact, a complication of some urological procedures, or reflux (backflow) of urine. The problem may also be associated with prostate infections and is usually painful, with the scrotal skin being tender, red, and warm to the touch.

Epididymitis is treated with antibiotics; the partner is also treated if it was sexually transmitted. Depending on the severity of the pain, the patient may be placed on bedrest with the scrotum elevated, possibly on ice packs, and also given analgesics. The pain and tenderness usually go away in about a week, although the swelling may last for several weeks. Complications may include chronic epididymitis, abscess formation, and sterility.

Orchitis

Orchitis is a rare inflammation or infection of the testes. The problem may be caused by trauma or surgical procedures, chemical substance, infection from epididymitis, UTI, or systemic diseases such as influenza, infectious mononucleosis, tuberculosis, gout, pneumonia, or mumps (after puberty). The patient has swollen, extremely tender testes, red scrotal skin, and a fever. Interventions are basically the same as for epididymitis and include bedrest, scrotal support, antibiotics, and medication to relieve pain and fever. Complications such as sterility from mumps orchitis can be prevented by giving boys the mumps vaccine at an early age.

Cancer of the Testes

Pathophysiology and Etiology

Cancer of the testes is the most common solid tumor in men 15 to 40 years of age and peaks between 20 and 34 years of age. The etiology of testicular cancer is unknown. Some of the known risk factors are cryptorchidism, family history, mother's use of DES (an estrogen preparation once used to prevent spontaneous abortion) while pregnant, white race, and high socioeconomic status. The tumors are mostly a germ cell type of cancer formed during normal embryo development.

Prevention

The best prevention is monthly testicular self-examination (TSE). The procedure is simple and easy to learn and should be taught to males between ages 15 and 40. See Chapter 41 for instructions on TSE.

Signs and Symptoms

Early warning signs of cancer may include a small, painless lump on the side or front of the testes. The patient may also notice that the scrotum is swollen and feels heavy. Late

orchitis: orch—testis + itis—inflammation

symptoms of back pain, shortness of breath, difficulty swallowing, breast enlargement, and changes in vision or mental status indicate metastasis of the cancer.

Complications

Emotional complications can range from fear of cancer and death to feelings of loss of masculine body image and sexual function. Physical complications may involve dealing with pain and the effects of metastasis to areas such as the lungs, abdomen, or lymph nodes. Other less common areas of cancer spread are the liver, brain, and bone. Treatments such as surgery, chemotherapy, and radiation therapy can all have negative side effects on the patient and require special care.

Diagnostic Tests

When a tumor is found, several laboratory and radiographic tests are done. An ultrasound of the testes is done first. If the test shows cancer, a chest x-ray examination is done to look for spread to the lungs. A scan of the lymph nodes, liver, brain, and bones may also be ordered. Blood is drawn to look for what are called tumor markers. An example of a tumor marker for testicular cancer is beta human chorionic gonadotropin (bHCG). An exploration, biopsy, and removal of the testes are done to decide the stage of the tumor.

Testicular tumors may be staged or classified in several ways. The simplest way to stage a testicular tumor is as follows:

- Stage I—tumor only in the testes
- Stage II—tumor spread to groin lymph nodes
- Stage III—tumor spread past lymph nodes, usually to the lungs

Therapeutic Interventions

Intervention depends on the stage of the cancer. All treatment begins with complete removal of the cancerous testes, spermatic cord, and local lymph nodes. Stage I tumor treatment then includes radiation to the groin area lymph nodes. Treatment for stage II involves chemotherapy. Stage III or metastatic cancer is treated with both radiation and chemotherapy. If the cancer is found in the beginning stages, the chances for complete recovery are about 75%. All patients should have regular follow-up testing.

Nursing Care

Nursing care is directed first at prevention, by teaching young men to practice monthly testicular self-examination and to see their health-care provider if they notice any changes. If a diagnosis of cancer has been made, provide emotional support for the patient. If the patient wants to have children, he should be encouraged to make deposits in a sperm bank before any surgery or treatment is started. The patient and his partner may have many questions about sexual activities as they go through treatment. Encourage them to talk with their health-care provider or a sex therapist about ways to express love and tenderness toward one another. Helping patients deal with pain and the side effects of chemotherapy or radiation therapy are also important nursing interventions for these men. See Chapter 10 for care of the patient with cancer.

CRITICAL THINKING

Mr. Cunningham

■ Mr. Cunningham is a 23-year-old college student engaged to be married next spring. While taking a shower one day he discovers a lump on his left testis.

1. What should he do?
2. What are the treatment options if Mr. Cunningham has cancer of the testes?
3. How can you help Mr. Cunningham cope with the diagnosis?

Suggested answers at end of chapter.

SEXUAL FUNCTIONING

Vasectomy

A **vasectomy** is the surgical cutting and sealing off of the vas deferens to prevent sperm from reaching the outside of the body. This 15- to 30-minute surgery is performed most often as a permanent birth control method but may also be performed on some men during prostate gland removal. The male patient should carefully discuss the surgery with his physician, so there is a clear understanding of the results following the procedure.

The testes continue to produce the male hormone testosterone and sperm. The prostate gland, along with the seminal vesicles, still ejaculate semen, but the semen does not contain sperm. There should be no major change in the way the ejaculate looks or feels following the procedure. The patient should be encouraged to continue using another birth control method for about 6 weeks after surgery to be sure there are no sperm left in the tract above the surgical site. A semen sample should be sent to be evaluated for the absence of sperm before the procedure is considered successful. The sperm continue to be produced in the testes but are absorbed by the body.

There are times when the man may decide he wants to have more children and asks to have the vasectomy “undone.” The surgical procedure to reverse a vasectomy is called a vasovasotomy. Using microscopic instruments, the surgeon reconnects the two pieces of the vas deferens. During the surgery the physician generally tries to determine whether the testes are still producing good sperm. If the vasectomy was done less than 10 years before, the fertility success rate is higher. A vasovasotomy is generally not an option if the vasectomy procedure is more than 10 years old.

Erectile Dysfunction

Problems with getting or keeping an erection can happen at any age and have been a concern of men and their partners for centuries. It is a unique problem because it affects not

vasectomy: vas—vas deferens+ ectomy—excision

only the man but his partner as well. Most men experience a temporary erection problem at some time during their life. It is often caused by stress, illness, fatigue, or an excessive use of alcohol or drugs. When the problem becomes persistent, as it does for more than 30 million men in the United States, it is time to seek medical help.

Before the 1980s, 90% of men who went to their physicians for help were told the problem was emotional, not physical. Through improved testing methods, it is now believed that 80% to 90% of erection problems have a physical cause.

Pathophysiology

The term *impotence* means powerlessness. This term is being replaced with the more accurate term **erectile dysfunction** (ED), which describes a physical condition. Erectile dysfunction means that a man cannot obtain or keep a usable erection that is firm enough and long-lasting enough for satisfactory sexual intercourse. For a man to have a usable erection, several conditions must be met.

1. *Circulatory system.* The blood supply coming into the penis from the arteries must be sufficient to fill the corpora cavernosa (spongy erectile tissue inside the penis), causing the penis to become rigid. The diameter of these vessels is about the size of pencil lead. The veins in the penis must then be able to constrict (narrow down) to trap the blood in the corporal bodies to keep the penis erect. The most common cause of erectile dysfunction is failure in the circulatory system.
2. *Nervous system.* Both the sympathetic and parasympathetic nerves are involved in the erection, ejaculation, orgasm, and resting phases of the penile response cycle. There are many nerve receptors and transmitters in the spinal cord and the penis that must be intact for a usable erection. Spinal cord injuries are the most common neurological cause of erection problems. The remarkable fact about spinal cord injuries is that higher cord injuries (cervical or thoracic) have less negative impact on erections than those in the lumbar or sacral area.
3. *Hormonal system.* There are three basic male hormones involved with an erection. The most important hormone, testosterone, affects a man's sex drive and desire. The testosterone level is highest when a man is in his late teens and begins to decline in middle age. Luteinizing hormone stimulates the production of testosterone, and prolactin in large amounts may block testosterone.
4. *Limbic system.* This is the center in the brain that affects how we feel emotionally. It works with our five senses to stimulate the desire for sex.

All these systems can be influenced by physical, emotional, and chemical factors. A good assessment is important to determine the cause of erectile dysfunction.

Etiology

The psychological causes of erectile dysfunction usually come from stress or anxiety. Marital problems, financial worries, job frustration, or even fear of not being able to perform resulting from an isolated incidence of erection problems may lead to sexual dysfunction. Even when the cause is physical, there are psychological (emotional) side effects. Fear of failure, ridicule, or rejection by the partner lead to a lack of self-esteem or self-confidence.

The list of physical causes is long because it includes anything that may interfere with the flow of blood, the nerve supply, the balance of hormones, or the effects of emotions (Table 43.2). There are many medications and chemicals that can interfere with desire, blood supply, or nerve transmission and cause problems with erections (Table 43.3). The most common types of medications that cause problems are high blood pressure and cardiovascular medications.

Diagnostic Tests

Assessment of erectile dysfunction has now been divided into primary and secondary diagnostic studies according to guidelines developed by the National Institutes of Health. The first step begins with a careful history that is especially designed to focus on the medical-surgical history, medications including any substance abuse, lifestyle patterns, and sexual history. The main areas to investigate are those that indicate vascular, neurological, endocrine, and psychological factors. Physical examination looks for evidence of abnormal genital disorders, hormonal imbalance (such as hair patterns or enlarged breasts), surgical interventions, decreased circulation, and lack of nerve sensations. Blood is taken to look at glucose levels; testosterone; evidence of liver, heart, or kidney disorders; signs of infection; or blood disorders. The health-care provider may also order specific blood tests if other problems exist that may have an impact on erections. Some physicians are also using intracorporeal injection of vasoactive medications that can create an erection to test the blood flow in the penis. A psychological evaluation is recommended to rule out any serious issues in the sexual relationship or emotional problems that may contribute to erectile dysfunction or affect the treatment outcome.

Secondary level of testing may involve the use of sophisticated vascular flow studies to locate areas where either the blood vessels are narrowed or the veins allow the blood to drain out of the penis too rapidly. Another area of testing may be related to sleep tumescence and apnea studies. These studies are based on the physiological process of erections during rapid eye movement (REM) sleep. A healthy man typically has erections every 60 to 70 minutes while he sleeps. Because of the expense of vascular flow studies and sleep studies, they are used on a limited basis.

Therapeutic Interventions

One of the most important treatment options begins with the couple's being able to share intimate communication. No matter what may be causing the problem, if the patient and

TABLE 43.2 CAUSES OF ERECTILE DYSFUNCTION

Psychogenic	Surgical	Vascular	Cardiorespiratory	Neurological
Excessive stress in family, work, or interpersonal relationships; depression; fatigue; fear of failure to perform	Coronary artery bypass Abdominal-perineal resection Cystectomy Radical prostatectomy Pelvic lymphadenectomy Renal transplant Sympathectomy TURP	Aortic aneurysm Arteriosclerosis Aortofemoral bypass Cerebrovascular disease/accident Venous leak Hypertension	Angina pectoris Myocardial infarction COPD Coronary insufficiency Congestive heart failure	Electroshock therapy Multiple sclerosis Parkinson's disease Cerebral palsy Myasthenia gravis Peripheral neuropathy Spinal cord tumor/transection Spinal cord trauma Head injury Spina bifida

COPD = chronic obstructive pulmonary disease.

his partner are not touching, talking, and sharing feelings with one another, any treatment option is going to have limited success.

When the problem has clearly been identified as psychological, counseling therapy is the treatment of choice. If long-term therapy has been tried with only limited success, the addition of oral medication or even intracorporeal injection therapy may be added to provide a boost in confidence and self-esteem. Medical treatment for physical erection problems begins with conservative, nonsurgical treatment and then progresses to surgical options if necessary.

MEDICATION CHANGES. Sometimes all that is needed to correct the problem is a change in medication. There are many prescription, over-the-counter, and street drugs that can cause erection problems (see Table 43.3). It is important for the patient to talk with the health-care provider before discontinuing any medication. Some men have been known to stop taking their blood pressure medication and risk a

stroke or heart attack because the medication interfered with their sexual activity.

HORMONE TREATMENT. If the testosterone level is low and it is not the result of a pituitary tumor or thyroid problem, replacement hormone may be needed. The health-care provider should first examine the patient carefully for any evidence of prostate cancer because testosterone replacement can cause the cancer to grow and spread. Testosterone replacement is given by IM injections or transdermal patch. Special care must be taken with the transdermal patch, which is placed on the penis, so that the partner does not absorb the medication. This can be prevented by having the male wear a condom over the patch.

