As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The author(s), editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

*To **our students**, this is for you. We hope it helps you achieve your dreams.*

Linda and Paula

In memory of my mother who was so proud of the book that she took it everywhere to show to people. I will miss her joy in seeing this edition. To my dad who has always been supportive and kept me company on my breaks from writing during this revision.

*To **Garland**,*

with love, whose support I needed more than ever before during this past year. Thank you.

*To **Jami and Anthony**, who's joy in life are their wonderful children, **Dimitri, Alex, and Ayla** who also bring me joy.*

*To my sister **Lisa** and her family **Ken, Michael, and Nathan** for their ongoing support.*

*To **Christine, Anna, and Suzee** for encouragement and a listening ear when it was needed most.*

LINDA S. WILLIAMS

*To **Dave**, with love, for his continued love and support.*

*To **Dan and Libby**, my two other favorite people in the world. I am so proud of you both.*

*And to my **Dad**, who proudly displays our books even though he doesn't have to read them.*

PAULA D. HOPPER

Preface

Welcome to the third edition of *Understanding Medical Surgical Nursing*! We have fully updated all the material, and have added exciting new information on home health care, end-of-life care, disaster response and bioterrorism, stroke, and more.

We continue to work hard to provide a text written at an understandable level, with features that help students understand, apply, and practice the challenging content required to function as practical/vocational nurses. We are thankful to the many students who tell us they find the book very readable, and actually enjoyable. We are overjoyed to hear from several nursing programs that their NCLEX scores soared after adopting this textbook.

We continue to emphasize understanding, critical thinking, and application throughout the book. We believe that a student who learns to think critically will be better able to apply information to new situations. We hope both students and instructors find this third edition a practical tool for learning and understanding medical-surgical nursing.

FEATURES OF THE BOOK

We have kept our most popular features from the first two editions, and added new ones based on reader input.

- *Questions to Guide Your Reading* begin each chapter. In our experience, the standard objectives found in many textbooks have little meaning and provide little assistance to students. Literature suggests that comprehension increases when students read guiding questions before reading the text. So we have provided a series of questions that students should keep in mind as they read. These questions can be translated easily back into objectives by instructors who prefer this format.
- Special features written by actual patients, called *Patient Perspectives*, were added in the second edition. Many more have been added to this edition. These stories help to make patients' experiences with illness more meaningful and personal for students.

- Web links are included in the text to help students do further research on topics of interest. Every effort was made to use only major established web sites that are unlikely to change in the near future.
- One of our most popular features, Critical Thinking Exercises, has been expanded to help students practice and think about what they are learning. We have added more math calculations and documentation practice to Critical Thinking Exercises where applicable.
- Review questions at the end of each chapter have been updated and include alternate format items to reflect NCLEX-PN.
- Suggested Answers for the Critical Thinking Exercises and Review Questions are included. Research supports the importance of immediate feedback to reinforce learning, so we feel strongly that students should have access to correct answers while they are studying, without having to wait for their next instructor contact. Since there can be many answers to some of the critical thinking questions, we have provided sample answers to help stimulate students' thinking.
- The effects of aging on body systems have been converted from text format to a mindmap format. We believe this visual representation is easier to understand and apply than the traditional text.
- We have changed our Nursing Process format from text to bullet lists. It is very easy to read, clearly stands out, and makes interventions with rationale very clear to students.
- More Learning Tips, a very popular feature in past editions, have been added. New to the third edition are Nursing Care Tips and Safety Tips.
- JCAHO National Patient Safety Goals are reflected in many of the safety tips to give students an introduction to these safety goals.
- Nursing assessment, laboratory tests, and medications have been placed in consistent tables that are easy to read and understand.

- Summary boxes including nursing diagnoses have been expanded and included for most major disorders.
- A pronunciation key for new words is found at the beginning of each chapter.
- A review of anatomy and physiology is presented at the beginning of each unit.
- Word-building footnotes are found throughout the chapters to make complex medical terminology easier to understand.
- Nursing care plans with geriatric considerations have been updated.
- Boxed presentations of Cultural Considerations, Gerontological Issues, Home Health Hints, Ethical Considerations, and Nutrition Notes provide valuable supplemental information and help students relate text material to real life situations.
- Many new photographs and drawings have been added to illustrate important concepts.
- A comprehensive, updated glossary of new words is included in the appendix.

TO STUDENTS: HOW TO USE THIS BOOK

As you begin each chapter, carefully read the section labeled *Questions to Guide your Reading*. Then, when you are finished reading each chapter, go back and make sure you can answer each question.

You will find a list of new words and their pronunciations at the beginning of each chapter. These words appear in bold at their first use in a chapter, and they also appear in the glossary at the end of the book. By learning the meanings of these words as you encounter them, you will increase your understanding of the material.

You also will encounter other learning tips to increase your understanding and retention of the material. You may want to develop your own memory techniques in addition to those provided. (If you think of a good one, send it to us and you may find it in the next edition!) Many of the learning tips have been developed and used in our own classrooms. We find them helpful in fostering understanding of complex concepts or as memory aids. However, we want to stress that memorization is not the primary focus of the text but rather a foundation for understanding and thinking about more complex information. Understanding and application will serve you far better than memorization when dealing with new situations.

Each chapter includes critical thinking case studies designed to help you apply material that has been presented. A series of questions related to the case study will help you integrate the material with what you already know. These questions emphasize critical thinking, which is based on a foundation of recall and understanding of material. To enhance your learning, try to answer the questions before looking up the answers at the end of the chapter.

Review questions appear at the end of each chapter to help you prepare for chapter tests, and also for the NCLEX-PN. Again, to assess your learning, try to answer the questions before looking up the answers at the back of the book.

A bibliography at the end of each unit provides sources for additional reading material. Web sites have been included in many chapters. We believe it is important for you to interact with current technology to expand your information resources.

The following appendices are included for easy reference:

- NANDA nursing diagnoses
- Lab values
- Common medical abbreviations (Although it is still important to know the abbreviations, many can increase risk of errors. Check www.JCAHO.org for a list of abbreviations to avoid.)
- Common prefixes and suffixes to help learn word building techniques

SUPPLEMENTAL MATERIALS

- A new *Electronic Student Guide* is included with the book. This provides practice in the form of objective (fill-in, labeling, and flashcard) exercises, and case studies. There are also review questions and a practice NCLEX test. We have also included a brief math tutorial using Unit Analysis, and practice calculation problems. Answers are provided to all exercises for immediate feedback.
- A paperback *Student Workbook* is available to provide the student additional contact and practice with the material. Each chapter includes vocabulary practice, objective exercises, a case study or other critical thinking practice and review questions written in NCLEX-PN format. Answers provide immediate feedback. Rationales are provided for non-anatomy review question answers.
- An *Instructor's Resource Disk* includes an *Electronic Instructor's Guide* that provides materials for use in the classroom. Each chapter has a chapter outline with suggested classroom activities. Also included are student activities for printing and using for individual practice or for collaborative learning activities. These activities help the student to interact with the material, understand it, and apply it. Many of the activities are based on real patient cases and have been used with our own practical nursing students. Feedback from students has helped to refine the exercises. We believe the use of collaborative learning has greatly enhanced our students' success in achieving their educational and licensure goals. Another benefit is the sense of community the students develop as a result of working in groups. A brief introduction and guidelines for using collaborative learning techniques is

included. Also included is an expanded *Electronic Test Bank*, available to instructors who adopt the textbook, which provides test questions that assist students to prepare for NCLEX-PN. These questions have been prepared according to test item writing protocols. The questions are in multiple choice and alternate format, and test recall, application, and analysis of material. Many of the test questions have been developed, used and refined by the authors in their own medical-surgical courses

for practical nursing students. The program allows instructors to choose and modify the questions that best suit their classroom needs. Finally, for the instructor's convenience, there is a comprehensive *Power Point* program for classroom presentations. Images from the text have been added for the third edition. Each presentation can be modified, reduced, or expanded by individual instructors to suit their needs.

Acknowledgements

Many people helped us make this book a reality. First and foremost are our students, who provided us with the inspiration to undertake this project. We hope that they continue to find this text worth reading.

The F.A. Davis Company has been an exceptional publishing partner. We feel fortunate to have had their continued enthusiasm and confidence in our book. The staff at F.A. Davis has guided us through this project for three editions to help us create a student-friendly book that truly promotes understanding of medical-surgical nursing.

Lisa Deitch, Shirley Kuhn, Ilysa Richman, Darlene Pedersen, Doris Wray, and many others have been extremely patient and kind as we worked hard to provide a quality text and meet deadlines.

We thank the staff of W.A. Foote Memorial Hospital in Jackson, Michigan for allowing us access to their facility and patients for a great photo shoot. Our photographer, Robert Conway, did a terrific job of obtaining some challenging shots.

Contributors from across the United States and Canada,

including many well-known experts in their fields, brought expertise and diversity to the content. Their hard work is much appreciated. Reviewers from throughout the United States provided insights that enhanced the quality of the text. Elizabeth Hopper provided invaluable organizational assistance.

Many of our co-workers have contributed to this book and given us ongoing encouragement and validation of the worthiness of this project. Elizabeth Ackley, Marina-Martinez Kratz, Sharon Nowak, Debra Perry-Philo, Carroll Lutz, Suzanne Fox, Linda Nabozny, and Anna Ricks were especially helpful in providing material, advice, and encouragement.

We wish to thank everyone who played a role, however large or small, in helping us to provide a tool to help students realize their dreams of becoming an LPN or LVN. We hope this book will help train nurses who can provide safe and expert care because we have helped them to learn to think critically.

Critical Thinking and the Nursing Process

PAULA D. HOPPER
AND LINDA S. WILLIAMS

KEY TERMS

assessment (ah-SESS-ment)

critical thinking (KRIT-i-kuhl THING-king)

data (DAY-tuh)

evaluation (e-VAL-yoo-AY-shun)

evidence based practice (ev-a-dense baste prack-tis)

intervention (in-ter-VEN-shun)

nursing diagnosis (NER-sing DYE-ag-NOH-sis)

nursing process (NER-sing PRAH-sess)

objective data (ob-JEK-tiv DAY-tuh)

subjective data (sub-JEK-tiv DAY-tuh)

QUESTIONS TO GUIDE YOUR READING

1. How is critical thinking of value in the nursing process?
2. What are objective and subjective data?
3. How can the documentation of data be improved?
4. How would you prioritize patient care based on Maslow's hierarchy of human needs?
5. What is your role as a licensed practical nurse/licensed vocational nurse in using the nursing process?
6. What is a nursing diagnosis?
7. What is the evaluation phase of the nursing process?

Excellence in the delivery of nursing care requires good thinking. Each day nurses make many decisions that will affect the care of their patients. For those decisions to be effective, the thought processes behind them must be sound.

CRITICAL THINKING AND SAFE CARE

Nurses must learn to think critically. This means they must use their knowledge and skills to make the best decisions possible in patient care situations. Halpern¹ says that “**critical thinking** is the use of those cognitive [knowledge] skills or strategies that increase the probability of a desirable outcome.” Critical thinking is sometimes called directed thinking because it focuses on a goal. Other terms used when talking about critical thinking include *reasoning*, *common sense*, *analysis*, and *inquiry*. Good thinking requires critical thinking attitudes and skills, which are described below. It also requires a good knowledge base, so your thinking is based upon correct factual material. These are the topics of the rest of this book.

Critical Thinking Attitudes

Researchers have identified attitudes that are associated with good critical thinking. Green identifies seven attitudes, summarized below.²

Intellectual Humility

Have you ever known people who think they “know it all”? They do not have intellectual humility. People with intellectual humility have the ability to say, “I am not sure about that.... I need more information.” Certainly, we want our patients to think we are smart and know what we are doing, but patients also respect nurses who can say, “I do not know; let me find out.” It is unsafe to care for patients when you are not sure of what you need to do.

Intellectual Courage

Intellectual courage allows you to look at other points of view even when you do not agree with them at first. Maybe you really believe that 8-hour shifts are best for nurses, and have a lot of good reasons for your belief. But if you have intellectual courage, you will be willing to really listen to the arguments for changing to 12-hour shifts. Maybe you will even be convinced. Sometimes you have to have the courage to say, “Okay, I see you were right after all.”

Intellectual Empathy

Consider the patient who snaps as you enter her room, “I’ve been waiting all morning for my bath. If you do not help me with it right now I am going to call your supervisor.” The first response that comes into your head is, “I have five other patients; you are lucky I am here now!” But, if you have intellectual empathy, you will be able to think, “If I were this patient, who is in chronic pain and is tired of being in the hospital, how would I feel?” It might change how you respond.

Intellectual Integrity

Your patient seems to ask a hundred questions when you bring her a medication that has been newly prescribed for her high blood pressure. But later you notice she is taking an herbal remedy from her purse. It is good that she is asking a lot of questions about her drug, which has been tested extensively by the Food and Drug Administration (FDA). Herbal remedies are not held to the same standards as medications in the United States. Someone with intellectual integrity would want the same kind of proof that both types of medications are safe and effective before using them.

Intellectual Perseverance

Do not give up. Consider this scenario. You have concerns about some side effects you have noticed when you administer a new drug to your patients. You mentioned it to the physician and he said not to worry about it, but you are still concerned. If you have intellectual perseverance, you might do some research on the web, then go to your supervisor or the pharmacist to discuss your concerns.

Faith in Reason

If you have faith in reason, you believe in your heart that good thinking, and reason, will indeed result in the best outcomes for your patients. And if you really believe, you will be more likely to attend a seminar or read an article on critical thinking skills.

Intellectual Sense of Justice

One of your co-workers wants to change the medication administration schedule on your unit. She says it is because it will be better for the patients, but you think it might be because it fits her break schedule better. If you have an intellectual sense of justice, you will be sure that your thinking is not biased by something that you just want for yourself, like your co-worker seems to be doing. You should examine your own motives as well as those of others when you are making decisions.

So, what does this all mean to you as a nursing student? The term “metacognition” means to “think about thinking.” It is important for you to try to develop the attitudes of a critical thinker, and to learn to think clearly and critically about your patient care. In order to do that, you need to constantly think about your thinking. Are you practicing intellectual humility? Are you trying to be courageous and empathetic? These attitudes create an excellent base on which to build a nursing knowledge base, and on which to develop further thinking skills.

Knowledge Base

Nurses must have a good knowledge base in order to safely care for their patients. You could not drive a car without first learning the basics of how a car works and how to follow the rules of the road. In the same way, you must understand the human body in health and illness before you can understand how to take care of an ill patient. This is the reason you are going to school and studying this book.

Information is found in many places; some information is good, and some is not as good. For example, health information found on a website may have been put there by a major university medical school, or it may have been put there by a patient who has a particular disorder. You may learn about a patient's experience by reading his or her website, but you certainly would not base care of your patients on this one person's personal experience.

The best knowledge upon which to base your practice comes from research. Nurse researchers try new methods for taking care of patients and compare them with traditional methods to determine what works best. For example, for many years nurses were taught to massage patients' reddened bony prominences to prevent pressure ulcers. Through research, we now know that this practice should be avoided because it can further harm tissue that is already damaged.

When nursing care is based on good, well-designed research studies, it is called **evidence based practice**. As nurses, we need to use as many interventions as we can that have been researched. Other interventions, until they are validated by research, have to be based on our best critical thinking skills. Some expert organizations are beginning to "bundle" best practice strategies together to increase their use. Bundles are groups of interventions that, when used together, have been shown to improve patient outcomes. To find more information on bundles, go to <http://www.ih.org/ih> and type "bundles" in the search window. It is nice to be able to tell a patient or family member that "Your loved one is being cared for based on the latest research recommendations."

Concern for Patient Safety

Safety is on everyone's mind. Many people know of someone who has been affected by a medical error or who has been unhappy with their care. Health-care providers are being held accountable for safe care by society. As a result, guidelines to reduce errors in health care and improve patient outcomes have been developed. The Joint Commission on Accreditation of Hospitals and Organizations (JCAHO) is an organization that accredits health-care agencies. JCAHO's 2006 patient safety goals can be found at <http://www.jcipatientsafety.org>. As you will see, care in various health-care settings is addressed in these goals. Following is an example of one of the goals which you will find throughout the book as safety tips.

These goals are throughout the book to increase your awareness and understanding of them. They address important areas of concern such as using medications safely, correctly identifying patients, identifying operative sites correctly, improving communication, reducing fall injuries, and reducing risk for infections in institutionalized elderly persons to name a few. So become familiar with them and look for annual updates on the web. Of course, it takes critical thinking to use them at the right times and in the right circumstances. Using them appropriately helps you provide safer care with fewer errors, which your patients appreciate.

SAFETY TIP

Use at least two patient identifiers (neither to be the patient's room number) when taking blood samples and other specimens for clinical testing, or providing any other treatments or procedures (JCAHO, 2006). 2006 National Patient Safety Goals from www.jcaho.org

Critical Thinking Skills

Problem Solving

Problem solving is one type of critical thinking skill. Nurses solve problems on a daily basis. However, a problem can be handled in a way that may or may not help the patient. For instance, consider Mr. Frank, who is in pain and requests pain medication. You check the medication record and find that his analgesic medication is not due for another 40 minutes. You can choose to manage this problem in a variety of ways. One obvious approach is to return to Mr. Frank and tell him that it is not time for the pain medication and that he will have to wait. This may solve your problem (you can move on to the next patient), but it does not solve the problem in an acceptable way for Mr. Frank. An alternative approach is to use a standard problem-solving method:

1. Gather **data**. When Mr. Frank requests pain medication, the first thing you do is obtain more data. As a good critical thinker, you can use intellectual empathy as well as your knowledge base about pain to decide what additional data you need. You decide to use a pain-rating scale on which the patient rates pain on a scale of 0 (no pain) to 10 (the greatest pain possible). Mr. Frank states that his pain is in his back and rates it as an 8 on the 10-point scale. You check his history and find he has compression fractures of his spine. Your empathetic attitude tells you that waiting for 40 minutes to relieve his pain is not acceptable. You next go to the medication record and find that he has no alternative pain medications ordered.
2. Identify the problem. Here you use your knowledge base to draw the conclusion that Mr. Frank is in acute pain, and the current medication orders are not sufficient to provide pain relief.
3. Decide what outcome (sometimes called a goal) is desirable. The outcome should be determined by you (the nurse) and the patient working together. The patient is intimately involved in this situation and deserves to be consulted. In this case you talk to Mr. Frank and determine that he needs pain relief now; he cannot wait until the next scheduled dose of medication. He states that he is able to tolerate a pain rating of 3 or less on a 10-point scale.
4. Plan what to do. Formulate and evaluate some alternative solutions. For example, you can decide to tell Mr. Frank that he has to wait 40 minutes;

however, this will not help him reach his desired outcome of pain control. Giving the medication early might relieve his pain, but this would not be following the physician's orders and may have harmful effects for Mr. Frank. You could decide to try some non-drug pain-control methods, such as relaxation, distraction, or imagery. These might be helpful, but you recall from pharmacology class that complementary methods should be used in conjunction with, not in place of, medications. Another alternative is to report to the physician that Mr. Frank's pain is not controlled with the current pain-control regimen. Once you have several alternative courses of action, decide which will best help the patient. Then you can discuss those options with the registered nurse (RN) and together decide the best thing to do; in this case, you might decide to have the RN contact the physician while you work with the patient on relaxation exercises. You might decide to ask Mr. Frank if he would like to listen to some of the music his wife brought in for him. You can also tell Mr. Frank that the physician is being contacted. This would assure him that his pain-relief needs are being taken seriously.

5. Implement the plan of care. The RN enters the room and informs you and the patient that the physician has changed the analgesic orders. You obtain and administer the first dose of the new analgesic, being sure to explain its effects and side effects to Mr. Frank. The RN also informs Mr. Frank that the physician has ordered a consultation with the pain clinic.
6. Evaluate the plan of care. Did the plan work? As you reassess Mr. Frank 30 minutes later, he rates his pain level at 2. You think back to the desired outcome, compare it with the current data collected, and determine that your **interventions** were successful.

Can you see how using good thinking attitudes, a good knowledge base, and the problem-solving process led to a better outcome than simply choosing the first obvious option? You were able to effect a positive change: assisting a patient in achieving pain relief. And you have undoubtedly earned Mr. Frank's trust in the process. Problem solving is how nurses make decisions on a daily basis. This is known as the *nursing process*.

Other Critical Thinking Skills

Problem solving is just one critical thinking skill. There are many others that are beyond the scope of this book. Following are a few questions to ask yourself as you continue to develop your critical thinking. There are many more questions you might ask. These are not in any order, nor would they all be asked for a given situation. They are just some ideas to get you started.

- Have I thought this through?
- What information do I need?
- How do I know?
- Is someone influencing my thinking in ways I am not aware of?
- What conclusions can I draw from the information I have?
- Am I basing this decision on assumptions that may or may not be true?
- Am I thinking creatively about this, or am I in a rut?
- Is there an expert I can consult that can help me think through this?
- Is there any research or evidence that this is true?
- Am I too stressed or tired to think carefully about this right now?

NURSING PROCESS

Previously you used the **nursing process** to solve a real problem. The nursing process is an organizing framework that links the process of thinking with actions in nursing practice. The nursing process can be used to assess patient needs, formulate nursing diagnoses, and plan, implement, and evaluate care. As a nursing student, you consciously use the nursing process with each patient problem. With experience, you will internalize the nursing process and use it without as much conscious effort.

Role of the Licensed Practical Nurse and Licensed Vocational Nurse

The licensed practical nurse (LPN) or licensed vocational nurse (LVN) carries out a specific role in the nursing process, as described in Table 1.1. The LPN/LVN collects data, assists in formulating nursing diagnoses, assists in determining outcomes and planning care to meet patient needs, implements patient care interventions, and assists in evaluating the effectiveness of nursing interventions in achieving the patient's outcomes. It is the role of the LPN/LVN to provide direct patient care. This gives the LPN/LVN an opportunity to develop a relationship with the patient that aids in assisting in the other parts of the nursing process. The LPN/LVN and the RN work as a team to analyze data and develop, implement, and evaluate the plan of care (Fig. 1.1).

TABLE 1.1 ROLE OF THE LPN/LVN IN THE NURSING PROCESS

Steps of the Process	Role of the LPN/LVN
<i>Assessment</i>	Assists in collecting data
<i>Nursing Diagnosis</i>	Assists in choosing appropriate nursing diagnoses
<i>Planning Care</i>	Assists in developing outcomes and planning care to meet outcomes
<i>Implementation</i>	Carries out those portions of the plan of care that are within the LPN/LVN's scope of practice
<i>Evaluation</i>	Assists in evaluation and revision of the plan of care

FIGURE 1.1 The nursing care team collaborating on a nursing care plan.

Data Collection

The first step in the nursing process is data collection. The LPN/LVN assists the RN in collecting data from a variety of sources. Data are divided into two types: **subjective data** and **objective data**.

Subjective Data

Information that is provided verbally by the patient is called subjective data. Symptoms are subjective data. Subjective data are often placed in quotes, such as “I have a headache” or “I feel out of breath.” You must listen carefully to the patient and understand that only the patient truly knows how he or she feels.

When collecting subjective data, begin with the patient’s main concern. Focus on the reason the patient is seeking health care. The question, “What happened that made you decide to come to the hospital (clinic, office)?” can be helpful.

Once the patient has identified the main concern, further questioning can elicit more pertinent information. Use the letters of the “WHAT’S UP?” questioning format to remember questions to ask the patient (Box 1.1 What’s Up? Guide to Symptom Assessment). Asking the right questions can help you obtain better data with which to make the best decisions.

Next, obtain a patient history. This is done by asking the patient and family questions about the patient’s past and present health problems, including specific questions about each body system, family health problems, and risk factors for health problems. The patient’s medical record may also be consulted for background history information.

In addition to assessment related to physiological functioning, ask the patient about personal habits that relate to

Box 1.1

WHAT’S UP? Guide to Symptom Assessment

W—Where is it?

H—How does it feel? Describe the quality.

A—Aggravating and alleviating factors. What makes it worse? What makes it better?

T—Timing. When did it start? How long does it last?

S—Severity. How bad is it? This can often be rated on a scale of 0 to 10.

U—Useful other data. What other symptoms are present that might be related?

P—Patient’s perception of the problem. The patient often has an idea about what the problem is, or the cause, but may not believe that his or her thoughts are worth sharing unless specifically asked.

health, such as exercise, diet, and the presence of stressors, per institutional assessment guidelines. Finally, assess the patient’s family role, support systems, and cultural and spiritual beliefs.

Objective Data

Objective data are pieces of factual information obtained through physical assessment and diagnostic tests and are observable or knowable through the five senses. Objective data are sometimes called *signs*. Examples of objective data include the following:

- 3-cm red lesion
- Respiratory rate 36
- Blood glucose 326 mg/dL
- Patient is moaning

Note that these are all observable or measurable by a nurse and do not require explanation by the patient.

Objective data are gathered through physical assessment. Inspection, palpation, percussion, and auscultation techniques are used to collect objective data (Fig. 1.2). Give special attention to areas that the patient has identified as potential problems.

Documentation of Data

Collected data are documented in the patient’s medical record. Identification of any significant problem or variation from normal is reported immediately to an RN or physician and then documented. The recorded data should be accurate and concise. You should document exactly what you observed or heard stated by the patient, significant other, or health team members. Avoid interpreting the data and using words that have vague meanings in your documentation. For example, “nailbed color is pink” gives clearer information than “nailbed color is normal.” “Capillary refill is 2 seconds” provides more precise data than “capillary refill is good.” The statement “the wound looks better” is not meaningful unless the wound has been previously observed by the

LEARNING TIP

Practice assessing a symptom on a classmate. Ask the “WHAT’S UP?” questions.

FIGURE 1.2 Nurse auscultating patient's chest.

reader. Stating that “the wound is 1 by 2 inches, red, with no drainage or odor” provides data with which to compare the future status of the wound and determine whether it is responding to treatment. When documenting subjective data, use direct quotations from the patient whenever possible. Quotes accurately represent the patient’s view and are least open to interpretation. Meaningful documentation promotes continuity of patient care.

LEARNING TIP

Documenting exactly what is observed is more appropriate, easier, and less time consuming than seeking other words or ways to state observations. Beginners may be tempted to search for elaborate phrases or words when simple, direct words are best. Stating exactly what is seen or heard usually provides the most clear and accurate information.

Nursing Diagnosis

Once data have been collected, the LPN/LVN assists the RN to compare the findings with what is considered “normal.” Data are then grouped, or clustered, into sets of related information that identify problems.

According to the North American Nursing Diagnosis Association (NANDA), a **nursing diagnosis** is a clinical judgment about individual, family, or community response to actual or potential health problems or life processes. Nursing diagnoses are standardized labels that make an identified problem understandable to all nurses. Nursing diagnoses are the foundation used to select interventions to achieve a desired outcome. A list of NANDA-approved nursing diagnoses can be found in Appendix A of this book.

Nursing actions are either independent or collaborative. Independent nursing actions can be initiated by the nurse.

Examples of independent nursing actions include teaching the patient deep breathing exercises, turning a patient every 2 hours, teaching about medications, and giving a back rub for comfort. Collaborative actions require a physician’s order to perform them in response to both nursing and medical diagnoses. Examples of this are giving prescribed medications, applying antiembolism stockings, requesting a referral to physical therapy, and inserting a urinary catheter.

A diagnosis is considered “nursing” instead of “medical” if the interventions necessary to treat the problem are primarily independent nursing functions. Even with independent nursing functions, nurses often consult with physicians about plans of care. When the physician directs most of the care related to a particular health problem, it is a medical diagnosis rather than a nursing diagnosis. For example, a patient with pneumonia (a medical diagnosis) has many needs that depend on physician orders, such as respiratory treatments and antibiotics. The nurse, however, can provide important assessment findings related to the health problem and provide nursing measures such as encouraging fluid intake, coughing, and deep breathing. When the physician and nurse work closely together on a patient problem, it is referred to as a collaborative problem.

One of the NANDA nursing diagnoses is acute pain. In Mr. Frank’s example, the pain was assessed as a health problem, and a plan of care was developed to manage the pain. The physician was contacted for analgesic orders, and independent nursing actions were used, including relaxation and distraction. These independent nursing actions did not require a physician’s order.

A well-written nursing diagnosis helps guide development of a plan of care. The three parts to a diagnosis follow:

- **Problem**—the nursing diagnosis label from the NANDA list
- **Etiology**—the cause or related factor (usually preceded by the words “related to”)
- **Signs and symptoms**—the subjective or objective data that are evidence that this is a valid diagnosis (often preceded by the words “as evidenced by”)

CRITICAL THINKING

Nursing Diagnosis

■ Which of the following are NANDA nursing diagnoses? Which are medical diagnoses?

1. Impaired mobility
2. Ineffective coping
3. Herniated disk
4. Fractured femur
5. Diabetes
6. Impaired gas exchange
7. Appendicitis
8. Health-seeking behaviors

Suggested answers at end of chapter.

The statement of problem, etiology, and signs and symptoms is called the PES format. Look again at the case study of Mr. Frank. A diagnosis using this format might read as follows: “Acute pain related to muscle spasms and nerve compression as evidenced by patient’s pain rating of 8.” Note how the complete diagnosis gives you more helpful information than simply the label “pain.” This additional information helps determine an appropriate outcome and guides intervention selection.

Plan of Care

Once nursing diagnoses are identified, an individualized plan of care to help the patient meet his or her care needs is designed. It is important to include the patient in the development of the plan of care. The patient must be in agreement with the plan for it to be successful in meeting the desired outcomes. The first step in planning care after diagnoses are selected is to prioritize the diagnoses and develop outcomes, or goals, for each. Actions that will help the patient meet the desired outcomes can then be determined.

Prioritizing Care

Once you know what problems need to be addressed, you must decide which problem or intervention needs to be taken care of first. You and the patient decide together which problems take priority. Maslow’s hierarchy of human needs is one commonly used psychological theory that can be used as a basis for determining priorities (Fig. 1.3). According to

Maslow, humans must meet their most basic needs (those at the bottom of the triangle) first. They can then move up the hierarchy to meet higher level needs.

Physiological needs are the most basic. For example, a person who is short of breath cannot attend to higher level needs because the physiological need for oxygen is not being met. Once physiological needs are met, the patient can concentrate on meeting safety and security needs. Love, belonging, and self-esteem needs are next; self-actualization needs are the last to be met.

Throughout life, individuals move up and down Maslow’s hierarchy in response to life events. If a need occurs on a level below the patient’s current level, the patient will move down to the level of that need. Once the need is fulfilled, the person can move upward on the hierarchy again.

In a nursing plan of care the patient’s most urgent problem is listed first. According to Maslow’s hierarchy of human needs, this usually involves a physiological need such as oxygen or water because these are life-sustaining needs. If several physiological needs are present, life-threatening needs are ranked first, health-threatening needs are second, and health-promoting needs, although important, are last.

Once physiological needs are met, needs related to the next level of the hierarchy, safety and security, can be addressed. Remaining diagnoses are listed in order of urgency as they relate to the hierarchy. Needs can occur simultaneously on different levels and must be addressed in a holistic manner, with prioritization guiding the care provided.

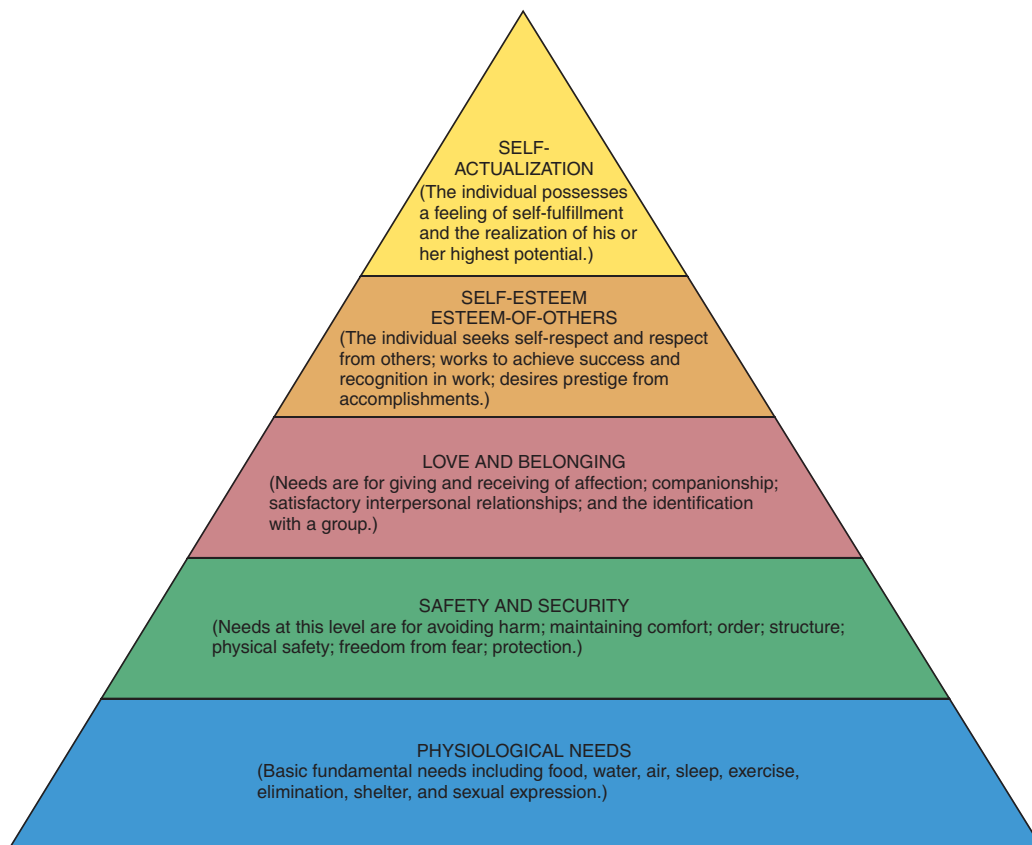

FIGURE 1.3 Maslow’s hierarchy of human needs.

LEARNING TIP

If you are developing a plan of care for a patient with complex needs and are not sure where to start, go back to the assessment phase. Often additional information can help you better understand the patient's needs and develop a plan of care that is individualized to the patient's specific problem areas.

Establishing Outcomes

An outcome is a statement that describes the patient's desired goal for a problem area. It should be measurable, be realistic for the patient, and have an appropriate time frame for achievement. *Measurable* means that the outcome can be observed, or is objective. It should not be vague or open to interpretation, with the use of subjective words such as *normal*, *large*, *small*, or *moderate*. Consider, for example, two outcomes:

- The patient's shortness of breath will improve.
- The patient will be less short of breath within 15 minutes as evidenced by the patient rating the shortness of breath at less than 3 on a scale of 0 to 10, respiratory rate between 16 and 20, and relaxed appearance.

Although the first outcome seems appropriate, in reality it is difficult to know when it has been met. There is nothing to objectively indicate when the problem has been resolved. The second outcome is objective. You can see that when the patient rates his or her shortness of breath less than 3, is breathing at a rate of 16 to 20, and appears relaxed, the desired outcome will have been met. The outcome is realistic, and the 15-minute time frame ensures that the patient's distress is minimized. If the plan of care does not achieve the desired outcome in the given time frame, it should be evaluated and revised as needed.

When determining criteria for a measurable outcome, look at the signs and symptoms portion of the nursing diagnosis. The resolution or continuation of the signs and

symptoms identified in the NANDA nursing diagnoses are evidence that nursing interventions were effective. If the desired outcome is not achieved, reevaluation of the problem and interventions is needed. Look at another outcome example to see how criteria are used for measurement:

Nursing diagnosis—Ineffective airway clearance related to excess secretions as evidenced by coarse crackles and nonproductive cough.

Outcome—Demonstrates clear lung sounds and productive cough within 8 hours.

Identifying Interventions

Interventions are the actions you take to help the patient meet the desired outcome. Therefore, interventions are considered goal directed. Any intervention that does not contribute to meeting the outcome should not be part of the plan of care.

One way to create a plan is to include interventions that can be categorized as “take, treat, and teach.” In the first intervention category, “take,” or identify data that should be routinely collected related to the problem. Next, “treat” the problem by identifying deliberate actions to help reach the outcome. Last, identify what to “teach” the patient and family for the patient to learn to care for himself or herself.

Look again at the nursing diagnosis of impaired airway clearance. A plan of care for this problem using the take, treat, and teach method might look like the following:

- Take:** Auscultate lung sounds every 4 hours and prn.
Assess respiratory rate every 4 hours and prn.
- Treat:** Provide 2 L of fluids every 24 hours.
Offer expectorant as ordered.
Provide cool mist vaporizer in room.
- Teach:** Teach the patient the importance of fluid intake.
Teach the patient to cough and deep breathe every 1 to 2 hours.

In addition to identifying interventions, it is important to understand how and why they will work. This is called identifying rationales. For example, assess lung sounds and respiratory rate every 4 hours because increased crackles and respiratory rate indicate retained secretions. Fluids are provided to help liquefy secretions and ease their removal. Sound rationale that is evidence (research) based should guide the selection of each nursing intervention.

Implementation

Once the plan of care has been identified, it must be communicated to the patient, family, and health team members and then implemented. One way a plan of care is communicated is by writing it as a nursing care plan. The nursing care plan is documented on the patient's medical record and allows other nurses to know the patient's priority problems, the desired outcomes, and the plan for meeting the outcomes. In this way, all nurses can provide consistent care for the patient.

When implementing the plan of care, the actions listed as interventions are performed. The patient's response to

CRITICAL THINKING

Prioritizing Care

■ Based on Maslow's hierarchy of needs, list the following nursing diagnoses in order from highest (1) to lowest (5) priority. Give rationales for your decisions.

- _____ Deficient knowledge
- _____ Constipation
- _____ Disabled family coping
- _____ Anxiety
- _____ Ineffective airway clearance

Suggested answers at end of chapter.

each intervention is noted and documented. This documentation provides the basis for **evaluation** and revision of the plan of care.

Evaluation

The last step of the process is evaluation. Evaluation examines both outcomes and interventions. The nurse continu-

ously evaluates the patient's progress toward the desired outcomes and the effectiveness of each intervention. If the outcomes are not reached within the given time frame, or if the interventions are ineffective, the plan of care is revised. Any part of the plan of care can be revised, from the diagnosis or desired outcome to the interventions. Acute care institutions require review and updating of the plan of care every 24 hours.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Nursing Diagnosis*

1. Impaired mobility = nursing
2. Ineffective coping 5 nursing
3. Herniated disk = medical
4. Fractured femur = medical
5. Diabetes = medical
6. Impaired gas exchange = nursing
7. Appendicitis = medical
8. Health-seeking behaviors = nursing

■ *Prioritizing Care*

- 1 Ineffective airway clearance—physiological need that can be life threatening
- 2 Constipation—physiological need that can be health-threatening
- 3 Anxiety—safety and security need
- 4 Deficient knowledge—safety and security need
- 5 Disabled family coping—love and belonging need

REVIEW QUESTIONS

1. In which of the following ways is critical thinking useful to the nursing process?
 - a. It highlights the obvious solution to a problem.
 - b. It can lead to a better outcome for the patient.
 - c. It simplifies the process.
 - d. It helps the nurse arrive at a solution more quickly.
2. Which nurse is exhibiting intellectual humility?
 - a. The nurse who is an expert at wound care.
 - b. The nurse who reports an error to the supervisor.
 - c. The nurse who tries to empathize with the patient.
 - d. The nurse who asks a co-worker about a new procedure.
3. Which of the following pieces of information is considered objective data?
 - a. The patient's respiratory rate is 28.
 - b. The patient states, "I feel short of breath."
 - c. The patient is short of breath.
 - d. The patient is feeling panicky.
4. An LPN/LVN is collecting data on a newly admitted patient who has an ulcerated area on his left hip. It is 2 inches in diameter and 1 inch deep, with yellow exudate. Which of the following statements best documents the findings in the patient's database?
 - a. Wound on left hip, 2 inches diameter, 1 inch deep, infected
 - b. Left hip wound is large, deep, and has yellow drainage
 - c. Pressure ulcer on left hip, yellow drainage
 - d. Wound on left hip 2 inches in diameter, 1 inch deep, yellow exudate
5. A 34-year-old mother of three children is admitted to a respiratory unit with pneumonia. Based on Maslow's hierarchy of needs, which of the following patient problems should the nurse address first?
 - a. Frontal headache from stress of hospital admission
 - b. Anxiety related to concern about leaving children
 - c. Shortness of breath from newly diagnosed pneumonia
 - d. Deficient knowledge about treatment plan
6. Place the steps of the nursing process in correct chronological order of use. Use all options.
 - a. Nursing Diagnosis
 - b. Evaluation
 - c. Assessment
 - d. Planning Care
 - e. Implementation

7. Which of the following parts of the nursing process can be carried out by an LPN/LVN?
 - a. Implementation of interventions
 - b. Nursing diagnosis
 - c. Analysis of data
 - d. Evaluation of outcomes
8. Which of the following is a nursing diagnosis?
 - a. Stroke
 - b. Renal failure
 - c. Fracture
 - d. Acute pain
9. A nurse teaches a patient the importance of stopping smoking. Which of the following patient responses would best indicate to the nurse the effectiveness of the instruction?
 - a. "I have a brother who died of lung cancer. I know smoking is bad."
 - b. "I tried to quit 5 years ago, and I really would like to, but it is very hard."
 - c. "Thank you for the information. I will call the Smoke Stoppers organization today."
 - d. "I know you are right; I should stop smoking."

QUESTIONS TO GUIDE YOUR READING

1. What are factors influencing changes in the health-care delivery system?
2. What is the LPN/LVN's role in the health-care delivery system?
3. What are three leadership styles?
4. What is the LPN/LVN's role in leadership?
5. Why are ethics important in health care?
6. What is an example of a character trait and how does it relate to nursing?
7. What are the definitions of the four major principles in ethics and how would you apply one to an ethical dilemma?
8. What are the steps of the ethical decision-making model?
9. Where is the regulation of nursing practice defined?
10. How can you provide quality care and limit your liability?
11. How would you define HIPAA (Health Insurance Portability and Accountability Act of 1996)?

HEALTH-CARE DELIVERY

The **health-care** delivery system continues to experience rapid and dramatic changes from acute care to outpatient and community settings. As nursing adapts to these changes, it is important to understand wellness and **illness** treatments, factors that influence health care, and application of principles of cultural diversity during care.

Health-Illness Continuum

The World Health Organization in the preamble of its constitution defines health as a “state of complete physical, mental and social well-being and not merely the absence of disease and infirmity.” This definition provides a narrow view of health that does not provide for chronic illness effects or fluctuating levels of wellness. The health-illness continuum, in contrast, addresses various levels of health that are continually shifting for an individual. One end of the continuum represents high-level health and the other end poor health with impending death. Individuals move along the continuum throughout their lives.

Health-Care Delivery Systems

A focus on prevention and providing services from birth to death under one integrated system is an approach being used in some health-care systems. Hospital consolidations have resulted in development of health-care systems that may cover large geographic areas. The hospital then provides the integrated care delivery network for the system (Fig. 2.1).

Factors Influencing Health-Care Change

Changing characteristics of the American population influence the health-care delivery system. These changing characteristics include increasing size of the national population,

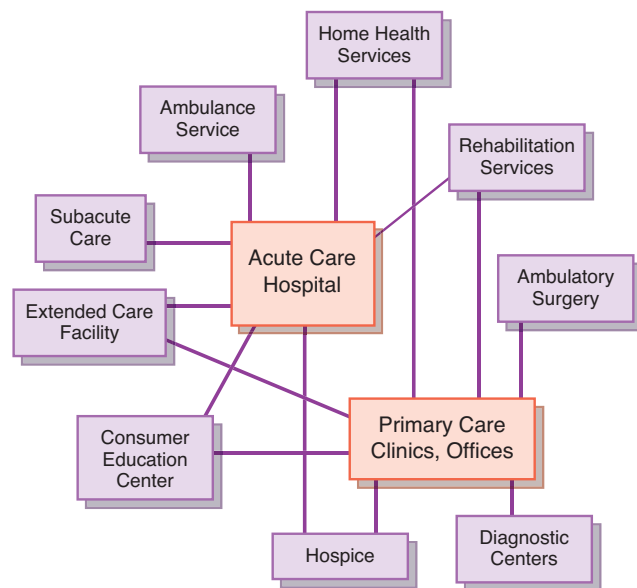

FIGURE 2.1 An integrated health-care system.

the increasing number of elderly people, the birth rate decline, the increase in the number of uninsured or underinsured, and increased cultural diversity. The size of the American population is projected to increase to over 350 million people by the year 2020.¹ The health-care needs of the elderly can be complex and chronic, which places increased demands on the health-care system. The declining birth rate means there will be fewer school-age children and fewer people in the future to care for the elderly. The increase in the uninsured places additional strains on the system, and the increase in cultural diversity impacts how health care is delivered.

The change in how diseases are being treated today greatly influences health-care delivery. Chronic diseases are the most frequently treated conditions. Increasing numbers of infectious diseases, such as AIDS, tuberculosis, and resistant infectious organisms are also challenging the health-care system.

Additionally, the development of new technology for communicating information and designing medical equipment for testing and treatment is changing the health-care industry. New expensive technology is continually being introduced that quickly outdates equipment in use. This makes change and relearning a constant in today's health-care environment.

ECONOMIC ISSUES

The health-care system is mainly funded by the government and private insurers. Costs have risen dramatically in recent years. Access to care is not available to everyone and is often linked to availability of resources. Preventive care is not an option for many people. Treatment is often sought in the costly emergency room after a medical problem has become complex.

Medicare and Diagnosis-Related Groups (DRGs)

Medicare was created in 1966 to provide health insurance as part of the Social Security Act. It is run by the United States government and currently covers all individuals age 65 and over and disabled people under 65 years of age who are eligible for Social Security. It is funded by a deduction from every person's paycheck that is matched by the government. There are two parts of coverage in the original Medicare plan. Part A covers inpatient hospital care, skilled nursing facilities, hospice services, and some home care. There is no premium or deductible for Part A. Part B is medical insurance that covers physician costs, outpatient services, some home care, supplies, and other things not covered by Part A. Some preventive services may also be covered. A monthly premium and yearly deductible are paid for Part B coverage. For more information, visit www.medicare.gov.

New prescription drug coverage for everyone with Medicare coverage became available January 1, 2006. For more information on this coverage visit www.medicare.gov.

Congress created the DRG payment system in 1983 for 470 diagnostic categories to help control costs in the Medicare program, which previously had no reimbursement limits. All hospitals are paid the same fee for patients in the same diagnostic category regardless of length of stay and supply costs. Hospitals lose money if the patient's costs exceed the DRG payment but make money if the costs are less than the payment. The incentive to deliver more cost-effective care within the DRG payment system lies with the hospital. Effective discharge planning and nursing involvement in maintaining quality but cost-effective care are essential in this payment system.

Medicaid

The Medicaid payment system was also created in 1966 to provide health insurance as part of the Social Security Act for low-income or disabled persons under 65 years of age and their dependent children. Some low-income people over 65 years of age may also qualify. Medicaid funding comes from federal, state, and local taxes. Medicaid benefits vary from state to state.

Managed Health Care

There are a variety of organizations that consist of groups of health-care providers who provide all or most of the health care required for a group of people in an effort to contain costs. Health maintenance organizations (HMOs) were first begun in the 1930s, but did not flourish until the 1970s. Their emphasis is on wellness, health promotion, and illness prevention. Preferred provider organizations (PPOs) are much newer. A PPO is a network of providers who provide care to plan members at set discounted rates. The early movement to contain health-care costs led to the formation of HMOs and then PPOs. HMOs deliver multiple forms of health-care services to individuals who enroll in this prepaid group practice health program. The purpose of the HMO is to reduce overlapping services and provide quality and cost-effective care. Healthy patients require fewer services so preventive care is promoted. PPOs are a method of reducing costs to businesses that insure employees. Hospitals and physicians develop a contract with employers to provide services at a negotiated fee.

LEARNING TIP

To understand what the term *managed care* means, reverse the words: Care management.

As managed care is implemented, trends are emerging. The need for hospital beds is decreasing. Shorter lengths of stay for more acutely ill patients are being seen. Discharged patients are requiring more home care for more complex needs. Home care is rapidly expanding to meet this need. Case management is a strategy for providing patient care to ensure that the best patient outcome is achieved while controlling costs. The health-care industry is being challenged

to provide cost-effective care while maintaining quality health care that meets the needs of the patient.

NURSING AND THE HEALTH-CARE TEAM

Nursing is an integral part of the health-care network. Nurses work as Licensed Practical Nurses (LPNs) or Licensed Vocational Nurses (LVNs); Registered Nurses (RNs); or Registered Nurses with advanced practice skills that include Nurse Practitioners (NPs), Clinical Nurse Specialists (CNSs), Certified Nurse Midwives (CNMs), and Certified Registered Nurse Anesthetists (CRNAs). The LPN/LVN provides direct patient care under the direct supervision of a registered nurse or physician. Certified nursing assistants are trained to assist nurses in providing health care to patients.

Nurses work in collaboration with other members of the health-care team to meet patient health-care needs. Educational requirements, titles, and duties are described for some health-care team members. Licensed *physicians* provide medical care to patients after graduating from a college of medicine or osteopathic medicine. *Physician assistants* after graduating from a physician's assistant program work under the supervision of a physician and perform certain physician duties such as history taking, injections, and suturing of wounds. Licensed *pharmacists* complete 5 or 6 years of college and dispense medications from prescriptions, consult with physicians, and provide medication information to patients. *Social workers* usually have a master's degree in social work and treat psychosocial problems of patients and their families. *Dietitians* provide nutrition information, analyze nutritional needs, and calculate special dietary needs. Licensed *physical therapists* complete a college physical therapy program and assist patients in reducing physical disability, bodily malfunction, movement dysfunction, and pain through evaluation, education, and treatment. *Physical therapy assistants*, whose educational requirements vary, may complete 2 years of education and be licensed and then work under the supervision of a physical therapist. *Respiratory therapists* have a 2-year college degree, may be registered (RRT), and work with patients who have respiratory problems. *Respiratory therapy technicians* have 1 year of education, may be certified (CRTT), and work under the supervision of a respiratory therapist to provide respiratory care. *Occupational therapists* complete a bachelor's or master's program, may be registered (OTR), and assist patients in restoring self-care, work, and leisure skills from developmental deficits or injury. *Health unit secretaries* manage the clerical work. *Student nurses* are enrolled in a nursing program and work under the supervision of nursing faculty in the clinical setting.

LEADERSHIP IN NURSING PRACTICE

Leadership skills are necessary for the LPN/LVN to effectively guide patient care and achieve goals. Leadership

involves decision making, communicating, motivating, and guiding others. The leadership process seeks to change behaviors in others in order to accomplish goals.

Anyone who influences others to achieve goals is a leader. Effective leaders must be knowledgeable in the management process and able to make decisions. They should be role models and an inspiration to others. Positive thinking and the use of humor are valuable assets of good leaders. Ultimately leaders must earn the respect of their co-workers to be successful. In order to prepare for a leadership role, you should understand and apply the following principles of leadership.

Leadership Styles

There are three leadership styles: **autocratic**, **democratic**, and **laissez-faire**.

Autocratic Leadership Style

An autocratic leader has a high degree of control. Almost no control is given to others. In autocratic leadership, the leader determines the goals and plans for achieving the goals. Others are instructed what to do but are not asked to provide input. The group usually achieves high-quality outcomes under this style of leadership. This is an efficient leadership style for situations when decisions must be made quickly as in an emergency such as evacuation of a building or a code for cardiac arrest.

Democratic Leadership Style

A democratic leader has a moderate degree of control. Others are given some control and freedom. In democratic leadership, participation is encouraged in determining goals and plans for achieving the goals (Fig. 2.2). Decisions are made within the group. The leader assists the group by steering and teaching rather than dominating. The leader shares responsibility with the group. The group usually achieves high-quality outcomes and is more creative under this style of leadership. This is an efficient leadership style for most situations. Group members are more satisfied and motivated to achieve goals because they are active participants.

FIGURE 2.2 Group participation in decision making.

Laissez-Faire Leadership Style

A laissez-faire leader exerts no control over the group. Others are given complete freedom under this leadership style. With laissez-faire leadership, no one is responsible for determining goals and plans for achieving the goals. This produces a feeling of chaos. If decisions are made, the group makes them. Very little is accomplished under this leadership and the quality of outcomes is poor.

Management Functions

There are five major components in the management process. They include planning, organizing, directing, coordinating, and controlling.

Planning

The first step of the management process is planning. A plan must be developed to ensure that desired patient care outcomes are achieved. To formulate the plan, desired outcomes or problems are identified and data are collected about them. Alternatives or solutions are considered using the collected data and input from others. A decision is then made about the best option or course of action. The leader should ensure that the choice is realistic and can be implemented. Involving others in the planning and decision-making process from beginning to end can assist in greater acceptance at the time of implementation.

Organizing

The purpose of organizing, the second step in the management process, is to provide an orderly environment that promotes cooperation and goal achievement. Providing a framework for goals and the activities that accomplish them is the initial step in organization. Policies and procedures provide this framework as well as guidance for those carrying out tasks designed to accomplish the organization's goals.

Directing

Making assignments is the primary function of directing. Nurses make assignments for patient care. One person, usually the nurse in charge or the team leader, makes the assignments. State Nursing Practice Acts define who can make assignments and delegate care. Communication is important in directing. Assignments must be clearly and specifically stated. The individual making assignments must be sure that they are correctly understood and should seek out the receiving person for clarification. Effective directing can be accomplished by providing verbal and written assignment information, making requests rather than giving orders, and giving instructions as needed.

Coordinating

Coordination is the process of looking at a situation to ensure that it is being handled in the most effective way for the organization or coordinating services for a patient. The nurse may assess a particular activity or issues related to patient care assignments. In a long-term care facility, for example, the nurse may want to review skin assessment and care throughout the facility to see if it is being done consis-

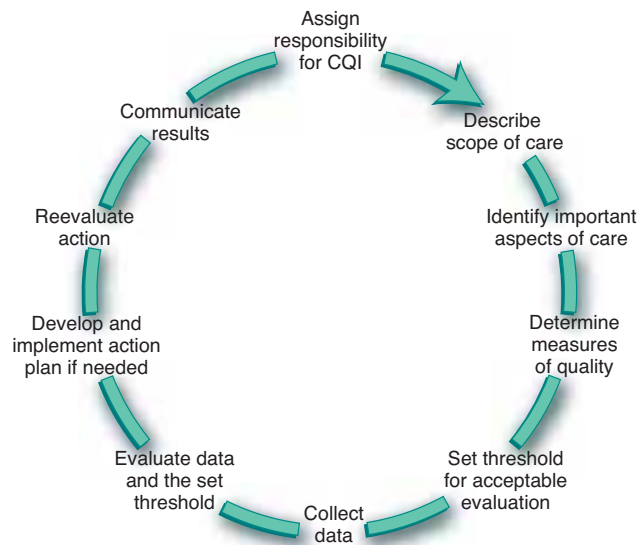

FIGURE 2.3 A continuous quality management model.

tently and uniformly. If a concern is found, problem-solving techniques are used.

Controlling

The final phase of the management process is controlling to evaluate the accomplishment of the organization's goals. Continuous quality improvement is linked with controlling. If the organization's efficiency or ability to reach its goals is impaired, the use of the continuous quality improvement model can facilitate correction of the concern (Fig. 2.3).

Leadership and Delegation for the LPN/LVN

LPN/LVNs are leaders and managers for the care of the patients to whom they are assigned under the supervision of a registered nurse, physician, or dentist. Beyond this application of a leader and manager role for the LPN/LVN, state nurse practice acts specify if the LPN/LVN can assume other leader or manager roles. Within this dependent role, some application of **delegation** may be allowed.

LEARNING TIP

Review your state nurse practice act. Does your state allow LPN/LVNs to delegate? If so, to whom and what can be delegated?

Delegation is the act of empowering another person to act. Delegation occurs in a downward manner, meaning RNs delegate to LPN/LVNs and unlicensed assistive personnel (UAP) and LPN/LVNs, in certain circumstances, delegate to LPN/LVNs and UAPs (see below). When delegation occurs, responsibility for the care is transferred to the delegate but accountability for the care remains with the delegator.

The LPN/LVN might function as a team leader or charge nurse primarily in the long-term care setting, requir-

ing some use of delegation to UAPs. When the LPN/LVN acts as a team leader or charge nurse, a registered nurse delegates the authority to provide supervision and delegation of tasks. Team leaders are responsible for the coordination and delivery of patient care to each of the patients assigned to the team. They assess the patients assigned to the team to plan appropriate care and contribute to the nursing care plan. Team leaders receive information from team members and communicate patients' needs to appropriate individuals. Since team leaders guide patient care provided by the team, they must be knowledgeable about safety policies, patients' rights, and the accountability of being a team leader. All patients are entitled to quality care and treatment with dignity and respect. The team leader is accountable for all care provided by the team. Supervision involves initial direction for the task and then monitoring of the task and outcome at intervals. At the end of the team's work shift, team leaders are responsible for transferring patient care to the oncoming team. This transfer of care is accomplished by reporting the patient's condition, status, and needs to the oncoming team leader (Fig. 2.4). Institutional policy specifies whether the RN or LPN/LVN communicates the report.

Within the leadership role, the LPN/LVN must decide when delegation would most benefit the situation and the patient. The nurse must follow the state practice act and the scope of practice when making any decisions regarding delegation. Consult the charge nurse, team leader, and nurse practice act for your state when deciding if delegation is appropriate. Ultimately, the nurse must ask several important questions to determine when delegation would best benefit the situation. These questions include:

- Does the state practice act allow for delegation in this situation?
- Is the person whom I am delegating to have the knowledge and education to perform this skill and is it documented for me to have access to make the decisions regarding delegation?

FIGURE 2.4 Communication of the patient's status when transferring the patient's care to another team leader.

- Would it benefit the patient if I delegated this skill to the support person?

Delegation Process

Delegation is a complex process. When delegation is considered, the following steps should be considered that encompass the decision to delegate, what to delegate, and to whom delegation can be made:

1. Know your state practice act rules for delegation. The LPN/LVN scope of practice usually does not provide for the legal authority for the LPN/LVN to delegate. However, some state board rules allow LPN/LVNs to delegate tasks that are within the LPN/LVN's scope of practice as long as the RN has given the LPN/LVN the authority to delegate the tasks.
2. Identify the skills of the person to whom you may delegate to determine if he or she has the knowledge and ability to carry out the task. When selecting a delegatee for a particular task, consider if there is potential for harm to the patient during the task, whether it is a complex task that will require problem solving, how predictable the outcome is, and how much interaction with the patient is needed. Match the skills and talents of the delegatee to the task being delegated. Remember, nursing judgment can never be delegated.
3. Use The National Council of State Boards of Nursing's five rights of delegation for the decision-making process for delegation.² Following these guidelines will give you a framework for your decision-making process and comfort in knowing you utilized them to make good choices.
 - Right task—is it appropriate to delegate?
 - Right circumstances—is this situation safe and appropriate for delegating?
 - Right person—is this delegatee the appropriate person for the task and this patient's needs?
 - Right communication—is there clear understanding between you and the delegatee for terms used, communication, and reporting needs?
 - Right supervision—is it defined how and when direct supervision will occur?

Delegation requires trust. You should be comfortable with your delegatee and know that you understand each other's methods of communicating so that miscommunications do not occur.

When you first begin your career, the process of delegating may seem difficult. As with any skill, it takes practice to feel confident in carrying out the process.

CAREER OPPORTUNITIES FOR LPN/LVNS

Today, LPNs can choose to work in a variety of settings in acute care or long-term care or expand their roles through additional education. Many schools provide for an acceler-

ated educational tract for LPN/LVNs seeking to become registered nurses with either an associate degree or a bachelor's degree. Advanced educational opportunities include a masters degree in nursing or a doctor of philosophy degree. Check with colleges/universities to see which program would best meet your needs for continuing your education. Other career opportunities include massage therapist or roles previously mentioned in the chapter. Travel nursing is one of the fastest growing areas within the health-care delivery system. It is an exciting way to see the world while working. Since licensure in other states is required, you should check these requirements with travel nursing agencies if you are interested in travel nursing.

The LPN/LVN of today must be equipped with knowledge and skills to be able to sufficiently function within a health-care delivery system. An understanding of leadership, delegation, and career opportunities will provide a basis to begin your journey in practicing as a LPN/LVN. We wish you well on your journey!

ETHICS AND VALUES

Preamble

... just because we are able to do something does not mean that it is right to do it. Moreover, what is possible and even legal might not be ethical. Therefore, we must ask, especially regarding the new science: Is it right? Is it ethical?

MARGARET SOMERVILLE, *THE ETHICAL CANARY*, XIII³

The term “ethics” itself is a branch of philosophy that seeks to understand the nature, purposes, justification, and founding **principles** of moral rules and the systems they comprise.⁴ We know that every society has a fairly regulated set of moral rules or guidelines that secure the boundaries of what is considered acceptable behavior. Often these rules are about *behavior*. Such examples of behaviors are:

- Harming other people (e.g., homicide, rape, theft)
- Concerning oneself with the well-being of others (e.g., helping others, responding to people in distress)
- Actions that touch on issues of respect for other persons (e.g., segregation, using other people for one's own ends without concern for their welfare)

Often the rules about such behavior are expressed in statements about what you *ought* to do or *should* do. These rules fit together, fairly consistently, to form the moral code by which a society lives.

One of the most exciting and challenging areas of nursing practice today is bioethics. Bioethics is a branch of ethics that studies moral **values** in the biomedical sciences. In the current practice of nursing, the term *bioethics* has come to be most closely associated with ethics in health-care: life and life choices as affected by health, sickness, disease, or trauma. Ethics is the study of systems of traditions, values, and beliefs as they relate to persons and their rela-

tionships with one another. To use words such as “good” and “bad” does not give the whole picture. Maybe there has to be a decision made about a patient and possibly the choice that we have to make may be the least harmful. What *should* we do? and What *ought* we to do? are part of ethics and we are responsible for knowing *why* we might take the intended action or decision.

Morals or **morality** are also related to ethics. Some individuals use the terms *ethics* and *morals* interchangeably; however, *morals* more specifically refers to our personal values, the standards set by our own conscience, and our personal choices of what *we* consider *good* and *bad*, *right* and *wrong*.

Values are standards, ideals, or concepts that give meaning to an individual’s life. Values are most commonly derived from societal norms, religion, and family traditions. They serve as a guide for making decisions and taking certain actions in everyday life. Individuals can change their value systems when they experience life-changing events. Values are not usually written down, but it can be helpful to make a list of your values and attempt to rank them by priority. Value conflicts often occur in everyday life and can force an individual to select a higher priority value over a lower priority value. For example, a nurse who values both her career and her family may be forced to decide between going to work or staying home with a sick child.

Values exist on many different levels. Individuals have personal values that govern their lives and actions. Many groups and organizations have values that may or may not be identical to personal values. When a person becomes a member of a group or organization, he or she agrees to accept the values of the group. Examples of groups include clubs, churches and religious organizations, political parties, and professions. The values of a profession are usually outlined in a **code of ethics**. Failure to adhere to a code of ethics of a profession may be an indication that the individual really does not want to belong, or possibly *cannot* belong, to that group. Society as a whole has values. As a member of a society or country, an individual accepts the values of that culture. Finally, societal values may change with the adoption of new laws.

Ethical issues surround us throughout our entire lifetime. Bioethical issues are particularly prevalent in our professional lives for several reasons. Health care has the potential to affect us and our patients at every milestone of human development. Life and death issues and decisions can be especially difficult for health-care professionals, who may be faced with these issues every day. Today’s sophisticated technology and complex treatments, which are advancing exponentially, present other challenges. When sophisticated interventions are available, one obvious ethical question is, should we use them? Ethical issues are raised when the organization of health-care delivery systems becomes more complex as mergers and alliances come and go. Despite the large percentage of our country’s wealth dedicated to health care, financial resources are not unlimited. How those resources are allocated can be troublesome,

with the needs and desires of many different groups and organizations competing for a slice of the pie.

Although bioethical issues abound, not all issues are problems and not all ethical problems make headline news. Nurses are involved in ethical decision-making every day that may not become problems. A promise might be extended to return to the patient and assess whether or not the pain medication was effective. Patients might share information that they want to remain confidential. A family agrees to a “do not resuscitate” (DNR) order for their loved one when they believe there is no hope for recovery. A young man in the prime of life is given cardiopulmonary resuscitation (CPR) when he suddenly goes into respiratory failure on the day of his proposed discharge. These examples usually are not problems but, depending on the situation, can develop into ethical dilemmas.

An ethical dilemma is created when:

- The required moral action is not clear
- Individuals in the situation do not agree on the proposed solution
- Neither of the available choices seems to offer a “best” option

It should be borne in mind that although while clinical decision making has been seen traditionally as the responsibility of the doctor, the consequences of those decisions fall largely on the nurses who are caring for such patients.

Potential solutions may appear to be equally good or, worse, equally risky: A promise cannot be kept; information cannot remain confidential; DNR orders may not be acceptable for some individuals. Not every patient should be the recipient of CPR endeavors, even those who are very young. When patients are conscious, their choices are usually respected, but on occasion even that premise can be difficult to apply. Often groups of individuals must work together to resolve a conflict that occurs if there is disagreement between physicians and families, nurses and physicians, or among family members.

A basic mastery of several elements enhances your ability to perform competently when bioethical issues present themselves and decision making is the focus. Understanding the ethical component of your nursing role is a first step. Discovering how your personal *value set* influences your nursing practice. Acquiring knowledge about relevant ethical material is also essential. An ethical decision-making process is a useful tool for examining ethical dilemmas. Together these elements provide a foundation from which you can begin to explore the meaning of bioethics in nursing practice today. For more information about bioethics, visit the *America Journal of Bioethics Online* at <http://www.ajobonline.com> or try The Center for Bioethics and Human Dignity at <http://www.cbhd.org>

Ethical Obligations and Nursing

As a nurse, you are an invaluable member of the health-care team. Members of the team contribute to patient care according to their educational preparation and assigned responsibilities. A common goal among all health team

members is to provide holistic care to the patient because not only is the individual's mind, body, and spirit affected by disease or trauma, the disease process impacts upon the patient's family and community. A central component of that holistic care encompasses your responsibility to practice ethically.

In addition to practicing within the law, nurses have ethical obligations related to the law. First, if the law is considered unethical or has serious limitations, a basic moral obligation of the nurse, if not the health-care profession as a whole, is to make an effort to change that law. As a by-product, laws can sometimes unfairly affect health care in relation to accessing, services, subsidizing health care, or allocating health care dollars. Laws sometimes can be unethical because they are enacted based on power, authority, and political influences rather than high moral standards. Laws are created to reflect current common ethical beliefs (e.g., do not kill, do not steal) and values. However, in a democratic society with a diverse population such as in the United States, there are serious questions about the degree to which society should enforce moral behavior through the law and vice versa.

Nursing Code of Ethics

Some of the major ethical obligations of nursing practice are addressed within the nursing code of ethics. As a professional guide for ethical practice, the National Association for Practical Nurse Education and Service (NAPNES) developed a code of ethics for the licensed practical nurse/licensed vocational nurse (LPN/LVN). Like all codes of ethics, this code is an important document because it is a public statement of the basic ethical principles and standards for LPN/LVNs. An organization's code of ethics should be supported by the majority of its members. The code should provide guidance for appropriate decision-making based upon the laws and expectations of that time. A code of ethics also provides a base for professional self-evaluation and reflection regarding ethical practice.⁵ Finally, the code of ethics is the tool by which the public can hold the professional accountable.

A code does not dictate a particular action, nor is it a legal document, although the code should not be in conflict with the law. The code is not enforced by any organization, and no punishment exists if a nurse fails to adhere to it. A code must be interpreted because it usually contains broad statements, but it does serve as a general guideline for professional ethical issues. Over time, the opinion of society changes and, as such, the codes are revised and updated. Although the Hippocratic oath (400 BC), the earliest Western code of ethics for physicians, contains fundamental moral advice, the passage of time and the occurrence of notable events make it incomplete for medical practice today. Changes in society prompt us to examine the profession's ethical standards and update them appropriately. There are several websites that offer information and guidance. The most important website for nurses is the American Nurses Association website (<http://www.nursingworld.org/>). This

website has a section that is entitled "The Centre for Ethics and Human Rights" dedicated to current statements on ethical dilemmas that contains the code of ethics for nurses. This can be found at http://www.nursingworld.org/ethics/code/protected_nwcoe303.htm

Virtues

Particular ethical obligations can be summarized in the form of virtues. Each individual is endowed with specific character traits. As we grow, develop, and experience life, we acquire certain other character traits. Virtues are character traits most often associated with one's values and morality or conscience and are different from the skills that we acquire as nurses. Skills are used to implement various actions, something we do, whereas virtues define who we are. The Nightingale Pledge is implicit in its expectation of certain virtues possessed by graduating nurses. Such virtues include faith, loyalty, trustworthiness, and temperance.⁶ These are all ideal traits, and although we may strive to act as virtuous persons, we are human and may not always succeed. The code of ethics specifically invokes faithfulness and respect for patient choice and acts as a constant reminder to that high standard to which we should always strive to maintain.

In addition, it should be remembered that virtues are related to roles and responsibilities and are therefore time dependent. For example, in the early decades of organized nursing in the United States, nurses occupied a handmaiden role relative to the physician. Obedience to the physician was considered a virtue, but such obedience is no longer held as a virtue by nurses.

FIDELITY (ALSO A PRINCIPLE). Fidelity is the obligation to be faithful to commitments made to self and others. In health care, fidelity includes faithfulness or loyalty to agreements and responsibilities accepted as part of the practice of nursing. It also means *not* promising a patient something that one cannot deliver or what they do not control (for example, a patient asks not to be resuscitated if they have a cardiac arrest, but the physician has not been consulted). Fidelity is the main support for the concept of accountability, although conflicts in fidelity might arise because of obligations owed to different individuals or groups. For example, nurses have an obligation of fidelity to the patients they care for to provide the highest quality care possible, as well as an obligation of fidelity to their employing institution to follow its rules and policies. Nurses can have an ethical dilemma when a hospital's policy on staffing creates a situation that does not allow the nurses to provide the quality of care they feel is necessary.

Maintaining a patient's privacy and **confidentiality** is related to fidelity (Fig. 2.5). Privacy and confidentiality may or may not be explicit promises. Nurses are obligated to only discuss the patient under circumstances in which it is necessary to deliver high-quality *holistic* health care such as:

- When given specific instructions to do so by the patient

FIGURE 2.5 Maintaining privacy is a patient right and conveys caring to the patient.

- When there is the grave possibility of harm coming to either the patient or others
- When legally mandated to do so

Confidentiality also includes the necessary communication of information through the posting of unit census and various schedules for tests, procedures, or special examinations (operating room, physical therapy, radiology), storage and access of patient information through computers, and the transmission of patient information via fax machines. Many individuals have legitimate access to the patient's chart in addition to direct caregivers: faculty members in the course of making student assignments, accrediting agencies, risk managers, quality assurance personnel, insurance companies, and researchers. Each is obligated to maintain patient confidentiality to the extent that concealing information:

- Does not compromise mandated reports (communicable diseases or gunshot wounds)
- Considers various releases already granted by the patient (such as when insurance coverage was obtained)
- Ensures gathering data in the aggregate without identification of specific patients (research or institutional statistics)

Other forms of necessary communication include regular shift changes and case conferences. Care should be taken to hold these information-sharing events in settings where the discussion remains private.

VERACITY. *Veracity* is the virtue of truthfulness. Within health care, it requires health-care providers, whenever possible, to tell the truth and not intentionally deceive or mislead patients. As with other rights and obligations, there are limitations to this virtue. The primary limitation occurs

when telling patients the truth would seriously harm their ability to recover, or when the truth may produce greater illness (this can be considered under the principle of **nonmaleficence** or doing no harm, which finds its origins in the Hippocratic Oath). Another difficult situation may be created in relation to diagnostic information. Although giving diagnostic information is the responsibility of the physician or registered nurse (RN), LPN/LVNs sometimes find themselves caught in situations in which they must deal with patients' questions. If LPN/LVNs feel uncomfortable about reinforcing physician or RN explanations about unpleasant information, they may avoid answering patients' questions directly. However, patients do have a right to know this information.

INTEGRITY. Integrity is a holistic, unwavering moral sense of self. Each individual has a cluster of values, beliefs, and traditions that form the basis for moral decision making; in a sense, the conscience. This sense of self can be compromised when the nurse is requested to act in a manner that requires setting aside or acting against values, beliefs, or traditions. The nurse who believes in the sanctity of life and that human life begins at conception, may not be able to maintain integrity if required to participate in abortion procedures. However, this nurse also has the responsibility not to accept a professional position where abortion is an issue, as a nurse cannot abandon a patient in need of nursing services. The nurse with integrity is faithful to professional responsibilities and obligations.

COMPASSION. Compassion or caring is a central virtue in nursing. Some label this **empathy** and connect it to the ability of a nurse to identify with a patient's suffering, pain, or disability. The difference between the two virtues is that in compassion, the nurse wishes to alleviate discomfort.⁷ Patients are comforted by the compassionate nurse, and such nurturing can assist in the healing process. A nurse without any emotion robs patients of the full potential for healing that is only possible when all parties are actively engaged in all aspects of the relationship. Compassion should not be so dominant that it clouds judgment and prevents effective and efficient provision of nursing services. Compassion, in order to be effective, needs to be tempered with rationality.

DISCERNMENT. Discernment has been described as practical wisdom or common sense. This is the ability to understand, to have insight into the hidden, as well as the obvious elements of a situation. A nurse who has a discerning approach is one who is sensitive to the patient's actions and responses and does not necessarily accept what is seen at face value. Verbal, nonverbal, and subconscious communication, as well as concrete signs and symptoms, all contribute to the overall evaluation of the patient by the discerning nurse. This is sometimes translated as practical wisdom because this type of nurse has a depth of understanding of patients that leads to the selection of the appropriate action, which in turn is implemented in a caring manner. It can be argued that possessing a discerning nature is a product of experience and knowledge, for in nursing it

is not enough to act upon *gut* instinct but to base opinion and action upon accepted approaches.

TRUSTWORTHINESS. It is vital that as health-care workers we inspire confidence in the patients we care for. We need to be considered trustworthy in order to have a true partnership with our patients. Sometimes, certain nurses may be preferred by patients because they convey a sense of confidence with the care they provide, and when one thinks that in many situations, patients' lives are truly in the nurse's hands, this preference is well grounded. When a patient feels that a nurse is worthy of their trust, an ease develops within the relationship that decreases stress and anxiety that diagnoses and treatment plans often bring. As a result, the patient develops more effective coping mechanisms. Indeed, studies have shown that it is the erosion of trust that is cited as a major factor in the escalating lawsuits that have been initiated against health professionals.