YOHIMBINE. Many men are looking for a magic pill or potion to correct the problem. Some health-care providers prescribe an herbal preparation called yohimbine, which is thought to be a mild aphrodisiac and vasodilator. When the cause may be psychological or mildly physical, this medication may be helpful in restoring confidence and erections.

INTRACORPOREAL MEDICATIONS. The use of vasoactive or smooth muscle relaxant medication is the latest nonsurgical treatment option. The medication causes the arterioles and cavernous tissue to relax, allowing more blood to flow in and lowering peripheral resistance, trapping blood in the cavernous bodies to maintain the erection. There are several methods of medication delivery.

Oral Pill. Oral medications (tadalafil [Cialis], vardenafil [Levitra], or sildenafil [Viagra]) are now the first line of therapy used to treat ED. The pill is usually taken 30 to 60 minutes before sexual intercourse. It provides an easy way to administer the medication and has a success rate of between 40% and 80%, depending on the cause of the problem. Men using nitrate medication (antianginal agents) should avoid using the pill because it is vasoactive. It can also cause abnormal visual problems for some men.

TABLE 43.3 MEDICATIONS CONTRIBUTING TO ERECTILE DYSFUNCTION

Antianxiety agents	Glucocorticoids
Antidepressants	H ₂ antagonists
Antihistamines	Major tranquilizers
Antineoplastic agents	Muscle relaxants
Blood-pressure medications	Commonly abused drugs
ACE inhibitors	Alcohol
Beta-blocking agents	Amphetamines
Others	Barbiturates
Diuretics	Caffeine
Drugs for Parkinson's disease	Cocaine
Estrogens	Marijuana
	Nicotine
	Opiates

ACE = angiotensin-converting enzyme; H₂ = histamine.

NOTE: Not all drugs in a category cause erectile dysfunction.

Injection Method. After careful evaluation, a patient or his partner may be taught how to inject a medication into the penis using a 26- or 27-gauge needle on a tuberculin syringe or a prefilled autoinjector. The injections are nearly painless and produce a natural erection in 10 to 15 minutes. The erection may last 1 to 2 hours, and patients are generally limited to a maximum of three injections per week. The dosage is regulated on an individual basis. The most serious side effect is priapism, which requires immediate reversal in a physician's office or emergency room. When the patient is taught and monitored carefully, the risk of complications is minimal.

Transurethral Suppository. In order to facilitate medication dispersion and absorption, a patient may choose to use a suppository. The patient is instructed to urinate before use of the suppository. A tiny pellet (microsuppository) is inserted into the urethra using a specialized single-dose applicator. The medication usually begins to work in 5 to 10 minutes, and the effects last for approximately 30 to 60 minutes. Side effects can occur with high medication doses.

OTHER NONSURGICAL TREATMENTS. Sexual Devices And Techniques. There are a variety of sexual aids, such as vibrators and dildos (hollow penises), that may be alternatives for patients who do not want or cannot afford expensive medical treatment. They should be encouraged to talk with a health-care provider or qualified sex therapist before trying these alternatives.

Suction devices are another nonsurgical treatment option. This is an external cylinder vacuum device that fits over the penis and draws the blood up into the corporeal bodies, causing an erection. A penile ring is then slipped onto the base of the penis. Once the cylinder is removed, sexual intercourse can begin. Special care must be taken to remove the penile ring within 15 to 20 minutes to prevent tissue damage. The suction device may be used alone or

with intracorporeal injection therapy for patients who have difficulty keeping an erection. The companies that manufacture the suction devices provide free videotapes and written patient instruction booklets.

SURGICAL TREATMENTS. Penile Implants (Prostheses). Penile implants are a pair of solid or fluid-filled chambers that are surgically placed into the corporeal bodies in the penis to produce an erection. This treatment option has been used successfully for more than 25 years. There are two basic types of implants—noninflatable and inflatable (Fig. 43.4). The noninflatable type is economical, can be surgically implanted in less than an hour, and provides firmness for penetration. The inflatable device contains a sterile saline solution that fills the cylinders using a manual pumping action. When activated, the inflatable implant provides both firmness and an increase in diameter of the penis. Although the inflatable device is more expensive and has a greater risk of mechanical failure, it provides a more natural-appearing and natural-functioning erection than the noninflatable implant.

Penile implants are considered secondary treatment options because they have a risk of complications such as mechanical failure, infection, and erosion. Patients at greatest risk for complications are those with uncontrolled diabetes and those with severe circulation problems. Patients should be taught that an implant will not restore ejaculation or orgasm if these functions have been lost before the surgery. Surgery recovery time varies from 4 to 6 weeks; the patient must receive approval from the health-care provider before having sexual intercourse.

Vascular Surgery. If a younger man (younger than age 35) has an erection problem caused by poor blood flow into the penis or from blood leaking out of the penis, rapidly causing the loss of the erection, corrective surgery may be performed. A bypass graft may be done to increase the blood flow into the penis or to go around a blockage (e.g.,

FIGURE 43.4 Penile implants. (A) Inflatable penile implant. Inflatable cylinders are implanted in the penis, the small hydraulic pump in the scrotum, and the fluid-filled reservoir in the lower abdomen. Sterile radiopaque saline from the reservoir fills the cylinders to provide an erection. (B) Malleable penile implant. Malleable rods are implanted into the penis. The penis is always firm, but the rods can be bent close to the body when erection is not desired. (*Alpha-1 implant [A] and Acu-Form implant [B] photographs courtesy Mentor Urology, Santa Barbara, CA.*)

Peyronie's disease). If the blood leaves the corporeal bodies too fast, a procedure to ligate (tie off) the leaking veins may be successful. Neither surgery works well in older men because the bypass graft rapidly becomes obstructed and the natural tendency of the older body is to form collateral circulation around the veins that are tied off.

Nursing Process for the Patient with Erectile Dysfunction

ASSESSMENT/DATA COLLECTION. Before the assessment begins, it is important to provide privacy and ensure confidentiality. A complete sexual history, often conducted by a nurse, is taken, with special focus on factors related to the circulatory, nervous, and endocrine systems. The questions cover the following:

- Medical problems
- Surgical treatments that might interfere with blood flow or nerve supply to the groin or spine
- Genitourinary problems
- A complete list of medications used, including over-the-counter drugs and any evidence of substance abuse
- General lifestyle patterns, including stress factors, depression, and excessive use of alcohol, caffeine, or nicotine
- Sexual patterns and practices

A physical examination is performed by the physician or health practitioner to assess for any evidence of congenital deformities, hormonal imbalance, decreased circulation, or nerve damage. Throughout the assessment process, it is important to observe for any signs of psychological or emotional distress.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. Nursing diagnoses and interventions related to sexual dysfunction may include:

Anxiety related to effect of pathology on sexual performance

EXPECTED OUTCOME: Patient will identify presence of anxiety and verbalize concerns about sexual dysfunction.

- Identify source of concern related to sexual activity and meaning assigned to disorder as described by the patient. *This will help in guiding interventions that are appropriate for the patient related to the etiology of concern.*
- Explore coping skills previously used by the patient to relieve anxiety. Reinforce these skills, and explore other outlets for stress. *Coping mechanisms that have been helpful in the past may aid patient in dealing with current stressors that result in anxiety. This will also allow the patient to sort through issues related to sexual dysfunction and be an active participant in working toward resolution.*

Ineffective health maintenance related to knowledge deficit of cause and treatment of sexual dysfunction

EXPECTED OUTCOME: Patient will verbalize understanding of the cause and treatment options for erectile dysfunction.

- Determine patient and partner's current knowledge and understanding about cause and treatment of the disorder. *This will allow for additional and/or correct information to be provided about sexual dysfunction for appropriate understanding.*
- Provide patient and partner with additional and/or correct information about cause and treatment of disorder. *This will allow the patient to have a full understanding of the etiology and care related to the disorder; and increase likelihood of patient compliance and success of treatment.*
- Refer patient and partner (as appropriate) for medical treatment, psychological treatment, or counseling. *An individualized treatment plan (determined by the etiology) is needed to move toward restoration of sexual functioning.*

Self-esteem disturbance related to inability to practice usual/expected sexual activity

EXPECTED OUTCOME: Patient will verbalize effect of sexual dysfunction on feelings of self-esteem.

- Provide privacy and be verbally and nonverbally nonjudgmental when allowing patient and his partner to express concerns about sexual dysfunction. *Treatment success rates are generally higher when a rapport is established with the caregiver and the partner is included in the decision-making process.*
- Validate the patient's feelings and let the patient know he is normal. *A sensitive nurse who has an understanding of sexual health can best direct those who need intervention.*
- Support realistic expectations about treatment and outcomes as unrealistic, unmet expectations will lead to further self-esteem impairment.

EVALUATION. The best indicator of a positive outcome is restoration of erectile function with a verbal account of understanding the disorder and satisfaction with the treatment process. Sometimes the physical problem is easier to correct than the emotional scars that the problem has created. It is important to evaluate both the physiological and emotional outcomes of treatment.

PATIENT EDUCATION. The nurse plays an important role in public education related to erectile dysfunction. Men need to know that they are not alone with their problem. More than 20 million men in the United States experience ongoing problems with erections. The majority of the causes are physical, and help is available through health-care providers who specialize in treating erectile dysfunction.

Conservative treatment options are tried first, with surgical interventions reserved as a last resort. Treatment may

be as simple as a change in lifestyle or in medication. Men need to be encouraged to seek help from appropriate health-care providers and recognize that erectile dysfunction is a treatable condition with positive outcomes.

See Box 43.3 Male Sexual Dysfunction Summary.

CRITICAL THINKING

Mr. Kittle

■ Mr. Kittle presents to the clinic with a complaint of not being able to sustain an erection long enough for sexual intercourse that is satisfactory for himself and his partner.

1. You have never had a patient tell you his sexual problems, and you feel a little uncomfortable. How should you respond?
2. What will your assessment include?
3. What treatment options might be offered?

Suggested answers at end of chapter.

Infertility

A growing number of couples in the United States are having difficulty conceiving children. Several factors can interfere with a man's ability to father a child.

Physiology

Eight fundamental male physiological factors are necessary for normal conception to occur:

- Proper endocrine function between the hypothalamus, pituitary gland, and testes
- At least one testis that produces quality sperm
- An epididymis, or storage place, to mature the sperm
- A duct system to transport sperm from the testes to the outside of the body
- Glands that secrete the right type and amount of seminal fluid to nurture and transport the sperm
- An intact nervous system that helps provide an erection and ejaculation
- Semen that meets the following criteria: volume 1.5 to 5 mL, a concentration of more than 20 million sperm per milliliter, 50% to 60% of the sperm classified as grade 2 mobility, 60% to 80% of sperm with a normal shape, pH between 7.2 and 7.8, a small amount of fructose (sugar, a food supply), and sperm (semen) that first coagulates and then liquefies
- A basic knowledge of sexual practices, along with a willing partner

Etiology

The factors related to infertility are divided into three general categories: pretesticular, testicular, and posttesticular.

Box 43.3

Male Sexual Dysfunction Summary

Signs and Symptoms

- Report of problems with obtaining and keeping an erection
- Reported dissatisfaction with sexual performance

Diagnostic Tests

- Primary: History and physical
- Secondary: Vascular flow evaluation, apnea studies

Therapeutic Interventions

- Counseling
- Medication to increase blood flow to the penis
- Surgical implants or repair of structural disorders

Complications

- Infection
- Injury to surrounding tissue during surgical treatment

Priority Nursing Diagnoses

- Anxiety related to effect of pathology on sexual performance
- Ineffective health maintenance: knowledge deficit related to cause and treatment of sexual dysfunction
- Self-esteem disturbance related to inability to practice usual/expected sexual activity

PRETESTICULAR (ENDOCRINE) FACTORS. The first factor involves the proper functioning of the hypothalamus, the pituitary gland, and the testes. These endocrine functions are complex and are a rare cause of infertility. Examples of endocrine causes might be pituitary or adrenal tumors, thyroid problems, or uncontrolled diabetes.

TESTICULAR FACTORS. The two most common causes of male infertility are a varicocele (40% to 50%) and idiopathic causes (40%). It is believed that a varicocele lowers the sperm count by raising the blood flow and temperature in the testes. Sperm cannot live if the temperature is too high or too low.

Congenital anomalies such as Klinefelter's syndrome (a chromosomal defect) or cryptorchidism result in absent or damaged testes. Failure of a part of the male reproductive system to develop as a result of the mother's use of DES or other drugs during pregnancy may also result in fertility problems.

Certain disease or inflammatory processes may cause damage to the storage area (epididymitis) or to the testes

themselves (mumps orchitis). Any high fever or viral infection can interfere with the production of sperm for up to 3 months.