RESPECTFULNESS. Respectfulness is an attitude of a nurse toward the patient that indicates valuing that patient and their feelings as a unique individual. All patients should be treated with dignity and their autonomy acknowledged. Nurses are obligated to make an effort to identify their own biases and prejudices and work to avoid stereotyping and "isms" in patient relationships (e.g., classism, sexism, racism, ageism, and ethnocentrism), as well as eliminate discrimination based on religion, sexual orientation, or disability. Attentiveness to bias and discrimination is not limited to private interactions, but nurses are also responsible for drawing attention to unacceptable statements or negative actions that reflect disrespect for race, religion, gender, class, age, culture, sexual orientation, or disability in any health-care situation.

Rights

Rights represent at least two ways to think about what we are owed or what we deserve. Harris (2001) puts forward the position that if all people are considered valuable and equal, then it follows that there are rights possessed by people by virtue of their humanity.⁴ These basic rights could be translated into goods and services (such as the right to clean water, the right to food). These are positive rights, and because something needs to be provided, there is a responsibility for someone to furnish these items. Second, other rights can be determined to protect us (e.g., right to privacy, right to self-determination). These are negative rights preventing some action that would intrude on our lives or prevent us from acting as we choose.

Laws guarantee some rights. Others are moral rights based on values and ethical principles but are not enforceable by law. "Basic human rights" is a common phrase that we hear when discussing the condition of various people around the world, especially when those rights are compromised. The United Nations has a document, "The Universal Declaration of Human Rights," that serves to represent what all people should be provided with or protected from.

In health care, there are increasingly heated discussions about rights of patients. It is true that in the past, patients

were seen simply as passive recipients of whatever treatments or actions professionals determined necessary for their conditions. Now, professionals recognize patient autonomy and patients' active participation in health care.⁸ The American Hospital Association (AHA) first devised a patients' bill of rights in 1973, which formally began recognition of what patients are entitled to but may not always receive. The revised bill includes statements on confidentiality, informed consent, and the right to refuse treatment. The 2005 version can be found at <http://www.aha.org/aha/ptcommunication/partnership/index.html>. It is an easy to understand brochure entitled "The Patient Care Partnership: Understanding Expectations, Rights and Responsibilities." The brochure is available in multiple languages. Many health-care organizations followed the patient bill of rights with other more specific bills of rights, such as those developed by nursing homes and veterans' hospitals.

In bioethics many issues can be framed within a rights context. An important rights issue is whether people have a "right" to health care. Such a right is discussed at every level of society, from local governments that determine services they will provide in city clinics and public schools to the federal government, which periodically grapples with the debate on national health insurance. Another prominent dispute is the "right to die" with dignity, which is arousing more interest as the largest cohort (the "baby boomers") edge toward the later decades of life. Combined threats of the loss of autonomy and the possibility of being subjected to endless, painful technological interventions while dying rightfully substantiates such concerns. By contrast, the "right to life" is another central concept in our society as groups organize politically to prevent abortions and overturn the *Roe v. Wade* decision of the Supreme Court.⁹ This right also extends to discussions of reproductive rights and the health care of pregnant women. These are but a few examples of rights issues and potential conflicts. Others can be identified as various areas in medical surgical nursing are explored.

Building Blocks of Ethics

The discipline of ethics, especially health-care ethics, provides us with useful tools and knowledge that can assist us when we encounter difficult situations. The professional's understanding of basic concepts, presented here in the form of ethical principles and ethical theories, helps specifically target the ethical components of the problem. Principles and theories offer frameworks for ethical problem solving. However, knowledge about "ethics" cannot in itself provide all the answers to a problem or dilemma. What such knowledge *does* do is assist us in focusing upon the ethical aspects of each case. When we apply appropriate ethical rationale in our problem solving, we become grounded within this analytical framework. Such frameworks have the ability to make us look at many facets of an ethical problem, and presenting a particular position relative to a situation or describing values, beliefs, and traditions using these common ethical terms helps clarify discussions and possibly prevents escalating arguments. When one becomes familiar with

health-care ethics, problems with communication, management of the unit, and legislation or the law can more easily be separated from the ethical dimension and resolved in their own problem-solving session.

Ethical Principles

Ethical principles derive from moral theory and have two purposes. The first is to provide some framework for society's moral conduct. Second, they enable us in taking consistent positions and approaches to moral dilemmas. Ethical principles can be found in many professional codes of conduct. The ethical principles that are widely used when examining bioethical and health-care dilemmas include autonomy, beneficence, nonmaleficence, and justice. Given these ethical principles' prominence in the bioethical literature, a basic understanding of them is necessary.

AUTONOMY. According to ethicists (and, e.g., behaviorists, social scientists, psychologists), what makes human beings different from nonhumans is that people have dignity based on their ability to choose freely what they will do with their lives. **Autonomy** is the right of self-determination, independence, and freedom founded on the notion that humans have value, worth, and moral dignity. Autonomy in health care refers to those individuals who are considered capable and competent making health-care decisions for themselves. Health-care providers do not have to agree with such decisions, but we must respect the autonomy of the person making that choice. Preventing patients from making autonomous decisions or deciding for patients without regard for their preferences is **paternalism**. Autonomy also encompasses the professional's self-determination and freedom.

Autonomy, as with most rights, is not an absolute right, and under certain conditions, limitations can be imposed on autonomy. Generally, these limitations occur when an individual's autonomy interferes with the rights, health, or well-being of others. For example, patients generally have an autonomous right to refuse any or all treatments. This autonomous right is guaranteed by federal legislation known as the Patient's Self-Determination Act. However, in the case of contagious diseases that affect society, such as tuberculosis (TB), an individual can be forced by the health-care and legal systems to take medications to cure the disease. Individuals can also be quarantined to prevent the spread of disease.¹⁰

BENEFICENCE. This principle proposes that one must take a positive action that does good for another and act in a way that will prevent harm to others. Within health care, **beneficence** is the principle of considering and offering treatments that are likely to provide relief.¹¹ At this point, it should be mentioned that the provision of *good* care means not just the provision of a technologically competent care of patients, but care that includes a respect for the patient's

beliefs, feeling, and wishes, as well those of their family and significant others. A common problem encountered when applying the principle of beneficence, is just *what* is good for another and who is the best person to make this decision.

NONMALEFICENCE. **Nonmaleficence**, one of the oldest obligations in health care, dating back to the Hippocratic Oath (400 BC), is related to beneficence and in a sense it is the opposite side of the coin as it is difficult to speak of one concept without mentioning the other. According to Burkhardt and Nathaniel,¹² nonmaleficence

... requires us to act in such a manner as to avoid causing harm to patients. Included in this principle are deliberate harm, risk of harm, and harm that occurs during the performance of beneficial acts.

It is the requirement that health-care providers do no harm to their patients either *intentionally* or *unintentionally* (which can be quite difficult!). In current health-care practice, the principle of nonmaleficence may be intentionally violated in order to produce a greater good in the long-term treatment of the patient. For example, a patient may undergo a painful and debilitating or mutilating surgery to remove a cancerous growth, thereby avoiding death and prolonging life.

By extension, the principle of nonmaleficence also requires a nurse to protect from harm those who cannot protect themselves. This protection from harm includes groups such as children, the mentally incompetent, the unconscious, and those who are too weak or debilitated to protect themselves.

JUSTICE. Justice is based upon the principle of fairness and equality. Concerns for justice may focus upon how we treat individuals and groups in society (psychologically, socially, legally, politically). How we distribute material resources such as health care (**distributive justice**) and burdens (taxes) equitably, and the appropriate compensation to those who have been harmed. When the patient makes an appointment for 9 a.m. at the outpatient clinic and his or her neighbor makes a 10 a.m. appointment, each expects to be seen by the primary care provider at the designated time unless some emergency prevails. Unequal treatment would result if a walk-in who has no pressing problem is seen by the provider in place of the 9 a.m. appointment, forcing each subsequent appointment to be delayed beyond the prearranged time. Distribution of material resources can be complex because it involves not only benefits (what we receive) but also burdens (what we may be taxed for but then do not receive). Burdens are not just monetary, but also include such factors as the unequal participation of individuals in medical research and the sacrifices family members make when caring for disabled individuals in the home.

One of the most serious limitations of these principles is the lack of any built-in priority when applying them to an

autonomy: auto—self + nimos—rule

beneficence: bene—good + facere—to do

nonmaleficence: non—not + maleficentia—evil doing

ethical dilemma. Autonomy is not automatically prioritized over justice or beneficence over nonmaleficence. However, these principles are helpful in categorizing various preferences and positions when examining a dilemma, and their categorization can lead to a clarification of various disagreements among participants in the ethical discussion. Working with principles moves the discussion to a focus on ethics rather than a particular personal viewpoint or feeling. Such a strategy can also avoid a power struggle between participants who simply want to win the argument. An example of an ethical dilemma is the following scenario. A nurse attempts to support a patient's refusal of surgery, while the physician claims that the patient must have surgery or she will lose her leg. Realizing that the nurse is arguing the case from the perspective of the patient's autonomy (self-determination), whereas the physician's desire to perform surgery is attributable to beneficence (obligation to come to the assistance of those in need¹³), moves the discussion to one based on conflicting principles rather than conflict between individuals. From this point of clarification, the discussion can focus on autonomy and beneficence and the rationale for the possible prioritizing of one principle over the other. This strategy does not resolve the dilemma, but it makes it less personal and forces participants to develop sound, ethical rationales for their solutions.

Ethical Theories

Ethical theories are concepts that are more complete than principles for analyzing ethical dilemmas. Such theories are used to explain variables, guide inquiry, and provide a foundation from which considered and thought-provoking questions emanate. However, only a brief description is included here; a more in-depth understanding can be obtained from other resources, such as the Web links, journals, and many books on the topic.

Two of the major theories used in bioethics are defined first, and then a subcategory of theories collectively known as feminist theories are introduced; finally, recognition of the relationship of theology or religion to bioethics completes this section.

UTILITARIANISM. Utilitarian theory is grounded in the premise that actions are judged right or wrong based purely upon their consequences and therefore outcomes are the most important elements to consider in decision making.¹⁴ Right actions are morally preferred if they produce more happiness or greater benefits than unhappiness or burdens, and in utilitarianism, each person's happiness is equally important. This approach may be used by institutions and organizations under the guise of cost-benefit ratios. A hospital that has the responsibility to care for hundreds of patients is not as concerned with the individual patient who unfortunately is caught in the bureaucracy of its functioning. This is not to say that all institutions operate on this theory at all times, but in general, rules, policies, and procedures are developed with the majority in mind. There are several major criticisms of this theory. One is that an individual is often sacrificed for the good of the majority (often seen in

wartime). The second is that it can be difficult to predict outcomes, especially when human nature is involved.

DEONTOLOGY. Deontology is a philosophical theory requiring human actions and attitudes to be based on *duty* and the moral worth of an action (the result) should not be judged only in terms of its consequences. For example, health professionals might operate by a rule that indicates that a moral person never lies. No matter how much the truth might hurt, the truth is revealed. Another rule might be to never use people as a means to an end. Translated this means that regardless of the benefits, individuals cannot be forced to participate in medical research studies to benefit others. An individual's right to voluntarily participate in research must be respected. Research does not have to benefit the individual participant as long as this is understood by the individual. However, the individual cannot be used simply to meet the investigator's needs. Acting morally only because one has a duty to do so, without any consideration of the outcome, is a serious limitation of this theory.

FEMINIST THEORIES. Feminist approaches challenge traditional theories in that they focus upon gender bias, discrimination, and prejudice in addition to the more serious actions of oppression and violence against women. The rise of such theories can find their origins in Carol Gilligan's original hypothesis that the moral orientation of a person is associated with their gender. In other words, the judgments of women are predominantly oriented toward the value of care and the judgments of men predominantly toward the value of justice.¹⁵

This view is important because of existing power differentials among the providers and recipients of health care, as well as the previous treatment of normal development, injury, illness, disease, and dying in women. Current, or *third wave* feminist theories are really a group of various approaches to ethical problems and decision-making rather than one uniform approach.¹⁶ Feminists may use utilitarian and deontological theories, as well as various other approaches, to develop a systematic organization of ethical rules and principles. Some feminist theories focus on feminine attributes (emotional attachment, caring, prominence of relationships, and connection with people), emphasizing their importance in ethical decision-making. In general, those who support this approach observe the devaluing of these attributes in society. Caring, as an example of one attribute, is important personally, but supporters recognize that caring is not systematically rewarded in our society. Other theories are more politically oriented and concentrate their energies on developing approaches to ethical decision making that minimize the subordination and marginalization of women, whatever other principles they support. For example, in a liberal approach to ethical decision making, human beings have a political responsibility to organize and maintain a particular society based on freedom and the various perceived rights that one has. Rules are supposed to protect privacy. From a feminist perspective, the liberal approach focuses on making sure that women are included in

the political processes when such rules are made, helping to develop a balanced legislation, this serves to shape the communities in which we live. In health care a liberal feminist approach focuses on providing women with educational and promotional opportunities for leadership positions in health-care systems. In leadership positions, it is hoped that women will use their power and authority in order to make the health-care system more accommodating for other women.

THEOLOGICAL PERSPECTIVES. Theological perspectives include the many religious traditions represented in our culture. Religious teachings are key concepts for ethical decision making for some individuals. In fact, many individuals consider these teachings as a divine source of values and morals. Jehovah’s Witness believers’ rejection of blood transfusions is a common example of how religious beliefs affect health-care decision making. This religious group has collected a large amount of information about blood substitutes and alternative therapies. Leaders of Jehovah’s Witnesses are prepared to provide education for health professionals about their beliefs and acceptable interventions. In another area, a number of religious traditions oppose abortion, which affects both health professionals and patients. Euthanasia is an issue addressed by numerous organized religious groups, which in turn can affect how patients make decisions regarding end-of-life issues. One of the difficulties with religious traditions is that it is not simply the official church teaching that is involved, but the individual member’s interpretation of that teaching. Assessment of the importance of this dimension of the patient’s life is important in the ethical analysis.

Ethical Decision Making

A variety of models and frameworks for ethical decision making are available. The steps listed in this section are a combination of several ideas that have been suggested. In its simplest form, ethical decision making is an informed problem-solving process. Similar to the nursing process, as discussed in the first chapter, the steps described in this section take the user through a set of strategies that assist in approaching a problem in an organized and systematic manner. Nurses applying these steps use critical thinking skills in order to be as logical and objective as possible. This is not to say that feelings and emotions are to be put aside. Indeed such feelings and associations as bonding, love, commitment, and other sentiments define our humanity. However, a balanced perspective is the goal, which includes respecting these feelings without allowing them to overshadow the process and the outcome. Although making the final decision may not be easy, the user knows that once these steps have been completed, the situation has been thoroughly examined and all viable and reasonable aspects explored before the decision was made.

Step 1: Gather and Verify the Information

Many kinds of information can contribute to an in-depth understanding of the situation, which provokes an ethical dilemma. Basically one needs to know who is involved,

what is involved, and the context of the problem. Foremost is information about the patient—what the patient says when conscious and competent. Determining competency itself can be an involved and frustrating process, especially when there are competing parties involved (e.g., a disagreement in a family about the competency of a parent). The chart is an obvious resource for clinical data, but so are the health professionals who are assigned to the patient because not every individual records all that is known about the patient. When appropriate, health-care records from previous hospitalizations may be helpful, as well as charts from other institutions and agencies. External factors also need to be included, such as legal aspects, governing policies and procedures of the institution, and available resources. The amount of information gathered depends on the time frame and urgency of the decision.

Step 2: Clarify the Values of All the Participants

The values, beliefs, and traditions of all participants are important, especially those of the patient, but more so when the patient is unconscious or incompetent (often called *non compos mentis* from the Latin *non* meaning not, *compos* in control, and *mentis* mind) and a group is attempting to reach a consensus based on some understanding of the patient. Advance directives or a living will prepared by the patient are often helpful as guides when the patient can no longer express personally held ethical beliefs (see Chapter 16). In addition, it is important to realize that sometimes the advance directive of a patient may be the polar opposite of the wishes of family. For example, a patient with a preexisting condition such as Parkinson’s disease may not wish aggressive action to be taken and wants to be allowed to die should he or she have a massive heart attack. The family, not wishing to let go of their loved one, may fight to keep the patient alive. Determining the ethical orientation of all participants clarifies their perspectives and moves decision making to a more objective level. Decision makers must be especially aware of assumptions, stereotyping, biases, and prejudices related to socioeconomic status, ethnic identification, gender, sexual and religious preferences, and other common characteristics of the participants.

Step 3: Identify the Ethical Dilemma and the Conflicts in Values

Separating the ethical aspects from the nonethical facets facilitates the decision-making process. For example, a conflict can arise as a result of gaps in communication rather than a conflict of ethical principles. When the communication channels are open and the decision-making process is transparent, it no longer is an issue. Sometimes both nonethical and ethical aspects need to be addressed in a parallel fashion to reach a resolution of the situation. The importance of various ethical values for each participant should be explored.

Step 4: Examine Possible Actions and the Consequences of Each Action

There is no magic number of “possible actions,” but it is easy to pose solutions at the extremes of possible actions.

Consider informing the patient as an example. The two obvious solutions are to tell and not to tell. But in clinical practice it is not that simple, and it is more useful also to pose solutions that are between the extremes. Suppose the issue is a critically injured patient who wants to know the condition of her spouse and child, who were also in the automobile accident. Her spouse was killed and her child is in critical condition. At the moment, her own status is unstable and telling her might have a deleterious effect on her own health. Telling her is certainly an option, just one with certain limitations at that time. Not saying anything in response to her question is a possibility but seems to show a lack of respect for her dignity as a person and her right to information. What might be some possible actions in between those extremes? Is there some response that tells part of the information while avoiding the worst part, her spouse's death? Even if the partial truths seem unacceptable at first glance, they ought to be added to the list of possible actions. Examination of a range of possible actions aids in identifying where the line is drawn for determining morally acceptable choices versus those not morally acceptable or for creating a list of each choice's risks and benefits.

Step 5: Determine the Ethical Foundation for Each Action

Each action should be based on selected ethical values, principles, or theories. Perhaps the code of ethics lends some support as ethical rationale. One strategy that is proposed on occasion, especially for an incompetent or unconscious patient, is an application of the **standard of best interest**. The best interest standard involves the determination of what action is in the best interest of the patient given the information that is known about the patient and the situation. Family members together with health-care providers usually make the best interest determination. Ideally, this decision is made in an objective manner, setting aside any special interests of the family or health professionals. For example, it may be in the best interest of the patient to be discharged and go home so that recovery can be optimized in that setting. Family members themselves may have other goals that make placement in a long-term care facility better for them. Health professionals may be pressured by administrative personnel to simply arrange a discharge, regardless of where the patient might be discharged to or what might be best for the patient, because of utilization review and financial reimbursement considerations. Under the best interest standard, the optimal placement is in the home because it is considered to have the best outcome for the patient.

Step 6: Determine the Best Action with the Strongest Ethical Support

Each action is judged based on its risks, benefits, and supporting rationale. The actions are then ranked in order of their priority. Strong ethical support for the first priority is required, as well as a reasonable potential for the action to be implemented. For example, if placement in a nursing home after discharge from the acute care facility is considered to be the best solution for a patient, but there is no room avail-

able in the potential facilities, that action must be set aside. If the preferred action fails, it is possible to move to choice number two. The designation of these priorities does not necessarily mean that their supporting ethical rationale always results in the same ranking, nor does it mean that principles or theories are always in opposition to one another.

Utilitarians and deontologists may disagree about the important principles in decision making. However, it should not be assumed that different **theorists** cannot reach a mutually agreeable decision. Although their rationale for the decision may differ, the final solution each proposes may be identical. A case in point involves the relief of pain and suffering. The deontologist might argue that there is a duty among health professionals to provide pain medications and make patients comfortable. This action shows respect for the value and dignity of the individual. A utilitarian might argue that pain and suffering should be relieved because doing so creates a positive outcome: the patient is more comfortable without pain and the family is helped too in that they do not have to watch a loved one suffer. In an even broader context, the more pain and suffering that is relieved, the greater the number of patients who benefit. So both theorists support the same action, but for different reasons.

Even theorists, such as utilitarians, can disagree among themselves. A classic case involving confidentiality was solved based on utilitarian concepts, yet both the ruling vote and the dissenting vote were based on utilitarian principles.¹⁷ The majority opinion of the court indicated that more good would be created by disregarding confidentiality obligations because overriding the patient's confidentiality would have saved the life of a third person who the patient threatened to murder. The minority opinion of the court stated that confidentiality should not be breached because it gave society the message that psychiatrists would not keep patient confessions secret and therefore would inhibit most individuals who have psychiatric problems from seeking professional help.

Step 7: Implement the Action

Needless to say, the selected action needs to be carried out. Responsibilities for the professionals and others in the situation can be assigned. Assigning a coordinator for the implementation of the action, especially if several individuals have responsibilities for portions of the action, enhances the potential for success, ensuring that someone will check on the process of implementation and that the action is evaluated.

Step 8: Evaluate the Outcome

We can learn from success and failure. Successful resolution of an ethical dilemma provides us with knowledge for the next ethical dilemma. Although no two dilemmas are exactly alike, selected features of a particular dilemma may parallel a subsequent situation and assist in solving the new dilemma. Failures also teach us a lesson. Retracing all the steps of the ethical decision-making process may provide insight and greater understanding of what steps of the process could have been better implemented. Evaluation is

also important because the next time we confront a similar dilemma we may not have the luxury of examining the new dilemma in as much detail. Prior experience enables us to face new dilemmas more confidently and to determine the better action more quickly. It is also important when making important decisions such as these that involve the life and care of vulnerable populations that absolute transparency is evident. Patients and family members have the right to know how and why decisions are made, especially if it is a resource allocation decision. One caution, however: It is very important to evaluate the outcome when decisions are made and the action taken within a limited time frame.

LEGAL CONCEPTS

To promote harmony, safety, and productivity as members of a society, we create rules. The rules of society can be informal or formal. An informal social rule, for example, is opening a door for someone. A criminal statute (law) is an example of a formal rule of society. Social rules or codes promote our social well-being. It would be unsafe to live in a community that existed without rules. All societies must require minimum standards of conduct for their members. Laws are the governmental mandates of a society that define individuals' duties to themselves, their neighbors, and the government. The failure to adhere to laws can result in punishment that may include imprisonment or monetary fines.

CRITICAL THINKING

Ethical Decisions

1. Identify a health-care-related ethical dilemma you have encountered as a student. How did you solve the dilemma? What expert resources did you use?
2. Apply the ethical decision-making model to the ethical dilemma. How are your decision-making process and proposed actions different when using the model?

Regulation of Nursing Practice

Nursing is a licensed health-care profession. Nurses must be licensed by their state to practice nursing. The rationale for state licensure is to improve the quality of health-care services and to protect the public. As such, state governments have created licensing boards to establish the entry-level requirements for nurses. These licensing boards also establish regulations that define the scope of appropriate nursing practice for licensed nurses. These licensing regulations are found in state nursing practice laws and within regulations that are made by the licensing agency.

The state nursing practice laws and the attendant nursing regulations establish the parameters within which nurses must practice to obtain and maintain state license. These regulations are referred to as **administrative laws**. These

considerations and mandates can be the basis for disciplinary actions by the licensing body. The failure to adhere to the regulatory mandates of the nursing licensing body can result in the loss of the privilege to practice nursing. Unprofessional conduct and conviction of a crime are examples of possible violations of nursing regulations.

Health Insurance Portability and Accountability Act of 1996 (HIPAA)

Since 1996, the federal government has regulated the distribution of personal health information. Licensed nurses along with other health workers are required to follow the requirements established by the Health Insurance Portability and Accountability Act of 1996 (HIPAA). This Act creates civil and criminal liability for health-care workers who wrongfully disclose an individual's health information. HIPAA has created a national standard for the protection of individual health information. The Department of Health and Human Services has developed a privacy rule that has, for the first time, established a basis for the federal protection of private health information. Licensed nurses must be sensitive to these legal limitations for the distribution of personal health information. Depending upon the seriousness of the violation of the HIPAA standards, one may be sentenced to up to 10 years in prison. HIPAA establishes very stringent guidelines. Licensed nurses should review their employer's HIPAA compliance policies and adhere to them. For more information on HIPAA and how it impacts health-care information and workers, please see the United States Department of Human Services website at www.hhs.gov/ocr/hipaa.

Nursing Liability and the Law

Liability refers to the level of responsibility that society places on individuals for their actions. In recent years, this responsibility has been interpreted to mean the financial responsibility owed to those who are injured by wrongful actions. Laws establish liability or responsibility for these wrongful actions. Following the law is a major part of the practice of nursing.

Administrative laws establish the licensing authority of the state to create, license, and regulate the practice of nursing. **Criminal law** regulates behaviors for citizens within this country. **Civil law** provides the rules by which individuals seek to protect their personal and property rights.

Criminal and Civil Law

All individuals, regardless of their occupations, are required to obey the criminal laws of the government. Criminal laws establish the rules of social behavior and define the punishment for the breaking of those rules, which can result in imprisonment or monetary fines.

Criminal law is different from civil law in the nature of remedies that are used for punishment. A crime is viewed as an action taken by an individual against society that the government will prosecute and punish. The breaking of a criminal law may result in criminal punishment and civil

liability. For instance, an intoxicated driver may go to jail for a crime and also be held civilly liable for any personal injury that resulted. Examples of criminal acts are assault, battery, rape, murder, and larceny.

Civil laws dictate how disputes are settled among individuals and how liability is assigned for wrongful actions. For health-care workers, civil liability is a constant concern. The potential for civil liability is demonstrated by an increased use of health-care procedures such as diagnostic testing, which results in higher health-care costs. Civil liability is a method by which a patient can seek financial recovery for injuries and losses caused by the wrongful action or lack of action by a health-care worker.

A civil liability suit begins with the filing of a complaint with a court. A copy of the complaint must be given or served by the plaintiff to the defendant. A **summons**, which is a notice to defendants that they are being sued, is attached to the complaint. The complaint describes the claim being made by the plaintiff, and the summons instructs the defendant that the complaint must be answered within a specified period, usually 20 to 30 days. Nurses served with a summons relating to work should notify their employers and take these documents seriously. The nurse must ensure that the summons is answered. If the employer does not answer the summons, the nurse must seek legal counsel to answer the summons within the specified time. If the nurse fails to answer the summons and complaint, it may result in a default judgment, which is acknowledgment of liability.

Civil wrongs caused by the act or omission of a health-care worker can be physical, emotional, and financial in nature. The person claiming a civil cause of action and injury is the plaintiff, and the person alleged to have caused the injury is the defendant. Lawsuits involving civil wrongs are called **torts**. The institution that employs the worker may also become liable for the acts or omissions of its employees. This theory of law is called **respondeat superior**. It is important for employees to understand that their work may result in civil liability for their employers.

Civil or tort liability for health-care workers can be based on intentional actions, unintentional actions, and even the omission of action. **Malpractice** may be defined as a breach of the duty that arises out of the relationship that exists between the patient and the health-care worker. This term includes liability that may arise from intentional torts and unintentional torts. Intentional torts are lawsuits wherein the defendant is accused of intentionally causing injury to the plaintiff. Examples of intentional torts are assault, battery, defamation, false imprisonment, outrage, invasion of privacy, and wrongful disclosure of confidential information (Box 2.1 Intentional Torts).

Negligence

An unintentional tort is known as **negligence**. Negligence occurs when injury results from the failure of the wrongdoer to exercise care. This failure to follow due care in the protection of the person injured is referred to as a breach of duty. Professionals owe a higher duty of care to their patients. The failure of a health-care professional to follow

Box 2.1

Intentional Torts

Assault	Unlawful conduct that places another in immediate fear of an unlawful touching or battery; real threat of bodily harm
Battery	Unlawful touching of another
Defamation	Wrongful injury to another's reputation or standing in a community; may be written (libel) or spoken (slander)
False Imprisonment	Unlawful restriction of a person's freedom
Outrage	Extreme and outrageous conduct by a defendant in the care of the patient or the body of a deceased individual
Invasion of Privacy and Wrongful Disclosure of Confidential Information	Liability when a patient's privacy is invaded physically or when records are released without authority

a prescribed duty of care is called malpractice. Professional negligence, therefore, is referred to as malpractice (Box 2.2, Components Necessary for a Finding of Negligence). All professionals, including LPN/LVNs, are responsible for their own actions whether they are intentional or negligent in nature. Although the employing agency is also responsible for the actions of its employees, employees always remain responsible for their own actions as well.

Limitation of Liability

All professions are concerned with the **limitation of liability**. Some examples of liability limitations are ensuring patient rights, accurately documenting procedures, following institutional policies, acquiring individual malpractice or liability insurance, pursuing continuing education, and practicing in accordance with the current standards of the nursing profession. Some states have enacted tort reform legislation. Much of this legislation is directed at limiting liability for health-care professionals and institutions. Examples of this reform legislation are limitations on the

Box 2.2

Components Necessary for a Finding of Negligence

- A duty of care owed to patients
- A breach of duty to exercise care
- Injury and damages occurring from this breach of duty

dollar amount allowable for a patient's damages, shortening the time in which a patient can file a lawsuit, and requiring stringent expert medical evaluation of a claim before a lawsuit can be filed.

All patients are entitled to quality care and treatment with dignity and respect. To provide quality care and limit liability, understand and provide the rights your patient is entitled to and question directions that are controversial, given verbally, concern situations of high liability, or involve a discrepancy between the direction and standard policy. Rights are defined as something due an individual according to just claims, legal guarantees, or moral and ethical principles. **Welfare rights**, also called legal rights, are rights that are based on a legal entitlement to some good or benefit. These rights are guaranteed by laws such as the Bill of Rights and if violated can come under the powers of the legal system. For example, citizens of the United States have a right to equal access to employment regardless of race, sex, or religion. The type of treatment and care a patient has the right to expect is outlined in the patient bill of rights. Stay informed on the status of patient rights' legislation as

you will be expected to follow it. Knocking before entering a patient's room and introducing oneself to the patient are examples of a patient's rights.

Documentation is a legal record of your actions. Document nursing actions based on orders given, as well as the name and title of the person who gave the verbal direction. Documentation must be clear, honest, and accurate. Always practice at a level that is generally accepted by the nursing profession. Failure to adhere to acceptable practice standards is cause for concern and can create potential liability for both you and the health-care institution.

It is important to understand that some employers do not provide malpractice insurance for their nursing employees. Always ask an employer exactly who is covered under the employer's liability insurance. If nursing employees are covered, the employer's insurance provides coverage from liability only as long as the employee follows the employer's work policies. For this reason, employer-provided liability insurance is not personal liability insurance. As a result, LPN/LVNs often carry personal liability insurance.

REVIEW QUESTIONS

- Factors influencing health care changes include which of the following?
 - Increasing birth rate
 - Increasing cultural diversity
 - Decreasing elderly population
 - Decreasing population size in America
- Which of these actions would the nurse correctly interpret as falling within the scope of practice of the LPN/LVN?
 - Performing an admission physical assessment on a critical care patient
 - Administering IV push morphine
 - Ambulating a 1-day postoperative patient
 - Developing the plan of care for a newly admitted surgical patient
- Which of the following describes how an autocratic leader makes decisions?
 - Seeks information from all staff members
 - Uses own knowledge to decide
 - Forms focus groups to gather information
 - Forms a staff committee to provide input
- Which of these situations would be an appropriate example of a leadership role for the LPN/LVN?
 - Consulting with an RN to modify care for assigned patient
 - Performing an annual employee evaluation on a nursing assistant
 - Supervising the RN and LPN/LVN staff on a surgical unit
 - Interviewing new graduate RN for a staff position
- As a nurse provides care to patients, it is important to have an understanding of ethics for which of the following reasons?
 - Resources are unlimited and available to everyone.
 - Technological interventions are always desirable.
 - Health-care systems are being simplified.
 - A health crisis can occur at any stage of human development.
- The nurse is planning quality care for a patient without regard to race, ethnicity, and gender. Which of the following ethical obligations does this exhibit?
 - Fidelity
 - Integrity
 - Respectfulness
 - Compassion
- A patient's family requests that a feeding tube be inserted. The patient has an advance directive indicating that a feeding tube is not to be inserted. As the nurse and physician consider what is best for the patient in this ethical dilemma, which of the following principles is represented?
 - Autonomy
 - Beneficence
 - Nonmaleficence
 - Justice
- The nurse reviews the advance directive for a patient who is comatose. Which of the steps in the ethical decision making process is the nurse performing?
 - Clarifying the values of all participants.

- b. Examining possible actions and the consequences of each.
 - c. Determining best action with strongest ethical support.
 - d. Implementing the outcome.
9. The nurse has a question about how a nursing license is regulated. In which of the following documents will the nurse find this information?
- a. An institutional policy
 - b. Nursing ethics code
 - c. State nursing practice laws
 - d. National nursing standards
- Multiple response item. Select all that apply.
10. In providing professional nursing care, the nurse understands that the law of negligence requires which of the following to create liability?
- a. A duty of care owed
 - b. Assault
 - c. Ethical violations
 - d. A breach of duty
 - e. Injury and damages
 - f. A crime
11. The Health Insurance Portability and Accountability Act of 1996 requires licensed professional nurses to do which of the following?
- a. Maintain continuing nursing education credit hours.
 - b. Protect the privacy of an individual's personal health information.
 - c. Limit nursing work hours to no more than 35 hours per week.
 - d. Forgo membership in any union or collective bargaining agreement unit.

QUESTIONS TO GUIDE YOUR READING

1. What are the meanings of the concepts common to culture and ethnicity?
2. What are examples of cultural characteristics, values, beliefs, and practices?
3. What are attributes of culturally diverse patients and their families and how do they affect nursing care?
4. What data should you collect from culturally diverse patients and their families?
5. How can you provide a holistic approach to patient care according to cultural characteristics and attributes?

CASE STUDY

Your clinical instructor has assigned you to provide care to Mary Williams, a 72-year-old African American woman. Ms. Williams has diabetes and hypertension (high blood pressure). She was admitted to the hospital for gangrene of her left foot. When you enter her room, you find Ms. Williams anxious and crying. She tells you that she is scheduled for surgery later in the day. When asked about her foot, she tells you that she has been applying a poultice to draw out the germs but it has not worked yet. She adds that she has been praying for the cure that she knows will come. As you are collecting history information about her diabetes, Ms. Williams admits that her doctor told her to attend diabetes classes years ago but she stopped going because she didn't like what she heard. She quickly changes the subject, wanting to talk about nothing but her grandchildren. Your attempts to complete preoperative teaching are unsuccessful.

Cultural diversity in the United States is increasing. The United States has become a multicultural society. Immigration from Spanish-speaking and Asian countries has resulted in dramatic shifts in census numbers. Table 3.1 illustrates the changes and projections in racial and ethnic makeup in the United States by the year 2010. As a result, **cultural** and **ethnic** differences between nurses and their patients are becoming more evident and must be recognized. Thus there is a need for you to become knowledgeable about **cultures** other than your own. This chapter provides you with the basics of culture and its impact on health promotion and wellness.

CONCEPTS RELATED TO CULTURE

Culture refers to the socially transmitted behavior patterns, **beliefs, values, customs**, arts, and all other characteristics of people that guide their view of the world (**worldview**). Cultural beliefs, values, customs, and **traditions** are primarily learned within the family on an unconscious level. They can also be learned from the community in which one lives, in religious organizations, and in schools. As you try to understand more about culture, keep in mind that it contains a number of characteristics (Box 3.1, Characteristics of Culture). All individuals and groups have the right to maintain their cultural practices as they feel are appropriate.

Box 3.1

Characteristics of Culture

- *Culture is learned.* Learning occurs through life experiences shared with other members of the culture.
- *Culture is taught.* Cultural values, beliefs, and traditions are passed down from generation to generation either formally (e.g., in schools) or informally (e.g., in families)
- *Culture is shared by its members.* Cultural norms are shared through teachings and social interactions.
- *Culture is dynamic and adaptive.* Cultural customs, beliefs, and practices are not static, but change over time and at different rates. Cultural change occurs with adaptation in response to the environment.
- *Culture is complex.* Cultural assumptions and habits are unconscious, which may make it difficult for members of the culture to explain to others.
- *Culture is diverse.* Culture demonstrates the variety that exists between groups and among members of a particular group.
- *Culture exists at many levels.* Culture exists in material (e.g., art, dress, or artifacts) and nonmaterial (as language, traditions, customs, beliefs, and practices) levels.
- *Culture has common beliefs and practices.* Members of the culture share the same beliefs, traditions, customs, and practices as long as they continue to be adaptive and satisfy their needs. Some members do not always follow all of these, but many do.
- *Culture is all encompassing.* Culture can affect everything its members think and do.
- *Culture provides identity.* Cultural beliefs provide identity for its members as long as there is no conflict with the dominant culture or lack of gratification by its members.

Culture has strong influences on a patient's understanding of health and responses to nursing care. You must understand the impact diversity can have on health behaviors in order to better meet the needs of your patients (Fig. 3.1). As you learn more about ethnic and cultural groups, you will be challenged to look at the differences and similarities across cultures.

TABLE 3.1 UNITED STATES DEMOGRAPHIC PERCENTAGES 1995–2010³

Race/National Origin	1995	2000	2005 Projections	2010 Projections
White, non-Hispanic	73.6	71.3	69.3	67.3
Spanish/Hispanics/Latinos	10.3	11.9	13.3	14.6
Black, non-Hispanic	12.0	12.2	12.3	12.5
American Indian or Alaska Native, non-Hispanic	0.7	0.7	0.8	0.8
Asian and Pacific Islander, non-Hispanic	3.4	3.8	4.3	4.8

FIGURE 3.1 The nurse must assess patients' special needs related to their cultural backgrounds.

Look for a minute at our patient, Ms. Williams. Did she behave as you would have in a similar situation? How do you think the characteristics of her culture affected her behavior?

While the terms **cultural sensitivity**, **cultural awareness**, and **cultural competence** are similar, they have different meanings. *Cultural sensitivity* is knowing politically correct language and not making statements that may offend another person's cultural beliefs. *Cultural awareness* focuses on history and ancestry and emphasizes an appreciation for and attention to arts, music, crafts, celebrations, foods, and traditional clothing. *Cultural competence* includes the skills and knowledge required to provide effective nursing care. In order for you to be culturally competent, you need to:

- Have an awareness of your own culture and not let it have an undue influence on your patient.
- Have specific knowledge about your patient's culture.
- Accept and respect cultural differences.
- Adapt your nursing care (when appropriate) to your patient's culture.

We will discuss more about cultural competence later in the chapter.

Even though you may have knowledge about another culture, there are barriers that can cause you not to appreciate cultural differences, especially ethnocentrism and stereotyping. **Ethnocentrism** is the tendency for human beings to think that their ways of thinking, acting, and believing are the only right, proper, and natural ways. Ethnocentrism perpetrates an attitude that beliefs that differ greatly from your own are strange or bizarre and therefore wrong. Additionally, you must be careful not to **stereotype** your patient. A stereotype is an opinion or belief about a group of people that is ascribed to an individual. For example, the statement "All Chinese people prefer traditional Chinese medicine" is a stereotype. This stereotype is not true. Although many Chinese people may prefer traditional Chinese medicine for some health conditions, not all Chinese people prefer

traditional Chinese medicine. Some Chinese people prefer the Western medicine that is practiced in the United States.

However, you can still make **generalizations** about an ethnic individual without stereotyping. Whereas a generalization, or assumption, may be true for the group, it does not necessarily fit the individual. Therefore, you must seek additional information to determine whether the generalization fits the individual. The challenge is for you to understand the patient's cultural perspective. If you have specific cultural knowledge, you can improve therapeutic interventions by becoming a co-participant with patients and their families. To do this, it is very important that you develop a personal, open style of communication and be receptive to learning from patients from cultures other than your own (Fig. 3.2).

A few additional terms are important for your understanding of culture relate to the socialization process of those who are learning to become a member of a society or group. As people immigrate to a new country they gradually accept the new culture through a learning process. They learn to accept their own beliefs and those of their new country. This is known as **acculturation**. This occurs because the new member must learn enough of the new culture to survive. A step further is when **cultural assimilation** occurs. This happens when the new member takes on the dominant culture's values, beliefs, and practices. This process could potentially be viewed as negative as the person may lose some of his rich heritage to become more like the dominant culture. Imagine for a moment that you have moved to China. At first you eat the food and attempt to understand the language of your new country. Over time, you may learn to cook the food, speak the language, and perhaps blend some of the Chinese beliefs, tradition, and practices with your own. As this practice continues to occur, acculturation is evident. This process may not always be smooth. When one's culture conflicts with the new culture **cultural conflict**

FIGURE 3.2 Health-care workers may come from a variety of cultural backgrounds.

occurs. Worse than that, **cultural shock** happens when values, beliefs, and practices sanctioned by the new culture are very different from the ones of the native culture. Let's look at another example. Chi Ling is a four-year-old boy who is a recent immigrant enrolled in a new school. He is alone and afraid although he is surrounded by other boys and girls his age. It is lunchtime and although his teacher is trying to help him with his food, he starts crying. The fork and spoon are foreign to him. At home he is used to eating his lunch with chopsticks. In addition he does not understand the words spoken to him. Little Chi is experiencing cultural shock.

HEALTH-CARE VALUES, BELIEFS, AND PRACTICES

Cultural values, beliefs, and practices are important in health care. Values can help shape one's beliefs and practices. Do you know what your values are regarding health and illness? A *value* can be defined as a principle or standard that has meaning or worth to an individual.¹ "Cleanliness" is an example of a value. A *belief* is something that an individual accepts as true (e.g., "I believe that germs cause illness and disease"). A *practice* is a set of behaviors that one follows; for example, washing hands before eating. It is important for you to understand the differences between these terms as we will be discussing them as they relate to cultural groups.

In order for you to be able to provide culturally competent care, you need to know how the people you encounter define health and illness. It is generally known that people follow one of the three major health belief systems: scientific (Western medicine or biomedical), spiritual, or holistic. You are already familiar with the scientific health system which dominates health care in Western societies. Belief in supernatural forces dominates the spiritual system, which is considered by many to be an alternative health-care system. (Some experts call this magicoreligious, but this is an offensive term to some religious individuals.) The holistic belief system focuses on the beliefs for the need of balance and harmony of the body and spirit with nature.

Health care typically focuses on the prevention of illness, health promotion, and acute care practices while considering traditional, religious, and biomedical (scientific) beliefs. Additionally, individual responsibility for health, self-medicating practices, views toward mental illness, and the patient's response to pain and the sick role are shaped by one's culture. Most societies combine biomedical health care with traditional, folk, and religious practices, such as praying for good health and wearing charms or amulets to ward off diseases and illnesses. There are many examples of individual and family folklore practices for curing or treating specific illnesses. Think for a minute about such practices that you may perform. What do you do for a fever or a sore throat? Does chicken noodle soup come to mind? Many times folk therapies are handed down from family members

and may have their roots in religious beliefs. Examples of folk medicines include covering a boil with axle grease, wearing copper bracelets for arthritic pain, and drinking herbal teas. As an addition to biomedical treatments, many people use complementary therapies, such as acupressure, reflexology, and other traditional therapies specific to the cultural group.

Often folk practices are not harmful and can be added into the patient's plan of care. However, some may conflict with prescription medications, intensify the treatment effect, or cause an overdose. It is essential to inquire about the full range of therapies being used by your patients, such as food items, teas, herbal remedies, nonfood substances, over-the-counter (OTC) medications, medications prescribed by others, and medications borrowed from others. If patients feel that you do not accept their beliefs and practices, they may be less open to sharing information and less compliant with prescribed treatment. You should try to encourage your patients' practices that could be helpful and discourage those that may be harmful. Before encouraging or discouraging such practices, you will need to discuss them with the appropriate health-care team member. Think about Ms. Williams. Does she use any folk practices? How would you address this specific situation?

Before moving on, we need to discuss the subjects of mental illness and cultural responses to pain and the sick role. Mental illness may be seen by many as being unimportant compared with physical illness. Mental illness is culture bound. What may be perceived as a mental illness in one society may not be considered a mental illness in another society. Among some cultures, having a mental illness or an emotional difficulty is considered a disgrace and is taboo. As a result, the family is likely to keep the mentally ill or handicapped person at home as long as they possibly can.

Cultural responses to pain and the sick role can vary among cultures. For example, some individuals are expected to openly express their pain. Others are expected to suffer their pain in silence. For some, the sick role is readily accepted, and any excuse is accepted for not fulfilling daily obligations. Others minimize their illness and make extended efforts to fulfill their obligations.

Nursing Assessment and Strategies

To begin your assessment of your patient's health beliefs, ask the following questions:

- What do you usually do to maintain your health?
- What do you usually do when you are sick?
- What kind of home treatments do you use when you are sick?
- Who is the first person you see when you are sick?
- What do you do when you have pain?
- Do you wear charms or bracelets to ward off illness?
- Do you take herbs or drink special teas when you are sick? What are they?
- Do you practice special rituals or prayers to maintain your health?

Cultural Self-Enrichment Exercise: HOW YOUR CULTURAL BELIEFS AFFECT YOUR HEALTH BEHAVIORS

- How do you define health for yourself?
- How do you define illness for yourself?
- Identify preventive health-care practices that you use.
- When you see a health-care provider for a minor illness, what do you expect the health-care provider to do for you?
- Identify your self-medicating behaviors.
- What home remedies do you use when you are ill?
- What meaning does pain have to you? What measures do you use when you are in pain?
- What are your personal views toward autopsy, organ donation, organ transplantation, and receiving blood or blood products?

CHARACTERISTICS OF CULTURAL DIVERSITY

Primary and secondary characteristics of diversity affect how people view their culture. The primary characteristics of diversity include nationality, race, skin color, gender, age, and religious affiliation. Secondary characteristics include socioeconomic status, education, occupation, military experience, political beliefs, length of time away from the country of origin, urban versus rural residence, marital status, parental status, physical characteristics, sexual orientation, and gender issues.

Culturally diverse care needs to take into account seven cultural phenomena that may vary with use but can be seen in all cultural groups: (1) communication, (2) space, (3) time orientation, (4) social organization, (5) environmental control/health beliefs, (6) biological variations, and (7) death and dying issues.

Communication Styles

Communication styles include verbal and nonverbal variations. Verbal communication includes spoken language, dialects, and voice volume. Dialects are variations in grammar, word meanings, and pronunciation of spoken language. Nonverbal communication includes the use and degree of eye contact, the perception of time, and physical closeness when talking with peers and perceived superiors. In some societies, people are expected to maintain eye contact without staring, which denotes that they are listening and can be trusted. However, in other societies, as a sign of respect, people should not maintain eye contact with superiors such as teachers and those in positions of higher status.

Nursing Assessment and Strategies

Ask the following questions:

- By what name do you prefer to be called?
- What language do you speak at home?

Cultural Self-Assessment Exercise: WHAT IS YOUR CULTURAL BACKGROUND?

- How do you identify yourself in terms of racial, cultural, or ethnic background? From what country did your ancestors originate? Were your parents from the same or similar ethnic backgrounds?
- What stories do you remember that your parents, grandparents, or other relatives told about relocating in the United States? Do you know why they originally came to America?
- How do these stories compare with those of others from similar backgrounds?
- How do these stories compare with those of others from different backgrounds?

Remember, one's values and beliefs are not better than another's—they are just different.

Cultural Self-Enrichment Exercise: COMMUNICATION

- How many languages do you speak? Do you speak a dialect of your dominant language? Does it interfere with communication with your patients?
- Do you speak in a soft, medium, or loud tone of voice? Does this tone change in different situations? How close do you stand when you speak with close friends? Does this distance change when you converse with your teacher, your religious leader, or a politician?
- Identify characteristics from your worldview in terms of being present, past, and future oriented.
- By what name do you prefer to be called? Why? Does this change in different situations?

Be sure to do the following:

- Take cues from the patient for voice volume.
- Be an active listener, and become comfortable with silence.
- Avoid appearing rushed.
- Be formal with greetings until told to do otherwise.
- Take greeting cues from the patient.
- Speak slowly and clearly. Do not speak loudly or with exaggerated mouthing.
- Explain why you are asking specific questions.
- Give reasons for treatments.
- Repeat questions if necessary.
- Provide written instructions in the patient's preferred language.
- Obtain an interpreter if necessary.

Space

Space refers to one's "personal space." Are you aware of your comfort zone? In other words, how close can someone

get to you before you feel less safe and secure? Like you, most people have such a comfort space. Personal space tends to be different when speaking with close friends versus strangers. For example, people from the Middle East tend to stand close together when talking, while others from European countries such as Germany require a much larger space. The need for space is important for the patient's privacy, autonomy, security, and self-identity. Understanding your patients' meaning of space can be important when you are trying to assess, treat, and teach them.

Cultural Self-Enrichment Exercise: SPACE

- Are you aware of your comfort zone? Is it different for close friends/family and strangers?
- How does it make you feel when someone violates your comfort zone?
- Do you respect other individuals' space when you communicate with them?
- How do you determine that you are protecting another's personal space?
- How do you feel when someone touches you?
- Do you have a firm handshake?

Nursing Assessment and Strategies

Ask the following questions:

- Are you comfortable?
- Do you have any concerns that you would like to discuss?

Be sure to do the following:

- Make sure you patients are comfortable before you interview them.
- Maintain appropriate physical distance (observe for cues).
- Be aware of cultural differences.
- Be aware of physical objects that may be a barrier to comfort.
- Make sure that the patient's physical environment is arranged to assure safety, security, and familiarity.

Time Orientation

Time orientation (past, present, future) can vary among people from different cultures. The perception of time has two dimensions. The first dimension is related to clock versus social time. For example, some cultures have a flexible orientation to time and events, and appointments take place when the person arrives. An event scheduled for 2 p.m. may not begin until 2:30 or when a majority of the people arrive. For others, time is less flexible, and appointments and social events are expected to start at the agreed-on time. For many, social events may be flexible, whereas medical appointments and business engagements start on time.

The second dimension of time relates to whether the culture is predominantly concerned with the past, present, or

future. Past-oriented individuals maintain traditions that were meaningful in the past and may worship ancestors. Present-oriented people accept the day as it comes, with little regard for the past; the future is unpredictable. Future-oriented people anticipate a bigger and better future and place a high value on change. However, some individuals balance all three views—they respect the past, enjoy living in the present, and plan for the future.

Hospitals, clinics, and physicians' offices maintain a tight time schedule. It is therefore important that you understand the patient's time orientation so that you can prepare them for the timing of appointments, tests, and treatments. In addition, it is important that you know their usual routines so that you can incorporate these as much as possible in their daily care.

Cultural Self-Enrichment Exercise: TIME ORIENTATION

- Are you aware of your time orientation (past, present, future)?
- Are you usually on time for appointments?
- Are your biological capacities (e.g., sleep and rest, eating) affected by your body rhythms?
- Do you have routines that you need to follow at certain times of the day?

Nursing Assessment and Strategies

Ask the following question to understand your patients' time orientation:

- Are you normally on time for appointments?
- Are there any routines that you need to follow?
- What time do you usually eat your meals? Take your bath?

Be sure to do the following:

- Have a clock in the patient's room.
- Assess for orientation and reorient to time as needed.
- Prepare patients ahead of time before a procedure or test.
- Give time options when appropriate.

Social Organization

Family organization includes the perceived head of the household, gender roles, and roles of the elderly and extended family members. The head of the household may be patriarchal (male dominated), matriarchal (female dominated), or egalitarian (shared equally between men and women). An awareness of the family dominance pattern is important for determining which family member to speak to when health-care decisions have to be made. Confidentiality issues can complicate this issue. Be sure to follow your institution's policies when communicating with family members. You may need to obtain the patient's permission before planning care with family members.

In some cultures, specific roles are outlined for men and women. Men are expected to protect and provide for the family, manage finances, and deal with the outside world. Women are expected to maintain the home environment, including child care and household tasks. You must accept that not all societies share or even desire an egalitarian family structure.¹

Roles for the elderly and extended family vary among culturally diverse groups. In some cultures, the elderly are seen as being wise, are deferred to for decision making, and are held in high esteem. Their children are expected to provide for them when they are no longer able to care for themselves. In other cultures, although the elderly may be loved by family members, they may not be given such high regard and may be cared for outside the home when self-care becomes a concern.

The extended family is very important in some groups, and a single household may include several generations living together out of desire rather than out of necessity. The extended family may include both blood-related and non-blood-related individuals who are provided with family status. For others, each generation lives separately and has its own living space.

You can assist your patients with their treatment plans when you have a better understanding of the family dynamics. It is important to know who to include for planning of care, discharge planning, and patient teaching. This will also help the appropriate hospital personnel to assist the patient and family to plan for home care.

Nursing Assessment and Strategies

Ask the following questions:

- Who makes the decisions in your household?
- Who takes care of money matters, does the cooking, or is responsible for child care?
- Who decides when it is time to see a health-care provider?
- Who lives in your household? Are they all blood related?

Be sure to do the following:

- Observe the use of touch between family members.
- Allow family members to decide where they want to stand or sit for comfort.

Cultural Self-Enrichment Exercise: SOCIAL ORGANIZATION

- Who is considered the head of the household in your family?
- Are there specified gender roles for family members?
- What are the roles of the elderly in your family?
- Do you identify with an extended family? Are they all blood relatives? What roles do they play?
- What kind of decisions do men make and what kind of decisions do women make?

FIGURE 3.3 Religious artifacts are central to many people's health and illness practices.

Environmental Control

Environmental control refers to one's perception of his or her ability to plan for activities that control nature or direct environmental factors. This concept is broader than where an individual lives, but it implies the systems and processes that affect individuals. While systems can include such things as cultural health beliefs and practices, processes can consist of interactions between individuals, families, and groups. Consideration is given to cultural values and beliefs, especially as they are different from those of the dominant health-care view (scientific, biomedical). Distinctions are made between health and illness and what individuals do to promote or maintain health and to prevent and treat illnesses. Not all of your patients will turn to the scientific health-care system or provider. In fact, many individuals try some form of alternative therapy before seeking treatment. If you use, for example, herbs or over-the-counter medications, you are doing just that. People also use alternative therapies and religious systems such as prayer in combination with the scientific medical system. Religious beliefs and practices may be very important to patients (Fig. 3.3).

Nursing Assessment and Strategies

Ask the following questions:

- How do you define health? Illness?
- Do you have any special beliefs about health and illness?

Cultural Self-Enrichment Exercise: ENVIRONMENTAL CONTROL

- How do you define health and illness?
- What are your health and illness values, beliefs, and practices?
- What do you do when you are sick?
- Do you use alternative or religious practices for healing?
- How do you tolerate pain? What do you do for pain?
- How do you handle grief?
- How are your health and illness values, beliefs, and practices different from others in your dominant culture?

- What do you do to keep well?
- When you feel ill, what is the first thing you do to get better?
- How do you deal with pain?
- How do you and your family express grief?
- Are there any cultural beliefs or practices that I need to know about in order to plan your care?

Be sure to do the following:

- Be aware of possible cultural beliefs and practices.
- Never stereotype what you know about different cultures; always ask for specifics.
- Perform a cultural assessment on all of your patients.
- Determine how your patients view health and illness.
- Ask if they have received any treatments for their illness of any kind.
- Ask about religions beliefs and practices.
- Encourage helpful practices and discourage those that are harmful.

Health-Care Practitioners

Health-care practitioner choices are made based on the patient's perceived status and previous use of traditional, religious, and biomedical health-care providers. In Western societies, educated health-care providers are treated with great respect. However, some people prefer traditional healers because they are known to the individual, family, and community.

It is important to respect differences in gender relationships when providing care. Some people may be especially modest because of their religion, seeking out same-gender nurses and physicians for intimate care. Respect these patients' modesty by providing privacy and assigning a same-gender care provider when possible.

Cultural Self-Enrichment Exercise HEALTH-CARE PRACTITIONERS

- What complementary health-care practitioners have you used? Were they successful?
- Identify complementary health-care practitioners used by your friends. Were they successful?
- When you are ill and need to see a health-care provider, do you prefer a same-gender provider? Why or why not?

Nursing Assessment and Strategies

Ask the following questions of your patients:

- What health-care providers besides physicians and nurses do you see when you are ill?
- Do you object to male or female health-care providers giving physical care to you?

Be sure to do the following:

- Observe for alternative care providers who may visit the patient in the health-care facility.

Biological Variations

Biological variations refer to ways in which people are different from one another physiologically and genetically. These differences can make them more susceptible to certain illnesses and diseases, and may also influence the effectiveness of different medications. Differences in biological variations can include (1) body build and structure, (2) skin color, (3) vital signs, (4) laboratory values, (5) susceptibility to disease, and (6) nutritional variations. Darker skin color can challenge you to be more observant when you are assessing the skin color of your patient. Laboratory test results can also be different in a number of cultures. For example, American Indians and Hispanic Americans may have higher blood glucose levels than whites.

Also included with biological variations are differences in nutritional practices. Nutritional practices are currently being scrutinized in our society. These practices include the meaning of food to individuals, food choices and rituals, food taboos, and how food and food substances are used for health promotion and wellness. Cultural beliefs influence what people eat or avoid. In addition to being important for survival, food offers security and acceptance, plays a significant role in socialization, and can serve as an expression of love.

Culturally congruent dietary counseling, such as changing amounts and preparation practices and including ethnic food choices, can reduce health risks. Whenever possible, you should determine a patient's dietary practices. Culturally diverse patients may refuse to eat on a schedule of American mealtimes or eat American foods. Counseling about food group requirements or dietary restrictions must respect an individual's cultural background. Most cultures have their own nutritional practices for health promotion and disease

Cultural Self-Enrichment Exercise: BIOLOGICAL VARIATIONS

- Do you know of any diseases or illnesses you are prone to because of your cultural background?
- Are you at ideal body weight for your height?
- What are your activity habits? Do they need to be improved?
- What is the meaning of food in your culture?
- Are there any dietary deficiencies or food limitations for you?
- What cultural or ethnic foods do you prepare at home?
- When you eat out for lunch or dinner, what are your favorite ethnic foods? Which ethnic foods do you not like? Why?
- What dietary practices do you engage in when you are ill?
- What kinds of foods do you eat to stay healthy?
- In your culture or personal belief system, are there any foods that are restricted or taboo?

prevention. For many, a balance of different types of foods is important for maintaining health and preventing illness. Common folk practices recommend specific foods during illness and for prevention of illness or disease. Therefore, a thorough history and assessment of dietary practices can be an important diagnostic tool to guide health promotion.

Nursing Assessment and Strategies

Ask the following questions of your patients:

- Are you at risk for any diseases or genetic disorders related to your cultural background?
- Are you satisfied with your weight?
- Are you active? What is your normal exercise pattern?
- Do you protect your eyes and skin from the sun? From possible injuries?
- Do you have any drug or food allergies?
- Has anyone in your family had any major illnesses?
- What do you eat to stay healthy?
- What do you eat when you are ill?
- Are there certain foods that you do not eat? Why?
- Do certain foods cause you to become ill? What are they?
- Who prepares the food in your household?
- Who purchases the food in your household?

Be sure to do the following:

- Teach about any biological variations that may pertain to your patient.
- Determine usual eating patterns and teach good nutrition habits, taking into account patient preferences. Refer to the dietician if appropriate.

Death and Dying and End of Life Issues

Death rituals of cultural groups are the least likely to change over time. To avoid cultural taboos, you must become knowledgeable about rituals surrounding death and bereavement. For some, the body should be buried whole. Therefore, an amputated limb may be buried in a future grave site, and organ donation would probably not be acceptable. Cremation may be preferred for some, whereas for others it is taboo and burial is the preferred practice. Views on autopsy vary accordingly. Some cultural groups have elaborate ceremonies that last for days in commemoration of the dead. To some individuals these rituals appear to be a celebration, and in a sense they are a celebration of the person's life rather than a mourning of the person's death. If you are uncertain, find out from the family if there is anything that the health-care team can do to facilitate cultural practices.

The expression of grief in response to death varies within and among cultural and ethnic groups. For example, in some cultures, loved ones are expected to suffer the grief of death in silence, with little display of emotion. In other cultures, loved ones are expected to demonstrate an elaborate display of emotions to show that they cared for the individual. These variations in the grieving process may cause confusion if you perceive some individuals as overreacting and others as not caring. You must accept that there are cul-

turally diverse behaviors associated with the grieving process. Bereavement support strategies include being physically present, encouraging reality orientation, openly acknowledging the family's right to grieve as they need to, assisting the family to express their feelings, encouraging interpersonal relationships, promoting interest in a new life, and making referrals to other staff and spiritual leaders as appropriate.

At times you may also be somewhat involved with other end-of-life decisions. Some of these may include advanced directives, resuscitation status, and organ transplantation.

Cultural Self-Enrichment Exercise: DEATH AND DYING

- What are the usual burial practices in your family?
- What is expected of family members and friends after a loved one dies?
- How is grief expressed in your family? Are there different expectations for men and women?
- Are any specific rituals associated with death?
- Do you believe in organ transplantations?
- Do you have advance directives?

Nursing Assessment and Strategies

Ask the following questions of your patients:

- What are the usual burial practices in your family?
- Do you believe in autopsy?

Be sure to do the following:

- Observe expressions of grief. Support the family in their expression of grief.
- Observe for differences in the expression of grief among family members.
- Offer to obtain a religious counselor/spiritual leader if the family wishes.

ETHNIC AND CULTURAL GROUPS

Cultural Groups in the United States

This chapter describes selected attributes of some of the cultural groups in the United States. These groups include European Americans (white), Spanish/Hispanics/Latinos, African Americans (black), American Indians/Alaskan Native, Arab Americans, and Asian/Pacific Islander Americans. The groups described here by no means represent all the cultural groups in North America; they do, however, represent the largest population percentages in the United States. As of the 2000 census, the federal government initiated new terminology for classifying people of diverse racial and ethnicity and it is used in this chapter.

Attributes presented for each group include communication styles, space, time orientation, social organization, environmental control, biological variation, health-care beliefs, traditional health-care practitioners, and death and

dying issues. Traditional health-care practitioners are those practitioners from the patient's native culture, such as shamans, herbalists, and other traditional healers. Racial and ethnic biological variations, susceptibility to disease, and genetic diseases are covered to a greater extent elsewhere in this textbook. (See Box 3.2 Ethical Consideration—Cultural Stereotyping and Box 3.3 Gerontological Issues.)

Cultural Self-Assessment Exercise

- Identify your primary and secondary cultural characteristics. How do they affect your worldview?
- Share these views with others in your class.

European Americans

European American is the term used to describe people living in the United States whose heritage is from the countries of England, Scotland, Wales, Ireland, Norway, Switzerland, France, Sweden, the Netherlands, Belgium, and other northern European countries. European American groups include

the white ethnic groups. Many of the descendants of these original European immigrants practice the unique attributes of the subcultures from which they originate. There is much diversity in the primary and secondary characteristics of diversity within this cultural group.

Many European Americans maintain the value of individualism over group norms and are activity oriented. Most European Americans practice Western medicine that uses high technology and emphasizes scientific discovery.¹ (See Box 3.4 Cultural Consideration.)

Spanish/Hispanics/Latinos

The term *Spanish/Hispanics/Latinos* is used to describe people whose cultural heritage has a strong Spanish influence. However, many people in this group prefer to identify themselves as Chicano or with terms that provide a country of origin, such as *Mexican, Peruvian, Puerto Rican, and Cuban*.¹ The population breakdown of Spanish/Hispanics/Latinos populations in the United States are Mexican Americans (67%), Puerto Ricans (9%), Central and South Americans (14%), Cubans (4%), and other groups, including Caribbean (7%).² Hispanics immigrate from any number of Central and South American countries, the Caribbean,

Box 3.2

Ethical Consideration—Cultural Stereotyping

Sharon, an experienced Licensed Practical Nurse, was on duty on the labor and delivery unit when Ruth and her husband Aaron arrived. Ruth was flushed and distressed and obviously in labor. Aaron was bending over his wife, attempting to coach her breathing, and trying to keep calm. The child was very early, only 30 weeks' gestation. Aaron was wearing a yarmulke, so Sharon assumed they were Jewish.

The usual expectation in labor and delivery is the arrival of a beautiful healthy child. Ruth and Aaron were no exception. Unfortunately, their infant son was stillborn due to gross prematurity and a "true knot" in the cord that had denied oxygen to the baby during the latter stages of the labor and delivery. After the delivery, Ruth was transferred to the medical-surgical unit for postpartum care, a practice commonly followed when stillbirths occur.

Sharon decided that she could make the situation a little easier for the couple by arranging care of the stillborn child. She expected that the parents would want help with contacting a funeral home and other details. She had done this many times before and it seemed to help the grieving parents when she took some of the burden from them by initiating the process.

Sharon told Ruth she had made some preliminary phone calls that would start the process of a funeral and accompanying activities. Ruth looked distressed, and Sharon misinterpreted this expression as her unfamiliarity with the funeral home that would be handling the arrangements.

Sharon tried to reassure Ruth, stating that she had been present at many funerals of children who had died either before, during, or after birth and the funeral home she had called was reputable and respectful. Sharon recounted her personal experience of these events and stated that sometimes the ritual of the wake, the burial, and the gathering afterward were therapeutic, bringing some closure. Aaron, who was visiting at the time, called Sharon out of the room and indicated his very strong displeasure that Sharon had begun arrangements. He explained rather tersely that he had contacted his rabbi, who as *mara d'atra* [halakhic authority] held the position of authority in Aaron and Ruth's community. The rabbi had made a *p'sak* [ruling/decision]. This *p'sak* meant that although the child was both premature and dead at birth, it was to be treated as a fetus. As such, it would be the family that would conduct the funeral, and there would be no ceremony attached. Aaron turned his back on Sharon and went back into the room.

Sharon completed her shift without additional communication with the couple, and Ruth was discharged before Sharon returned the next day. Sharon was plagued with a feeling that she had made a major error in caring for this woman and had failed to meet her emotional needs.

It is evident from this case that several major ethical principles were either ignored or transgressed. What do you think they were and why? (Suggested answers at end of chapter.)

**Box 3.3****Gerontological Issues****Aging, Ethnicity, Health, and Illness**

Compared with white or European American older adults, ethnic minorities are more likely to:

- Live in poverty
- Have a shorter life expectancy
- Experience debilitating disease processes or functional disability at a higher rate and at an earlier age
- Have difficulty accessing health-care services

Remember that older adults need to be assessed within their personal cultural context. Avoid generalizing

cultural practices to individuals or families without first assessing whether this practice or belief is true for them. For example, it would be wrong to assume that an older Mexican American woman who lives with her extended family will get the family's support for assistance with bathing and other activities of daily living. If an older Chinese woman uses herbs and folk treatments for common complaints, it does not mean that she will not use the services, treatments, or medications of Western medicine. Always assess individual preferences.

and other Spanish-speaking countries. Thus, there is much diversity in the Spanish/Hispanics/Latino population in the United States.

Some Spanish/Hispanics/Latinos speak only Spanish, only English, or both Spanish and English, while others speak neither Spanish nor English but rather an Indian dialect. The spoken language depends on individual circumstances and the length of time spent in the United States. Spanish is the second most common spoken language in the United States.

Spanish/Hispanics/Latinos compose approximately 13% of the U.S. population; they recently became the majority minority population. They live in all 50 states with more than 90% living in and around cities. Four of every five Spanish/Hispanics/Latinos are born and raised in the United States. Many of these individuals have come from poverty; for them money has little value. They sacrifice for their basic needs (Figs. 3.4 and 3.5).

The majority of Spanish/Hispanics/Latinos practice adaptations from the Roman Catholic religion. Their close relationship with God makes it acceptable for people to

experience visions and dreams in which God or the saints speak directly to them. Thus, health-care providers must be careful not to attribute these culture-bound visions to hallucinations that indicate a need for psychiatric services.¹ (See Box 3.4, Cultural Consideration.)

African Americans/Blacks

African Americans/blacks are the second largest ethnic group in the United States and represent more than 100 racial strains.¹ They make up 12.3% of the population.³

Box 3.4

Cultural Consideration*1,5,6

	European Americans (White)	Spanish/Hispanics/Latinos	African Americans (Black)	American Indian/Alaskan Natives	Arab Americans	Asian/Pacific Islanders
Communication	Primary language is usually English; often speak own national language. Eye contact should be maintained, without staring. Loud voice volume is the norm.	Primary language either English, Spanish, or Portuguese (many dialects). Dramatic body language. Some believe direct eye contact can cause illness (“evil eye”).	Primary language is usually English. May speak “black English” occasionally depending on the situation. Usually loud voice volume. Nonverbal communication important; direct eye contact may be interpreted as aggression.	English, tribal languages. Silence. Talking loudly may be considered rude. Use body language. Avoid eye contact.	Primary language is Arabic. Most speak some English. May use spirited, loud voice. May be reluctant to disclose personal information. Maintain intense eye contact.	English (may prefer national language and specific to each country); many dialects. Loud talking is considered rude. Silence is acceptable. Avoid eye contact. Avoid use of “no.”
Space	Depends on area; tend to avoid physical closeness. Handshake proper.	Value physical closeness and touching.	Close personal space. Touch frequently with friends, less so with strangers. Touching another’s hair considered improper.	Space very important; has no boundaries. Touch is not acceptable from strangers. Pointing and direct eye contact may be considered rude.	Stand very close when talking. Touch only between same gender.	Avoid physical closeness and touching.
Time Orientation	Future over present	Present	Present over future	Usually present	Present or future	Present
Social Organization	Nuclear family basic, extended family important. Man dominant figure. Judeo-Christian religions.	Nuclear family basic, extended family highly valued. Man is decision maker; woman is homemaker.	Many female single-parent families. Large, extended families important.	Extended family basic unit. Very family oriented. Elders honored.	Patriarchal household, with well-defined gender roles. Elders respected and cared for by family.	High value on immediate and extended family. Hierarchical family structure.

(Continued on following page)

Box 3.4 (Continued)
Cultural Consideration*1,5,6

	European Americans (White)	Spanish/Hispanics/Latinos	African Americans (Black)	American Indian/Alaskan Natives	Arab Americans	Asian/Pacific Islanders
	Community social organizations important. Many concerned with status.	Catholicism.	Strong social and church affiliations. Protestant (often Baptist).	Strong community affiliations. Sacred myths and legends.	Extended family important; may live in close proximity. May be Christian, Jewish, or Muslim.	Family honor and loyalty honored. Tradition important. Male has power; woman is obedient. High value placed on children and education. Christianity, Buddhism, Taoism, and Islamic religions
Environmental Control/Health Beliefs	Rely primarily on modern health-care system. Value individual responsibility for health. Believe human can control nature. Have strong belief and value in technology. Most use folk remedies or OTCs before seeing a health-care provider. Use of prayers and religious symbols for good health. Have controlled expression of pain but need little encouragement for pain relief.	Traditional health and illness beliefs. Folk medicine traditions. Health beliefs are strongly affected by religion, believing in God's will. May have shrines or statues in the home to pray for good health. Theory of hot and cold foods used for health maintenance and treatment of disease. Expressive with pain.	Traditional health and illness beliefs. Folk medicine tradition. May believe that serious illness sent from God. Use prayers for prevention and health recovery. Pain is seen as a sign of illness. Sick role not seen as a burden. Folk healers. A respected elderly female community member commonly	Traditional health and illness beliefs. Folk medicine traditions. Promote harmony with nature. Inanimate objects ward off evil spirits. Elderly may request same-gender direct-care provider. Pain is something to be endured. Sick role not usually supported. Traditional healers: shamans, medicine man, diviners, crystal gazers.	Focus on acute care over prevention. Illness may be considered punishment for sins. May pray five times a day for health. Acceptable to purchase organs for transplantation. Sick role supported.	Traditional health and illness beliefs. Traditional medicine traditions. Good health is a gift from ancestors. Imbalances in the yin and yang cause illness. Believe blood is the source of life and is not replenished. Amulets worn to ward off disease. Traditional healers: doctors, herbalists, acupuncturists who use such therapies as acupuncture, acumasage, coining, and cupping.

	European Americans (White)	Spanish/Hispanic/Latinos	African Americans (Black)	American Indian/Alaskan Natives	Arab Americans	Asian/Pacific Islanders
	Sick role not well accepted except with a major illness. Traditional healers: Western-educated health-care providers; recent trend to use complementary therapists.	Easily enter the sick role. Traditional healers: curandero, espiritista, patera, senora.	sought for initial health care. Use spiritualists, voodoo priest or priestess, or root doctor.			
Biological Variations	Nutritional preferences include meats (especially red) and carbohydrates. Diets tend to be high in fat and sodium; Eating and drinking may be social rituals. Culture stresses thinness to be attractive. Susceptibility: heart disease, breast cancer, diabetes mellitus, thalassemia, Tay-Sachs disease (Eastern European Jewish).	Nutritional preferences include spicy and fried foods, beans, and rice. Important for food to be served warm. Many subscribe to the hot and cold theory (e.g., illness caused when body is exposed to imbalance of hot/cold substances). Food choices vary by specific country.	Nutritional preferences include fried foods, barbecued foods, greens, legumes. Diet commonly high in fat and sodium. Food selections may vary according to socioeconomic status and rural versus urban residence. Being overweight is seen as positive. Food is seen as a symbol of health and wealth.	Nutritional preferences vary greatly depending on location and tribe. Nontraditional diets tend to be high in fat and commonly lack fruits and vegetables. Herbs used to cleanse the body of evil spirits and poison. Susceptibility: heart disease, alcoholism, liver disease, diabetes mellitus, tuberculosis, arthritis, glaucoma.	Nutritional preferences include fresh meats and vegetables; may avoid pork and alcohol (Islam). High risk for diabetes, hypertension, hypercholesterolemia. Less likely than general population to smoke, drink alcohol, or use illicit drugs.	Nutritional preferences include raw fish and rice. Foods are balanced between the yin and yang. Diet is high in salt. Food is fundamental form of socialization. Susceptibility: lactose intolerance, thalassemia, liver and stomach cancer, hypertension, coccidioidomycosis.

(Continued on following page)

Box 3.4 (Continued)
Cultural Consideration*^{1,5,6}

	European Americans (White)	Spanish/ Hispanics/ Latinos	African Americans (Black)	American Indian/ Alaskan Natives	Arab Americans	Asian/Pacific Islanders
		Susceptibility: lactose intolerance, diabetes mellitus, parasites, coccidiomycosis, gout.	Susceptibility: keloid formation, lactose intolerance, sickle cell anemia, glucose-6-phosphate dehydrogenase deficiency, thalassemia, sarcoidosis, hypertension, coccidiomycosis, esophageal and stomach cancers.			
Death and Dying Issues	Autopsy and burial or cremation usually connected with religious practices or individual decisions. Have varied expressions of grief. Men are expected to be in more control of grief than women.	Burial is the usual practice, rarely cremation; many resist autopsy, the body should be buried whole. May have elaborate ceremonial burial. Women very expressive with grief; men are expected to maintain control.	Death does not end connection between people; body is kept intact after death; prefer no autopsy. Relatives may communicate with the dead person. Offer eulogy at burial with religious songs. Usually prefer burial. Express grief openly.	Believe body should go into the after-life whole. Some engage in a cleansing ceremony after touching a dead body. Tribal laws may dictate cremation versus burial. Openly express grief.	Believe death is God's will. At time of death, bed should face the holy city of Mecca (for Muslims). May perform ritual washing of the body after death. Cremation or autopsy not acceptable. May weep with grief, but limited.	Autopsy not understood by many. Cremation acceptable, but burial also common. Extended grieving time (7 to 30 days) for the more traditional. Expression of grief is highly varied between men and women and among specific countries.