Medications, radiation, substance abuse, environmental hazards, and lifestyle practices have all been identified as possible factors that can interfere with spermatogenesis (sperm production). Medications such as cimetidine (Tagamet), sulfasalazine (Azulfidine), anabolic steroids (testosterone), anticancer drugs (cyclophosphamide [Cytosan], methotrexate), recreational drugs (cocaine, marijuana), and antihypertensives (methyldopa) have all been identified as possible causes of infertility. Radiation damage, whether as treatment for cancer or job related, tends to depend on the dosage received. A small amount of radiation causes temporary loss of sperm. Permanent sterility occurs with large doses or prolonged treatment. The relation between use of drugs such as cocaine and marijuana and infertility has been documented in several studies, but there is no clear indication of the amount or length of time it takes for these substances to cause infertility problems. Environmental hazards such as pesticides, Agent Orange, and lead poisoning have been listed as possible causes of infertility and are still under investigation. Excessive use of hot tubs and saunas, wearing tight jeans, and long-haul truck driving have all been identified as raising the temperature level in the scrotum to the extent that the sperm production is decreased.

POSTTESTICULAR FACTORS. The most common factor in post-testicular surgery infertility is the result of surgery or injury along the pathway from the testes to the outside of the man's body. Examples of surgical causes are vasectomy, bladder neck reconstruction, pelvic lymph node removal, or any surgery that causes retrograde ejaculation. Congenital anomalies and various types of infections may also cause infertility problems.

Prevention

Prevention involves possible lifestyle changes to avoid excessive heat to the scrotum, substance abuse, exposure to toxins, and environmental hazards. Problems related to medication or infections should be discussed with the health-care provider.

Signs and Symptoms

A couple is considered infertile if they have been unsuccessful at becoming pregnant after at least 1 year of unprotected intercourse. If pregnancy has occurred during the year but there was no delivery, the problem is generally considered a female rather than a male factor.

Diagnostic Tests

Diagnosis begins with a detailed history and physical examination that looks for known male causes of infertility.

History

SEXUAL PRACTICES. Assessment includes frequency of intercourse, positions, timing (according to ovulation cycle), use of contraceptives, problems with premature ejaculation, and erection problems.

LIFESTYLE PRACTICES. Weight lifting or use of steroids, hot tubs, or saunas; tight jeans; use of nicotine, caffeine, alcohol, or marijuana; and the strength of desire for children on the part of the man are all assessed.

OCCUPATION. High stress, long periods of sitting, and exposure to environmental toxins are determined.

MEDICAL-SURGICAL HISTORY. Assessment includes any sexually transmitted viruses or diseases, endocrine problems, congenital urinary problems, serious illnesses or groin injuries, cancer, and treatment with chemotherapy or radiation.

Physical Examination

The examiner (generally a primary care practitioner) will observe for normal hair pattern and growth, muscle development, size of testes, and any evidence of a varicocele or hydrocele.

Diagnostic Tests

A semen analysis is done after collecting several specimens following a special collection technique. It is analyzed to see if it contains the right amount and type of healthy sperm needed for a pregnancy. Infection should be ruled out. There are several other tests that may be done, depending on the level of desire and the financial resources of the couple. Many insurance companies do not pay for the tests or treatment options for infertility.

Therapeutic Interventions

Treatment may be as simple as making a change in sexual or lifestyle practices. If the couple is able to handle the emotional and financial strain, they may try male surgery to correct a varicocele or a variety of in vitro fertilization procedures. The success rates for in vitro fertilization range from 8% to 60% and generally cost several thousand dollars each time an attempt is made. Another possible option that should be presented to the couple is adoption.

You can play an important role in the emotional support a couple needs during infertility studies. It is important that the couple feel comfortable in communicating their feelings and frustrations with one another and their health-care provider. You may need to be the communication link, explaining various tests and cost factors and discussing how long the couple may want to continue trying the various treatment options. It may also help them to talk with other couples or attend a support group designed for couples experiencing infertility. For more information, visit <http://www.nlm.nih.gov/medlineplus/infertility.html>.

REVIEW QUESTIONS

- A patient with benign prostatic hyperplasia expresses concern that he has cancer. Which response by the nurse is best?

 - “Don’t worry; prostatic hyperplasia is not the same thing as cancer.”
 - “Since it is called benign, you don’t have to worry about it. No treatment should be necessary; you will just need to have it watched.”
 - “Hyperplasia means your prostate is growing too many cells. They are not cancerous, but they could interfere with your ability to urinate, so it is important to have it treated.”
 - “You are correct, it is a form of cancer, but it is very slow growing and very treatable. Your doctor will recommend treatments for you.”
 - Which of the following is the most commonly used surgical treatment for BPH?

 - TUIP
 - TUMA
 - TURP
 - TULIP
 - A patient who is 1 day post–transurethral resection of the prostate says he is having pain in his bladder, and the nurse notices urine leakage around his catheter. Which of the following responses by the nurse is best?

 - “Bladder spasms are common after your surgery. Take some deep breaths while I get a B&O suppository.”
 - “You should not be experiencing spasms. I will notify the RN right away.”
 - “Spasms can be very painful. Would you like an injection of Demerol?”
 - “Your catheter is leaking; we will need to replace it right away.”
 - A nurse working in a nursing home notes that it is difficult but not impossible to retract the foreskin for washing on an elderly gentleman. Which action is correct?

 - Avoid retracting the foreskin for cleaning to prevent paraphimosis. The penis secretes an anti-bacterial substance that is self-cleaning.
 - Gently retract the foreskin for cleaning, then replace it and notify the physician.
 - Retract the foreskin for cleaning, and leave it retracted to prevent infection.
 - Retract the foreskin and leave it retracted until the physician can evaluate it.
 - Which of the following is the most common cause of erectile dysfunction?

 - Endocrine problems
 - Circulatory problems
 - Nervous system problems
 - Excessive alcohol use
 - A patient is admitted to a medical unit for complications of diabetes. The nurse asks if he is satisfied with his level of sexual functioning, and he becomes tearful. Which initial response by the nurse is best?

 - “You seem upset with my question. Are you having a problem you would like to talk about?”
 - “Impotence is common with diabetes. Don’t let it worry you.”
 - “What kind of sexual dysfunction are you experiencing?”
 - “I am sorry you are having problems with your sexual functioning. Would you like a referral to a sex therapist?”
- Multiple response item. Select all that are correct.
- What are common complications of varicocele?

 - Infertility
 - Infection
 - Erectile dysfunction
 - Pain
 - Priapism
 - Cancer
 - Which of the following might be included in the treatment plan for male infertility?

 - Penile implants
 - Prostatectomy
 - TURP
 - Decrease in nicotine and alcohol use

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ **Mr. Atkinson**

$$1. \quad \frac{5 \text{ mg} \quad | \quad 1 \text{ tablet}}{\quad \quad \quad | \quad 2 \text{ mg}} = 2.5 \text{ tablets}$$

Mr. Atkinson should be alert for signs of hypotension, such as dizziness or lightheadedness on arising. He should not drive until effects/side effects of the medication are known.

- Mr. Atkinson should be instructed not to lift anything heavier than 10 lb for the first 6 weeks, and he will not be able to plow or drive for the first 6 weeks. It is important that his son understand his father's limitations and how important it is for him or someone else to help out with the farm chores.
- Mr. Atkinson will notice a change in his ejaculation (either very little ejaculate or none at all). If he could get an erection before surgery, the chances are very good that he will continue to be able to have intercourse; however, he will not ejaculate.

■ **Mr. Cunningham**

- Mr. Cunningham should be encouraged to see his health-care provider immediately for an evaluation to rule out cancer of the testes.
- Depending on the stage of the cancer, he will have the cancerous testis, cord, and lymph nodes removed. He may need chemotherapy or radiation treatments as well.
- Mr. Cunningham should be encouraged to make deposits at a certified sperm bank before any treat-

ments. It is also important to include his future wife and his family in the decision-making process and encourage them to share their feelings and concerns with one another. Cancer support groups may also be helpful to Mr. Cunningham.

■ **Mr. Kittle**

- It is okay to “pretend” here! Act like you are perfectly comfortable, and that you hear this sort of thing every day. (Of course, you would never pretend to know something you don't—it is always okay to say you don't know.) Have a matter-of-fact communication style. If you get nervous and forget what questions you should ask, start with something general like, “Can you tell me more about your symptoms?”
- Subjective and objective assessment related to Mr. Kittle's erectile dysfunction should include assessing for medical and surgical factors that might affect his ability to obtain and sustain an erection. This history should primarily focus on the cardiovascular, respiratory, neurological, and reproductive systems. A psychosocial assessment to identify presence of stress, fear, depression, fatigue or problems with interpersonal relationships should also be performed. A medication review may lead to identification of substances that influence erectile ability.
- Treatment options will depend on the cause. Options may include: Psychotherapy/support group therapy, oral/absorbable/injectable medications, surgical implants or vascular surgery, and nonsurgical devices/techniques which include vibrators and dildos.

QUESTIONS TO GUIDE YOUR READING

1. What pathogens are involved with each of the common sexually transmitted diseases (STDs)?
2. What are the signs and symptoms of each of the common STDs?
3. What teaching would you provide to promote prevention of STDs?
4. What are current treatment options for the common STDs?
5. What nursing care will you provide for patients with STDs?
6. How will you know if your nursing interventions have been effective?

Sexually transmitted diseases (STDs) are infections that may be transmitted through intimate contact with the genitals, mouth, or rectum of another individual. Some STDs may also be spread by other routes such as blood or body fluids. A nurse's best protection against catching diseases from blood and body fluids of infected patients is the strict practice of standard precautions and maintaining his or her own healthy, intact skin.

Physically, STDs may cause tremendous suffering through pain, scarring of genitourinary structures, damage to other body organs, infertility, birth defects, nervous system damage, development of cancer, and even death of infected patients and sometimes their children. Psychologically and socially, these diseases also have profound effects on individuals, families, and relationships. Guilt about passing on an incurable disease to a loved one or feelings of betrayal because of being infected as a result of someone else's choices is only part of the emotional consequences of STDs.

Changing social values have been associated with increasing incidence of almost all types of sexually transmitted diseases, including some previously rare diseases related to anal intercourse. Coexistence of more than one STD in an individual is also occurring more often. There are more than 50 diseases and syndromes associated with sexually transmitted diseases; the more common ones are discussed here. Human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) are discussed separately in Chapter 19.

Symptoms, diagnostic techniques, and treatment regimens vary for different geographical areas, depending on availability of equipment for diagnosis and health-care provider preferences. As an introduction for practical/vocational nurses, general overviews are presented in this chapter.

One of the most important ways you can help those who experience STDs is by being kind, polite, nonjudgmental, and sensitive to the patient's communication. Maintaining an open posture and eye contact that is appropriate for the patient's culture relays a sense of openness and willingness to talk and preserves the possibility of continuing health promotion with these individuals in the future.

DISORDERS AND SYNDROMES RELATED TO SEXUALLY TRANSMITTED DISEASES

Vulvovaginitis

Vulvovaginitis is an inflammation of the vulva and vagina and can be asymptomatic or involve redness, itching, burning, excoriation, pain, swelling of the vagina and labia, and discharge. A variety of sexually transmitted and nonsexually

vulvovaginitis: vulvo—vulva + vagin—vagina + itis—inflammation

SAFETY TIP

Observe standard precautions and careful hand washing to avoid contact with infectious organisms. Go to www.cdc.gov and type in “hand hygiene” for complete guidelines.

transmitted infectious agents can cause vulvovaginitis. The odor, consistency, and color of the discharge varies with the different microbes involved. Nonsexually transmitted vaginitis, vulvovaginitis, and vaginosis are described in Chapter 42. Some microorganisms may be acquired either by sexual or nonsexual routes, so they are also mentioned in this chapter. Bartholin's glands may develop abscesses as a result of infection with nonsexually transmitted microbes or STDs such as gonorrhea and chlamydia.

Urethritis

Both STDs and nonsexually transmitted microorganisms can cause **urethritis** in men and women. In men, inflammation of the urethra, prostate, and epididymis can result in difficult, painful, and frequent urination and a urethral discharge, which may be clear, cloudy, or yellow. Female partners of men with urethritis may also suffer from urethritis, but they may also develop **mucopurulent cervicitis** (MPC) and a variety of other symptoms of the particular infection. Some causative agents for urethritis include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, *Candida albicans*, and herpes simplex. Often this disease category is divided into gonococcal urethritis caused by *N. gonorrhoeae* (GU) and nongonococcal urethritis (NGU).