*While many other cultural groups are represented in the United States, the most common are presented here.

Although African Americans/blacks live in all 50 states, more than half live in the South. It is important to understand that not all people with black skin identify themselves as African American. Many black-skinned people from the Caribbean prefer terms more specific to their identity, such as *Haitian*, *Jamaican*, or *West Indian*.

African Americans/blacks have been called by many names. Their ancient African name is Nehesu or Nubian. During slavery days in America, they were called *Negro*, a Spanish-Portuguese word meaning “black.” After emancipation in 1863, they were called *colored*, a term adopted by the First Colored Men’s Convention in the United States in 1831. The United States Bureau of the Census adopted the word *Negro* in 1880. During the civil rights movements in the 1960s, the term *black* was used to signify a philosophy of life instead of color. In the 1970s, these ethnic peoples referred to themselves as African Americans because they were proud of both their African and American heritages. In 1988, the term *African American* was widely adopted in the United States by individuals whose ancestry originated from Africa. These terms continue to cause confusion when people attempt to use the “politically correct” term for this group in the United States. Additionally, titles such as the National Black Nurses Association and the National Association for the Advancement of Colored People (NAACP) still exist.¹

African Americans/blacks are underrepresented in colleges and universities, managerial and administrative positions, and the health-care professions. They are overrepresented in high-risk, hazardous occupations such as the steel and tire industries, construction industries, and high-pollution factories (See Box 3.4 Cultural Consideration.)

CRITICAL THINKING

■ Now that you have learned more about the black culture, let’s look at Ms. Williams again. Review Box 3.4 Cultural Consideration and answer the following questions:

1. What does your interaction with Ms. Williams tell you about her time orientation?
2. What is evident about her social organization?
3. What biological variations may Ms. Williams demonstrate that are likely due to her culture?

American Indians/Alaskan Natives

There are more than 400 American Indian/Alaskan Native tribes in the United States, totaling 0.8% of the population.³ Although there are similarities among Native Americans, each tribe has its own unique perspective on health and illness. Many traditional American Indians/Alaskan Natives live on reservations; others live in urban areas and practice few of their traditions. Many American Indians/Alaskan Natives have a strong belief that illness is caused by an

imbalance with nature and the universe. Tribal identity is maintained through powwows, ceremonial events, and arts and crafts that are taught to children at a young age. Communicating with nature is important for maintaining life forces.¹ American Indians/Alaskan Natives are the original inhabitants of North America.

American Indians/Alaskan Natives are underrepresented in all the health professions. They are consistently identified as the most underrepresented minority group in institutions of higher learning.⁴ (See Box 3.4 Cultural Consideration.)

Arab Americans

Arab Americans are a large and diverse population, with over 3,000,000 in the United States. Some common bonds include the Arabic language and the Islamic religion. Arab Americans include people from Morocco, Algeria, Tunisia, Libya, Sudan, and Egypt and the western Asian countries of Lebanon, occupied Palestine, Syria, Jordan, Iraq, Iran, Kuwait, Bahrain, Qatar, United Arab Emirates, Saudi Arabia, Oman, and Yemen. Many early Arab immigrants were Christians from Lebanon and Syria.

Although many Arab Americans favor professional occupations, many are underemployed, have their own businesses, and work in a variety of other occupations. Arab Americans, whether born in the United States or in Arab countries, are more educated than the average American. They are more likely to be in managerial and professional specialty occupations than any other ethnic group in America. However, a significant number of primarily foreign-born Arab Americans are unemployed and live in poverty.

Asian Americans/Pacific Islanders

This large group is far from homogeneous. The term *Asian*, as used in most references, includes 32 different groups. These groups include Asians, Pacific Islanders, Indochinese, and other Asian groups. Asians include people from Korea, Japan, and 54 ethnic groups from China. Pacific Islanders include Hawaiians, Polynesians, Filipinos, Malaysians, and Guamanians. Indochinese populations include Cambodian, Vietnamese, Hmong, and Laotian. Other Asian groups include Asian Indian, Pakistani, and Thai.

Although it is difficult to determine exact numbers of Asians from specific countries because of the method of keeping population statistics, they are a significant and fast-growing population in the United States. It is important for many Asian patients to “save face.” Individual shame is shared with the family and community. Most Asians see the nurse as an authority figure. Although known by different names, most Asian cultures practice the *yin* and *yang* balance of forces for illness prevention and maintaining health. Yin is considered female and represents cold and weakness. Yang is considered male and represents strength and warmth. Foods and all forces are classified as yin or yang and must be balanced or illness occurs. Yin and yang forces are major components of traditional Chinese medicine,

which includes acupressure, acumassage, and cupping. (See Box 3.4 Cultural Consideration.)

CULTURALLY COMPETENT CARE

The American Nurses' Association supports the need for nurses to understand cultural diversity and to become culturally competent. However, there is no real agreement as to how your knowledge, skills, and attitudes will best help these diverse populations. You certainly cannot achieve cultural competence overnight; it is a developmental process. Each time you care for a patient from a different culture, you learn more, become more aware and sensitive to individual needs, and move toward becoming culturally competent.

There are a number of models and theories that describe cultural competence. In addition, you will find that there are a number of good resource books and websites that will assist you on this journey.

The following strategies for culturally competent care may be helpful:

- Consider each of your clients as unique, influenced but not defined by their culture.
- Know your own cultural values, beliefs, and practices and appreciate how they may be different from those of others.
- Never let your own biases about people and groups stand in the way of good care.
- Learn as much as you can about cultural groups in your community.
- Make an effort to include beliefs and practices from other cultures into your care when appropriate.
- Try to encourage helpful cultural practices and discourage harmful ones.
- Be aware of how you communicate with others; be aware of verbal and nonverbal patterns.
- Respect your patients regardless of their cultural background.
- Learn from your mistakes.

The list does not include everything you can do. Can you think of other strategies?

CRITICAL THINKING

The Lopez Family

■ Jose, age 23, and his wife, Louisa, age 19, immigrated to the United States 3 years ago from Mexico. They have two children, Maria, 3 years old, and Jesus, 6 months old. The young couple brings the children to the emergency room for the treatment of ear infections. Jose informs you that Maria is complaining of a sore throat and ear pain and Jesus is “fussy” and not eating. He states that he has been to his *curandero*,

but neither child has improved. You also notice that the children are dressed in heavy clothing, although it is quite warm outside. When you question the parents, Louisa responds that they are “cold.”

Jesus is admitted to the hospital for dehydration. As you are admitting the infant to your unit, you are aware that Jose is answering all of your questions and making decisions for Jesus' care. He states that they will all need to spend the night with Jesus. Jose further adds that Jesus needs more clothes on and that the temperature in the room needs to be increased. The parents refuse the warmed bottle of formula for Jesus but ask for it to be chilled. Louisa sits in the corner of the room chanting, crying, and rubbing some beads.

1. What nonverbal communication characteristics do these parents display that are common among people of Spanish descent?
2. Why do you think the children are dressed inappropriately for the weather?
3. Do Jose's demands mean that he is uncooperative and trying to control the care of his son?
4. Why do you think Jose refused his son's warm bottle?
5. What is the significance of Louisa's behavior?
6. What might you do to improve Jesus' care?
7. How will you handle the father's request for the entire family to stay in your patient's room?
8. How can you become more culturally competent in this situation?

Suggested answers at end of chapter.

Home Health Hints

- The effect of the patient's cultural beliefs and practices related to health care are more evident when care is provided in the home. The nurse must adapt care to the patient's environment rather than the patient adapting to the nurse's hospital environment. The nurse is a guest in the patient's house.
- When scheduling a home visit, it is important to find out the primary language spoken in the home. It is also helpful to carry a translation book when the language is known. If necessary, arrange to have an interpreter, either a family member or co-worker, available to ensure understanding of what is discussed.
- Be aware of the cultural significance of family hierarchy. If possible, avoid having children translate for parents.

REFLECTIONS ON CASE STUDY

After learning more about culture, how do you think the characteristics of Ms. Williams's culture affected her behavior? At her age, it is evident that she has learned many of her beliefs and practices about health and illness from others. While many of her behaviors can be explained by fear and denial, it is probable that other things are going on in this situation. Ms. Williams may feel more comfortable with people of her own culture, at least when it comes to asking for health information. Like a number of other cultures, your patient may not trust biomedical or Western medicine treatments. She may be more comfortable with the practices and healers that she knows better. Can you think of other explanations?

Rarely do practicing nurses have the luxury to assess each patient comprehensively on a first encounter. The essentials for culturally competent care are obtained as

needed. As you meet patients from other cultures, continue to learn about these new cultures. Astute observations, an openness to diversity, and a willingness to learn from patients are what you need for effective cross-cultural competence in clinical practice. Through these avenues, you can provide culturally competent nursing care. Cultural competence is not a luxury; it is a necessity.

Remember that it is important that you acknowledge that there are similarities within a group. This does not mean that ALL of the people in the group have all of those characteristics. You must see each of your patients as being unique. In summary, let's take a trip to BALI:

Be aware of your own cultural heritage.

Appreciate that your patient is unique; influenced, but not defined by his culture.

Learn about your patient's cultural group.

Incorporate your patient's cultural values, beliefs, and practices into their plan of care.

REVIEW QUESTIONS

- A nurse who assumes all patients have the same beliefs as his or her own culture is exhibiting
 - Cultural stereotyping.
 - Ethnocentrism.
 - Cultural sensitivity.
 - Cultural dominance.
- A 12-year-old Mexican child needs an appendectomy. His parents bring in the priest from their church to pray over the child. The prayers are continuing when it is time to take the child to surgery. How should the nurse respond?
 - Gently tell the parents that they must stop praying so the child can be taken to surgery.
 - Give the parents and priest as much time as they need for prayers prior to surgery.
 - Tell the parents that the child could die from a ruptured appendix if surgery is delayed.
 - Permit the parents and priest to stay and pray as the child goes into surgery.
- An Osage American Indian woman is slow at giving responses and does not maintain eye contact with you when you are doing her intake interview. Which of the following interpretations of her behavior is most likely accurate?
 - Direct eye contact may be interpreted as rude in her culture.
 - She does not want to answer personal questions.
 - She does not understand you.
 - She does not want to talk with a nurse and prefers a physician.
- An Arab American man is refusing his dinner tray, which consists of potatoes with cheese, a slice of ham, and green beans. What knowledge should guide the nurse's data collection related to this incident?
 - Arabs do not like foods from different sources on the same plate.
 - Some Arabs do not eat dairy products.
 - Islamic Arabs may not eat pork.
 - Arabs generally do not eat vegetables.
- A Puerto Rican man has been admitted for reconstructive orthopedic surgery on his knee. His wife brings jars of special blends of spices that he wants to put on his food because the hospital food is too bland. He is on a general diet. What action should you take?
 - Allow him to use them.
 - Carefully explain that family cannot bring food items to the hospital.
 - Have the dietitian speak with the family.
 - Report the situation to the physician.

ETHICAL CONSIDERATION DISCUSSION

It is evident from this story that the traditional American or Christian conception of the rituals associated with the death of a child may not be held by other cultures, including this Jewish patient and her husband. Upon reflection, Sharon realized that she had not respected this couple's **autonomy**, or even provided an environment that would foster the **creation of autonomy**. She had failed to **minimize harm**, failed to produce the most **beneficial outcome** for Aaron and Ruth, and had not familiarized herself with the wishes of the couple.

Sharon did not serve her clients' needs first. She should have determined what Ruth and Aaron needed at that sensitive time. Instead, she assumed she knew what was required and subsequently made poor choices for her clients. Were her clients harmed? If Sharon had known that there were significant religious protocols to be observed in this situation, would she have gone ahead and made phone calls, in essence, to interfere with the designated roles of the parents? Sharon did

cause some anxiety in this case. Sharon could have been most helpful by asking respectful questions about what she could do to assist the couple during this sad time. Aaron and Ruth may indeed have asked Sharon to be involved in the preparations and funeral.

Instead of holding assumptions and applying our own vision of what a client may need, nurses need to assess a family's values, gather appropriate information about their culture, and find what the role expectations are in each situation. There should be an atmosphere of mutual respect and open communication. Patients' values and preferences cannot be assumed, even when nurses can correctly identify the culture of the family. Cultural stereotyping is a mistake that is easy to make. However, if we approach our clients with an open and nonjudgmental attitude, we will be able to gather the data that is essential to providing culturally competent nursing care.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Ms. Williams*

1. Ms. Williams's time orientation is the present. She is not only concerned with the future effects of her uncontrolled diabetes.
2. Family is very important. She prays for healing.
3. We do not know Ms. William's weight, but overweight is seen as positive, and excess weight is a risk factor for diabetes and hypertension.

■ *The Lopez Family*

1. Jose's behavior indicates that he is the primary decision maker and in charge of this situation. Louisa's crying is normal. She is most likely praying.
2. This may relate to the couple's beliefs in the hot and cold theory.
3. His role as father may dictate that he should main-

tain control. He probably does not mean to be uncooperative.

4. Again, this may be related to hot and cold beliefs about treatment of diseases.
5. Culture-bound role does not dictate that she assume control of the situation. She is upset and praying.
6. Attempt to incorporate the family's cultural beliefs and practices when possible.
7. Explain that it would not be good for Maria to remain in the hospital, because she will be at greater risk for exposure to infection. Ask if there are other relatives who can care for Maria. Find out if the parents can divide their time with their son.
8. Be aware of your own cultural beliefs, appreciate you patient's culture, learn more about the Lopez family's culture (ask questions), and include their beliefs and practices when possible. Explain when other practices cannot be followed. Ask for alternatives.

Alternative and Complementary Therapies

LYNN KEEGAN

KEY TERMS

acupuncture (ak-yoo-PUNGK-chur)

allopathic (AL-oh-PATH-ik)

Ayurvedic (AY-YUR-VAY-dik)

chiropractic (ky-roh-PRAK-tik)

homeopathy (HO-mee-AH-pa-thee)

naturopathy (NAY-chur-AH-pa-thee)

osteopathic (AHS-tee-ah-PATH-ik)

QUESTIONS TO GUIDE YOUR READING

1. What is the difference between an alternative and complementary therapy?
2. What are some systems of health care that have contributed to the development of new therapies?
3. How can the different types of therapies be classified?
4. What are some safety issues in alternative and complementary therapies?
5. What is the role of the licensed practical nurse/ licensed vocational nurse (LPN/LVN) in assisting a patient with alternative and complementary therapies?

Health care in the 21st century requires that nurses recognize the shift of thinking toward the incorporation of alternative and complementary approaches to care. Nurses at all levels and in every area of practice are answering the call to use new methods to care for the ill and to enhance the health of those who are well.

Holistic nursing was a precursor to many of the now popular alternative and complementary therapies. It was introduced in the 1970s and has been growing ever since. Holistic nursing is simply defined as caring for the whole person—body, mind, and spirit—in a constantly changing environment.

ALTERNATIVE OR COMPLEMENTARY: WHAT'S THE DIFFERENCE?

The words *alternative* and *complementary* are sometimes used interchangeably, but they are not the same. *Alternative* therapy, sometimes called “unconventional” therapy, refers to a therapy used instead of conventional or mainstream therapy. An example is using **acupuncture** instead of analgesics. *Complementary therapy* refers to a therapy used in addition to a conventional therapy. For example, a nurse might suggest guided imagery, music, and relaxation techniques for pain control in addition to prescribed drug therapy.

A good all-around website for alternative and complementary medicine is <http://www.healthy.net>. To learn about holistic nursing and complementary therapies, visit the American Holistic Nurses Association at <http://www.ahna.org>.

INTRODUCTION OF NEW SYSTEMS INTO TRADITIONAL AMERICAN HEALTH CARE

There are many new and different philosophies within the scope of expanded medical and nursing practice. These systems reflect cultures and attitudes in healing that range from East to West and from ancient to modern.

In the United States, the primary system of medicine is just called *medicine*, although some people refer to it as **allopathic** medicine. A number of other schools of thought and philosophies are also being increasingly used. The most frequently seen new systems include **Ayurvedic**, Chinese, **chiropractic**, naturopathic, American Indian, and **osteopathic** medicine. Each philosophical system can stand alone or, as in most instances in the United States, be used in combination with other systems. Most of these recently

acupuncture: acus—needle + punctura—puncture
allopathic: allos—other + pathic—disease or suffering
Ayurvedic: ayu—life + veda—knowledge or science
chiropractic: cheir—hand + praktos—to do
osteopathic: osteo—bone + pathy—disease

introduced systems use alternative and complementary therapies.

Allopathic/Western Medicine

The most common name for allopathic medicine is *Western medicine*. Other commonly used terms for Western medicine are *conventional medicine* and *mainstream medicine*. Many people have not heard the term *allopathic* because most doctors and nurses do not refer to themselves or their practice by this name. Practitioners of other systems of medicine more often use the term when referring to what most of us consider mainstream medicine. Allopathy is a method of treating disease with remedies that produce effects different from those caused by the disease itself. For example, when a patient has a bacterial infection, a Western medical practitioner prescribes an antibiotic to eliminate the invading pathogen.

Practitioners of Western medicine are medical doctors, nurses, and allied health personnel. This system of medicine uses scientific data to determine the validity of a diagnosis and the effectiveness of treatment. It is evidence-based medicine. This means that peer-reviewed medical literature is very important. In scientific investigations, results can be verified and reproduced through various types of studies and statistical analyses. Practitioners use a variety of therapies, including drugs, surgery, and radiation therapy. Western medicine practitioners have made most of the significant advances and developments in modern medicine.

For further information see the American Medical Association site at <http://www.ama-assn.org>.

Ayurvedic Medicine

Ayurveda is the ancient Hindu system of medicine, which originated in India. Its main goals are to maintain the health of healthy people and cure the illnesses of sick people. Ayurveda maintains that illness is the result of falling out of balance with nature. Diagnosis is based on three metabolic body types call *doshas*. An Ayurvedic doctor determines which dosha type is most appropriate for the patient: vata, pitta, or kapha. Treatment usually involves prescribing a diet, herbal remedies, breath work, physical exercise, yoga, meditation, massage, and a rejuvenation or detoxification program.

Ayurveda is rapidly becoming more popular in America. The books and videos of Deepak Chopra are examples of this increasingly popular system of therapy. An introduction to Ayurveda can be found at <http://www.ayurveda.org>.

Traditional Chinese Medicine

Traditional Chinese medicine is thousands of years old and involves such techniques and practices as acupuncture, acupressure, herbs, massage, and qi gong. The diagnosis and treatment of disturbances of qi (pronounced “chee”)—or vital energy—is a distinctive characteristic of Chinese medicine.

Acupuncturists, one segment of traditional Chinese medicine practitioners, claim to be able to tell much about a

patient's state of health by checking pulses, looking at the color of the tongue, checking facial color, assessing voice and smell, and asking a variety of questions. To treat patients, acupuncturists insert one or more needles along the meridians (pathways) where qi flows (Fig. 4.1). Many acupuncturists also prescribe herbal remedies as well.

Chiropractic Medicine

Daniel David Palmer founded chiropractic therapy in 1895. Chiropractic medicine holds that illness is a result of nerve dysfunction. The main treatment modality of chiropractors is manual adjustment and manipulation of the vertebral column and the extremities. They use direct hand contact and mechanical and electrical treatment methods to manipulate joints. The goal is to remove the interference with nerve function so the body can heal itself. Chiropractors do not perform surgery, nor do they prescribe drugs. See the American Chiropractic Association site at <http://www.amerchiro.org>.

Homeopathic Medicine

Homeopathy was developed by Samuel Hahnemann in Germany in the early 19th century. Homeopathy is based on

homeopathy: homeo—like + pathos—disease

Hahnemann's principle that “like cures like,” meaning that tiny doses of a substance that create the symptoms of disease in a healthy person will relieve those symptoms in a sick person.

Although there are schools and courses to train homeopaths, no diploma or certificate from any school or program is a license to practice homeopathy in the United States. Medical doctors and doctors of osteopathy are granted certificates of competency to practice homeopathy. Other health-care practitioners may be allowed to use homeopathy within the scope of their state licenses.

See The National Center for Homeopathy website at <http://www.homeopathic.org>. This site has a research section with annotated listings from the medical literature discussing the value of homeopathy. In addition, there is a good review of licensing laws regarding homeopathy.

Naturopathic Medicine

Naturopathy primarily uses natural therapies such as nutrition, botanical medicine (herbs), hydrotherapy (water-based therapy), counseling, physical medicine, and homeopathy to treat disease, promote healing, and prevent illness.

naturopathy: naturo—nature + pathy—disease

FIGURE 4.1 Qi meridians are used in the Chinese medicine techniques of acupressure and acupuncture.

Naturopathic physicians have a doctor of naturopathy (ND) degree and can be licensed in 11 states. There are three schools of naturopathic medicine in the United States. For more information about naturopathy, visit <http://www.naturopathic.org>.

American Indian Medicine

American Indian medical practices vary from tribe to tribe. In general, American Indian medicine is a community-based system with rituals and practices such as the sweat lodge, herbal remedies, the medicine wheel, the sacred hoop, the “sing,” and shamanistic healing. For example, an ill person may be placed in a small, enclosed sweat lodge while singing or chanting is done outside the lodge. It is believed that toxic substances are drawn out in the sweat of the person inside the lodge. After the ceremony, the ill person may be placed on a cot outside and be prayed over. You can learn more about American Indian Medicine at the Association of American Indian Physicians’ website at <http://www.aaip.com>.

Osteopathic Medicine

Osteopathic medicine was founded in the United States in 1874 by Andrew Taylor Still, a frontier physician who was dissatisfied with the state of medicine at that time. This practice of medicine emphasizes the interrelationship of the body’s nerves, muscles, bones, and organs. The osteopathic philosophy involves treating the whole person, recognizes the body’s ability to heal itself, and stresses the importance of diet, exercise, and fitness with a focus on prevention. For more information about osteopathy, visit the American Osteopathic Association website at <http://www.aoa-net.org>.

TABLE 4.1 CATEGORIES AND TYPES OF ALTERNATIVE AND COMPLEMENTARY THERAPIES

Category of Therapy	Types of Individual Therapies
Herbal medicine and nutritional supplements	Herbal medicine Nutrition and special diet therapies Nutritional supplements
Mind-body therapies	Art therapy Music/sound therapies Guided imagery Hypnosis and hypnotherapy Meditation and relaxation Movement therapies Tai chi and qi gong Yoga
Posture and mobility therapies	Massage and related massage therapies Acupressure
Touch therapies and bodywork	Biofeedback Healing touch Magnet therapy Polarity therapy Reiki
Energetic therapies	Spiritual healing Therapeutic touch
Miscellaneous therapies	Aquatherapy/hydrotherapy Aromatherapy Chanting Chelation therapy Colon therapy Kinesiology Light therapy Pet therapy

ALTERNATIVE AND COMPLEMENTARY THERAPIES

Discussion of all alternative and complementary therapies is beyond the scope of this text. Table 4.1 is a summary of the most commonly used therapies.

Herbal Therapy

Many people use herbs for healing. However, when doing so, the patient should only take herbs under the supervision of a health-care provider. Herbs can aid in healing, but they also can harm. Some of the more common herbs are described in Table 4.2. Figure 4.2 shows echinacea, an herb commonly prepared for use as an immune system booster.

It is important to note that herbal remedies are not foods. They have potent medicinal effects and can interact with prescribed medications and even surgery. This can be problematic, both because herbs are readily available in health food stores and drugstores and because many patients do not tell their doctors or nurses about their herb use. Be sure to assess patients’ use of herbs and supplements, and educate them about the need to inform primary care providers when using herbs.

Relaxation Therapies

Progressive Muscle Relaxation

Progressive muscle relaxation is a simple technique that anyone can learn. It is the process of alternately tensing and relaxing muscle groups. Often this process is performed in a systematic manner, such as from head to toe. The purpose of the technique is to help the participant identify subtle levels of mental and physical tension that accompany mental and emotional stress. When our conscious awareness of the tensions increases, we can learn to relax and thus reduce the effects of stress and tension. The idea is to become aware of the ability to fine tune the relaxation response.

LEARNING TIP

Try using progressive muscle relaxation the next time you are anxious during a nursing examination.

Guided Imagery

Guided imagery is another example of a complementary therapy that many nurses use. Guided imagery involves

TABLE 4.2 COMMON HERBS AND THEIR INTENDED PROPERTIES AND USES

Herb	Purported properties/uses
Aloe vera	Soothing agent, used for skin lesions; toxin absorber
Bee pollen	Increases energy, stamina, and strength
Capsaicin	For tenderness and pain of osteoarthritis, fibromyalgia, diabetic neuropathy, and shingles
Chamomile	For anxiety, stomach distress, and infant colic
Echinacea	Antiviral; used for colds, flu, and other infections
Feverfew	Anti-inflammatory; used for migraine headaches and as an appetite stimulant; promotes menstruation, eliminates worms, suppresses fever
Ginger	For nausea and vomiting, hypertension, and high cholesterol
Ginkgo	May improve memory and help cognitive function in Alzheimer's disease
Kava	For anxiety, insomnia, low energy, muscle tension
St. John's wort	For mild to moderate depression; viral infections, including human immunodeficiency virus (HIV); and herpes

using mental images to promote physical healing or changes in attitudes or behavior (Box 4.1 Guided Imagery). Practitioners may lead patients through visualization exercises or offer instruction in using imagery as a self-help tool. Guided imagery is often used to alleviate stress and to treat stress-related conditions such as insomnia and high blood pressure. People with cancer, acquired immunodeficiency syndrome (AIDS), chronic fatigue syndrome, and other disorders can use specific images to boost the immune system. Guided imagery is often an added layer of therapy for someone who has learned the progressive relaxation skill discussed previously.

A common guided imagery technique begins with a general relaxation process. For those new to the process, it is good to begin with the progressive muscle relaxation as explained above. Guided imagery works best when all the senses are used. This exercise is very basic but gives an idea of how the technique works. When used for healing, many more steps are involved. For additional information read journal articles, books, and Internet sites. It is important to

FIGURE 4.2 Echinacea is a commonly used herb for colds and flu.

note that with this and any of the alternative and complementary therapies, you must have some training and skill before using the technique with patients. Find more on guided imagery at <http://www.healthy.net>; type “guided imagery” into the search window.

LEARNING TIP

When you are stumped on a test question, close your eyes and imagine yourself asking the question of your favorite instructor. Imagine what his or her answer would be.

Box 4.1

Guided Imagery

Assist your patient to progress through the following steps:

- Assume a comfortable position in a quiet environment.
- Close your eyes and keep them closed until the exercise is completed.
- Breathe in and out deeply to the count of four, repeating this step four times.
- When relaxed, think of a favorite peaceful place and prepare to take an imaginary journey there.
- Picture what this place looks like and how comfortable you feel being there.
- Listen to all the sounds; feel the gentle, clean air; and smell the pleasant aromas.
- Continue to breathe deeply, and appreciate the feeling of being in this special place.
- Feel the sense of deep relaxation and peace of this place.
- As you continue to breathe deeply, slowly and gently bring your consciousness back to the setting in this room.
- Slowly and gently open your eyes, stretch, and think about how relaxed you feel.

Biofeedback

Biofeedback might be considered the third tier of learning of progressive relaxation. It is a technique used especially for stress-related conditions such as asthma, migraines, insomnia, and high blood pressure. Biofeedback is a way of monitoring and controlling tiny metabolic changes in one's body with the aid of sensitive machines that provide feedback. (See Box 4.2 Patient Perspective.)

Massage Therapy

Massage is the use of touch to achieve therapeutic results, and may include pressure, friction, and kneading of the body. Massage may be used to relax muscles, reduce anxiety, increase circulation, and reduce pain.

Massage also provides a caring form of touch. In the past, a back massage was a nightly routine for hospitalized patients, helping them relax for sleep. Sadly, today, patients are often not touched except for technical procedures.

You can learn basic massage techniques in nursing school. Or you may also choose to obtain formal massage therapy education in order to practice more advanced techniques.

**SAFETY TIP**

Do not use firm massage on a patient taking anticoagulant agents or a patient with a low platelet level. Tissue injury could cause bleeding.

Aquatherapy

If you have ever sat in a warm tub, you already know how good it can feel when your muscles are tired or aching, and how mentally relaxing it can be. People who suffer from arthritis or other chronic pain understand how warm water can ease their discomfort. Relaxing in water feels good for three reasons: warmth, water movement causing massage, and buoyancy.

Long before there were analgesics, the human body relied on its own naturally occurring, internally generated, painkilling chemicals called endorphins. Through research we now know that warm water stimulates the release of endorphins. They are released in response to both acute and chronic pain. The most recognized methods to release endogenous (naturally occurring) endorphins are physical exercise, acupuncture, and electrical nerve stimulation. Any type of skin stimulation, even the mechanical impact of water, can cause the release of endorphins. However, pain reduction is only part of the healing process. Ultimately, blood flow is what brings nutrients to damaged cells and facilitates healing. When the body is immersed in warm water, the blood vessels nearest the skin relax, allowing more blood to flow. The results are fatigue relief, faster tissue repair, and relief of pain.

**Box 4.2****Patient Perspective****Polly**

I am scared to death of flying. The minute I get on an airplane, I feel jittery, my heart races, and I can't calm down until we are safely back on the ground. Several years ago, I decided to try biofeedback therapy to overcome this fear.

My therapist was wonderful. She immediately put me at ease, and assured me I wasn't a crazy person to be afraid to fly. She then put a temperature sensor on my finger (my hands were usually pretty cold). In her calm, soft voice, she guided me through a relaxation exercise, using imagery and progressive muscle relaxation. By the time we were finished, my hands would be several degrees warmer than when we had started! This showed my vessels were dilating, a sign that my sympathetic nervous system was slowing down its activity. So, I felt calmer. The sensor gave me feedback that told me when my relaxation was working well. We did this every week for a couple of months, until I got really good at warming my hands and relaxing.

Now when I fly, I close my eyes, imagine a peaceful scene and use my relaxation techniques. I still don't like it much, but at least I feel a bit calmer!

Heat and Cold Application

Local application of heat or cold provides additional methods of skin stimulation. A warm compress can soothe sore muscles and dilate vessels in a defined area, bringing healing circulation as well as endorphin release. Ice or a cold gel pack can help numb an area. It also causes overdilated vessels to constrict, yielding relief from pain and throbbing of overstimulated nerve endings. Ice can be helpful on an acute injury and for some types of headaches. Check institution policy before applying heat or cold—a physician's order may be required.

**SAFETY AND EFFECTIVENESS OF ALTERNATIVE THERAPIES**

Safety generally means that the benefits outweigh the risks of a treatment or therapy. If your patient is interested in using an alternative or complementary therapy, first counsel the patient to talk with the primary care provider. The patient also should ask the practitioner of the therapy about its safety and effectiveness. Patients should tell their primary care providers and alternative practitioners about all therapies they are receiving because this information may be used to consider the safety of their entire treatment plan.

The patient should be as informed as possible and continue gathering information even after a practitioner has

Box 4.3**Questions Patients Should Ask Before Starting an Alternative or Complementary Therapy**

1. What will this therapy do for me?
2. What are the advantages of this therapy?
3. What are the disadvantages?
4. What are the side effects?
5. What risks are associated with this therapy?
6. How much will it cost? Will my insurance cover the cost?
7. How long will it take? How many treatments will be necessary?
8. How will it interact with my other therapies and medications?
9. What research has been done on this therapy?

been selected. You can find information about specific therapy or therapies in journal articles and books. (See Box 4.3 Questions Patients Should Ask Before Starting an Alternative or Complementary Therapy.)

ROLE OF THE LPN/LVN

Patients may ask you about the use of an alternative or a complementary therapy. Because the safety and effectiveness of many therapies is still unknown, advising patients presents a challenge. The following steps are suggestions for helping to advise patients regarding the use of these kinds of therapies:

1. Take a close look at the background, qualifications, and competence of the proposed practitioner. Check credentials with a state or local regulatory agency with authority over the area of practice they seek. Are they licensed or certified? By whom?
2. Visit the practitioner's office, clinic, or hospital. Evaluate the conditions of the setting.
3. Talk with others who have used this practitioner.
4. Consider the costs. Are the treatments covered by insurance, or is it direct pay?
5. Discuss use of an alternative or complementary therapy with their primary care provider.

NURSING APPLICATIONS

There are ways to gain confidence with alternative and complementary therapies:

1. Begin by trying one or two of these therapies yourself. Start by choosing a basic therapy such as massage, music, or guided imagery. Follow the guidelines listed in Box 4.3 (Questions Patients Should Ask Before Starting an Alterna-

tive or Complementary Therapy) to make sure it is a safe strategy. Not only will you encounter the benefits firsthand, but you will also come away with a better understanding of what patients experience.

2. Ask your patients if they use any alternative or complementary therapies and what their responses to them have been. Try to eliminate any preconceived notions you might have. Your patients will feel more comfortable mentioning them to you if they feel you understand the treatment and why they decided to use it.
3. If you decide to become involved, get adequate instruction in the therapies before you administer them. Many universities and agencies offer continuing education courses on these therapies, and some nursing schools incorporate alternative and complementary therapies in their skills courses.

If you wish to incorporate alternative and complementary therapies into your practice, be sure to check your state's nurse practice act for any regulations. Discuss them with the patient and his or her primary care provider before using them. If you work for a hospital or other health care institution, also check institutional policy.

As the public understands more about alternative and complementary therapies, you can expect to see even greater demand for these treatments. Nurses have been in the forefront of developing the holistic philosophy that has now become an accepted standard of care.

CRITICAL THINKING**Mr. Jones**

■ Mr. Jones asks you whether he should stop his chemotherapy and try magnet therapy for his prostate cancer. How do you respond?

Suggested answers at end of chapter.

**Home Health Hints**

- When taking a health history, ask the patient or caregiver about the use of complementary or alternative therapies because these may influence the effects or side effects of some prescription medications.
- Be mindful of the importance of complementary and alternative therapies to the patient's health-care belief system.
- Consider the alternative practitioner as part of the patient's health care team.
- Discuss concerns regarding potential interactions with the registered nurse or physician.

SUGGESTED ANSWERS TO**CRITICAL THINKING**■ **Mr. Jones**

As with all medical treatments, it is important to support the established therapy the physician has prescribed. Therefore a good response might be the following:

“Mr. Jones, chemotherapy is an established medical treatment for your condition. There is a lot of evidence for its effectiveness in the medical literature. If you want to supplement your therapy, there may be some other treatments you can add. I suggest that you discuss your feelings about seeking some additional treatments with your doctor.”

REVIEW QUESTIONS

- Which of the following statements best defines a complementary therapy?
 - An alternative treatment that is used in place of a conventional treatment
 - A treatment that is often dangerous and should be avoided
 - A treatment that can be used in addition to a conventional treatment
 - A treatment that is used after conventional treatments have failed
- Which of the following therapies is most likely to use research-based interventions?
 - Naturopathy
 - Osteopathy
 - Allopathy
 - Homeopathy
- A patient with high blood pressure tells his nurse he has been taking a ginger supplement in addition to his prescribed medications at home. What is the best response by the nurse?
 - “Nonprescription supplements can interact with prescription medications. You should not take it any longer.”
 - “Ginger can be effective for hypertension. Be sure to monitor your blood pressure while you are taking it.”
 - “Ginger is a safe supplement because it is a food. It should not interact with your medications.”
 - “You should check with your physician to make sure the ginger doesn’t interact with your other medications before you continue to take it.”
- Which of the following complementary therapies are considered relaxation therapies? Select all that apply.
 - Progressive muscle relaxation
 - Tai chi
 - Biofeedback
 - Homeopathic therapies
 - Guided imagery
- Which of the following statements best describes the most important role of the LPN in alternative and complementary therapies?
 - The LPN should become familiar with and practice at least one alternative or complementary therapy.
 - The LPN should become adept at collecting and reporting data related to patients’ use of alternative and complementary therapies.
 - The LPN should discourage use of alternative and complementary therapies because they can interact negatively with conventional therapies.
 - The LPN does not need to become involved in alternative and complementary therapies.

QUESTIONS TO GUIDE YOUR READING

1. What are the purposes of fluids and electrolytes in the body?
2. What are the signs and symptoms of common fluid imbalances?
3. Which patients are at the highest risk for dehydration and fluid excess?
4. What data should you collect in patients with fluid and electrolyte imbalances?
5. What are therapeutic interventions for patients with fluid and electrolyte disturbances?
6. What are education needs of patients with fluid imbalances?
7. What are common causes, signs and symptoms, and treatments for sodium, potassium, calcium, and magnesium imbalances?
8. Which foods have high sodium, potassium, and calcium content?
9. What are common causes of acidosis and alkalosis?
10. How do arterial blood gases change for each type of acid-base imbalance?

The body undergoes continuous dynamic change. The proper amount of fluid is needed to support these changes and to transport building and waste materials. Approximately 60% of a young adult's body weight is water. Elderly people are less than 50% water, and infants are between 70% and 80% water. Women have less body water because they have more fat than men. Fat cells do not contain water.