Mucopurulent Cervicitis

Mucopurulent cervicitis (MPC) is an inflammation of the cervix that can produce a mucopurulent yellow exudate on the cervix or may have no noticeable symptoms. MPC during pregnancy can result in **conjunctivitis** and pneumonia in newborn infants, as well as **puerperal** infection of the mother. MPC can be caused by such organisms as *Chlamydia trachomatis*, *N. gonorrhoeae*, *T. vaginalis*, *Candida albicans*, and herpes simplex. MPC may spread to become pelvic inflammatory disease (PID).

Proctitis and Enteritis

Proctitis is inflammation of the rectum and anus that may be due to either nonsexually transmitted microbes or to STDs.

urethritis: ureth—urethra + itis—inflammation

mucopurulent cervicitis: muco—involving mucus + purulent—involving pus + cervic—cervix + itis—inflammation

conjunctivitis: conjunctiv(a)—lining of the eyelids and sclera of the eye + itis—inflammation

puerperal: childbirth

proctitis: proc—anus + itis—inflammation

This is especially prevalent among those who practice both heterosexual and homosexual anal intercourse. Enteritis, which is inflammation of the lining of the intestine, may occur as a result of contamination during anal intercourse. Infection with *Campylobacter* spp, *Shigella* spp, and *Giardia lamblia* can be a problem for homosexual men. Care of patients who have gastrointestinal disorders is discussed in Unit 8.

Genital Ulcers

Genital ulcers are formed when papules or macules erode and leave often painful raw, pitted, or excoriated areas on or around the genitals. Not all genital ulcers are caused by STDs—injury, some non-STD viruses, some types of drug reactions, radiation, and some forms of cancer can also produce genital ulcers. STDs that can produce genital ulcers include syphilis, herpes, and HIV. Genital ulcers from one type of disease may increase the risk of infection with other STDs during sexual activity because the open areas present an easy portal of entry for the infecting organism.

Cellular Changes

Cellular changes can also be caused by STDs, including **condylomatous** (wartlike) growths and dysplasia or neoplasia, which may result in precancerous or cancerous conditions. Herpes viruses, HIV, and human papillomavirus (HPV) have all been linked to the development of cancer.

Pelvic Inflammatory Disease

Pathophysiology, Etiologies, and Signs and Symptoms

Pelvic inflammatory disease (PID) is an infection of the upper genital tract that may cause chronic pelvic pain due to inflammation. The primary sources of infection include *Chlamydia trachomatis* and *N. gonorrhoeae*, but it may result from any organism that is associated with a sexually transmitted infection. These organisms can invade the endocervical canal, resulting in **cervicitis**, and move upward resulting in infection of the endometrium (**endometritis**), fallopian tubes (**salpingitis**), and pelvic cavity. The chronic inflammation results in extensive scarring and adhesions, which can cause infertility and increase the risk of ectopic pregnancy. Increased risk for PID occurs with a history of multiple sexual partners, sexually transmitted diseases (STDs), substance abuse, frequent vaginal douching, and IUD (intrauterine device) contraceptive use.

Some women with PID are asymptomatic or have minimal symptoms. Other women present with lower abdominal pain and tenderness, purulent vaginal discharge or vaginal bleeding, pain with sexual intercourse, fever, nausea and

vomiting, and pain with urination. Findings during physical examination include adnexal tenderness upon palpation, and pain of the uterus and cervix when moved during a bimanual examination. Laboratory tests may reveal positive culture of causative organism(s) and leukocytosis. Urinary tract infection may need to be ruled out.

Therapeutic Interventions

With serious infection, hospitalization and intravenous antibiotics may be indicated. Intravenous therapy can be changed to oral therapy after 48 hours if status improves. Laparoscopic surgery may be done to release adhesions and reduce complications. Testing and treatment for other sexually transmitted diseases should be considered for both the patient and her partner. Education on the cause of the infection and prevention of future episodes are essential.

SEXUALLY TRANSMITTED INFECTIONS

Chlamydia

Etiology and Signs and Symptoms

Chlamydia is the most commonly diagnosed STD in the United States. It can be transmitted sexually and by blood and body fluid contact. There are several different strains of the bacteria *Chlamydia trachomatis*. Chlamydia is often asymptomatic in women (a “silent” STD), but it can cause urethritis, MPC, and conjunctivitis. Fitz-Hugh–Curtis syndrome, a surface inflammation of the liver, can also be caused by *C. trachomatis*. This inflammation may cause nausea, vomiting, and sharp pain at the base of the ribs that sometimes refers to the right shoulder and arm. Chlamydia is a frequent cause of pelvic inflammatory disease (PID) and infertility, and it increases the risk of ectopic pregnancy. The infection can be passed from mother to baby during birth, resulting in neonatal pneumonia and conjunctivitis. It also increases the risk of HIV infection.

Lymphogranuloma venereum (LGV) is also caused by some strains of *C. trachomatis* but is more commonly seen in tropical climates or among people who emigrated from these areas. This disease also causes urethritis and proctitis, and it inflames lymph nodes that drain the pelvic area, resulting in draining sores and fistula development. Scarring from this disease can complicate vaginal deliveries.

Diagnostic Tests

There are several tests for chlamydia. Samples are gathered in a special collection tube to send to a laboratory for culture. Culturing is difficult and expensive and generally requires 2 to 6 days for results. A newer type of testing, called nucleic acid amplification testing (NAT or NAAT) identifies the presence of chlamydial DNA or RNA in urine, cervical, or urethral specimens. Because this disease is so common, it is wise to set out an unopened *Chlamydia* collection kit within easy reach of the health-care provider for each pelvic examination.

condylomatous: condyl—rounded projection + oma(t)—growth + ous—like

cervicitis: cervic—cervix + itis—inflammation

endometritis: endo—inside + metr—womb + itis—inflammation

salpingitis: salping—tube + itis—inflammation

Therapeutic Interventions

Antibiotics are generally given to treat chlamydia in adults. These antibiotics include erythromycin, azithromycin, doxycycline, ofloxacin, and levofloxacin (Table 44.1). Erythromycin or azithromycin is used during pregnancy, as other antibiotics may pose an increased risk to the fetus. Use of an ophthalmic ointment or solution containing silver nitrate, erythromycin, or tetracycline is recommended as treatment of the neonate shortly after birth for the prevention of conjunctivitis. This is done regardless of whether or not the mother is diagnosed with chlamydia, as asymptomatic or undiagnosed chlamydia is common, and this simple treatment can prevent serious complications later. Institutional policies and state regulations determine the type of eye preparation to be used and whether administration of the medications requires specific consent of the parents.

See Box 44.1 Common STDs Summary.

Gonorrhea

Etiology and Signs and Symptoms

According to the Centers for Disease Control and Prevention (CDC), 361,705 new cases of gonorrhea were reported to the CDC in 2001 (the most recently available complete statistics), but it is estimated that only half of all cases actually get reported. The cost of care and treatment of gonorrhea in the United States is approximately \$56 million each year.¹ It is caused by the bacterium *N. gonorrhoeae*, and may be transmitted vaginally, rectally, orally, or via contact with other mucous membranes, or through contact with blood and body fluids. It can produce a variety of signs and symptoms. Men may be asymptomatic or may have urethritis with a yellow urethral discharge. Women who have gonorrhea may have either no noticeable symptoms or have a sore throat, MPC, urethritis, or abnormal menstrual symptoms such as bleeding between periods. Many cases of PID are caused by gonorrhea. Intercourse with an infected partner during menstruation may be especially risky for development of PID because removal of the cervical mucous barrier can promote the growth of the gonococcus in the higher reproductive tract. Gonorrhea can also cause Fitz-Hugh–Curtis syndrome. Fever, nausea, vomiting, and lower abdominal pain may be present. Gonorrhea may also infect the throat and the rectum and may cause disseminated gonococcal infection, resulting in inflammation of the joints, skin, meninges, and lining of the heart.

Newborns born to mothers who have gonorrhea can develop **ophthalmia neonatorum**, which involves inflammation of the conjunctivae and deeper parts of the eye and can, ultimately, result in blindness. The newborn may also experience a gonorrheal infection at other sites following birth. Abscesses may develop where fetal scalp monitors were attached during labor, and infection of the nose, lungs, and rectum may occur.

ophthalmia neonatorum: ophthalmia—eye disease + neonatorum—of the newborn

Diagnostic Tests

Diagnosis is done by microscopic examination of smears and cultures of the discharge or identification of bacterial DNA (nucleic acid testing) in the urine. More than one test may be done to verify the diagnosis.

Therapeutic Interventions

Development of antibiotic resistance by *N. gonorrhoeae* and coinfection with other microorganisms, such as *Chlamydia trachomatis*, is making treatment more complicated. Cefixime, ceftriaxone, ciprofloxacin, or ofloxacin is recommended for the treatment of gonorrhea (see Table 44.1). It is also recommended that the patient be treated for chlamydia as coinfection is common. Ophthalmia neonatorum may be prevented by use of antibiotic eye preparations which contain silver nitrate, erythromycin, or tetracycline. It is recommended, as with prophylactic treatment of chlamydial conjunctivitis, that all infants be treated shortly after birth regardless of diagnostic status of the mother. The treatment is simple, and may prevent a devastating outcome for the newborn. Institutional policies and state regulations determine the type of eye drops to be used and whether administration of the drops requires specific consent of the parents.

CRITICAL THINKING

Mrs. Miller

■ Mrs. Miller delivered an infant boy 1 hour ago. The nurse is currently applying erythromycin ointment to the infant's eyes bilaterally. Mrs. Miller asks if the medication is necessary.

1. How will you respond?
2. Should *all infants* receive prophylactic eye treatment at birth?

Suggested answers at end of chapter.

Syphilis

Etiology and Signs and Symptoms

Syphilis is an ancient disease that has not disappeared, although it is overshadowed by more commonly occurring diseases such as chlamydia. The primary stage of syphilis begins with the entry of the *Treponema pallidum* spirochete through the skin or mucous membranes. Between 3 and 90 days later, a papule develops at the site of entry, then sloughs off, leaving a painless, red, ulcerated area called a **chancre** (Fig. 44.1). Chancres may also develop in other areas of the body at this time. Chancre formation is generally the only symptom of this stage of syphilis. The chancre eventually heals, but the spirochete remains active in the infected individual and can be passed on to others. Secondary syphilis begins 2 to 8 weeks later and affects the body more generally, causing such problems as flulike symptoms, joint pain,

chancre: hard ulceration

TABLE 44.1 MEDICATIONS USED TO TREAT STDs

STD Medication Drug Classification	Medication/Mode of Action	Route	Side Effects	Nursing Implications
Chlamydia <i>Antibiotics</i>	Macrolides: Erythromycin Azithromycin Inhibit bacterial protein synthesis	PO or IV	Abdominal pain Cramping GI upset Rash. Overgrowth of nonsusceptible bacteria.	Administer on empty stomach. Do not administer with antacids. Caution with hepatic disorders.
	Tetracyclines: Doxycycline <i>Inhibit protein synthe- sis by binding to ribosomes</i>	PO or IV	GI upset Anorexia Dysphagia Photosensitivity Rash Urticaria Increased pigmentation May increase anticoagulation	Do not administer during pregnancy due to bone/teeth effects. Do not take with antacids or dairy prod- ucts. Administer on empty stom- ach. Avoid unnecessary exposure to sunlight.
	Fluoroquinolones: Ofloxacin Levofloxacin <i>Inhibit cell wall synthesis</i>	PO or IV	GI upset Dizziness Headache CNS disturbances Flatulence Rash Photosensitivity Rare but serious: Tendon rupture	Safety under age 18 not established. Do not administer with antacids. Caution with other medication use; renal, hepatic, or CNS dis- orders.
Gonorrhea <i>Antibiotics</i>	Cephalosporins: Ceftriaxone Cefixime <i>Inhibit cell wall synthesis</i>	PO, IM, or IV	GI upset CNS disturbance Rash Pruritus Elevated liver enzymes Pain at injection site	Caution with penicillin allergies; renal, or hepatic dysfunction. Avoid excess sun exposure.
	Fluoroquinolones: Ciprofloxacin Ofloxacin <i>(see information above)</i>			
Syphilis <i>Antibiotics</i>	Penicillin: Penicillin G <i>Inhibits cell wall synthesis</i>	PO, IM, or IV	GI upset CNS disturbance Rash Itching	Administer deep IM or slow IV. Apply ice packs to injection site prn. Administer PO on empty stomach. Instruct patient to report fever/rash.
	Tetracyclines: Tetracycline Doxycycline <i>(see information above)</i>		Fever Chills Pain at injection site Allergy	
Trichomoniasis <i>Amebicides/ Antiprotozoals</i>	Metronidazole <i>Bind to DNA to inhibit synthesis and cause cell death</i>	PO or IV	GI upset Anorexia Headache Metallic taste or dry mouth Dysuria Rare but serious: Seizures and peripheral neuropathy ECG changes	Administer with food. Caution use with alcohol; abstain for a mini- mum of 48 hr following treatment to prevent severe flulike reaction.
Herpes <i>Antivirals</i>	Acyclovir Valacyclovir Famciclovir <i>Inhibit DNA synthesis</i>	PO, IV, or topical	GI upset CNS disturbance Rash Urticaria Elevated liver enzymes/BUN levels	Use systemic preparations cau- tiously with CNS, hepatic, or renal disorders. Infuse IV slowly. Maintain hydration. Caution patient that viral transmission can still occur during treatment.
Genital Warts <i>Antimitotics and Acidic Agents</i>	Podophyllin/ trichloroacetic acid (TCA)/bichloroacetic acid (BCA)	Topical applica- tion to wart(s)	Local reactions (e.g., pain, burning, inflammation, erosion, itching)	Instruct patient to return for repeated applications as necessary. Avoid medication contact with eyes or tissue surrounding lesion.

CNS = central nervous system; GI = gastrointestinal.

Box 44.1**Common STDs Summary**

<p>Chlamydia Conjunctivitis; in men, urethritis, epididymitis, prostaticitis; in women, MPC, urethritis</p>	<p>Gonorrhea In men, urethritis, penile discharge, epididymitis, prostaticitis; in women, MPC, urethritis, abnormal menses</p>	<p>Syphilis Primary syphilis, chancre; secondary syphilis, flu-like symptoms, rashes, condylocomatous growths</p>	<p>Trichomoniasis Genital redness, swelling, itching, burning, foul discharge; in men, urethritis, prostaticitis; in women, “strawberry cervix”</p>	<p>Herpes Simplex Vesicles/ulcerations in mouth, genitals; flulike symptoms, lymphadenopathy, urethritis, cystitis, MPC</p>	<p>Condylomata (HPV) Fleshy tumors, primarily on genitalia</p>
<p>Diagnostic Tests</p>	<p>NAT Culture</p>	<p>NAT Culture</p>	<p>VDRL, ELISA, RPR, FTA-ABS</p>	<p>Culture, Western blot</p>	<p>Colposcope examination biopsy, visualization of lesions</p>
<p>Therapeutic Interventions</p>	<p>Antibiotics (see Table 44.1)</p>	<p>Antibiotics (see Table 44.1)</p>	<p>Metronidazole</p>	<p>Antiviral medication (Table 44.1)</p>	<p>Wart removal, interferon therapy</p>
<p>Complications</p>	<p>Fitz-Hugh-Curtis syndrome, increased susceptibility to HIV infection; PID, infertility, transmission to baby at birth; coinfection with gonorrhea</p>	<p>PID, disseminated gonococcal infection, Fitz-Hugh-Curtis syndrome, transmission to fetus during pregnancy</p>	<p>Preterm delivery, infertility, increased risk of HIV transmission</p>	<p>Lifelong infection, disseminated infection, nervous system invasion, increased risk of cervical cancer, transmission to baby at birth</p>	<p>Cancers of the reproductive organs and anus, including cervical cancer, transmission to fetus during pregnancy</p>
<p>Priority Nursing Diagnoses</p>	<p>Pain related to inflammation, skin lesions Fear related to unknown outcome of disease Risk of transmission to others</p>				

ELISA = enzyme-linked immunosorbent assay; FTA-ABS = fluorescent treponemal antibody absorption; HPV = human papillomavirus; MPC = mucopurulent cervicitis; PID = pelvic inflammatory disease; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory.

FIGURE 44.1 Syphilis chancre. (From Reeves, JRT, and Maibach, H: *Clinical Dermatology Illustrated: A Regional Approach*. FA. Davis, Philadelphia, 1991, p 88)

hair loss, skin rashes (primarily on the soles of the hands and feet), mouth sores, and condylomatous growths in moist areas of the body.

Serious damage can occur if syphilis is untreated in the early stages. The disease may not progress to the tertiary (or late) stage for 3 to 15 years. At this stage, it can involve any organ system of the body. In the tertiary stage, the spirochete may form **gummas**, which are tumors of a rubbery consistency that can break down and ulcerate, leaving holes in body tissues. The gummas can damage the heart, circulatory system, and nervous system (neurosyphilis). Ulceration of gummas can destroy areas of vital tissue and lead to mental and physical disability or early death.

Syphilis can be passed on to the unborn children of women who carry the spirochete, resulting in **hepatosplenomegaly**, increase in bilirubin, destruction of red blood cells, birth defects (especially of the face), **lymphadenopathy**, and a baby who can transmit the spirochete through nasal drainage. If left untreated, syphilis during pregnancy may cause lesions in various organs of the unborn baby and result in higher rates of spontaneous abortion, stillbirth, and premature birth.

Diagnostic Tests

Several tests for syphilis exist, and a combination may be used for accurate diagnosis. Cultures may be done but are difficult to grow. **Serological** (blood) tests include the Venereal Disease Research Laboratory (VDRL) test, the rapid plasma reagin (RPR) test, and the automated reagin test (ART). These tests indirectly check for syphilis by detecting the presence of antibodies that the body forms in response to treponema and, unfortunately, in response to some other disorders, so false-positive results can occur. Diagnosis of neurosyphilis is even more difficult because some testing of cerebrospinal fluid may result in false-

gummas: from the word meaning “rubber”—rubber tumors

hepatosplenomegaly: hepato—liver + spleno—spleen + megaly—enlargement

lymphadenopathy: lymph—lymph nodes + adeno—node + pathy—disorder

serological: sero—blood + logical—science

negative results. Treponemal enzyme-linked immunosorbent assay (ELISA), fluorescent treponemal antibody absorption (FTA-ABS), and polymerase chain reaction (PCR) tests for treponemal DNA are some newer methods that reduce the risk of false results.

Therapeutic Interventions

Penicillin G is the treatment of choice for patients diagnosed with syphilis (see Table 44.1). For those who are allergic to penicillin, doxycycline and tetracycline are recognized as treatment options. When HIV and syphilis are seen in the same individual, symptoms of neurosyphilis are more likely to occur.

Trichomoniasis

Etiology and Signs and Symptoms

Trichomoniasis is generally a sexually transmitted disease, but it may be transmitted through nonsexual contact with infected articles because it can survive for quite a long time outside the body. Carriers of *Trichomonas vaginalis* may be asymptomatic for several years until changes in vaginal or urethral conditions encourage an outbreak of the disease. A decrease in resident bacteria, injuries to the vaginal tissues, and development of lesions from other STDs or from some forms of cancer may activate the organism. Symptoms include redness, swelling, itching, and burning of the genital area; pain with intercourse and voiding; and a frothy, foul-smelling discharge. Men with trichomonal infection can develop prostatitis and infertility, and men who are also infected with HIV are more likely to transmit it to others. Women who are pregnant risk preterm delivery and low birth weight babies.

Diagnostic Tests

Visualization of the cervix during pelvic examination shows a characteristic “strawberry cervix.” When wet-mount slides of the discharge are viewed under a microscope, the organisms can be identified by their motility and whiplike flagella. Trichomoniasis may produce abnormal Papanicolaou (Pap) smear readings, which require that more frequent Pap smears be done to provide adequate surveillance of cellular changes.

Therapeutic Interventions

The drug treatment of choice is metronidazole (see Table 44.1). Some strains of *Trichomonas* may exhibit resistance to this medication, but generally succumb to much higher doses of the drug. Because some people carry the organism without symptoms, sexual partners should also be treated regardless of symptoms.

Herpes

Etiology and Signs and Symptoms

Herpes infection is caused by the herpes simplex virus types I and II (HSV-I and HSV-II). Herpes viruses have an affinity for tissues of the skin and nervous system and can lie dormant in nervous system tissues and then reactivate periodically when the body undergoes stress, fever, or immune system compromise. Both HSV-I and HSV-II can cause “fever blisters” of the mouth (Fig. 44.2), as well as genital

CRITICAL THINKING

Kerri

■ Kerri presents to the health clinic with a complaint of generalized redness, swelling, itching, and burning of her external genitalia. Following history, physical, and microscopic examination, trichomoniasis is diagnosed. Kerri is upset, stating she has been in a monogamous relationship for 2 years.

1. What should your response to Kerri include?
2. Kerri is placed on metronidazole (Flagyl), but you are not comfortable with the dose prescribed, so you look it up. You find that she should receive 7.5 mg/kg every 6 hours. Kerri weighs 140 pounds. What should her dose be every 6 hours?
3. What teaching should you provide for Kerri?

Suggested answers at end of chapter.

lesions. However, HSV-I is more frequently associated with oral lesions and HSV-II with genital lesions.

Genital HSV-II outbreaks are more severe than genital HSV-I outbreaks. After infection, vesicles develop, spontaneously rupture, and produce painful ulceration of the underlying skin tissues. Asymptomatic latent periods are generally interspersed between the **vesicular** outbreaks. Although not as common, the virus may still be transmitted even during latent periods.

An initial outbreak following infection with the herpes virus occurs 2 days to 2 weeks after exposure and may produce a flulike condition. Urethritis, cystitis, and MPC with vaginal discharge may also be evident. Infection of the spinal nerve roots by HSV may result in **sacral radiculopathy**, causing retention of urine and feces. Although rare, dis-

FIGURE 44.2 Herpes simplex. (From Reeves, JRT, and Maibach, H: *Clinical Dermatology Illustrated: A Regional Approach*. FA. Davis, Philadelphia, 1991, p 64)

vesicular: vesicul—blister + ar—type

sacral radiculopathy: sacral—sacrum + radiculo—root + pathy—disorder or disease

seminated herpes infection can result in inflammation of the spinal cord, meninges, nerve pathways, and lymph nodes. Urethral strictures and increased risk for development of cervical cancer in women are also consequences of herpes.

It is estimated that one in five of all pregnant women carry herpes, although most of their babies do not develop **herpetic** disease. If infected, the baby's skin, eyes, mucous membranes, and nervous system may be involved and death from disseminated herpes infection may occur. The greatest risk of herpes transmission from mother to child during pregnancy occurs if there is an active genital lesion at the time of delivery. If an active genital lesion is present when a woman is close to the time of delivery, a cesarean section is likely to be performed. However, an active lesion at any time during pregnancy poses a risk for transmission.

Diagnostic Tests

Testing for HSV requires special viral collection kits for swabbed or scraped specimens from lesions. Follow the directions on the viral collection kit as well as institutional policies. Blood tests are improving; the Western blot assay can determine whether the person has HSV-I or HSV-II antibodies.

Therapeutic Interventions

There is presently no known cure for herpes infection, although antiviral medications such as acyclovir, valacyclovir, and famciclovir may be given to decrease the severity of symptoms (see Table 44.1). Only acyclovir, a treatment that may reduce the risk of transmission of the herpes virus to the fetus, may be given during pregnancy. See also Box 44.2 Nursing Care Plan for the Patient with Genital Herpes.

Genital Warts

Signs and Symptoms

Condylomata acuminata (genital warts) is a common sexually transmitted viral disease, and its incidence is increasing rapidly. Infection with human papillomavirus (HPV) produces the condylomata—soft, raised, **verrucous** fleshy tumors, which may also have fingerlike projections and resemble cauliflower (Fig. 44.3). Lesions most commonly develop on the external genitalia and perineum, as well as on the internal vaginal wall and cervix in women. However, lesions can also develop on other areas of the body after contact with the virus. Some people remain asymptomatic, but can still transmit the infection. More than 100 types of HPV have been identified, and several have been closely linked to the development of cancers of the reproductive organs and anus in both males and females. There may be a long latent period of as much as 3 years' duration from the time of exposure to development of the warts.

herpetic: herpet—herpes + ic—pertaining to

condylomata acuminata: condyl—rounded projection + oma—growth + ta—pluralizes the word (singular form is condyloma) + acuminata—genital growths

verrucous: verruc—wart + ous—like

Box 44.2 NURSING CARE PLAN for the Patient with Genital Herpes

Nursing Diagnosis: Pain related to inflammation, skin lesions

Expected Outcome The patient will express pain relief at an acceptable level and will rest and move well.

Evaluation of Outcome Does patient state relief of pain level is acceptable?

Interventions

Assess pain using the WHAT'S UP? format.

Recommend pain relief measures appropriate to the type and location of the pain (both alternative measures, such as heat, ice, and change of position, and medication may be offered).

Document results of pain relief measures.

Instruct patient about self-care for pain and STD treatment at home.