In addition to water, body fluids also contain solid substances that dissolve, called solutes. Some solutes are **electrolytes** and some are nonelectrolytes. Electrolytes are chemicals that can conduct electricity when dissolved in water. Examples of electrolytes are sodium, potassium, calcium, magnesium, acids, and bases; these are discussed later in this chapter. Nonelectrolytes do not conduct electricity; for example, glucose and urea.

FLUID BALANCE

Fluids are located both inside the cells (**intracellular** fluid [ICF]) and outside the cells (**extracellular** fluid [ECF]). ECF can be further divided into three types: **interstitial** fluid, **intravascular** fluid, and **transcellular** fluid (Fig 5.1).

Interstitial fluid is the water that surrounds the body's cells and includes lymph. Fluids and electrolytes move between the interstitial fluid and the intravascular fluid, which is the plasma of the blood. Transcellular fluids are those in specific compartments of the body, such as cerebrospinal fluid, digestive juices, and synovial fluid in joints.

FIGURE 5.1 Normal distribution of total body water.

intracellular: intra—within + cellular—cell

extracellular: extra—outside of + cellular—cell

interstitial: inter—between + stial—tissue

intravascular: intra—within + vascular—blood vessel

transcellular: trans—across + cellular—cell

electrolyte: electro—electricity + lyte—dissolve

Control of Fluid Balance

The primary control of water in the body is through pressure sensors in the vascular system, which stimulate or inhibit the release of **antidiuretic** hormone (ADH) from the pituitary gland. A diuretic is a substance that causes the kidneys to excrete more fluid. ADH works in just the opposite way. ADH causes the kidneys to retain fluid. If fluid pressures within the vascular system decrease, more ADH is released and water is retained. If fluid pressures increase, less ADH is released and the kidneys eliminate more water.

Movement of Fluids and Electrolytes in the Body

Fluids and electrolytes move in the body by active and passive transport systems. Active transport depends on the presence of adequate cellular adenosine triphosphate for energy. The most common examples of active transport are the sodium-potassium pumps. These pumps, located in the cell membranes, cause sodium to move out of the cells and potassium to move into the cells when needed.

In passive transport, no energy is expended specifically to move the substances. General body movements aid passive transport. The three passive transport systems are **diffusion**, **filtration**, and **osmosis**.

Diffusion is a process in which the substance moves from an area of higher concentration to an area of lower concentration. If you pour cream into a cup of coffee, the movement of the molecules causes the cream to eventually be dispersed throughout the beverage. If you stir the coffee, this process occurs at a faster rate. Body movement assists passive transport, like stirring the coffee. It causes the diffusion to occur at a faster rate.

Filtration is the movement of both water and smaller molecules through a **semipermeable** membrane. The semipermeable membrane works like a screen that keeps the larger substances on one side and permits only the smaller molecules to filter to the other side of the membrane. Filtration is promoted by **hydrostatic** pressure differences between areas.

Hydrostatic pressure is the force that water exerts; sometimes called water pushing pressure. In the body, filtration is important for the movement of water, nutrients, and waste products in the capillaries. The capillaries serve as semipermeable membranes allowing water and smaller substances to move from the vascular system to the interstitial fluid, but larger molecules and red blood cells remain inside the capillary walls.

Osmosis is the movement of water from an area of lower substance concentration to an area of higher concen-

antidiuretic: anti—against + diuretic—urination

diffusion: diffuse—spread, scattered

filtration: filter—strain through

osmosis: osmo—impulse + osis—condition

semipermeable: semi—half or part of + permeable—passing through

hydrostatic: hydro—water + static—standing

tration. The substances exert an osmotic pressure sometimes called water pulling pressure. The term *osmolarity* refers to the concentration of the substances in body fluids. The normal osmolarity of the blood is between 270 and 300 milliosmoles per liter (mOsm/L).

Another term for osmolarity is *tonicity*. Fluids or solutions can be classified as **isotonic**, **hypotonic**, or **hypertonic**. A fluid that has the same osmolarity as the blood is called isotonic. For example, a 0.9% saline solution (normal saline) is isotonic to the blood and is often used as a solution for intravenous (IV) therapy. A solution that has a lower osmolarity than blood is called hypotonic. When a hypotonic solution is given to a patient, the water leaves the blood and other ECF areas and enters the cells. Hypertonic solutions exert greater osmotic pressure than blood. When a hypertonic solution is given to a patient, water leaves the cells and enters the bloodstream and other ECF spaces.

Fluid Gains and Fluid Losses

Water is very important to the body for cellular metabolism, blood volume, body temperature regulation, and solute transport. Although people can survive without food for several weeks, they can survive only a few days without water.

Water is gained and lost from the body every day. In addition to liquid intake, some fluid is obtained from solid foods. When too much fluid is lost, the brain's thirst mechanism tells the individual that more fluid intake is needed. Older adults are more prone to fluid deficits because they have a diminished thirst reflex and their kidneys do not function as effectively. An adult loses as much as 2500 mL of sensible and insensible fluid each day. Sensible losses are those of which the person is aware, such as urination. Insensible losses may occur without the person recognizing the loss. Perspiration and water lost through respiration and feces are examples of insensible losses.

FLUID IMBALANCES

Fluid imbalances are common in all clinical settings. Elderly people are at the highest risk for life-threatening complications that can result from either fluid deficit, more commonly called **dehydration**, or fluid excess. Infants are at risk for fluid deficit because they take in and excrete a large proportion of their total body water each day.

Dehydration

Although there are several types of dehydration, only the most common type is discussed in this chapter. Dehydration occurs when there is not enough fluid in the body, especially in the blood (intravascular area).

Pathophysiology and Etiology

The most common form of dehydration results from loss of fluid from the body, resulting in decreased blood volume.

isotonic: iso—equal + tonic—strength

hypotonic: hypo—less than + tonic—strength

hypertonic: hyper—more than + tonic—strength

dehydration: de—down + hydration—water

Box 5.1

Common Causes of Dehydration

- Long-term nothing by mouth (NPO) status
- Hemorrhage
- Profuse diaphoresis (sweating)
- Diuretic therapy
- Diarrhea
- Vomiting
- Gastrointestinal suction
- Draining fistulas
- Draining abscesses
- Severely draining wounds
- Systemic infection
- Fever
- Frequent enemas
- Ileostomy
- Cecostomy
- Diabetes insipidus

This decrease is referred to as **hypovolemia**. Hypovolemia occurs when the patient is hemorrhaging or when fluids from other parts of the body are lost. For example, severe vomiting and diarrhea, severely draining wounds, and profuse diaphoresis (sweating) can cause dehydration.

Hypovolemia may also occur when fluid from the intravascular space moves into the interstitial fluid space. This process is called third spacing. Examples of conditions in which third spacing is common include burns, liver cirrhosis, and extensive trauma. See Box 5.1 for Common Causes of Dehydration.

As described previously in this chapter, the body initially attempts to compensate for fluid loss by a number of mechanisms. If the cause of dehydration is not resolved or the patient is not able to replace the fluid, a state of dehydration occurs.

Prevention

You can help prevent dehydration by identifying patients who have the highest risk for developing this condition. High-risk patients include the elderly, infants, children, and any patient who has one of the conditions listed in Box 5.1 (Common Causes of Dehydration). Also see Box 5.2, Gerontological Issues.

Adequate hydration is another important intervention to help prevent dehydration. You should encourage patients to drink adequate fluids. Adults need 30 mL/kg/day of fluids. If a patient is unable to take enough fluid by mouth, alternate routes may be necessary.

Signs and Symptoms

Thirst is the initial symptom experienced by otherwise healthy adults in response to hypovolemia. As the percentage of water in the blood goes down, the percentage of other substances goes up, resulting in the thirst response. As the

hypovolemia: hypo—less than + vol—volume + emia—blood

Box 5.2

Gerontological Issues

As a person ages, total body water decreases from 60% to 50% of total body weight. The age-related decrease in total body water is secondary to an increase in body fat and a decrease in thirst sensation. These factors increase the risk of developing dehydration.

Manifestations of dehydration in an older adult are different from typical manifestations in a younger person, and may include altered mental status, light-headedness, and syncope. These occur because a patient with hypovolemia has an inadequate circulatory volume and, therefore, oxygen supply to the brain.

blood volume decreases, the heart pumps the remaining blood faster but not as powerfully, resulting in a rapid, weak pulse and a low blood pressure. The body pulls water into the vascular system from other areas, resulting in decreased tear formation, dry skin, and dry mucous membranes.

The individual with dehydration has poor skin turgor. Turgor is poor if the skin is pinched and a small “tent” remains (called *tenting*). Temperature increases because the body is less able to cool itself through perspiration. Temperature may not appear elevated in an elderly person because an elder’s normal body temperature is often lower than a younger person’s. Urine output decreases and the urine becomes more concentrated as water is conserved. Dehydration should be considered in any adult with a urine output of less than 30 mL per hour. The urine may appear darker because it is less diluted. The patient becomes constipated as the intestines absorb more water from the feces. A major method of evaluating dehydration is weight loss. A pint of water weighs approximately 1 pound. Symptoms of dehydration in the elderly may be atypical (see Box 5.2, Gerontological Issues).

Complications

If dehydration is not treated, lack of sufficient blood volume causes organ function to decrease and eventually fail. The brain, kidneys, and heart must be adequately supplied with blood (perfused) to function properly. The body protects these organs by decreasing blood flow to other areas. When these organs no longer receive their minimum requirements, death results.

LEARNING TIP

The magic fluid number is 30: Healthy adults should drink approximately 30 mL of fluid per kilogram of body weight per day, and they should urinate at least 30 mL per hour. Of course, this is just a basic rule of thumb and may vary based on the person’s individual circumstances.

Diagnostic Tests

The patient with dehydration usually has an elevated blood urea nitrogen (BUN) level and elevated hematocrit. Both values are increased because there is less water in proportion to the solid substances being measured. The specific gravity of the urine also increases as the kidneys attempt to conserve water, resulting in a more concentrated urine.

Therapeutic Interventions

The goals of therapeutic interventions are to replace fluids and resolve the cause of dehydration. In a patient with moderate or severe dehydration, IV therapy is used. Isotonic fluids that have the same osmolarity as blood are typically administered.

PATIENT SAFETY TIP

Use at least two patient identifiers (neither to be the patient’s room number) whenever administering medications or blood products; taking blood samples and other specimens for clinical testing, or providing any other treatments or procedures. 2006 National Patient Safety Goals from www.jcaho.org

Nursing Process

Nurses can play a major role in identifying and caring for patients who are dehydrated.

ASSESSMENT/DATA COLLECTION. Assess the patient for signs and symptoms of dehydration. All the classic signs and symptoms may not be present.

When assessing an elderly patient for skin turgor (tenting), assess the skin over the forehead or sternum. The skin over these areas usually retains elasticity and is therefore a more reliable indicator of skin turgor. Also check mucous membranes, which should be moist.

Weight is the most reliable indicator of fluid loss or gain. A loss of 1 to 2 pounds or more per day suggests water loss rather than fat loss. The patient in the hospital setting should be weighed every day. The patient in the nursing home or home setting should be weighed at least three times a week if the patient is at risk for fluid imbalance. Weigh the patient before breakfast using the same scale each time. Intake and output are also typically measured (Box 5.3 Cultural Consideration).

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. **Actual or risk for deficient fluid volume related to fluid loss or inadequate fluid intake.** The primary nursing diagnosis and interventions for the patient with dehydration include:

EXPECTED OUTCOME: The patient will be adequately hydrated as evidenced by stable weight, moist mucous membranes, and elastic skin turgor.

Box 5.3

Cultural Considerations

Muslims who celebrate Ramadan fast for 1 month from sunup to sundown. Although the ill are not required to fast, the pious may still wish to do so. Fasting may include not taking fluids and medications during daylight hours. Therefore, the nurse may need to alter times for medication administration, including intramuscular medication. Special precautions may need to be taken to prevent dehydration in Muslim patients.

- Monitor daily weights and input and output (I&O) *so problems can be detected and corrected early.*
- Plan with the patient and other members of the health-care team the type and timing of fluid intake. *Planning with the patient increases the likelihood the plan is followed.*
- Offer fluids often to the confused patient *since he or she may not drink independently.*
- Correct the underlying cause of the fluid deficit, *so it does not recur.*
- Be careful not to overhydrate the patient, *so fluid excess does not occur.*

See Box 5.4, Best Practice Recommendations for Maintaining Oral Hydration in Older People.

EVALUATION. The patient who is adequately hydrated will have elastic skin turgor, moist mucous membranes, and stable weight.

Patient Education

The patient, family, and significant others need to be taught the importance of reporting early signs and symptoms of dehydration to a physician or other health care provider. At home or in the nursing home, infections often cause fever

CRITICAL THINKING

Mrs. Levitt

■ Mrs. Levitt is a 92-year-old widow who has been in a nursing home for 4 years. Today she complains that her urine smells bad and that her heart feels like it is beating faster than usual. You suspect that she is becoming dehydrated. You check her urine and find that it is a dark amber color and has a strong odor. Her heart rate is 98, blood pressure 126/74, respiratory rate 20, and temperature 99.2.

1. What other data should you collect, and what results do you expect?
2. Which interventions should you provide at this time?
3. How should you document your findings?

Suggested answers at end of chapter.

Box 5.4

Best Practice Recommendations for Maintaining Oral Hydration in Older People

- A fluid intake sheet is the best method of monitoring daily fluid intake.
- Urine specific gravity may be the simplest, most accurate method to determine patient hydration status.
- Evidence of a dry furrowed tongue and mucous membranes, sunken eyes, confusion, and upper body muscle weakness may indicate dehydration.
- Regular presentation of fluids to bedridden older people can maintain adequate hydration status.
- Owing to the observation that medication time can be an important source of fluids, fluids should be encouraged at this time.

Source: Adapted from Joanna Briggs Best Practice Recommendations: Maintaining Oral Hydration in Older People, 5:6, 2001.

and sepsis, a serious condition in which the infection invades the bloodstream. The body attempts to decrease the temperature through perspiration. The patient becomes dehydrated as a result and can become increasingly ill.

Fluid Excess

Fluid excess, sometimes called overhydration, is a condition in which a patient has too much fluid in the body. Most of the problems related to fluid excess result from too much fluid in the bloodstream or from dilution of electrolytes and red blood cells.

Pathophysiology and Etiology

The most common result of fluid excess is **hypervolemia** in which there is excess fluid in the intravascular space. Healthy adult kidneys can compensate for mild to moderate hypervolemia. The kidneys increase urinary output to rid the body of the extra fluid.

The causes of fluid excess are related to excessive intake of fluids or inadequate excretion of fluids. Conditions that can cause excessive fluid intake are poorly controlled IV therapy, excessive irrigation of wounds or body cavities, and excessive ingestion of water. Conditions that can result in inadequate excretion of fluid include renal failure, heart failure, and the syndrome of inappropriate antidiuretic hormone. These conditions are discussed elsewhere in this book.

Prevention

One of the best ways to prevent fluid excess is to avoid excessive fluid intake. For example, you should monitor the

hypervolemia: hyper—more than + vol—volume + emia—blood

patient receiving IV therapy for signs and symptoms of fluid excess. In at-risk patients, an electronic infusion pump or a quantity-limiting device, such as a burette, should be used to control the rate of infusion.

Also monitor the amount of fluid used for irrigations. For example, when a patient's stomach is being irrigated (gastric lavage), be sure an excessive amount of fluid is not absorbed.

Signs and Symptoms

The vital sign changes seen in the patient with fluid excess are the opposite of those found in patients with dehydration. The blood pressure is elevated, pulse is bounding, and respirations are increased and shallow. The neck veins may become distended, and pitting **edema** in the feet and legs may be present. The skin is pale and cool. The kidneys increase urine output, and the urine appears diluted, almost like water. The patient rapidly gains weight. In severe fluid excess, the patient develops moist crackles in the lungs, dyspnea, and ascites (excess peritoneal fluid).

Complications

Acute fluid excess typically results in congestive heart failure. As the fluid builds up in the heart, the heart is not able to properly function as a pump. The fluid then backs up into the lungs, causing a condition known as pulmonary edema. Other major organs of the body cannot receive adequate oxygen, and organ failure can lead to death.

Diagnostic Tests

In the patient experiencing fluid excess, the BUN and hematocrit levels tend to decrease from hemodilution. The plasma content of the blood is proportionately increased when compared with the solid substances. The specific gravity of the urine also diminishes as the urinary output increases.

Therapeutic Interventions

Once the patient's breathing has been supported, the goal of treatment is to rid the body of excessive fluid and resolve the underlying cause of the excess. Drug therapy and diet therapy are commonly used to decrease fluid retention.

POSITIONING. To facilitate ease in breathing, the head of the patient's bed should be in semi-Fowler's or high Fowler's position. These positions allow greater lung expansion and thus aid respiratory effort. Once the patient has been properly positioned, oxygen therapy may be necessary (Fig. 5.2).

OXYGEN THERAPY. Oxygen therapy is typically used to ensure adequate perfusion of major organs and to minimize dyspnea. If the patient has a history of chronic obstructive pulmonary disease, such as emphysema or chronic bronchitis, do not administer more than 2 L per minute of oxygen. At higher oxygen doses, the patient may lose the stimulus to breathe and may suffer respiratory arrest.

DRUG THERAPY. Diuretics are frequently administered to rapidly rid the body of excess water. A diuretic is a drug that

FIGURE 5.2 Patient in high Fowler's position with oxygen.

increases elimination by the kidneys. The drug of choice for fluid excess when the patient has adequately functioning kidneys is usually furosemide (Lasix). Furosemide is a loop (high-ceiling) diuretic that causes the kidneys to excrete sodium and water. Sodium (Na^+) and water tend to move together in the body. Potassium (K^+), another electrolyte, is also lost, which can lead to a potassium deficit, which is discussed later in this chapter.

Furosemide may be given by the oral, intramuscular, or IV route. The oral route is used most commonly for mild fluid excess. IV furosemide is administered by a registered nurse (RN) or physician for severe excess. The patient should begin diuresis within 30 minutes after receiving IV furosemide. If not, another dose is given. Strict intake and output should be monitored when a patient is receiving IV furosemide.

DIET THERAPY. Mild to moderate fluid restriction may be necessary, as well as a sodium-restricted diet. In collaboration with the dietitian, a physician prescribes the specific restriction necessary, usually a 1- to 2-g Na^+ restriction for severe excess. Different diuretics result in differing electrolyte elimination. Specific diet therapy depends on the medications the patient is receiving and the patient's underlying medical problems.

Nursing Process

The nurse plays a pivotal role in the care of a patient with fluid excess. Prompt action is needed to prevent life-threatening complications.

ASSESSMENT/DATA COLLECTION. Observe a patient who is at high risk for fluid excess and monitor fluid I&O carefully. If the patient is drinking adequate amounts of fluid (1500 mL per day or more) but is voiding in small amounts, the fluid is being retained by the body.

Assess for edema, which is fluid that accumulates in the interstitial tissues. If the edema is pitting, a finger pressed

edema: swelling

against the skin over a bony area such as the tibia leaves a temporary indentation. For patients in bed, check the sacrum for edema. For patients in the sitting position, check the feet and legs. Also assess lung sounds since excess fluid accumulation in the lungs can cause crackles (see Chapter 29).

As mentioned earlier, weight is the most reliable indicator of fluid gain. A gain of 1 to 2 pounds or more per day indicates fluid retention even though other signs and symptoms may not be present.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. Actual or risk for excess fluid volume related to excessive fluid intake or inadequate excretion of body fluid

EXPECTED OUTCOME: Patient will return to a normal hydration status as evidenced by return to weight that is normal for patient, absence of edema, and clear lung sounds.

- Weigh the patient daily and report any increase to the physician. *Increased weight indicates fluid retention.*
- Implement fluid restriction as ordered to reduce excess. Work with the patient and RN to determine how it should be implemented. For example, if a patient is on a 1000 mL per day fluid restriction, you might plan for 150 mL with each meal, 450 mL to be given to the patient to use as he or she likes during the day, and 100 mL to be used during the night. Be sure to include the patient in your planning, and remember to reserve enough fluid for swallowing medications. Post a sign in the patient's room so other caregivers know how much fluid the patient can have.
- Administer diuretics as ordered, and monitor patient response. Be sure to monitor potassium in patients receiving potassium-losing loop or thiazide diuretics. *Diuretics promote diuresis.*
- Report urinary output below 30 mL per hour to the physician or RN *because it may signify increasing renal complications.*

EVALUATION. If interventions have been effective, the patient will return to his or her normal weight with clear lung sounds and no edema. Many patients must remain on drug and diet therapy after hospital discharge to prevent the problem from recurring.

Patient Education

In collaboration with the dietitian, the patient, family, or other caregiver should be instructed about the fluid and sodium restrictions to prevent further problems (Box 5.5 Nutrition Notes). High-sodium foods to avoid are listed in Box 5.6 Common Food Sources of Sodium.

Teaching caregivers about diuretic therapy is essential to prevent electrolyte imbalances. If a potassium-losing diuretic is prescribed, teach which foods are high in potassium, such as oranges and other citrus fruits, melons, bananas, and potatoes (Box 5.7 Food Sources of Potassium).

The patient's serum potassium level must be periodically monitored by a physician or home-care nurse. If it becomes too low, an oral potassium supplement is needed.

The family or other caregiver also needs to be taught common signs and symptoms of fluid excess that should be reported to a physician or other health-care provider. Of special importance is weight gain. The patient should be weighed at least three times a week in the home or nursing home if he or she is at high risk for fluid excess, and weight gain should be reported.

CRITICAL THINKING

Mr. Peters

■ Mr. Peters is a 32-year-old man with a congenital heart problem. He has been recovering from congestive heart failure and fluid excess. Today, his blood pressure is higher than usual and his pulse is bounding. He is having trouble breathing and presses the call light for your assistance.

1. What should you do first when you assess Mr. Peters's condition?
2. What questions should you ask him?
3. What other assessments should you perform?

Suggested answers at end of chapter.

ELECTROLYTE BALANCE

Natural minerals in food become electrolytes or ions in the body through digestion and metabolism. Electrolytes are usually measured in milliequivalents per liter (mEq/L) or in milligrams per deciliter (mg/dL).

Electrolytes are one of two types: **cations**, which carry a positive electrical charge, and **anions**, which carry a negative electrical charge. Although there are many electrolytes in the body, this chapter discusses the most important ones, including sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}). These electrolytes are maintained in different concentrations inside the cell and outside the cell because of pumps in the cell wall (Fig. 5.3).

ELECTROLYTE IMBALANCES

The two types of electrolyte imbalances are deficit and excess. In general, if a patient experiences a deficit of an electrolyte, the electrolyte is replaced either orally or intravenously. If the patient experiences an excess of the electrolyte, treatment focuses on getting rid of the excess, often by the kidneys. The underlying cause of the imbalance must also be treated.

The most important aspect of nursing care is prevent-

cation: cat—descending + ion—carrying

anion: an—without + ion—carrying

Box 5.5

Nutrition Notes

Reducing Sodium Intake

Many foods, such as dairy products, grain products, and some vegetables, are naturally high in sodium, but the major sources of sodium in the diet are salted and processed foods, including baked goods and condiments. For example, American cheese has more sodium than Cheddar, and cured ham has more than fresh pork. Drinking water may contain significant amounts of sodium, particularly if it is a softened or mineral water. Because of the numerous “hidden” sources of sodium, patients on low-sodium diets benefit from education by a dietician.

The Adequate Intake (AI) of sodium is 1.5 g per day for adults through age 49, 1.3 g for those 50 to 70 years of age, and 1.2 g for those 71 years of age and older. The upper tolerable intake level (UL) for sodium is 2.3 g per day, obtainable in slightly more than teaspoon of salt. None of these amounts applies to individuals losing large amounts of sweat daily or to unacclimatized persons exercising in a hot environment.

Specific definitions for reduced sodium food products have been adopted. Note that serving size is an important variable.

- Salt or sodium free: <5 mg sodium per serving
- Very low sodium: <35 mg sodium per serving (per 100 g if main dish)
- Low sodium: <140 mg sodium per serving (per 100 g if main dish)

ing and assessing electrolyte imbalances. High-risk patients should be identified and monitored carefully. Serum electrolytes are measured on a regular basis. As a general rule, patients should be checked for electrolyte imbalance when there is a change in their mental state (either increased irritability or decreased responsiveness) or when muscle function changes. Patient education is another important nursing role for patients with electrolyte imbalances.

Sodium Imbalances

The normal level of serum sodium is 135 to 145 mEq/L. Because sodium is the major cation in the blood, it helps maintain serum osmolarity. Therefore, sodium imbalances are often associated with fluid imbalances, described earlier in this chapter. Sodium is also important for cell function, especially in the central nervous system. The two sodium imbalances are **hyponatremia** (sodium deficit) and **hypernatremia** (sodium excess).

hyponatremia: hypo—less than + natr—sodium + emia—blood

hypernatremia: hyper—more than + natr—sodium + emia—blood

Box 5.6

Common Food Sources of Sodium*

Food Group	Serving Size	Range (mg)
Breads, all types	1 oz	95–210
Frozen pizza, plain, cheese	4 oz	450–1200
Frozen vegetables, all types	1/2 cup	2–160
Salad dressing, regular fat, all types	2 tbsp	110–505
Salsa	2 tbsp	150–240
Soup (tomato), reconstituted	8 oz	700–1260
Tomato juice	8 oz (~1 cup)	340–1040
Potato chips [†]	1 oz (28.4 g)	120–180
Tortilla chips [†]	1 oz (28.4 g)	105–160
Pretzels [†]	1 oz (28.4 g)	290–560

*The ranges of sodium content for selected foods available in the retail market. This table is provided to exemplify the importance of reading the food label to determine the sodium content of food, which can vary by several hundreds of milligrams in similar foods.

[†]All snack foods are regular flavor, salted.

Source: Agricultural Research Service Nutrient Database for Standard Reference, Release 17 and recent manufacturers label data from retail market surveys. Serving sizes were standardized to be comparable among brands within a food. Pizza and bread slices vary in size and weight across brands.

Note: None of the examples provided was labeled low-sodium.

Hyponatremia

Hyponatremia occurs when the serum sodium level is less than 135 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Many conditions can lead to either an actual or a relative decrease in sodium. In an actual decrease, the patient has inadequate intake of sodium or excessive sodium loss from the body. As the percentage of sodium in the ECF decreases, water is pulled by osmotic pressure into the cells. In a relative decrease, the sodium is not lost from the body but leaves the intravascular space and moves into the interstitial tissues (third spacing). Another cause of a relative decrease occurs when the plasma volume increases (fluid excess), causing a dilutional effect. The percentage of sodium compared with the fluid is diminished.

PREVENTION. Additional sodium is commonly administered to patients at high risk for hyponatremia (Box 5.8 Conditions that Place Patients at Risk for Hyponatremia), usually by the IV route. Individuals who have high fevers or who engage in strenuous exercise or physical labor, especially in the heat, need to replace both sodium and water. Hyponatremia is especially dangerous for the elderly patient.

Box 5.7

Food Sources of Potassium*

Food, Standard Amount	Potassium (mg)	Calories
Sweet potato, baked, 1 potato (146 g)	694	131
Beet greens, cooked, 1/2 cup	655	19
Potato, baked, flesh, 1 potato (156 g)	610	145
Yogurt, plain, nonfat, 8-oz container	579	127
Prune juice, 3/4 cup	530	136
Soybeans, green, cooked, 1/2 cup	485	127
Bananas, 1 medium	422	105
Spinach, cooked, 1/2 cup	419	21
Tomato juice, 3/4 cup	417	31
Tomato sauce, 1/2 cup	405	39
Milk, non-fat, 1 cup	382	83
Pork chop, center loin, cooked, 3 oz	382	197
Apricots, dried, uncooked, 1/4 cup	378	78
Cantaloupe, 1/4 medium	368	47
1%-2% milk, 1 cup	366	102-122
Kidney beans, cooked, 1/2 cup	358	112
Orange juice, 3/4 cup	355	85
Split peas, cooked, 1/2 cup	355	116

*Food sources of potassium ranked by milligrams of potassium per standard amount, also showing calories in the standard amount. (The adequate intake [AI] for adults is 4,700 mg/day potassium.)

Foods are from ARS single nutrient reports, sorted in descending order by nutrient content in terms of common household measures. Food items and weights in the single nutrient reports are adapted from those in 2002 revision of USDA Home and Garden Bulletin No. 72, Nutritive Value of Foods. Mixed dishes and multiple preparations of the same food item have been omitted from this table.

FIGURE 5.3 Extracellular and intracellular electrolytes.

SIGNS AND SYMPTOMS. Unfortunately, the signs and symptoms of hyponatremia are vague and depend somewhat on whether a fluid imbalance accompanies the hyponatremia. The patient with sodium and fluid deficits has signs and symptoms of dehydration (discussed previously). The patient with a sodium deficit and fluid excess has signs and symptoms associated with fluid excess.

In addition, the patient experiences mental status changes, including disorientation, confusion, and personality changes caused by cerebral edema (fluid around the brain). Weakness, nausea, vomiting, and diarrhea may also occur.

COMPLICATIONS. In severe hyponatremia, respiratory arrest or coma can lead to death. The patient who also has fluid excess may develop pulmonary edema, another life-threatening complication.

DIAGNOSTIC TESTS. The primary diagnostic test is to obtain the serum sodium level, which is lower than the normal value when hyponatremia is present. The serum osmolality also decreases in patients with hyponatremia. Other laboratory tests may be affected if the patient

Box 5.8**Conditions that Place Patients at High Risk for Hyponatremia**

Nothing by mouth (NPO)
 Excessive diaphoresis (sweating)
 Diuretics
 Gastrointestinal suction
 Syndrome of inappropriate antidiuretic hormone
 Excessive ingestion of hypotonic fluids
 Freshwater near-drowning
 Decreased aldosterone

experiences an accompanying fluid imbalance. Serum chloride (Cl^-), an anion, is often depleted when sodium decreases because these two electrolytes commonly combine as NaCl (salt in solution, or saline).

THERAPEUTIC INTERVENTIONS. Therapeutic interventions focus on resolving the underlying cause of hyponatremia and replacing the lost sodium. The physician orders IV saline for patients who have hyponatremia without fluid excess.

For patients who have a fluid excess, a fluid restriction is often ordered. Diuretics that rid the body of fluid but do not cause sodium loss may also be used. For patients with cerebral edema, steroids may be prescribed to reduce **intracranial** swelling. I&O are strictly monitored, and the patient is weighed daily.

Hypernatremia

Hypernatremia occurs when the serum sodium level is above 145 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Serum sodium increase may be an actual increase or a relative increase. In an actual increase, the patient receives too much sodium or is unable to excrete sodium, as seen in renal failure. In a relative increase, the amount of sodium does not change but the amount of fluid in the intravascular space decreases. The percentage of sodium (solid) is increased in relationship to the amount of plasma (water).

In mild hypernatremia, most excitable tissues, such as muscle and neurons of the brain, become more stimulated. The patient becomes irritable and has tremors. In severe cases, these tissues fail to respond.

PREVENTION. Prevention of hypernatremia is not as simple as prevention of hyponatremia. Most patients have a sodium excess as a result of an acute or chronic illness. Patients with a potential for electrolyte imbalance must always have their IV fluids carefully regulated.

SIGNS AND SYMPTOMS. Thirst is usually one of the first symptoms to appear. If you eat salty foods, such as potato

chips, the amount of sodium in the body increases and you become thirsty. Other signs and symptoms of hypernatremia are vague and nonspecific until severe excess is present. Like the patient with a sodium deficit, the patient experiencing sodium excess has mental status changes, such as agitation, confusion, and personality changes. Seizures may also occur.

At first, muscle twitches and unusual contractions may be present. Later, skeletal muscle weakness occurs that can lead to respiratory failure. If fluid deficit or fluid excess accompanies the hypernatremic state, the patient also has signs and symptoms associated with these imbalances.

COMPLICATIONS. The patient experiencing severe hypernatremia may become comatose or have respiratory arrest as skeletal muscles weaken.

DIAGNOSTIC TESTS. The most reliable diagnostic test is the serum sodium level, which indicates an increase above the normal level. Serum osmolarity may also increase. If the patient has a fluid imbalance, other laboratory values, such as BUN, hematocrit, and urine specific gravity, are affected (see earlier discussion).

THERAPEUTIC INTERVENTIONS. If a fluid imbalance accompanies hypernatremia, it is treated first. For example, fluid replacement without sodium in a patient with dehydration should correct a relative sodium excess. If the kidneys are not excreting adequate amounts of sodium, diuretics may help if the kidneys are functional. If the kidneys are not functioning properly, dialysis may be ordered. I&O and daily weights are strictly monitored.

The cause of hypernatremia is also treated in an attempt to prevent further episodes of this imbalance. For some patients, a sodium-restricted diet is prescribed.

Potassium Imbalances

Potassium is the most common electrolyte in the ICF compartment. Therefore, only a small amount, 3.5 to 5 mEq/L, is found in the bloodstream. Minimal changes in this laboratory value cause major changes in the body.

Potassium is especially important for cardiac muscle, skeletal muscle, and smooth muscle function. As the serum potassium level falls, the body attempts to compensate by moving potassium from the cells into the bloodstream.

The two potassium imbalances are **hypokalemia** (potassium deficit) and **hyperkalemia** (potassium excess). Hypokalemia is the most commonly occurring imbalance.

Hypokalemia

Hypokalemia occurs when the serum potassium level falls below 3.5 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Most cases of hypokalemia result from inadequate intake of potassium or

hypokalemia: hypo—less than + kal—potassium + emia—
blood

hyperkalemia: hyper—more than + kal—potassium + emia—
blood

intracranial: intra—within + cranial—cranium (skull)

excessive loss of potassium through the kidneys. Hypokalemia most often occurs as a result of medications. Potassium-losing diuretics (e.g., furosemide [Lasix]), digitalis preparations (e.g., digoxin [Lanoxin]), and corticosteroids (e.g., prednisone [Deltasone]) are examples of drugs that cause increased excretion of potassium from the body. Potassium may also be lost through the gastrointestinal (GI) tract, which is rich in potassium and other electrolytes. Severe vomiting, diarrhea, and prolonged GI suction cause hypokalemia (Box 5.9. Patient Perspective). Major surgery and hemorrhage can also lead to potassium deficit.

PREVENTION. Most patients having major surgery receive potassium supplements in their IV fluids to prevent hypokalemia. For patients receiving drugs known to cause hypokalemia, foods high in potassium may prevent a deficit (see Box 5.7, Food Sources of Potassium). Patients receiving digitalis must be closely monitored because hypokalemia can enhance the action of digitalis and cause digitalis toxicity.

SIGNS AND SYMPTOMS. Many body systems are affected by a potassium imbalance. Muscle cramping occurs with either a deficit or an excess of potassium. Vital signs change because the respiratory and cardiovascular systems need potassium to function properly. Skeletal muscle activity diminishes, resulting in shallow, ineffective

respirations. The pulse is typically weak, irregular, and thready because the heart muscle is depleted of potassium. A major danger is an irregular heartbeat (**dysrhythmia**), which can lead to a cardiac arrest. Orthostatic (postural) hypotension may also be present.

The nervous system is usually affected as well. The patient experiences changes in mental status followed by lethargy. The motility of the GI system is slowed, causing nausea, vomiting, abdominal distention, and constipation. Vomiting may further increase potassium loss.

COMPLICATIONS. If not corrected, hypokalemia can result in death from dysrhythmia, respiratory failure and arrest, or coma. The patient must be treated promptly before these complications occur.

DIAGNOSTIC TESTS. The primary laboratory test is to obtain a serum potassium level. The patient's electrocardiogram (ECG) may show cardiac dysrhythmias associated with potassium deficit. In addition to a decrease in the serum potassium level, the patient may have an acid-base imbalance known as metabolic **alkalosis**, which commonly accompanies hypokalemia. In metabolic alkalosis, the serum pH of the blood increases (above 7.45) so that the blood is more alkaline than usual. Acid-base imbalances are discussed later in this chapter.

THERAPEUTIC INTERVENTIONS. The goal of treatment is to replace potassium in the body and resolve the underlying cause of the imbalance. For mild to moderate hypokalemia, oral potassium supplements are given.

For severe hypokalemia, IV potassium supplements are given. Because the kidneys eliminate excess potassium, potassium should be added to IV fluids only after the patient has voided. Potassium is a potentially dangerous drug, especially when administered intravenously. In too high a concentration, it causes cardiac arrest. Only IV solutions which are premixed and carefully labeled should be used. Potassium is *never* given by IV push. The patient's laboratory values must be monitored carefully to prevent giving too much potassium. Administration of IV potassium is done by a registered nurse.

Teach the patient about the side effects of oral potassium and precautions associated with potassium administration. Box 5.10 (Tips for Receiving Oral Potassium Supplements) summarizes the precautions you need to be aware of when giving oral potassium supplements.

Hyperkalemia

Hyperkalemia is a condition in which the serum potassium level exceeds 5 mEq/L. It is rare in a person with healthy kidneys.