Rationale

Assessment of the characteristic of the pain assists the nurse in providing appropriate relief measures.

Not all types of pain respond well to the same treatment.

Documentation alerts other caregivers about what works and does not work, thus providing more consistent, effective pain relief.

Most STDs are treated at home.

Evaluation

Can patient describe the pain characteristics?

Does patient express satisfactory relief of pain?

Does patient move and rest without evidence of pain?

Have you gained sufficient information from patient to document results?

Does patient verbalize understanding of self-care measures?

Nursing Diagnosis: Risk for transmission of infection to others related to lack of knowledge about transmission, symptoms, and treatment

Expected Outcome Patient will verbalize understanding of measures to prevent transmission to others.

Evaluation of Outcome Does patient verbalize understanding of transmission prevention? Does patient practice preventive behaviors?

Interventions

Assess patient's understanding of transmission, symptoms, complications, and treatment of STDs.

Assess whether patient is engaging in high-risk behaviors.

Use universal precautions and strict aseptic technique for *all* procedures involving blood and body fluids.

Instruct patient in appropriate strategies to reduce risk of infecting others:

- Abstinence
- Monogamy (if no active infection)
- Use of barrier methods and spermicides
- Adherence to treatment regimen

Teach patient signs and symptoms of STDs to report immediately.

Rationale

New instruction should be based on patient's previous knowledge.

If patient is continuing to engage in high-risk behaviors, the risk for infection of others is high.

The health team, in addition to other patient contacts, must be protected.

These measures may help prevent transmission of infection to others.

Prompt treatment of patient and partners further reduces risk of transmission of infection.

Evaluation

Is patient's current understanding accurate?

What teaching is necessary?

Is patient protecting self and others appropriately?

Are universal precautions observed?

Does patient verbalize understanding of methods to prevent transmission and intent to practice them?

Does patient verbalize understanding of signs and symptoms to report?

(Continued on following page)

Box 44.2 NURSING CARE PLAN for the Patient with Genital Herpes (Continued)

Nursing Diagnosis: Fear related to diagnosis of an incurable illness and effects on sexual relationships and reproduction

Expected Outcome Patient will verbalize realistic and accurate information about disease process and relate control of excessive fear.

Evaluation of Outcome Does patient relate accurate knowledge? Is fear manageable?

Interventions

Assess patient's fears.

If fear is based on misconceptions, provide factual information.

Allow patient to verbalize feelings. Be empathetic, but do not offer false hope.

Explain all procedures and treatments.

Help patient identify support systems and coping strategies that have worked in the past.

Rationale

Fear is a normal response and may be appropriate.

When fear is based on misconceptions, they should be corrected.

Sharing fears may help patient gain insight into dealing with them.

Unfamiliar procedures or treatments may contribute to fear.

Methods that have worked for patient before are likely to be helpful again.

Evaluation

What does patient fear?

Are fears based on factual information?

Is patient able to verbalize feelings?

Does patient understand procedures and treatments?

Does patient have effective coping skills and support systems?

HPV can be passed on from a pregnant woman to her fetus, resulting in the growth of genital warts on the baby, HPV infection of the baby's respiratory tract, and a possible future increased risk of cancer development. HPV infection during pregnancy can cause particularly difficult problems. Genital warts tend to grow more rapidly in pregnant women and to bleed more easily with injury than in nonpregnant women.

FIGURE 44.3 Condylomata, commonly known as genital warts. (From Lemone, P, and Burke, KM: *Medical-Surgical Nursing: Critical Thinking in Client Care*. Addison-Wesley, Menlo Park, CA 1996, p 2079, with permission.)

Diagnostic Tests

Diagnosis may be made by applying dilute acetic acid (vinegar) to the skin of the external genital area, vagina, cervix, and anus and then closely examining with a colposcope the areas that turn a lighter color. Biopsy specimens of the suspicious areas can be sent for further study of the cells. Other tests to diagnose HPV include an antigen test and the Southern and dot blot tests, which use radioactive probes. Cancerous changes stimulated by this virus may be identified on Pap smears.

Therapeutic Interventions

There is presently no known cure for papillomavirus infection. The warts may be treated by freezing, burning, or chemically destroying them or by manipulating the patient's immune system to attack the virus. Cryotherapy (freezing) of the warts may be done by touching each wart with a cryoprobe or a liquid nitrogen-soaked swab. Warts may also be burned or **electrocoagulated** with an **electrocautery** or a laser. Heat causes the proteins to coagulate, resulting in death of the wart tissue. Podophyllin, trichloroacetic acid (TCA), and bichloroacetic acid (BCA) are some of the chemical agents that may be applied topically to treat the

electrocoagulated: electro—electrical + coagul—curdled or hardened + ated—process completed

electrocautery: electro—electrical + cautery—branding iron

warts (see Table 44.1). Some options are not appropriate for use during pregnancy because of their **cytotoxic** effects, which might damage the fetus, but cryosurgery and laser destruction of the wart tissue may be done during pregnancy. All treatments may require multiple applications and generally result in a great deal of discomfort as the warts degenerate, ulcerate, and slough over a long period. Wart removal does not cure the infection, and new wart growth can occur after treatment.

Various types of immunotherapy have been used against HPV. Interferons are proteins produced by the body that can inhibit viral growth. Several types of interferons have been used to combat HPV. These substances may be applied topically, injected into the condyloma, or administered systemically. Interferons can produce side effects of flulike symptoms, a drop in the number of white blood cells, and changes in liver function. Systemic interferon treatment, however, may offer the advantage of being able to attack warts all over the body at the same time, rather than individually as with topical treatments, thus speeding the process of treatment. Research to develop vaccines against HPV strains is ongoing, but the multitude of varieties makes this difficult.

Home Care

Patients who have genital warts (condylomata acuminatam) burned off need to recuperate at home. If the burns (there may be multiple areas treated) are near the urethra or rectum, the patient may need a Foley catheter inserted to avoid contamination and irritation of the lesions after treatment. Also, the patient is instructed to increase dietary roughage and fluids to prevent constipation. Consult the health-care provider for orders on care of the burns. Use sterile technique for dressing changes, and premedicate the patient for pain control as needed for dressing changes.

Hepatitis B

Etiology and Signs and Symptoms

There are several main hepatitis viruses, but this section deals only with hepatitis B virus (HBV), which is generally considered within the STD category because it can be transmitted through sexual contact with blood and body fluids. (See Chapter 35 for a full discussion on hepatitis.) Early signs of hepatitis are loss of appetite, rashes, malaise, muscle and joint pain, headaches, nausea, and vomiting. As the virus affects the liver, the urine may darken and the stool color lighten (as a result of changes in bile excretion), liver enzymes may rise, and jaundice may appear. Enlargement of the spleen, enlargement and tenderness of the liver, necrosis of liver cells, cirrhosis, coma, and death may follow if the disease is severe. Chronic asymptomatic carrier status may follow hepatitis virus infection, with an increased risk of liver cancer.

During pregnancy, hepatitis B virus may be transmitted to the unborn baby, which can result in acute hepatitis and the possibility of becoming a chronic carrier of HBV.

Diagnostic Tests

Diagnosis of hepatitis is generally made using a variety of blood tests based on antigen and antibody responses.

Therapeutic Interventions

Supportive medical care with avoidance of drugs that require liver metabolism may help the patient through the active stage of the disease. Treatment of the disease may involve injection of serum immune globulins to confer passive immunity. It is recommended that all babies of HBV-positive mothers receive HBV immune globulin less than 12 hours after birth and then be immunized with HBV vaccine 1 week, 1 month, and 6 months after birth. See Chapter 35 for more information. Interferon alpha is also available for patients with chronic hepatitis B.

Prevention

Prevention is better than treatment and may be accomplished by using HBV vaccine. This is especially recommended for health-care workers who come in contact with blood and body fluids. Standard precautions should be used when contact with any body fluids is expected.

Genital Parasites

Etiology and Signs and Symptoms

Genital parasites are not a true STD, but they may be transmitted during close body contact. The two most commonly seen parasites are pubic lice (*Phthirus pubis*, commonly called “crabs” because of the shape of the lice) and scabies (*Sarcoptes scabiei*). These parasites cause itching, redness, and, for scabies, tracks under the skin where the females burrow to lay their eggs.

Diagnostic Tests

History, physical assessment, and direct visual or magnified view of the parasites aids in diagnosis.

Therapeutic Interventions

Parasites are treated with topical insecticides. Advise the patient to refer to package inserts for application instructions and precautions to avoid reinfection.

REPORTING OF SEXUALLY TRANSMITTED DISEASES

The nurse may be required to facilitate the reporting and public health follow-up of STDs by filling in patient information on the STD reporting form and placing the form in the patient’s chart for completion by the health-care provider. The requirements for reporting STDs may vary for different states, provinces, and countries. In some areas, laboratories are also required to submit a report form for positive reportable STD tests. Laboratory reports that are not followed by a health-care provider’s report may result in investigation of the situation by an STD investigator. Generally, the report form has spaces for listing of sexual contacts who should be notified of possible STD exposure. Depending on the laws of the state, province, or country,

cytotoxic: cyto—cell + toxic—poison

health-care providers may notify identified sexual contacts or patients may do so themselves. Contacts may also be notified by a public health authority that they have been listed as a sexual contact by an anonymous person who has tested positive for a particular STD.

NURSING PROCESS FOR SEXUALLY TRANSMITTED DISEASES

Assessment/Data Collection

STDs are usually assessed, diagnosed, and treated in health-care providers' offices and in clinics. It is important to evaluate the patient's reason for seeking health care with every outpatient visit. Sometimes patients visit clinics or health-care providers' offices for stated reasons other than STDs, yet their real concern is an STD.

The nurse should inquire about whether the patient is presently experiencing any irritation, pain, lesions, or discharge of the genital region when an individual presents with complaints that could lead to an STD diagnosis. Explaining to the patient the need to know what examination supplies to prepare for an appropriate assessment may allow him or her to share concerns and true reasons for the visit. Establishing a rapport and conveying acceptance may also facilitate communication. Often the nurse is present during the examination to assist the health-care provider and to serve as a chaperone or patient support person.

STDs may also be discovered in hospitalized patients. Nurses are often the ones who bathe and give perineal care to patients. It is important to be aware of signs and symptoms in older adults as well as younger people (Box 44.3 Gerontological Issues). Unusual discharges, redness, blisters, swollen areas, ulcers, and evidence of parasites in the genital area may be observed during patient care. STD awareness can sensitize you to the possible significance of patient complaints such as persistent pelvic pain, dysuria, discharges, and rectal soreness. Such problems should be accurately documented and reported, so that further investigation and possible treatment can take place.

Box 44.3

Gerontological Issues

Older adults retain interest and are capable of engaging in sex. Do not assume that because an older adult is single or widowed he or she is not sexually active.

Older adults who have enjoyed active and fulfilling sex lives with a spouse or partner may seek that in new relationships. Older adults who engage in high-risk sexual behaviors (multiple partners, genital-anal sex, no use of barriers during sexual intercourse) are also at risk for sexually transmitted diseases.

NURSING CARE TIP

Neighbors, friends, or family members may seek information from you because they know nurses are educated about health issues. Such questions may be stated in indirect terms, such as, "I have a friend who is having a problem. . . ." You can provide accurate information and stress the importance of diagnosis and treatment to prevent the serious consequences of untreated STDs, without asking probing or embarrassing questions.

Nursing Diagnoses, Planning, and Implementation

Nursing diagnoses and interventions for patients with an STD may include:

Pain related to inflammation or skin lesions

EXPECTED OUTCOME: The patient will express pain relief at an acceptable level.

- Assess pain using a culturally appropriate scale. *This will aid in providing appropriate relief measures.*
- Recommend pain relief measures appropriate to the type and location of the pain (see Chapter 9). *Not all pain will respond to the same treatment.*
- Document results of pain relief measures. *This will communicate to others effective pain interventions.*
- Instruct patient about self-care for pain and STD treatment *to promote resolution of infectious process and related symptoms.*

Risk for transmission of infection to others

EXPECTED OUTCOME: Patient will verbalize understanding of measures to prevent transmission to others.

- Assess whether patient is engaging in high-risk behaviors *to determine risk of transmission to others.*
- Assess patient's understanding of symptoms, complications, treatment, and transmission of STDs. *This will allow for additional, appropriate information to be given.*
- Use universal precautions and strict aseptic technique for *all* procedures involving blood and body fluids *to limit risk of transmission of infectious organism to health-care members.*
- Instruct patient in appropriate strategies to reduce risk of infecting others, such as abstinence, monogamy, use of barrier and spermicidal contraceptives, and adherence to the treatment regimen *in order to reduce the risk of disease transmission.*
- Explain importance of follow-up evaluation *in order to affirm treatment was successful.*

Ineffective sexuality pattern related to illness and risk for transmission of infectious organism

EXPECTED OUTCOME: Patient will describe acceptable, alternative sexual practices and safer sex practices.

- Provide privacy and be verbally and nonverbally nonjudgmental when allowing patient and patient's partner to express concerns about sexual practice. *Treatment success rates are generally higher when a rapport is established with the health-care provider and the partner is included in the decision-making process.*
- When teaching patients, the terms *safe sex* and *STD prevention* are misnomers. You should more accurately refer to information about barrier methods as *safer sex practices*, which may decrease the risk of (but not absolutely prevent) transmission of STDs (Table 44.2).
- Discuss alternative sexual expression, as appropriate, *as this may allow for intimacy when desired sexual expression is not recommended.*
- Support realistic expectations about treatment and outcomes. *Unrealistic expectations may lead to additional undesired issues related to sexuality pattern.*

Fear related to diagnosis of possible incurable illness

EXPECTED OUTCOME: Patient will verbalize realistic and accurate information about the disease process and relate that fear is at an acceptable level.

- Assess patient's fears as *understanding basis of fear will aid in implementation of coping strategies.*
- If fear is based on misconceptions, provide factual information. *Knowledge may decrease fear.*
- Allow patient to verbalize feelings, while being empathetic. *Sharing fears may help patient gain insight into dealing with issues of concern.*
- Explain all procedures and treatments. *Unfamiliar practices may increase fear.*
- Help patient identify support systems and coping strategies that have worked in the past. *These may be helpful in dealing with current fears.*

Health-seeking behaviors related to lack of knowledge about STDs

EXPECTED OUTCOME: Patient will verbalize correct understanding related to STD prevention and testing.

- Assess the patient's health beliefs and correct misconceptions. *Many myths about sexual activity are sincerely believed by some patients (Table 44.3).*

TABLE 44.2 BARRIER METHODS FOR SAFER SEX

Barrier	Related Information
Male condoms	<p>Latex condoms are less likely to break during intercourse than other types. Lubrication decreases the chances of breakage during use, but only water-soluble lubricants should be used, because substances such as petroleum jelly (Vaseline) may weaken the condom.</p> <p>Condoms should never be inflated to test them, because this can weaken them. Condoms should be applied only when the penis is erect.</p> <p>Either condoms with a reservoir tip or regular condoms that have been applied while holding approximately 1/2 inch of the closed end flat between the fingertips allow room for expansion by the ejaculate without creating excessive pressure, which might break the condom.</p> <p>The penis should be withdrawn after ejaculation before the erection begins to subside while holding the top of the condom securely around the penis to avoid spillage.</p> <p>Condoms should never be reused and should be discarded properly after use so that others will not come in contact with the contents.</p>
Female condoms	<p>Female condoms should be applied before any penetration occurs (even preejaculation fluid can contain microorganisms).</p> <p>Lubrication decreases the chances of breakage during use, but only water-soluble lubricants should be used, because substances such as petroleum jelly may weaken the condom.</p> <p>Female condoms should never be reused and should be discarded properly after use so that others will not come in contact with the contents.</p>
Cervical caps or diaphragms	<p>These may provide some protection for the cervix only. They are not effective barriers against STD infection.</p>
Rubber gloves, rubber dental dams, split (opened) male condoms	<p>These may provide some barrier protection for manual and oral sexual activity. Although some groups suggest that male condoms may be split down one side and opened or rubber dental dam material may be taped over areas that have lesions to avoid direct contact with blood and body fluid, especially during sadomasochistic sexual activity, this <i>very-high-risk behavior</i> is not recommended.</p>
Double condoms	<p>Anal intercourse is a <i>very-high-risk activity</i> for transmission of many types of STDs, as well as many intestinal organisms, and is not recommended. Homosexual networks advise wearing double condoms and using water-soluble lubricants, preferably containing nonoxynol-9, to decrease risk somewhat if engaging in this type of sexual activity.</p>

TABLE 44.3 COMMON MYTHS ABOUT SEXUALLY TRANSMITTED DISEASES

Myth	Factual Data
People who have STDs are easily identifiable.	Inspection of the potential partner's genitals before sexual activity may decrease the risk (if one does not participate in sexual activity with a person who has visible lesions), <i>but</i>
Avoiding persons who have a history of casual sex, intravenous drug use, homosexual activity, bisexual activity or a previous sexual relationship with persons who engage in these high-risk practices effectively protects one from infection with STDs.	<ul style="list-style-type: none"> • Not all people who are infected have visible symptoms. • There is no standard personality or physical profile for people who can be infected with STDs—<i>anyone</i> can be infected.
STDs never happen the first time. Intact genital skin is impervious to the germs (and gentle sexual activity does no harm).	<p>Avoiding people with these types of history may decrease risk, <i>but</i></p> <ul style="list-style-type: none"> • Not everyone is honest when responding to questions about sexual history. • Not everyone is aware of their previous partners' histories or the histories of others with whom their previous partners have had sexual relationships. • Asking these kinds of questions is difficult and may be postponed at times until emotional factors complicate such communication.
Condoms prevent the spread of all STDs.	<p>Only one contact with one microorganism is necessary for infection. Intact skin is the body's first line of defense, <i>but</i></p> <ul style="list-style-type: none"> • Some microorganisms can be transmitted without a noticeable tissue injury. • Minor injuries can occur during many types of sexual activity, including vaginal intercourse. <p>Condoms can greatly decrease the risk of STDs, <i>but</i></p> <ul style="list-style-type: none"> • Condoms can have tiny channels in the rubber (or other elastic material), which can allow microorganisms to pass through. • Condoms can break, slip off, or be applied improperly. • Petroleum-based lubricants may weaken latex condoms. • Condoms do not provide a barrier for any area other than the penis and most of the vagina (or anus). Some STDs may still be transmitted by contact of surrounding uncovered tissues.
The female condom prevents all transmissions of STDs. Manual, oral, and anal stimulation cannot transmit STDs.	<p>It does cover more surface area, but it may have problems similar to male condoms (see previous).</p> <p>Contact of hands to genitals can allow for transmission of microorganisms through breaks in the skin.</p>
Nonoxynol-9 spermicide kills all STD germs.	<p>Oral sex can transmit some STD-causing microorganisms. Anal intercourse is a very high-risk activity for transmission of STDs because anal tissues are easily injured and the gastrointestinal tract can be a reservoir for many microorganisms.</p>
People get AIDS only by homosexual sexual activity or by blood transfusion. A woman cannot transmit HIV to a man. A man cannot transmit HIV to a woman.	<p>Nonoxynol-9 can reduce the risk of transmission of STDs, <i>but</i></p> <ul style="list-style-type: none"> • Nonoxynol-9 is <i>not</i> guaranteed to kill all microorganisms. <p>Homosexual activity may result in a higher incidence of transmission of human immunodeficiency virus, <i>but</i></p> <ul style="list-style-type: none"> • HIV can be transmitted during heterosexual activity. • The gender of the individual does not protect him or her from being infected with HIV.
Sexual activity during menstruation is less likely to result in STDs.	<p>Sexual activity during menstruation is more likely to result in transmission of some microorganisms that cause STDs because of the vulnerability of the lining of the uterus caused by sloughing of the outer layers of cells and because blood and cellular debris may serve as a nutritious medium for growth of microorganisms.</p>
Lesbian sexual activity cannot transmit STDs.	<p>Transmission of microorganisms can occur by contact with mouth, anal, or genital tissues or fomites (inanimate objects, such as vibrators and other sex paraphernalia) that have been contaminated with microorganisms from an infected individual—regardless of the original source of the infection.</p>
Individuals who have not been infected after sexual activity with several people are naturally immune to STDs.	<p>There is no known natural immunity to STDs. The individual may not yet have had contact with someone with an active STD.</p>
Those who have had an STD and have been cured of it by taking medicine are now immune to that disease.	<p>Infection that has been eradicated by medication does not confer immunity.</p>
People can be certified free of all STDs by having a blood test and taking a simple medication if an infection is present.	<p>Testing of those who suspect they may have contracted an STD and treatment (if possible) may decrease the spread of STDs, <i>but</i></p>

Myth

Oral contraceptive (OC) pills give protection against STDs.

Factual Data

- No one test identifies all STDs. Some are identified by examination, and not all infected people show symptoms.
 - Some STDs do not show positive test results for long periods yet may be transmitted by the individual while the tests are still negative.
 - People may be infected with more than one causative agent at a time and each must be treated (if possible). One STD may obscure the symptoms of other concurrent STDs, so that one or more types may go unnoticed and untreated or may not be evident until other STDs have been treated.
 - There are no known cures for some STDs.
- OC preparations are *not* antibiotics—they provide only some protection against conception.
- Use of a barrier method with spermicide along with the OC can decrease risk of STDs, as well as pregnancy.

- Explain the importance of patients knowing the sexual and lifestyle history of any potential partner before sexual activity has occurred. *Having a sexual relationship with someone is the epidemiological equivalent of engaging in sexual activity with all of that person's previous partners.*
- Provide pamphlets or other reading materials to reinforce teaching.
- Explain that abstinence or lifelong monogamy of both sexual partners in a relationship is the only sure prevention against sexually transmitted diseases. *These practices eliminate risk of exposure.*
- Educate the patient that consumption of alcohol or other psychoactive drugs can reduce inhibitions and may result in unintended sexual encounters, which can transmit STDs. *Avoiding or limiting alcohol and other drug consumption when with potential partners may help prevent STD infection from occurring.*

Evaluation

Goals have been met if the patient is able to state that pain is controlled at an acceptable level; verbalizes understanding

epidemiological: epi—on + demio—people + logical—pertaining to

of transmission prevention and practices preventive behaviors; describes acceptable, alternative sexual practices and safer sexual practices; and relates accurate information and reduction in fear.

For more information on STDs, visit http://www.cdc.gov/std/healthcomm/fact_sheets.htm and <http://www.ashastd.org/>.

CRITICAL THINKING**Stephanie**

■ As you seat a young woman in an examining room of the clinic where you work, she comments, “I am new to this area and I’ve heard that there are three guys in this town who have syphilis and are spreading it around. Is that true?”

1. What are some concerns this question might reflect?
2. You find out that Stephanie knows very little about syphilis. List in outline form a teaching plan that includes the information that is important for Stephanie to know about syphilis.

Suggested answers at end of chapter.

REVIEW QUESTIONS

1. Which of the following pathogens causes syphilis?
 - a. *Treponema pallidum*
 - b. *Chlamydia trachomatis*
 - c. Human papillomavirus
 - d. Human immunodeficiency virus
2. What signs and symptoms of STDs should nurses assess for in all patients? Choose all that are correct.
 - a. Itching
 - b. Discharge
 - c. Dysuria
 - d. Genital ulcers
 - e. Genital warts
 - f. Rectal pain
3. A young woman is seen at a walk-in clinic and is diagnosed with an STD. She says, “How could I have an STD? I only have sex with my boyfriend. I don’t sleep around!” Which of the following responses is best?
 - a. “You are right, that should have kept you safe. There just are no guarantees.”

- b. "If your boyfriend is not infected, then obviously you have had sex with someone else."
 - c. "You or your boyfriend could be infected from past sexual encounters. He should also be tested at this time for STDs."
 - d. "Even lifelong monogamy cannot prevent many STDs."
4. A home care nurse is preparing to change a dressing on a patient who had genital warts removed the previous day. Which intervention should be completed first?
 - a. Clean the wounds.
 - b. Remove the old dressing.
 - c. Assess for drainage.
 - d. Administer an analgesic.
 5. An older man is admitted to the hospital with mental status changes. As the nurse begins the shift assessment, the patient begins to cry and says his doctor thinks his problems stem from an untreated syphilis infection
 - a. "Why didn't you have it treated when it occurred?"
 - b. "What's done is done; it's unfortunate that treatment is too late now."
 - c. "That must be upsetting for you. Do you want to talk about it?"
 - d. "Don't cry; I am sure there is treatment that can help now."
 6. A nurse has completed instruction related to risk reduction with a 17-year-old woman. Which statement by the patient indicates that teaching has been effective?
 - a. "I should avoid drinking alcohol when I will be in situations with potential sex partners."
 - b. "If I make sure my partners wear condoms, I will be protected from STDs."
 - c. "Use of a barrier method of birth control will prevent infection with an STD."
 - d. "As long as I know my partner well, I am safe."