PATHOPHYSIOLOGY AND ETIOLOGY. Hyperkalemia may result from an actual increase in the amount of total body potassium or from the movement of intracellular

Box 5.9

Patient Perspective

Patricia

I take hydrochlorothiazide for my high blood pressure. Since it can make me lose potassium, I also take a potassium supplement. So I thought I was all set. But recently I ate something that did not agree with me, and had diarrhea for a couple of days. One morning as I was driving to work, I felt so weak it made me frightened. I drove back home and asked my husband to drive me to work. I arrived safely, but as I walked down the hallway, I again felt so weak I had to sit down. I felt like I could not put one foot in front of the other. I kept thinking “this is all in my head.” I decided maybe I was dehydrated from the diarrhea, so I drank a bottle of Gatorade and a glass of orange juice. Slowly I began to feel a bit better, and made it through the day. After work I had to take my daughter to the doctor, so I asked about my symptoms. I was sent to the lab where I had my potassium level checked and it was 3.1! Normal is 3.5 to 5 mEq/L. Mine must have been even lower before I drank the juice and Gatorade. I learned that I probably lost a lot of potassium because of the diarrhea. I also learned that low potassium made my muscles weak and could have affected my heart function. Next time I have diarrhea, I plan to call my doctor.

dysrhythmia: dys—bad or disordered + rhythmia—measured motion

alkalosis: alkal—alkaline + osis—condition

Box 5.10**Tips for Patients Receiving Oral Potassium Supplements**

- Do not substitute one potassium supplement for another.
- Dilute powders and liquids in juice or other desired liquid to improve taste and to prevent gastrointestinal irritation. Follow manufacturer's recommendations for the amount of fluid to use for dilution, most commonly 4 oz per 20 mEq of potassium.
- Do not drink diluted solutions until mixed thoroughly.
- Do not crush potassium tablets, such as Slow-K or K-tab tablets. Read manufacturer's directions regarding which tablets can be crushed.
- Administer slow-release tablets with 8 oz of water to help them dissolve.
- Do not take potassium supplements if taking potassium-sparing diuretics such as spironolactone or triamterene.
- Do not use salt substitutes containing potassium unless prescribed by the physician.
- Take potassium supplements with meals.
- Report adverse effects, such as nausea, vomiting, diarrhea, and abdominal cramping, to the physician.
- Have frequent laboratory testing for potassium levels as recommended by the physician.

potassium into the blood. Overuse of potassium-based salt substitutes or excessive intake of oral or IV potassium supplements can cause hyperkalemia. Use of potassium-sparing diuretics (e.g., spironolactone [Aldactone]) may also contribute to hyperkalemia. Patients with renal failure are at risk for hyperkalemia because the kidneys cannot excrete potassium.

Movement of potassium from the cells into the blood and other ECF is common in massive tissue trauma and metabolic **acidosis**. Metabolic acidosis is an acid-base imbalance commonly seen in patients with uncontrolled diabetes mellitus. Acid-base imbalances are discussed later in this chapter.

PREVENTION. For patients receiving potassium supplements, hyperkalemia can be prevented by monitoring serum electrolyte values and the patient's signs and symptoms.

SIGNS AND SYMPTOMS. Most cases of hyperkalemia occur in patients who are hospitalized or those undergoing therapeutic interventions for a chronic condition. The classic

manifestations are muscle twitches and cramps, later followed by profound muscular weakness; increased GI motility (diarrhea); slow, irregular heart rate; and decreased blood pressure.

COMPLICATIONS. Cardiac dysrhythmias and respiratory failure can occur in severe hyperkalemia, causing death.

DIAGNOSTIC TESTS. In addition to an elevated serum potassium level, an irregular ECG is associated with hyperkalemia. If the patient also has metabolic acidosis, the serum pH falls below 7.35.

THERAPEUTIC INTERVENTIONS. For mild, chronic hyperkalemia, dietary limitation of potassium-rich foods may be helpful. Potassium supplements are discontinued, and potassium-losing diuretics are given to patients with healthy kidneys. For patients with renal problems, a cation exchange resin, such as sodium polystyrene sulfonate (Kayexalate), is administered either orally or rectally. This drug releases sodium and absorbs potassium for excretion through the feces and out of the body.

In cases in which cellular potassium has moved into the bloodstream, administration of glucose and insulin can facilitate the movement of potassium back into the cells. During treatment of moderate to severe hyperkalemia, the patient should be in the hospital on a cardiac monitor.

Calcium Imbalances

Calcium is a mineral that is primarily stored in bones and teeth. A small amount is found in ECF. The normal value for serum calcium is 9 to 11 mg/dL, or 4.5 to 5.5 mEq/L. Minimal changes in serum calcium levels can have major negative effects in the body.

Calcium is needed for the proper function of excitable tissues, especially cardiac muscle. It is also needed for adequate blood clotting. The two calcium imbalances are **hypocalcemia** and **hypercalcemia**.

Hypocalcemia

Hypocalcemia occurs when the serum calcium falls below 9 mg/dL, or 4.5 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Although calcium deficit can be acute or chronic, most patients develop hypocalcemia slowly as a result of chronic disease or poor intake. The woman who is postmenopausal is most at risk for hypocalcemia. As a woman ages, calcium intake typically declines. The parathyroid glands recognize this decrease and stimulate bone to release some of its stored calcium into the blood for replacement. The result is a condition known as **osteoporosis**, in which bones become porous and brittle and fracture easily. The woman who is

hypocalcemia: hypo—less than + calc—calcium + emia—blood

hypercalcemia: hyper—more than + calc calcium + emia—blood

osteoporosis: osteo—bone + porosis—porous

acidosis: acid—acidic + osis—condition

postmenopausal has a decreased level of estrogens, hormones that help prevent bone loss in the younger woman. Immobility or decreased mobility also contributes to bone loss in many patients. The patients at highest risk for osteoporosis are thin, petite, Caucasian women.

Hypocalcemia can also result from inadequate absorption of calcium from the intestines, as seen in patients with Crohn's disease, a chronic inflammatory bowel disease. An insufficient intake of vitamin D prevents calcium absorption as well. Conditions that interfere with the production of parathyroid hormone, such as partial or complete surgical removal of the thyroid or parathyroids, can also cause hypocalcemia.

Finally, patients with hyperphosphatemia (usually those with renal failure) often experience hypocalcemia. Calcium and phosphate have an inverse relationship. When one of these electrolytes increases, the other tends to decrease and vice versa.

PREVENTION. In the United States, the typical daily calcium intake is less than 550 mg. The adequate intake (AI) of calcium for adults ages 19 to 50 is 1000 mg; the AI for adults over age 50 is 1200 mg.

Hypocalcemia can be prevented in premenopausal and postmenopausal women by consuming calcium-rich foods and by taking calcium supplements. These supplements can be purchased over-the-counter in any pharmacy or large food store. An inexpensive source of calcium for patients who do not require vitamin D supplementation is calcium carbonate (Tums), which provides 240 mg of elemental calcium in each tablet.

Vitamin D supplementation may be required in addition to calcium for homebound or institutionalized patients who have no exposure to the sun. The ultraviolet light causes the skin to manufacture vitamin D.

SIGNS AND SYMPTOMS. Chronic hypocalcemia is usually not diagnosed until the patient breaks a bone, usually a hip. Acute hypocalcemia, which can occur after surgery or in patients with acute pancreatitis, has several signs and symptoms. These include increased and irregular heart rate, mental status changes, hyperactive deep tendon reflexes, and increased GI motility, including diarrhea and abdominal cramping. Two classic signs that can be used to assess for hypocalcemia are Trousseau's sign and Chvostek's sign.

To test for Trousseau's sign, inflate a blood pressure cuff around the patient's upper arm for 1 to 4 minutes. In a patient with hypocalcemia, the hand and fingers become spastic and go into palmar flexion (Fig. 5.4). A positive Chvostek's sign test also indicates calcium deficit. To test for this sign, tap the face just below and in front of the ear. Facial twitching on that side of the face indicates a positive test (Fig. 5.5).

FIGURE 5.4 Trousseau's sign.

COMPLICATIONS. In severe hypocalcemia, seizures, respiratory failure, or cardiac failure can occur and lead to death if not aggressively treated. The patient may have a sudden laryngospasm that will stop air from entering the patient's lungs.

DIAGNOSTIC TESTS. The patient with hypocalcemia has a lowered serum calcium and an abnormal ECG. The parathyroid hormone level may be increased because it stimulates bone to release more calcium into the blood.

THERAPEUTIC INTERVENTIONS. In addition to treating the cause of hypocalcemia, calcium is replaced. For mild or chronic hypocalcemia, oral calcium supplements with or without vitamin D are given. Calcium supplements should be administered 1 to 2 hours after meals to increase intestinal absorption.

For patients with acute or severe hypocalcemia, IV calcium gluconate or calcium chloride is given. When a patient has had thyroid or parathyroid surgery, this medication must be readily available for emergency use.

For patients with hyperphosphatemia, usually those with renal failure, aluminum hydroxide is used to bind the excess phosphate for elimination via the GI tract. As the phosphate decreases, the serum calcium begins to increase closer to normal levels.

Diet therapy is an important part of treatment. Teach the patient, family, or other caregiver which foods are high in calcium (Table 5.1). Many foods today are fortified with

FIGURE 5.5 Chvostek's sign.

LEARNING TIP

You can remember which sign is **CH**vostek's sign because it causes spasm near the **CH**eck.

calcium. Vitamin D foods are also encouraged, especially milk and other dairy products. For patients experiencing difficulty digesting dairy products and those who choose not to use dairy products, special attention must be paid to including other dietary calcium sources.

CRITICAL THINKING

Mrs. Wright

■ Mrs. Wright is a 77-year-old petite Caucasian woman who lives alone at home. She is on a fixed income and rarely eats calcium-rich foods. She recently fell and broke her hip. After surgery she returned home under the care of a home health agency.

1. What made the patient at high risk for a fracture?
2. What would you expect her serum calcium level to have been before the fall?
3. What patient teaching related to diet and calcium supplements should the home health-care nurse include during his or her home visits?

Suggested answers at end of chapter.

Hypercalcemia

Hypercalcemia occurs when the serum calcium is above 11 mg/dL, or 5.5 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Chronic hypercalcemia can result from excessive intake of calcium or vitamin D, renal failure, hyperparathyroidism, cancers, and

overuse or prolonged use of thiazide diuretics, such as hydrochlorothiazide (HydroDiuril). Acute hypercalcemia can occur as an emergency in patients with invasive or metastatic cancers.

PREVENTION. Although many causes of increased calcium cannot be prevented, a person receiving calcium supplements should be monitored carefully. Some women believe that if 2 or 3 tablets a day are helpful, consuming twice that much will help even more. The result can be serum calcium excess. Educating the public about the proper amount of calcium needed each day and the danger of too much calcium is very important.

SIGNS AND SYMPTOMS. Patients who have mild hypercalcemia or a slowly progressing calcium increase may have no obvious signs and symptoms. However, acute hypercalcemia is associated with increased heart rate and blood pressure, skeletal muscle weakness, and decreased GI motility. The patient also has a decreased blood clotting capability.

COMPLICATIONS. In some cases, the patient may experience renal or urinary calculi (stones) resulting from the build-up of calcium. In more severe cases of acute hypercalcemia, the patient may experience respiratory failure caused by profound muscle weakness or heart failure caused by dysrhythmias.

THERAPEUTIC INTERVENTIONS. Patients with severe hypercalcemia should be hospitalized and placed on a cardiac monitor. Unless contraindicated by other conditions, the primary treatment is to give large amounts of fluids and

TABLE 5.1 FOOD SOURCES OF CALCIUM*

Food, Standard Amount	Calcium (mg)	Calories
Fortified ready-to-eat cereals (various), 1 oz	236–1043	88–106

*Food sources of calcium ranked by milligrams of calcium per standard amount; also calories in the standard amount. The bioavailability may vary. (The adequate intake [AI] for adults is 1000 mg/day.)

Source: Adapted from Nutrient Values from Agricultural Research Service (ARS) Nutrient Database for Standard Reference, Release 17. Foods are from ARS single-nutrient reports, sorted in descending order by nutrient content in terms of common household measures. Food items and weights in the single nutrient reports are adapted from those in 2002 revision of USDA Home and Garden Bulletin No. 72, Nutritive Value of Foods. Mixed dishes and multiple preparations of the same food item have been omitted from this table.

promote diuresis. Saline infusions are the most useful solutions to promote renal excretion of calcium.

The physician also discontinues thiazide diuretics if the patient was receiving them and prescribes diuretics that promote calcium excretion, such as furosemide (Lasix). Other drugs that bind with calcium to lower calcium levels may also be used, such as plicamycin (Mithramycin, Mithracin) and D-penicillamine (Cuprimine).

If hypercalcemia is so severe that cardiac problems are present, hemodialysis, peritoneal dialysis, or ultrafiltration may be necessary to cleanse the blood of excess calcium. (See Chapter 37 for discussion of these procedures.)

Magnesium Imbalances

Magnesium and calcium work together for the proper functioning of excitable cells, such as cardiac muscle and nerve cells. Therefore, an imbalance of magnesium is usually accompanied by an imbalance of calcium.

The normal value for serum magnesium is 1.5 to 2.5 mEq/L. The magnesium imbalances are called **hypomagnesemia** and **hypermagnesemia**.

Hypomagnesemia

Hypomagnesemia occurs when the serum magnesium level falls below 1.5 mEq/L. It results from either a decreased intake or an excessive loss of magnesium. Causes of inadequate intake include malnutrition and starvation diets. Patients with severe diarrhea and Crohn's disease are unable to absorb magnesium in the intestines.

One of the major causes of hypomagnesemia is alcoholism, which causes both a decreased intake and an increased renal excretion of magnesium. Certain drugs, such as loop (high-ceiling) and osmotic diuretics, aminoglycosides (e.g., gentamicin), and some anticancer agents (e.g., cisplatin), can increase renal excretion of magnesium.

The signs and symptoms of hypomagnesemia are similar to those for hypocalcemia, including positive Trousseau's and Chvostek's signs, described earlier in this chapter.

The goal of management is to treat the underlying cause and replace magnesium in the body. Magnesium sulfate is administered intravenously. If the serum calcium is also low, calcium replacement is prescribed. The patient is placed on a cardiac monitor because of magnesium's effect on the heart. Life-threatening dysrhythmias can lead to cardiac failure and arrest.

Hypermagnesemia

Hypermagnesemia results when the serum magnesium level increases above 2.5 mEq/L. The most common cause of hypermagnesemia is increased intake coupled with decreased renal excretion caused by renal failure.

Signs and symptoms are usually not apparent until the serum level is greater than 4 mEq/L. Then the signs

and symptoms include bradycardia and other dysrhythmias, hypotension, lethargy or drowsiness, and skeletal muscle weakness. If not treated, the patient experiences coma, respiratory failure, or cardiac failure.

When kidneys are functioning properly, loop diuretics such as furosemide (Lasix) and IV fluids can help increase magnesium excretion. For patients with renal failure, dialysis may be the only option.

ACID-BASE BALANCE

The cells of the body function best when the body fluids and electrolytes are within a very narrow range. Hydrogen (H^+) is another ion that must stay within its normal limits. The amount of hydrogen determines whether a fluid is an acid or base.

An acid is a substance that releases a hydrogen ion. The stronger the acid, the more hydrogen ions are released. A common acid in the body is hydrochloric acid (HCl), which is found in the stomach. A base is a substance that binds hydrogen. A common base in the body is bicarbonate (HCO_3^-). *Alkali* is another word for base.

Sources of Acids and Bases

Acids and bases are formed in the body as part of normal metabolic processes. Acids are formed as end products of glucose, fat, and protein metabolism. These are called fixed acids because they do not change once they are formed. A weak acid, carbonic acid, can be formed when the carbon dioxide resulting from cellular metabolism combines with water. This acid can again change to bicarbonate (a base) and hydrogen and therefore is not a fixed acid.

The ECF maintains a delicate balance between acids and bases. The strength of the acids and bases can be measured by pH. The pH of a solution can vary from 0 to 14, with 7 being neutral, 0 to 6.99 being acid, and 7.01 to 14 being base, also called alkaline. The normal serum pH is 7.35 to 7.45, or slightly alkaline. It must remain in an extremely narrow range to sustain life. A pH lower than 6.9 or higher than 7.8 is usually fatal.

Control of Acid-Base Balance

As discussed in the sections on fluid and electrolyte balance, the body has several ways in which it tries to compensate for changes in the serum pH. Three major mechanisms are used: cellular buffers, the lungs, and the kidneys.

Cellular buffers are the first to attempt a return of the pH to its normal range. Examples of cellular buffers are proteins, hemoglobin, bicarbonate, and phosphates. These buffers act as a type of sponge to "soak up" extra hydrogen ions if there are too many (too acidic) or release hydrogen ions if there are not enough (too alkaline).

The lungs are the second line of defense to restore normal pH. When the blood is too acidic (pH is decreased), the lungs "blow off" additional carbon dioxide through rapid, deep breathing. This reduces the amount of carbon dioxide available to make carbonic acid in the body. If the blood is

hypomagnesemia: hypo—less than + magnes—magnesium
+ emia—blood

hypermagnesemia: hyper—more than + magnes—magnesium
+ emia—blood

too alkaline (pH is increased), the lungs try to conserve carbon dioxide through shallow respirations.

The kidneys are the slowest to respond to changes in serum pH, taking as long as 24 to 48 hours to assist with compensation. The kidneys help in a number of ways, including regulating the amount of bicarbonate (base) that is kept in the body. If the serum pH lowers and becomes too acidic, the kidneys reabsorb additional bicarbonate rather than excreting it so that it can help neutralize the acid. If the serum pH increases and becomes too alkaline, the kidneys excrete additional bicarbonate to get rid of the extra base. The kidneys also buffer pH by forming acids and ammonium (a base).

Acidosis or alkalosis that is corrected for by the body is referred to as compensated. The pH is returned to normal or near normal, but the PCO_2 and HCO_3 are abnormal.

ACID-BASE IMBALANCES

Most acid-base imbalances are caused by a number of acute and chronic illnesses or conditions. The primary treatment for each of the imbalances is to manage the underlying cause, which corrects the imbalance. The role of the nurse is to identify patients at risk and monitor laboratory test values for significant changes.

The laboratory tests that are used to evaluate acid-base balance are called arterial blood gases (ABGs). As the name implies, the blood sample that is analyzed must be from an artery rather than a vein. The femoral, brachial, and radial arteries are most often used to obtain the sample. Table 5.2 lists ABG values and what they indicate.

The two broad types of acid-base imbalance are acidosis and alkalosis. Each of these types can occur suddenly, which is called an acute imbalance, or develop over a long period, referred to as a chronic imbalance.

When the serum pH falls below 7.35, the patient has acidosis because the blood becomes more acidic than normal. Too much acid in the body or too little base causes acidosis. Acidosis can be divided into two types: respiratory and metabolic. Respiratory acidosis is caused by problems occurring in the respiratory system. Metabolic acidosis is the result of problems in the rest of the body.

When the serum pH increases above 7.45, the patient

has alkalosis because the blood becomes more alkaline or basic. Alkalosis is caused by too little acid in the body or too much base. It can also be divided into two types: respiratory alkalosis and metabolic alkalosis.

Respiratory Acidosis

As the name indicates, the primary cause of this type of acidosis is respiratory problems. Carbon dioxide is not adequately “blown off” during expiration, causing a build-up of carbon dioxide in the blood. As mentioned earlier, carbon dioxide mixes with water to create a weak acid in the body, thus increasing the acidity of the blood.

Acute respiratory acidosis is caused by hypoventilation, usually as a result of an acute flare up of chronic respiratory disease, drugs, or neurological problems that depress breathing. Patients with chronic respiratory disease may have chronic respiratory acidosis.

The signs and symptoms of respiratory acidosis involve the central nervous system and the musculoskeletal system. As carbon dioxide increases, mental status is altered, progressing from confusion and lethargy to stupor and coma if not treated. The lungs are not able to get rid of excess carbon dioxide. Instead respirations become more depressed and shallow as muscle weakness worsens.

The treatment of respiratory acidosis is aggressive management of the underlying respiratory problem, discussed in the respiratory unit (Unit Seven) of this text.

Metabolic Acidosis

Metabolic acidosis can result from too much acid in the body (usually fixed acids) or too little bicarbonate in the body. Uncontrolled diabetes mellitus and end-stage renal failure are the two most common causes of metabolic acidosis resulting from increased fixed acids.

The GI tract is rich in bicarbonate. Patients experiencing severe diarrhea or prolonged nasointestinal suction are at high risk for metabolic acidosis as a result of bicarbonate (base) loss. The serum pH decreases as the bicarbonate level decreases (see Table 5.2). As mentioned earlier in the discussion on hyperkalemia, serum potassium tends to increase in the presence of metabolic acidosis. Excess hydrogen in the ECF moves into the cells in exchange for potassium, which leaves the cells and enters the blood. In a sense, this is a way of compensating for the acidotic state.

TABLE 5.2 ARTERIAL BLOOD GAS VALUES AND CHANGES IN ACID-BASE IMBALANCES

	pH	PCO_2	HCO_3
Normal values	7.35–7.45	32–45 mm Hg	20–26 mEq/L
Respiratory acidosis	↓	↑	Normal
Respiratory acidosis with compensation	Nearly normal	↑	↑
Respiratory alkalosis	↑	↓	Normal
Respiratory alkalosis with compensation	Nearly normal	↓	↓
Metabolic acidosis	↓	Normal	↓
Metabolic acidosis with compensation	Nearly normal	↓	↓
Metabolic alkalosis	↑	Normal	↑
Metabolic alkalosis with compensation	Nearly normal	↑	↑

The signs and symptoms are similar to those associated with respiratory acidosis, with the exception of the respiratory pattern. To help compensate for the acidotic state, the lungs get rid of extra carbon dioxide through Kussmaul's respirations. Kussmaul's respirations are deep and rapid and can occur only in patients with healthy lungs.

The treatment for the patient with metabolic acidosis is management of the underlying disease or condition. Information about disease management, such as diabetes, is found elsewhere in this book.

Respiratory Alkalosis

Respiratory alkalosis occurs when there is excessive loss of carbon dioxide through **hyperventilation**. Patients may hyperventilate when they are severely anxious or fearful. Patients who hyperventilate have rapid shallow respirations, are light-headed, and may become confused. The heart rate increases and the pulse becomes weak and thready. The serum pH is increased and the PaCO_2 is very low. Mechanical ventilation can also cause respiratory alkalosis, and it can occur as a result of being at high altitudes. You may have experienced this while deep breathing during a pulmonary examination.

Respiratory alkalosis is treated by having patients hold their breath or rebreathe their own carbon dioxide with the use of either a rebreathing mask or a plain paper bag. The underlying cause must also be treated.

hyperventilation: hyper—more than ventilation—air

Metabolic Alkalosis

Metabolic alkalosis results from excessive ingestion of bicarbonate or other bases into the body or loss of acids from the body. Overuse or abuse of antacids or baking soda (sodium bicarbonate) can lead to metabolic alkalosis. Because the stomach contains hydrochloric acid, prolonged vomiting or nasogastric suction can cause loss of acid and also lead to metabolic alkalosis.

The serum pH is increased, as is bicarbonate. As discussed under potassium imbalances, the serum potassium decreases. Hydrogen from the ICF moves into the blood in exchange for potassium, which moves from the blood into the cells. This is one way that the body works to keep an acid-base balance. Hypocalcemia may also accompany hypokalemia.

The signs and symptoms of metabolic alkalosis are related to hypokalemia and hypocalcemia rather than the alkalotic state itself. Treatment involves identifying the underlying cause and managing it as quickly as possible.

Compensation

If the respiratory system is compensating for metabolic acidosis the PCO_2 will be decreased to return the pH to normal or near normal. In a similar fashion, if there is metabolic alkalosis, the breathing pattern will change to conserve CO_2 and restore the pH level. In chronic respiratory conditions, the kidneys conserve HCO_3 to buffer in the case of respiratory acidosis and excrete HCO_3 in cases of chronic respiratory alkalosis.

REVIEW QUESTIONS

- Which of the following are functions of sodium in the body? Choose all responses that are correct.
 - Maintenance of serum osmolarity
 - Formation of bones and teeth
 - Control of bronchodilation
 - Control of serum glucose
 - Maintenance of cellular function
- A 93-year-old patient with diarrhea and dehydration is admitted to the hospital from an extended care facility. For which of the following symptoms of dehydration should the nurse assess?
 - Pale-colored urine, bradycardia
 - Disorientation, poor skin turgor
 - Decreased hematocrit, hypothermia
 - Lung congestion, abdominal discomfort
- Which patient is most at risk for fluid excess?
 - An infant with pneumonia
 - A teen with multiple injuries following an automobile accident
 - A middle-aged man who has just had surgery
 - An elderly patient receiving IV therapy
- Which of the following is the most reliable way to monitor a patient's fluid status?
 - I&O
 - Skin turgor
 - Daily weights
 - Lung sounds
- When caring for a patient with fluid excess, which of the following interventions will help relieve respiratory distress?
 - Elevate the head of the bed.
 - Encourage the patient to cough and deep breathe.
 - Increase fluids to promote urine output.
 - Perform percussion and postural drainage.
- A patient is being discharge following hospitalization for fluid imbalance. Which instruction by the nurse should take priority?
 - "Weigh yourself every day and report changes."
 - "Call your doctor immediately if you feel weak or fatigued."
 - "Drink eight glasses of water a day."
 - "Measure everything you drink, and measure how much you urinate each day."

7. A patient is being treated for hypokalemia. When evaluating his response to potassium replacement therapy, which of the following changes in his assessment should you observe for?
 - a. Improving visual acuity
 - b. Worsening constipation
 - c. Decreasing serum glucose
 - d. Increasing muscle strength
8. A patient is being placed on a potassium-losing diuretic. Which foods are high in potassium and should be recommended to the patient by the nurse? Choose all responses that are correct.
 - a. Bread
 - b. Potato
 - c. Tomato juice
 - d. Banana
 - e. Gelatin
9. Which patient is at risk for respiratory acidosis?
 - a. The patient with uncontrolled diabetes mellitus.
 - b. The patient with chronic pulmonary disease.
 - c. The patient who is very anxious.
 - d. The patient who overuses antacids.
10. Which pH value represents acidosis?
 - a. 7.26
 - b. 7.35
 - c. 7.4
 - d. 7.49

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Levitt

1. Check her weight and compare it with her previous weights. Dehydration is associated with weight loss. Monitor mental status for disorientation. Check skin turgor for tenting. Continue to monitor vital signs.
2. Encourage increased fluid intake; notify the RN or physician if Mrs. Levitt is unable to take in additional fluids or if the fluids do not normalize assessment findings.
3. S: "My urine smells bad, and my heart is beating fast."
O: Pt's urine is dark amber and strong smelling. VS P 98, BP 126/74, RR 20, T 99.2. Fluids encouraged. RN notified.

■ Mr. Peters

1. Raise the head of the bed to assist breathing.
2. Questions to ask might include the following: When

did your symptoms begin? Have you had these symptoms before? (If the patient is too dyspneic to answer, do not ask many questions.)

3. Check breath sounds for crackles, observe for dependent edema and ascites, observe for distended neck veins, assess skin for color and temperature, check weight and compare with previous weight, and monitor I&O.

■ Mrs. Wright

1. The patient is at high risk for osteoporosis, and thus fracture, because she is an elderly, petite, Caucasian woman.
2. Her serum calcium levels would be low or low normal, since the body will mobilize calcium in the bones in an attempt to maintain serum calcium levels.
3. Teach her about consuming foods high in calcium, the need to be compliant with taking her calcium supplements, and to take them 1 to 2 hours after meals for best absorption by the body.

Nursing Care of Patients Receiving Intravenous Therapy

LYNN DIANNE PHILLIPS

KEY TERMS

bolus (BOH-lus)

cannula (KAN-yoo-lah)

extravasation (eks-TRA-vah-ZAY-shun)

intravenous (IN-trah-VEE-nus)

phlebitis (fla-BYE-tis)

QUESTIONS TO GUIDE YOUR READING

1. How is the practice of intravenous therapy regulated?
2. What are the indications for intravenous therapy?
3. What factors influence the condition, size, and long-term use of veins?
4. What steps are used for insertion of an intravenous catheter?
5. What techniques can be used for visualization of difficult veins?
6. How will you know if your nursing interventions to prevent complications of intravenous therapy are effective?
7. How will you calculate a drip rate for a patient receiving a parenteral solution?
8. What is the difference between isotonic, hypertonic, and hypotonic solutions?
9. How would you explain the basic differences between central venous access devices: percutaneous catheters, peripherally inserted central catheters, tunneled catheters, and implanted ports?

CASE STUDY

Mrs. Brown, 85 years old, is admitted to the hospital with weight loss of 6% of her total body weight due to gastroenteritis. Her blood pressure is 102/80, pulse is 96 beats per minute, and respirations are 14 per minute. Her physical assessment shows decreased turgor over the sternum, dry, cracked lips, and a weak, thready pulse. The physician has ordered an IV to be started of 5% dextrose and 0.45% sodium chloride at 100 mL per hour. As you read this chapter, reflect on the challenges of fluid volume deficit in the elderly and initiation of infusion therapy.

Intravenous (IV) therapy is the administration of fluids or medication via a needle or catheter (sometimes called a **cannula**) directly into the bloodstream. The practice of IV therapy is governed by state nurse practice acts as statutory laws. Some states now include IV therapy within the licensed practical nurse (LPN) and licensed vocational nurse (LVN) roles. The practice acts define the parameters within which individuals are qualified and licensed to practice nursing in a particular state and serve to codify the nursing obligation to act in the best interest of society.

Various specialty organizations, such as the Infusion Nurses Society (INS, <http://www.ins1.org>), set forth guidelines for standards of practice for infusion therapy. The Centers for Disease Control and Prevention (CDC, <http://www.cdc.gov/niosh/2000-108.html>) provides information on needlestick injuries, which can occur during initiation of IV therapy. The Occupational Safety and Health Administration (OSHA, <http://www.osha.gov>) oversees workplace safety including safety issues related to IV therapy, and the American Society for Parenteral and Enteral Nutrition (ASPEN, <http://www.clinnutr.org>) provides resources related to IV nutrition.

INDICATIONS FOR INTRAVENOUS THERAPY

Patients receive a variety of substances via IV therapy, including fluids, electrolytes, nutrients, blood products, and medications. Patients can receive life-sustaining fluids, electrolytes, and nutrition when they are unable to eat or drink adequate amounts. The IV route also allows rapid delivery of medication in an emergency. Many medications are faster acting and more effective when given via the IV route. Other medications can be administered continuously via IV to maintain a therapeutic blood level. Patients with anemia or blood loss can receive lifesaving IV transfusions. Patients who are unable to eat for an extended period can have their nutritional needs met with total parenteral nutrition (TPN).

When a patient needs intermittent rather than continuous IV therapy, access to the venous system can be provided by a locking device whereby an IV catheter is inserted and

capped with a port or cap that seals after each use. (See the Intermittent Infusion section later in this chapter.) This is to provide access to the bloodstream for intermittent or emergency medications, without the need for continuous fluid infusion.

TYPES OF INFUSIONS

Continuous Infusion

In a continuous infusion, the physician orders the infusion in milliliters (mL) to be delivered over a specific amount of time; for example, 100 mL per hour. The infusion is kept running constantly until discontinued by the physician. An IV controller or roller clamp allows the solution to infuse at a constant rate.

Intermittent Infusion

Intermittent IV lines are “capped off” with an injection port and used only periodically. Thus intermittent IV therapy is administered at prescribed intervals. You must ensure that an intermittent catheter is patent (not occluded with a clot) before injecting a drug or solution. Draw back with a syringe to check for backflow of blood before injection.

Sites that are capped with an injection cap are called saline or heparin locks. A diluted solution of heparin, an anticoagulant, may be used to “flush” the catheter after each use and every 8 hours or according to institution policy. However, many institutions are changing this practice and specifying saline solution for flushes, which is believed to be safer and less costly. In 2000 Standards of Practice,¹ the INS recommends the use of saline (0.9% sodium chloride) solution for maintaining peripheral locking devices, whereas heparin is recommended for central venous access devices. Check your institution’s policy for specific guidelines.

Regular flushing ensures catheter patency. Flushing also prevents the mixing of incompatible medications and solutions. Positive pressure must be maintained in the lumen of the catheter during the administration of the flush solution to prevent a backflow of blood into the catheter lumen. This is accomplished by continuing to slowly inject the saline or heparin solution even as the catheter is withdrawn from the cap. Intermittent catheters should be flushed after administration of IV medication, blood sampling, and conversion from continuous to intermittent IV therapy.

If resistance is met while a catheter is being flushed, a clot may be occluding the catheter. Do not exert pressure on the syringe plunger in an attempt to restore patency because doing so may dislodge the clot into the vascular system or rupture the catheter.

Some medications that are given intermittently are not compatible with heparin and therefore are given by the SASH method as follows:

1. Flush with Saline solution.
2. Administer the medication.
3. Flush with Saline solution.
4. Flush with Heparin solution.

intravenous: intra—within + venous—vein

cannula: tube or sheath

NURSING CARE TIP

Always check for catheter patency before injecting any substance into the circulatory system.

Bolus

A **bolus** drug (sometimes called an IV push or IVP drug) is injected slowly via a syringe into the IV site or tubing port. It provides a rapid effect because it is delivered directly into the patient’s bloodstream. Bolus drugs can be dangerous if they are given incorrectly, and a drug reference should always be checked to determine the safe amount of time over which the drug can be injected. IV push drugs are usually administered by registered nurses (RNs) and are not within the scope of practice of the LPN/LVN in many states. However, you should be aware of the drugs being given so you can assist in observing the patient for desired or adverse effects.

Piggy Back/Secondary Infusion

Some IV medications, such as antibiotics, need to be infused over a short period of time. For example, an antibiotic may be mixed with 50 mL of dextrose solution and infused over 30 minutes. This may be done as an intermittent infusion, as described above. If the patient already has a primary continuous IV infusing, the antibiotic (secondary) infusion can be “piggybacked” into the primary IV line. In order for the piggyback medication to infuse, it must hang higher than the primary infusion (Fig. 6.1). Piggyback medications can be infused using either gravity or a controller. The medication in the piggyback must be compatible with any other solution that is in the primary IV tubing.

FIGURE 6.1 Gravity drip setup with piggyback infusion.

To administer the same amount using a set with 15-drop factor tubing, a flow rate of 25 drops per minute is necessary. Check the label on the administration set to determine how many drops per milliliter (drop factor) are delivered by the set. Sets delivering 10, 15, or 20 drops per minute are called macrodrip sets, and are used for fluids that need to be infused more quickly. Sets delivering 60 drops per milliliter are called minidrip or microdrip sets and are used for solutions that need to be infused more slowly.

To determine drops per minute of an IV solution, the nurse needs to know the amount of fluid to be given in a specified time interval and the drop factor of the administration set to be used. The formula for determining drops per minute is as follows:

$$\frac{\text{mL}}{\text{hr or hrs}} \times \frac{1 \text{ hr}}{60 \text{ min}} \times \frac{\text{gtt}}{1 \text{ mL}} = \text{gtt per minute}$$

If a controller or pump is being used, the calculation is even easier:

$$\frac{\text{Total mL}}{\text{Total number of hours}} = \text{mL per hour}$$

Sample problems:

- Order:** Zinacef 1 g in D5W 100 mL over 1 hour
- Drop factor:** 10 gtt/mL

METHODS OF INFUSION

Gravity Drip

Gravity can be used to drip a solution into a vein (see Fig. 6.1). The solution is positioned about 3 feet above the infusion site. If it is positioned too high above the patient, the infusion may run too fast. Positioned too low, it may run too slowly. Flow is controlled with a roller, screw, or slide clamp. A mechanical flow device can be added to achieve accurate delivery of fluid with minimal deviation.

Calculating Drip Rates

When using a gravity set, the nurse must calculate the drops (gtt, *L. guttae*) required per minute to deliver fluid at the ordered rate. Commercial parenteral administration sets vary in the number of drops delivering 1 mL. Sets typically deliver 10, 15, 20, or 60 drops per milliliter of fluid. For example, to deliver 100 mL per hour using a set with 10-drop factor tubing, a flow rate of 17 drops per minute is necessary.

bolus: mass or lump

100 mL	1 hr	10 gtt	= 16.66 or 17 gtt per minute
1 hr	60 min	1 mL	

Order: Normal saline 1000 mL over 8 hours

$$\frac{1000 \text{ mL}}{8 \text{ hours}} = 125 \text{ mL per hour}$$

Factors Affecting Flow Rates

CHANGE IN CATHETER POSITION. A change in the catheter's position may push the bevel either against the wall of the vein, which will decrease the flow rate, or away from the wall of the vein, which may increase the flow rate. Careful taping and avoidance of joint flexion above the site minimizes this problem. Patients may need to be reminded to keep flexion to a minimum when an IV is placed near a joint.

HEIGHT OF THE SOLUTION. Because infusions flow by gravity, a change in the height of the infusion bag or bottle or a change in the level of the bed can increase or decrease the flow rate. The flow rate increases as the distance between the solution and the patient increases. A patient may alter the flow rate greatly simply by standing up. The ideal height for a solution is 3 feet above the level of the heart.

PATENCY OF THE CATHETER. A small clot or fibrin sheath may occlude the catheter lumen and decrease or stop the flow rate. Clot formation can result from irritation, increased venous pressure, or backup of blood into the line. Avoid use of a blood pressure cuff on the affected extremity because of the resulting transient increase in venous pressure. A regular flush schedule helps maintain patency. NEVER exert pressure with a saline or heparin flush in an attempt to restore patency; doing so may dislodge a clot into the vascular system or rupture the catheter.

Electronic Control Devices

Electronic pumps and controllers regulate the rate of infusion (Fig. 6.2). Controllers measure the amount of solution delivered and depend on gravity to deliver the infusion. Pumps use positive pressure to deliver the solution. Pumps are often used for central lines to help overcome the high pressure of the central circulation.

FIGURE 6.2 Infusion pump.