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ **Mrs. Miller**

1. You can educate Mrs. Miller about the possibility of neonatal infections from *C. trachomatis* or *N. gonorrhoeae*, especially of the eyes. Institutional and governmental policies related to treatment should be explained. Care should be taken to explain to Mrs. Miller that treatment is widely used, so as not to make her feel she has a condition she has not been told about.
2. Because the benefits for prophylactic eye treatment of the neonate for *C. trachomatis* and *N. gonorrhoeae* exposure are generally seen as greater than the risks, it is recommended by governmental agencies and supported by most institutional policies to treat all newborns, regardless of known exposure, shortly after birth.

■ **Kerri**

1. Explain to Kerri the fact that trichomoniasis is generally considered to be an STD, but that the organism that causes the disorder can be transmitted through infected articles (during nonsexual contact), can survive a long time outside the body, and that one can be asymptomatic for many years following exposure to the organism before an outbreak occurs.
- 2.

7.5 mg	1 kg	140#	= 477 mg
kg	2.2#		

Her dose will probably be rounded to 500 mg every 6 hours.

3. Teach Kerri that it is possible that her partner could have an undiagnosed infection, and that the possibility of being infected during a monogamous relationship is real. Treatment should be provided to Kerri's partner regardless of symptoms. Also, reinfection may occur if both partners are not treated. Also, be sure to tell her that she should abstain from alcohol for at least 48 hours following completion of the metronidazole. Patients who drink alcohol while taking it are VERY likely to vomit.

■ **Stephanie**

1. Concerns might include (a) a wish to speak with a health-care worker; (b) uncertainty about whether patient information will be kept confidential (give assurance that if you knew about anyone with syphilis, it would be your professional responsibility to keep it confidential); (c) fear that she might have become infected through heterosexual contact; (d) a desire to protect herself by avoiding those who have syphilis; and (e) a desire for information about syphilis and its transmission routes.
2. The teaching plan might include information about (a) the spirochete that causes syphilis; (b) signs and symptoms; (c) diagnostic tests; (d) means of transmission; (e) strategies for risk reduction; (f) treatment; (g) research; and (h) rights and responsibilities of those who have the disease.

QUESTIONS TO GUIDE YOUR READING

1. What is the normal structure and function of the musculoskeletal system?
2. What areas are included in a nursing assessment of the musculoskeletal system?
3. What areas are reviewed when performing a neurovascular assessment?
4. How would you describe diagnostic tests for musculoskeletal problems?
5. What nursing care would you provide for each musculoskeletal diagnostic test?

REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY

The skeletal and muscular systems may be considered one system because they work together to enable the body to move. The skeleton is the framework that supports the body and to which the voluntary **muscles** are attached. The skeletal framework includes the **joints**, or articulations, between **bones**. Contraction of a muscle pulls a bone and changes the angle of a joint. It is important to remember that movement would not be possible without the proper functioning of the nervous, cardiovascular, and respiratory systems. Voluntary muscles require nerve impulses to contract, a continuous supply of blood provided by the circulatory system, and oxygen provided by the respiratory system.

SKELETAL SYSTEM TISSUES AND THEIR FUNCTIONS

The tissues that make up the skeletal system are bone tissue; cartilage, which covers most joint surfaces; and fibrous connective tissue, which forms the ligaments that connect one bone to another and also form part of the structure of joints. The tissues of the muscular system are skeletal (also called striated or voluntary) muscle; fibrous connective tissue, which forms the tendons that connect muscle to bone; and the fasciae, the strong membranes that enclose individual muscles. Smooth muscle (also called involuntary or nonstriated) has the same function as skeletal muscle (i.e., contraction) but is not considered part of the skeletal system tissues as it is not involved with articulation or skeletal movement.

Besides its role in movement, the skeleton has other functions. It protects organs and tissues from mechanical injury. For example, the brain is protected by the skull and the heart and lungs are protected by the rib cage. Flat and irregular bones contain and protect the red bone marrow, the hematopoietic (blood-forming) tissue. The bones are also a storage site for excess calcium, which may be removed from bones to maintain a normal blood calcium level. Calcium in the blood is necessary for blood clotting and for the proper functioning of nerves and muscles.

Although the primary function of the muscular system is to move or stabilize the skeleton, the voluntary muscles collectively contribute significantly to heat production, which maintains normal body temperature. Heat is one of the energy products of cellular respiration, the process that produces adenosine triphosphate (ATP), the direct energy source for muscle contraction. Another important function of the muscular system is that it aids in returning blood from the legs through muscular compression on the leg veins.

Bone Tissue and Growth of Bone

Bone tissue is composed of bone cells, called osteocytes, within a strong nonliving matrix made of calcium salts and the protein collagen. In compact bone, the osteocytes and matrix are in precise arrangements called osteons (or haver-

sian systems). Compact bone is very dense and to the unaided eye appears solid. In spongy bone, the arrangement of cells and matrix is less precise, giving the bone a spongy appearance. Compact bone forms the diaphyses (shafts) of the long bones of the extremities and covers the spongy bone that forms the bulk of short, flat, and irregular bones.

A living bone is covered by a fibrous connective tissue membrane called the periosteum, which is the anchor for tendons and ligaments because the collagen fibers of all these structures merge to form connections of great strength. This membrane also contains the blood vessels that enter the bone itself (most of the bone has a very good blood supply) and bone-producing cells called osteoblasts that are activated to initiate repair when bone is damaged.

The growth of bone from fetal life until a person attains final adult height depends on many factors. Proper nutrition (particularly vitamins and minerals) provides the raw material to produce bone matrix: comprised of calcium, phosphorus, and protein. Vitamin D is essential for the efficient absorption of calcium and phosphorus from food in the small intestine. Vitamins A and C do not become part of bone but are needed for the production of bone matrix (a process called calcification or ossification). Hormones directly necessary for growth include growth hormone (GH) from the anterior pituitary gland, thyroxine from the thyroid gland, and insulin from the pancreas. Growth hormone increases mitosis and protein synthesis in growing bones; thyroxine stimulates osteoblasts, as well as increasing energy production from food. Insulin is essential for the efficient use of glucose to provide energy. If a child is lacking any of these hormones, growth is much slower and the child does not reach his or her genetic potential for height.

Bone is not a fixed tissue, even when growth in height has ceased. There is a constant removal and replacement of calcium and phosphate (usually the rates are equal) to maintain normal blood levels of these minerals. Parathyroid hormone secreted by the parathyroid glands increases the removal of calcium and phosphate from bones; the hormone calcitonin from the thyroid gland promotes the retention of calcium in bones, although its greatest effects may be during childhood.

Osteoblasts produce bone matrix during normal growth to replace matrix lost during normal turnover and to repair fractures. Other cells called osteoclasts reabsorb bone matrix when more calcium is needed in the blood and during normal growth and fracture repair when excess bone must be removed as bones change shape.

The sex hormones, estrogen from the ovaries or testosterone from the testes, are important for the retention of calcium in adult bones. For women after menopause, more calcium may be removed from bones than is replaced, leading to a thinning of bone tissue and the possibility of spontaneous fractures.

Structure of the Skeleton

The 206 bones of the human skeleton are in two divisions: the axial skeleton and the appendicular skeleton. The axial

skeleton consists of the skull, hyoid, vertebral column, and rib cage; all are flat or irregular bones and contain red bone marrow (hematopoietic tissue). The appendicular skeleton consists of the bones of the arms and legs and the shoulder and pelvic girdles, by which the extremities attach to the axial skeleton (Fig. 45.1).

The long bones of the limbs are those of the arm, forearm, hand, and fingers and those of the thigh, leg, foot, and toes. All long bones have the same general structure: a central diaphysis, or shaft, with two ends called epiphyses. The diaphyses of long bones contain yellow bone marrow, which is mostly adipose—that is, stored energy. The bones of the wrist and ankle are short bones (except for the calcaneus, which is an irregular bone). The scapula is considered a flat

bone, and the pelvic girdle is made of irregular bones. These bones contain red bone marrow.

Skull

The skull consists of 8 cranial bones and 14 facial bones and also contains the 3 auditory bones found in each middle ear cavity. The cranial bones that enclose and protect the brain are frontal, two parietal, two temporal, occipital, sphenoid, and ethmoid (Fig. 45.2). All the joints between cranial bones and those between most of the facial bones are immovable joints called sutures (comprised of dense collagenous connective tissue). The mandible is the only movable facial bone. It articulates with the temporal bone of the skull forming a combined hinge and planar joint called the tempo-

FIGURE 45.1 The full skeleton in anterior view. (Modified from Scanlon, VC, and Sanders, T: *Anatomy and Physiology*, ed. 5. F.A. Davis, Philadelphia, 2007, with permission.)

FIGURE 45.2 Anterior (upper) and lateral (lower) views of the skull. (Modified from Scanlon, VC, and Sanders, T: *Anatomy and Physiology*, ed. 5. F.A. Davis, Philadelphia, 2007, with permission.)

mandibular joint (Table 45.1). The maxillae are the upper jaw bones, which also form the front of the hard palate (part of the roof of the mouth). The rest of the facial bones are shown in Figure 45.2.

Vertebral Column

The vertebral column (or spinal column) is made of individual bones called **vertebrae** (see Fig. 45.1). From top to bottom there are 7 cervical, 12 thoracic, 5 lumbar, 5 sacral fused into 1 sacrum, and 4 or 5 coccygeal vertebrae fused into 1 coccyx.

The first cervical vertebra, the atlas, articulates with the occipital bone of the skull and forms a pivot joint with the axis, the second cervical vertebra. The thoracic vertebrae articulate with the posterior ends of the ribs. The lumbar vertebrae are the largest and strongest. The sacrum permits the articulation of the two hip bones, at the sacroiliac joints. The coccyx serves as an attachment point for some muscles of the perineum.

The vertebrae as a unit form a flexible backbone that supports the trunk and head and contains and protects the spinal cord. Openings, or intervertebral foramina, between

TABLE 45.1 JOINTS OF THE APPENDICULAR SKELETON

Type of Joint and Description	Examples
Symphysis—disk of fibrous cartilage between bones	Between vertebrae Between pubic bones
Ball and socket—movement in all planes	Scapula and humerus (shoulder) Pelvic bone and femur (hip)
Hinge—movement in one plane	Humerus and ulna (elbow) Femur and tibia (knee) Between phalanges (fingers and toes)
Combined hinge and planar	Temporal bone and mandible (lower jaw)
Pivot—rotation	Atlas and axis (neck) Radius and ulna (distal to elbow)
Gliding—side-to-side movement	Between carpals (wrist)
Saddle—movement in several planes	Carpometacarpal of thumb

Modified from Scanlon, VC, Sanders, T: *Essentials of Anatomy and Physiology*, ed. 5. F.A. Davis, Philadelphia, 2007, p. 120, with permission.

the vertebrae allow for the exit of spinal nerves and entry of blood vessels. The joints between vertebrae are symphysis joints in which a disk of fibrous cartilage serves as a cushion and permits slight movement.

Rib Cage

The rib cage consists of the 12 pairs of ribs and the sternum, or breast bone. All the ribs connect posteriorly with the thoracic vertebrae. The seven pairs of true ribs articulate directly with the sternum by means of costal cartilages; the three pairs of false ribs join indirectly with the sternum, and the inferior two pairs of floating ribs do not connect to the sternum at all.

The rib cage protects the heart and lungs, as well as upper abdominal organs such as the liver and spleen, from mechanical injury. During breathing, the flexible rib cage is pulled upward and outward by the external intercostal muscles to expand the chest cavity and bring about inhalation.

Appendicular Skeleton

The bones of the appendicular skeleton are shown in Figure 45.1. The important joints of the appendicular skeleton are summarized in Table 45.1.

Structure of Synovial Joints

All freely movable joints (this excludes amphiarthroses and synarthroses) are synovial joints in that they share similarities of structure (Fig. 45.3). On the joint surface of each bone is the **articular** cartilage, which provides a smooth surface. The joint capsule is similar to a sleeve. It is made of fibrous connective tissue and forms a strong sheath that encloses the joint. Lining the joint capsule is the synovial membrane, which secretes synovial fluid into the joint cav-

FIGURE 45.3 Longitudinal section through a typical synovial joint. (Modified from Scanlon, VT, and Sanders, T: *Workbook for Essentials of Anatomy and Physiology*, ed. 5. F.A. Davis, Philadelphia, 2007, with permission.)

ity. Synovial fluid is a mixture of hyaluronic acid, proteins, fat, and cells that provides a slippery consistency that prevents friction as the bones move.

Many synovial joints also have **bursae**, which are small sacs of synovial fluid between the joint and the tendons that cross over the joint. Bursae permit the tendons to slide easily as the joint moves.

MUSCLE STRUCTURE AND ARRANGEMENTS