Pumps and controllers are used for the infusion of precise volumes of solution. Institution policy often dictates use of controllers for infusion of potent medications, such as heparin, concentrated morphine, and chemotherapy solutions, and for very fast or slow rates. Some electronic infusion devices are portable and are designed to be worn on the body. These are called ambulatory infusion devices. It is important to know the type of pump being used and its manufacturer's guidelines.

Filters

It is recommended by the Infusion Nursing Standards of Practice that filters be used routinely for the delivery of IV therapy. Filters fit onto the IV tubing between the solution and the insertion site and remove contaminants from the IV fluid. A 0.22- μm filter removes bacteria and fungi from IV fluids. Check institution policy and manufacturers' guidelines for use of filters.

TYPES OF FLUIDS

Fluids and electrolytes administered intravenously pass directly into the plasma space of the extracellular fluid compartment. They are then absorbed based on the characteristics of the fluid and the hydration status of the patient. The most commonly infused fluids are dextrose and sodium solutions. These are called crystalloid solutions.

Dextrose Solutions

Dextrose in water is available in many concentrations and provides carbohydrates in a readily usable form. Solutions of 2.5%, 5%, and 10% dextrose in water are used for continuous peripheral infusions. Concentrations of 20% and above must be given into a large vein and are infused via a central line. These high concentrations can be used for treating hypoglycemia or in combination with TPN because they supply a large number of calories.

Sodium Chloride Solutions

Sodium chloride solutions are available in concentrations of 0.25%, 0.33%, 0.45%, 0.9% (normal saline), 3%, and 5%. Combination dextrose and sodium chloride solutions, such as 5% dextrose with 0.45% sodium chloride (often referred to as "D5 and a half"), are commonly used.

Electrolyte Solutions

Electrolyte solutions are used to replace lost fluids and electrolytes. Lactated Ringer's solution is an example of a premixed electrolyte solution. Potassium is an electrolyte that is commonly added to a solution to replace deficits. Potassium is limited to 10 to 20 mEq per hour and is never administered as an IV bolus because of the risk of cardiac complications and death with rapid infusion.

Tonicity of IV Solutions

Intravenous fluids may be classified as isotonic, hypotonic, or hypertonic. (See Chapter 5 to review these concepts.)

Isotonic fluids have the same concentration of solutes to water as body fluids. Hypertonic solutions have more solutes (i.e., are more concentrated) than body fluids. Hypotonic solutions have fewer solutes (i.e., are less concentrated) than body fluids. Water moves from areas of lesser concentration to areas of greater concentration. Therefore, hypotonic solutions send water into areas of greater concentration (cells), and hypertonic solutions pull water from the more highly concentrated cells.

Isotonic Solutions

Normal saline (0.9% sodium chloride) solution is an isotonic solution that has the same tonicity as body fluid. When administered to a patient requiring water, it neither enters cells nor pulls water from cells; it therefore expands the extracellular fluid volume. A solution of 5% dextrose in water (D5W) is also isotonic when infused, but the dextrose is quickly metabolized, making the solution hypotonic.

Hypotonic Solutions

Hypotonic fluids are used when fluid is needed to enter the cells, as in the patient with cellular dehydration. They are also used as fluid maintenance therapy. An example of a hypotonic solution is 0.45% sodium chloride solution.

Hypertonic Solutions

Examples of hypertonic solutions include 5% dextrose in 0.9% sodium chloride and 5% dextrose in lactated Ringer’s solution. Hypertonic solutions are used to expand the plasma volume, as in the hypovolemic patient. They are also used to replace electrolytes.

 **INTRAVENOUS ACCESS**

Intravenous therapy can be administered into the systemic circulation via the peripheral or central veins. Peripheral veins lie beneath the epidermis, dermis, and subcutaneous tissue of the skin. They usually provide easy access to the venous system. Central veins are located close to the heart. Special catheters that end in a large vessel near the heart are called central lines. This chapter primarily discusses peripheral catheters. The definitions of the various central venous access devices are discussed briefly at the end of the chapter.

 **ADMINISTERING PERIPHERAL INTRAVENOUS THERAPY**

Starting a Peripheral Line

The Phillips 15-step approach to starting a peripheral line offers an organized and thorough method, as described in Table 6.1. Remember to always check your institution’s policy before performing any procedure.

Check Physician’s Order

A physician’s order is necessary to initiate IV therapy. According to the INS, a prescriber’s verbal order written by a nurse in the medical record in a hospital setting should be

TABLE 6.1 PHILLIPS 15-STEP METHOD FOR STARTING A PERIPHERAL LINE

Phase	Step
Precatheterization (preparation)	1. Check physician’s order.
	2. Wash your hands for 15 to 20 seconds.
	3. Prepare the equipment.
	4. Assess the patient.
	5. Select the site and dilate the vein.
Catheterization (venipuncture)	6. Select the needle (catheter).
	7. Put on gloves.
	8. Prepare the site.
	9. Enter the vein using the direct or indirect method.
	10. Stabilize the catheter with tape, and apply a dressing.
Postcatheterization (cleanup)	11. Label the site, tubing, and bag.
	12. Properly dispose of used equipment.
	13. Educate the patient.
	14. Calculate the drip rate, if applicable.
	15. Document the procedure.

Source: Phillips, L: Manual of IV Therapeutics, ed. 4. F.A. Davis, Philadelphia, 2005.

signed by the prescriber within an appropriate time (according to institution policy). The order should include solution, volume, rate, and route. If medication is ordered, the order should also include the medication, dosage, and frequency.

Wash Hands

Before beginning the procedure, wash your hands for 15 to 20 seconds. Wear gloves when inserting the catheter and any time you have a risk of exposure to body fluid.

Gather Equipment

Obtain the following equipment and inspect it for integrity:

- Clean gloves
- Prepping solution (70% isopropyl alcohol, povidone-iodine [Betadine], or chlorhexidine)
- Sterile 2-inch by 2-inch gauze pads
- 1/2-inch or 1-inch tape
- Disposable latex (or nonlatex, in the case of allergy) tourniquet
- Catheters (over-the-needle sizes 18, 20, 22, and 24 are the most common)
- Appropriate administration set
- IV solution (inspected for puncture holes, visible contamination, and expiration date)
- prn device (locking device) if the catheter is maintained as a saline lock
- IV pole if needed

Some institutions have IV start kits that contain a tourniquet, gloves, alcohol, bandages, and prepping solution.

Once the solution is verified and inspected for integrity, the administration set is spiked to puncture the solution bag or bottle, taking care to keep the spike and the bag opening sterile. The administration set is then primed with the IV solution ordered by the physician.

PATIENT SAFETY TIP

Comply with current Centers for Disease Control and Prevention (CDC) hand hygiene guidelines (2006 National Patient Safety Goals from www.jcaho.org).

The CDC recommends the following for hand hygiene²: Decontaminate hands after removing gloves

- Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with antimicrobial soap and water.
- Antimicrobial-impregnated wipes may be considered as an alternative to washing hands with nonantimicrobial soap and water.
- When using an alcohol-based hand gel, apply product to palm of one hand and rub hands together, covering all surfaces of hands and fingers until hands are dry.

Assess and Prepare Patient

Several factors should be considered before venipuncture. The type of solution, condition of vein, duration of therapy, catheter size needed, patient age, patient activity, presence of disease or previous surgery, presence of a dialysis shunt or graft, medications being taken by the patient (such as anticoagulants), and allergies must be assessed before a venipuncture. Provide privacy for the procedure, explain the procedure to the patient, and evaluate the patient's knowledge of the procedure by talking with the patient before assessing the upper arms for suitable venipuncture sites.

Select Site and Dilate Vein

Proper vein selection is important to accommodate the prescribed therapy and to minimize potential complications (Box 6.1 Considerations for Vein Selection). Avoid use of an arm on the side where the patient has had a mastectomy, has a dialysis access site, or is scheduled for a surgical procedure. The patient's condition and diagnosis, age, vein condition, size, location, and type and duration of therapy should

Box 6.1

Considerations for Vein Selection

- Age of patient
- Availability of sites
- Size of catheter to be used
- Purpose of infusion therapy
- Osmolarity of solution to be infused
- Volume, rate, and length of infusion
- Degree of mobility desired

Box 6.2

General Considerations When Initiating Intravenous Therapy

1. Use veins in the upper part of the body.
2. When multiple sticks are anticipated, make the first venipuncture distally and work proximal with subsequent punctures.
3. If therapy will be prescribed for longer than 3 weeks, a long-term access device should be considered.
4. Avoid using venipunctures in affected arms of patients with radical mastectomies or a dialysis access site.
5. If possible, avoid taking a blood pressure on the arm receiving an infusion because the cuff interferes with blood flow and forces blood back into the catheter. This may cause a clot or cause the vein or catheter to rupture.
6. No more than two attempts should be made at venipuncture before getting help.
7. Immobilizers should not be placed on or above an infusion site.

be considered before initiation of intravenous therapy (Box 6.2 General Considerations When Initiating Intravenous Therapy). The vein should be able to accommodate the gauge and length of catheter used.

Hand veins are used first if long-term intravenous therapy is expected (Box 6.3 Cultural Considerations). This allows each successive venipuncture to be made proximal to the site of the previous one, which eliminates the passage of irritating fluids through a previously injured vein and discourages leakage through old puncture sites. Hand veins can be used successfully for most hydrating solutions, but they are best avoided when irritating solutions of potassium or antibiotics are anticipated.

Vein size must also be considered. Small veins do not tolerate large volumes of fluid, high infusion rates, or irritating solutions. Large veins should be used for these purposes. Figure 6.3 shows peripheral veins that may be used for IV therapy.

If veins are constricted, venipuncture is more difficult. Fever, anxiety, and cold temperatures can cause veins to

Box 6.3

Cultural Considerations

Among the Vietnamese, the head is considered sacred. Thus, the practice of starting IV lines in the scalp may cause a Vietnamese patient significant anxiety. Consider other sites first. If the patient must have an IV line in the scalp, carefully explain why it is necessary.

FIGURE 6.3 Peripheral veins used for IV therapy. (Modified from Phillips, L: *Manual of IV therapeutics* [4th ed.], FA Davis, Philadelphia, 2005.)

constrict. Smoking before the insertion of an IV line also causes veins to constrict.

DILATE VEIN. A tourniquet helps to dilate and stabilize the vein, easing venipuncture and threading of the catheter. Place the tourniquet 6 to 8 inches above the insertion site. If the tourniquet is too close to the insertion site, it will create

too much pressure and cause the vein to burst. The tourniquet should be tight enough to impede venous flow while maintaining arterial flow. A tourniquet should be at least 1 inch wide and should not be left on for more than 3 minutes to prevent impaired blood flow to the extremity.

Occasionally, additional techniques are necessary to distend the vein. Placing the arm in a dependent position or placing a warm towel over the site for several minutes before applying the tourniquet help to dilate a vein. The whole extremity must be warmed to improve blood flow to the area. Opening and closing the fist pumps blood to the extremity and increases blood flow to help dilate the vein. A blood pressure cuff inflated to 30 mm Hg is an appropriate method for vein dilation, especially with fragile veins in the elderly. Box 6.4 (Techniques for Patients with Difficult Venous Access) lists additional tips for difficult to find veins.

NURSING CARE TIP

Use a tourniquet only once. Using the same tourniquet on more than one patient can result in cross contamination. Tourniquets may be sources of latex exposure; use a nonlatex tourniquet or blood pressure cuff technique for patients with latex allergy.

Choose the Catheter

Needles have been largely replaced with flexible plastic catheters that are inserted over a needle (Fig. 6.4B). The needle (or stylet) is removed after the catheter is in place. These are available in a variety of sizes (gauges) and lengths. For patient comfort, choose the smallest gauge catheter that will work for the intended purpose. Use smaller gauge catheters (20 to 24 gauge) for fluids and slow infusion rates. Use larger catheters (18 gauge) for rapid fluid administration and viscous solutions such as blood. Also consider vein size when choosing a catheter gauge. Refer to institution policy and equipment stock for specific recommendations. Keep in mind that the INS recommends that short peripheral catheters be removed every 72 hours and immediately upon suspected contamination.

Gloves

The CDC recommends following standard precautions whenever exposure to blood or body fluids is likely. Wearing latex or vinyl gloves provides basic protection from blood and body fluids.

Prepare the Site

Clean the peripheral insertion site with an antimicrobial solution before catheter placement. If the patient’s skin is dirty, wash it with soap and water before applying the antimicrobial solution. If the patient has excess hair, it can be clipped with scissors. Be sure to follow institution policy when choosing a solution. Most institutions use an alcohol-

NURSING CARE TIP

Many patients know from experience that their veins are difficult to access. Asking the patient for his or her “best vein” may decrease the number of attempts prior to successful IV catheterization. In addition, when selecting a hand vein, consider avoiding the patient’s dominant hand to avoid possible accidental patient removal of the IV.

Box 6.4**Techniques for Patients with Difficult Venous Access**

Altered Skin Integrity (Lesions, Burns, or Disease Process)

- Use indirect light (tangential lighting)
- Do not flatten veins or cause damage to skin
- Use light directed toward the side of patient's extremity to illuminate the blue veins (*Note:* also can be used on dark-skinned individuals.)

Hard sclerosed vessels (related to disease process, personal misuse, frequent drug therapy)

- Assess for collateral circulation.
- Use multiple tourniquet technique to increase oncotic pressure inside the tissue, forcing small vessels of periphery to be visualized.
 - Place one tourniquet high on arm for 2 minutes and leave in place; stroke downward toward hand.
 - After 2 minutes, place a second tourniquet at mid arm just below the antecubital fossa; leave along with first tourniquet for 2 minutes
 - This should bring peripheral veins into view; if necessary, place a third tourniquet at wrist.
 - Do not leave on more than 6 minutes total.

Obesity or Edema

- Use 2-inch catheter
- Use multiple tourniquet technique
- Displace edema to side to visualize veins

Source: Phillips, LD: Manual of IV Therapeutics, ed. 4. F.A. Davis, Philadelphia, 2005.

or iodine-based product. A newer preparation called ChlorPrep (Medi-Flex Hospital Products, Inc., Leawood, KS) is a chlorhexidine preparation solution that does not stain the skin or cause the irritation to the skin that Betadine products can. Avoid using alcohol after an antimicrobial preparation because alcohol negates the anti-infective action of the prep agent.

Apply the solution in a circular motion, starting at the intended site and working outward to clean an area 2 to 3 inches in diameter. If alcohol is used, it should be applied with friction for at least 30 seconds or until the final applicator is visually clean. Blotting of excess solution at the insertion site is not recommended. Allow the solution to air dry completely.

Insert the Catheter

Venipuncture can be performed using a direct (one-step) or indirect (two-step) method. The direct method is appropriate for small-gauge catheters, fragile hand veins, or rolling veins. The indirect method can be used for all venipunctures.

Hold the catheter with the bevel (slanted opening) of the needle facing up. With the tourniquet in place, enter the vein using either the direct or indirect approach. When using

FIGURE 6.4 (A) SAF-T EZ set IV needles. (B) BD IV Safety Catheters. (Courtesy Becton Dickinson, Franklin Lakes, NJ.)

the direct entry approach, hold the needle at a 30- to 45-degree angle directly above the vein and then penetrate the skin and vein in one motion (Fig. 6.5). When using some newer catheters, the angle of insertion is minimal.

FIGURE 6.5 Insert the needle of choice bevel up at a 30- to 45-degree angle, depending on the vein location and catheter.

FIGURE 6.6 Pull skin below the intended puncture site using a downward motion to stabilize the skin and prevent the vein from rolling.

NURSING CARE TIP

Use traction (a downward pulling motion to make the skin taut below the puncture site) before venipuncture to stabilize the skin and prevent the vein from rolling during venipuncture (Fig. 6.6).

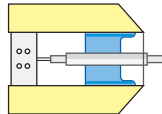

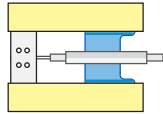

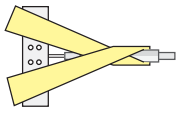

The indirect approach may help decrease vein collapse. To use it, hold the needle at a 30- to 45-degree angle over the skin next to (not over) the vein. Once the skin is punctured, lower the needle angle and locate and puncture the vein. Depending on the type of device used, a small flash of blood may be seen in the tubing or at the hub of the catheter when the needle is in the vein. The angle of the needle is then lowered so that it is parallel with the skin as it is threaded into the lumen of the vein. If a catheter-over-needle device is used, the needle is advanced 1/4 inch and then the catheter is advanced for its remaining length as the metal needle (stylet) is withdrawn.

The tourniquet is then released, and the IV solution or injection cap is connected to the hub of the catheter. Blood may ooze from the hub at this time. If an injection cap is being used, the catheter is flushed with 0.9% sodium chloride solution to check for patency. A smooth, easy flush and no signs of infiltration indicate that the catheter is patent and that the prescribed solution can be administered.

Stabilize the Catheter and Dress the Site

A common problem in IV therapy is dislodgement of the catheter. Secure taping keeps the catheter in place and stable, thus preventing complications caused by damage to the intima of the vein. There are several different techniques for taping a catheter securely, including the U, H, and chevron methods (Fig. 6.7). Take care to apply tape in a manner that does not constrict blood flow to the extremity.

A transparent, semipermeable membrane dressing allows the nurse to stabilize the catheter and monitor the venipuncture site for redness or swelling and provides an occlusive dressing for the site. Another acceptable method of dressing management is the use of sterile 2-inch by

U Method	H Method	Chevron Method
		
Use for Winged Set	Use for Winged Set	Use for Winged Set
<ol style="list-style-type: none"> 1. Cut three strips of 1/2-in tape. With sticky side up, place one strip under tubing. 2. Bring each side of the tape up, folding it over the wings of the needle. Press it down, parallel with the tubing. 3. Loop the tubing and secure it with a piece of 1-in tape. 	<ol style="list-style-type: none"> 1. Cut three strips of 1-in tape. 2. Place one strip of tape over each wing, keeping the tape parallel with the needle. 3. Place another strip of tape perpendicular to the first two. Place over the wings to stabilize wings and hub. 	<ol style="list-style-type: none"> 1. Cover the venipuncture with transparent dressing or 2 x 2 gauze dressing. 2. Cut a long 5- to 6-in strip of 1/2-in tape. Place one strip of tape, sticky side under hub, parallel with the dressing. 3. Cross the end of the tape over the opposite side of the needle so that the tape sticks to the patient's skin. 4. Apply a piece of 1-in tape across the wings of the chevron. Loop the tubing and secure it with another piece of 1-in tape.

* For all methods, include on the last piece of tape the date, time and insertion, size of gauge, length of needle or catheter, and your initials.

FIGURE 6.7 Taping techniques for IV access devices. (Modified from Phillips, L: *Manual of IV therapeutics* [4th ed.]. FA Davis, Philadelphia, 2005.)

2-inch gauze over the venipuncture site and a piece of 1-inch tape over the gauze. Band-Aids are not acceptable dressings over catheters.

Arm boards are not used routinely. However, if a confused patient places the IV site in danger, the extremity can be immobilized as a last resort; this requires a physician's order.

Label the Site

The IV setup should be labeled in three areas: the insertion site, the tubing, and the solution container. Once the venipuncture procedure is completed, label the setup with the date, time, catheter type and size, and your initials.

Dispose of Equipment

All needles, catheters, and blood-contaminated equipment should be disposed of according to institution policy in a tamper-proof, nonpermeable container.

Educate the Patient

Patients have the right to receive information on all aspects of their care in a manner they can understand. They also have the right to accept or refuse treatment. Explain the rationale for the IV therapy that has been ordered. Explain

your actions as you start the IV, and be sure the patient understands how to protect the site and problems to report.

Calculate Drip Rate

All IV infusions should be monitored frequently for accurate flow rates and complications associated with infusion therapy. (See the section on calculating drip rates earlier in this chapter.)

Document

Document your actions and the patient's response in the medical record according to institution policy. All IV solutions are also documented on the medication administration record. Include the following:

- Date and time of insertion
- Manufacturer's brand name and style of device
- Gauge and length of the device
- Location of the accessed vein
- Solution infusing and rate of flow
- Method of infusion (gravity or pump)
- Number of attempts needed for a successful IV start
- Patient's response and specific comments related to the procedure
- Signature

CRITICAL THINKING

Mrs. Green

■ Mrs. Green is admitted with a diagnosis of symptomatic anemia and has an atrioventricular (AV) dialysis shunt in her left arm. An IV line is ordered for administration of 2 units of packed red blood cells. What must be taken into consideration when assessing Mrs. Green for an appropriate venipuncture site?

Suggested answers at end of chapter.

NURSING PROCESS FOR THE PATIENT RECEIVING IV THERAPY

Assessment/Data Collection

A patient receiving IV therapy is assessed routinely. IV therapy is a medical intervention, and the nurse is responsible primarily for appropriate monitoring, documenting, and reporting related to the therapeutic goals. Some institution policies require assessment as often as every hour. Assessment should be systematic and thorough. It begins with observation and evaluation of the patient for signs of fluid imbalance. This is especially important when caring for an older patient (Box 6.5 Gerontological Issues). Daily weights and measurement of intake and output help determine whether the patient is retaining too much fluid. Skin turgor, mucous membrane moisture, vital signs, and level of consciousness also indicate hydration status. New onset of fine crackles in the lungs can indicate fluid retention. Table 6.2 lists other symptoms of complications, along with prevention and treatment strategies.

Inspect the site for redness or swelling, evaluate the integrity of the dressing, and document your findings. Inspect the tubing to ensure tight connections and the absence of kinks or defects. Inspect the solution container and compare it with the physician's order for type, amount, and rate. Report complications to the RN or physician.

Nursing Diagnosis, Planning, and Implementation

Priority nursing diagnoses for IV-related issues include:
Fear related to insertion of catheter

EXPECTED OUTCOME: *The patient will be able to cooperate with the procedure; patient will verbalize minimal fear.*

- Explain the IV therapy to the patient. *Lack of knowledge is associated with fear.*

Box 6.5

Gerontological Issues

Care of the Older Adult Receiving Intravenous Therapy

When an older patient is receiving IV fluids, the nurse must regularly assess the patient for potential fluid volume excess. Symptoms of fluid volume excess include:

- elevated blood pressure.
- increasing weight.
- full bounding pulse.
- shallow but rapid respirations.
- jugular-venous distention.
- increased urine output.
- development of moist crackles in the lungs.

If these signs are present:

- Immediately notify the RN or turn down the IV to a minimum drip rate (1 mL per minute); do not discontinue the IV because the physician may want to administer IV diuretics.
- Position the patient to maximize lung expansion.
- Check peripheral oxygen saturation with an oximeter.
- Apply oxygen by mask or nasal cannula if indicated and per institution guidelines.
- Closely monitor patient's vital signs, level of consciousness, and oxygen saturation along with fluid output.
- Assist the physician or RN with IV push administration of diuretic medication such as furosemide if ordered.

TABLE 6.2 COMPLICATIONS OF PERIPHERAL IV THERAPY

Local Complications of IV Therapy			
Complication	Signs and Symptoms	Treatment	Prevention
Hematoma	Ecchymoses Swelling Inability to advance catheter Resistance during flushing	Remove catheter Apply pressure with 2×2 Elevate extremity	Use indirect method of venipuncture Apply tourniquet just before venipuncture
Thrombosis	Slowed or stopped infusion Fever/malaise Inability to flush catheter	Discontinue catheter Apply cold compress to site Assess for circulatory impairment	Use pumps Choose microdrip sets with gravity flow if rate is below 50 mL/hr Avoid flexion areas
Phlebitis	Redness at site Site warm to touch Local swelling Pain Palpable cord Sluggish infusion rate	Discontinue catheter Apply cold compress initially; then warm Consult physician if severe	Use larger veins for hypertonic solutions Choose smallest catheter appropriate Use good hand hygiene Add buffer to irritating solutions Change solutions and containers every 24 hr Rotate infusion sites every 72–96 hours
Infiltration (Extravasation)	Coolness of skin at site Taut skin Dependent edema Backflow of blood absent Infusion rate slowing	Discontinue catheter Apply cool compress Elevate extremity slightly Follow extravasation guidelines Have antidote available	Stabilize catheter Place catheter in appropriate site Avoid antecubital fossa
Local Infection	Redness and swelling at site Possible exudate Increase WBC count Elevated T lymphocytes	Discontinue catheter and culture site and catheter Apply sterile dressing over site Administer antibiotics if ordered	Inspect all solutions Use sterile technique during venipuncture and site maintenance
Venous Spasm	Sharp pain at site Slowing of infusion	Apply warm compress to site Restart infusion in new site if spasm continues	Take thorough history Verify allergies Use proper patient identification Warm solutions with appropriate warming device if appropriate.
Systemic Complication of Peripheral IV Therapy			
Septicemia	Fluctuating temperature Profuse sweating Nausea/vomiting Diarrhea Abdominal pain Tachycardia Hypotension Altered mental status	Restart new IV system Obtain cultures Notify physician Initiate antimicrobial therapy as ordered Monitor patient closely	Use good hand hygiene Carefully inspect fluids Use Luer-Loks Cover infusion sites with appropriate dressings Follow standards of practice related to rotation of sites/hang time of infusions Use appropriate preparation solutions
Fluid Overload	Weight gain Puffy eyelids Edema Hypertension Changes in input and output (I&O) Rise in central venous pressure (CVP) Shortness of breath Crackles in lungs Distended neck veins	Decrease IV flow rate Place patient in high Fowler's position Keep patient warm Monitor vital signs Administer oxygen Use microdrip set or controller	Monitor infusion Maintain flow at prescribed rate Monitor I&O Know patient's cardiovascular history Do not "catch up" infusion if behind schedule
Air Embolism	Lightheadedness Dyspnea, cyanosis, tachypnea, expiratory wheezes, cough Mill wheel murmur, chest pain, hypotension Changes in mental status Coma	Call for help! Place patient in Trendelenburg's position Administer oxygen Monitor vital signs Notify physician	Remove all air from administration sets Use Luer-Loks Attach piggyback to appropriate port

Complications	Signs and Symptoms	Treatment	Prevention
Speed Shock	Dizziness Facial flushing Headache Tightness in chest Hypotension Irregular pulse Progression of shock	Call for help! Give antidote or resuscitation medications	Reduce the size of drops by using microdrip set Use electronic infusion device (EID) Monitor infusion sites Dilute IV push medications if possible, give slowly
Catheter Embolism	Sharp sudden pain at IV site Rough, uneven catheter noted on removal Chest pain Tachycardia	Apply tourniquet above elbow Contact physician Start new IV Measure remainder of catheter	Use radiopaque catheters! Do not apply pressure over site. Avoid joint flexions. Never reinsert stylet that has been removed from sheath

Source: Adapted from Phillips, LD: IV Notes. Philadelphia F.A. Davis, 2005, Table 9–9, pp. 396–398.

- Insertion procedure
- Rationale for IV therapy
- Care of the IV
- Importance of reporting pain or swelling, or pump alarm
- Use techniques to minimize discomfort. *Pain may increase fear.*

Impaired physical mobility related to placement and maintenance of IV catheter

EXPECTED OUTCOME: The patient will experience minimal inability to move; the patient will not experience complications related to immobility.

- Use insertion site away from joints if at all possible. *Joint areas are mobile and it will be difficult to maintain an intact site.*
- If you must use a mobile site, such as the antecubital fossa or wrist area, immobilize with arm board or gauze wrapping to reduce catheter movement.
- If site must be wrapped, be sure to leave insertion site visible or remove dressing to view site according to agency policy. *The site must still be visualized for complications even if it is covered.*
- Assist patient with activities of daily living (ADLs). *The patient may have difficulty with ADLs if movement is limited.*

Risk of infection related to broken skin or traumatized tissue

EXPECTED OUTCOME: The patient will be free from infection as evidence by no redness, swelling, or purulence at IV insertion site, no fever, and normal white cell count.

- Monitor for signs of infection so the IV can be changed and infection treated quickly if it occurs
- Use good handwashing and strict aseptic techniques during catheter insertion to prevent introduction of pathogens.
- Change catheter, tubing, and solutions regularly according to agency policy to prevent growth of microorganisms.

Evaluation

The RN is responsible for evaluation and thus monitors the patient for evidence that the goals of therapy are being met

and that complications are avoided. The LPN/LVN collects data that contribute to the evaluation. For example, if antibiotic therapy is administered, monitor the patient's temperature and other signs that the infection is resolving. If IV therapy is ordered to correct dehydration, monitor skin turgor, vital signs, and other appropriate signs of improved fluid balance. Document all findings and report them to the RN.

CRITICAL THINKING

Mr. Rick

■ Mr. Rick's IV has blood backed up in the tubing. When you open the clamp to increase the flow, nothing happens. What should you do?

Suggested answer at end of chapter.

COMPLICATIONS OF IV THERAPY

See Table 6.2 for complications, their prevention, and treatment. Any complication or unusual incident should be reported to the physician, and an incident report should be prepared according to institution policy. This applies to the hospital and the home situation.

CRITICAL THINKING

Mrs. Gonzalez

■ Mrs. Gonzalez is receiving 5% dextrose in water at 83 mL per hour. One hour after the infusion starts, she complains of pain at the site. The site is cool to the touch and swollen, and the infusion rate is sluggish.

1. What might be happening?
2. How do you further assess the patient?
3. What action do you take?
4. How should you document your findings?

Suggested answers at end of chapter.

ALTERNATIVE ACCESS ROUTES

The role of the LPN/LVN in central venous access in most states is limited to assisting the RN with assessments. It is important for you to be able to recognize the different central venous access devices.

Central Venous Catheters

Central venous catheters terminate in the superior vena cava near the heart (Fig. 6.8). They are used when peripheral sites are inadequate or when large amounts of fluid or irritating medication must be given. Central catheter devices include a percutaneous catheter, peripherally inserted central catheter (PICC), tunneled catheter, and implanted port. These devices can have one, two, or three lumens in the catheter or one or more port chambers. Each lumen exits the site in a separate line, called a tail. Multilumen catheters allow for the administration of incompatible solutions at the same time.

Be careful not to confuse a central catheter with a dialysis catheter. Dialysis catheters should be used only for dialysis and not for IV therapy, and should be accessed only by physicians or specially trained dialysis nurses.

Percutaneous Central Catheter

A percutaneous central catheter is inserted by a physician into the jugular or subclavian vein. After insertion, correct placement is determined by x-ray before the catheter is used. These short-term central venous catheters may remain in place up to several weeks, but usual placement time is 7

days. These catheters are inserted at the bedside and are cost effective for short-term central venous access in the acute care setting.

Peripherally Inserted Central Catheter (PICC)

A PICC line is a long catheter that is inserted in the arm and terminates in the central circulation. This device is used when therapy will last more than 2 weeks or the medication is too caustic for peripheral administration. Specially trained RNs insert PICC lines. They can be left in place for long periods, minimizing the trauma of frequent IV insertions. Consult with a physician if long-term therapy is anticipated.

It is important to follow the manufacturer’s recommended guidelines for flushing the catheter and to be aware of your institution’s policy. An RN removes the PICC or midline catheter when therapy is terminated. An LPN/LVN may assist the RN with this procedure if the state nursing practice act permits.

Tunneled Catheters

Central venous tunneled catheters (CVTCs) are intended for use for months to years to provide long-term venous access. CVTCs are composed of polymeric silicone with a Dacron polyester cuff that anchors the catheter in place subcutaneously. The catheter tip is placed in the superior vena cava.

Advantages of a CVTC are that a break or tear in a catheter is easy to repair, and they can be used for many purposes. Disadvantages include weekly site care, cost of maintenance supplies, and they can affect the patient’s body image (see Fig. 6.8).

FIGURE 6.8 Central lines. (A) Triple-lumen subclavian catheter. (B) PICC line. (C) Tunneled catheter. (B and C modified from Phillips, L: *Manual of IV therapeutics* [4th ed.]. FA Davis, Philadelphia, 2005.)

Ports

A port is a reservoir that is surgically implanted into a pocket created under the skin, usually in the upper chest. An attached catheter is tunneled under the skin into a central vein. An advantage of a port is that, when not in use, it can be flushed and left unused for long periods. Because the port is under the skin, the patient can swim and shower without risk of contaminating the site.

Ports come in a variety of sizes and styles and are now being used in many areas of the body. Ports can be used to administer chemotherapeutic agents and antibiotics that are toxic to tissues and are suitable for long-term therapy. Ports should be accessed only by specially trained RNs. Most ports require the use of special noncoring needles that are specifically designed for this purpose. Regular needles can cut a “core” in the septum (self-sealing covering), which can travel through the catheter and cause an embolism.

Nursing Management of Central Access Devices

Central lines have sterile, occlusive dressings to protect the site. Sterile gloves and mask should be worn during the dressing change. Whenever tubing is disconnected for changing, the patient is instructed to perform Valsalva’s maneuver if able. This maneuver increases thoracic pressure and prevents air from entering the central line. Institution policy directs specific dressing and tubing change procedures.

NUTRITIONAL SUPPORT

Total parenteral nutrition (TPN) is complete IV nutrition that is administered to patients who are unable to take adequate nutrients via the enteral route (mouth or tube feeding). TPN may be used to promote wound healing or to help a patient achieve optimal weight before surgery, or it may be used to avoid malnutrition from chronic disease or after surgery. Patients with ulcerative colitis, trauma, or cancer cachexia are candidates for TPN. Every effort should be made to return a patient on TPN to oral or tube feedings as soon as possible (Box 6.6, Nutrition Notes).

TPN provides and maintains the essential nutrients required by the body. Solutions contain carbohydrates, amino acids, lipid emulsions, electrolytes, trace elements, and vitamins in varied amounts according to the patient’s needs. Parenteral nutrition requires filtration and an electronic infusion device for administration. In the home setting an ambulatory infusion device is used to allow the patient more mobility.

Initial assessment includes the patient’s height, daily weight, nutritional status, and current laboratory values. Because of the high glucose concentration of TPN, the patient is at risk for infection and blood glucose disturbances. Insulin therapy may be necessary during TPN administration. Ongoing assessments include blood glucose levels according to institution policy and monitoring for signs and symptoms of infection, hyperglycemia, and hypo-

Box 6.6

Nutrition Notes

Total Parenteral Nutrition

Serious metabolic complications of total parenteral nutrition can occur quickly. Rapid shifts in potassium, magnesium, phosphorus, and glucose among the body’s fluid compartments can become life-threatening. Glucose in excess of the body’s needs can produce carbon dioxide retention, hyperlipoproteinemia, and fatty deposits in the liver. Therefore, administration of TPN requires careful monitoring. The goal is to provide sufficient nutrients but not excessive amounts that create physiological stress.

To avoid complications, TPN infusions are started slowly at low concentrations. Adjustments are made cautiously, changing one component (amount, concentration, or rate) at a time and observing the patient’s reaction. In particular, nurses and pharmacists involved in home parenteral nutrition need to carefully follow agency guidelines for mixing and storing TPN since problems can occur with degradation of components. Serious complications including death can occur when guidelines are not carefully observed. In addition, administration of drugs in TPN (or mixing in the same tubing) should be avoided if at all possible.

In a patient whose only nutrition is obtained from TPN, the gastrointestinal cells will atrophy. Therefore, the patient must be weaned from parenteral feeding while oral or tube feedings are slowly restarted. As gastrointestinal intake increases, TPN is decreased. Sometimes, when circumstances permit, gastrointestinal function can be maintained throughout TPN administration by giving the patient a liquid or light diet along with TPN.

glycemia. When TPN therapy is begun, the rate is increased gradually to the prescribed rate to help prevent hyperglycemia. When it ends, the rate is gradually decreased to prevent hypoglycemia.

When nutritional solutions contain final concentrations exceeding 10% dextrose or 5% protein, they must be administered via a central catheter. When final concentrations are less than 10% dextrose or 5% protein, they may be administered through a peripheral vein. Peripheral therapy is a short-term intervention because it does not provide adequate nutrition over an extended period.

It is essential that the entire health-care team be involved in TPN therapy because TPN is total replacement for food. The pharmacist, dietitian, physician, and nurse communicate in a team conference to discuss the assessment, plan, and outcome criteria. Many institutions have nutrition teams that assess the appropriateness of TPN for individual patients.

HOME INTRAVENOUS THERAPY

As health-care costs continue to escalate, patients are using more alternatives to hospitalization. Subacute care, skilled nursing care in nursing homes, and home health care are growing. Home IV therapy allows many patients the benefit of early discharge and the ability to accomplish health care in the privacy and comfort of their own homes. Some home health agencies employ nurses to instruct patients and their families in the administration of home IV therapy (see Home Health Hints).

Home IV antibiotic therapy is becoming the method of choice in the long-term treatment of a number of infections, including bacterial endocarditis, osteomyelitis, and septic arthritis. Other patients with chronic diseases choose to receive TPN at home. The health team can assess patients and their families for their ability to manage home IV therapy.

REFLECTIONS ON CASE STUDY

Think again about Mrs. Brown from the beginning of the chapter. She will need monitoring of intake and output, daily weights, and close monitoring of her IV infusion. You should anticipate that serum electrolytes, BUN, and creatinine laboratory studies will be ordered. When initiating the infusion, use care in application of a tourniquet because elderly skin is thin and bruising can occur. Choose a number 20- or 22-gauge catheter to start the infusion. Once it is started, continue to monitor weights and lung

sounds because elderly patients can quickly go from fluid depletion to fluid overload (see Box 6.5 Gerontological Issues).

Home Health Hints

- If IV therapy is to be continued after hospital discharge, assist the RN in teaching the patient and caregiver the skills to oversee the IV therapy. Obtain a referral for a home-care nurse to continue monitoring and teaching after discharge.
- In addition to basic IV care, teach the caregiver the effects and side effects of the medications and signs and symptoms that should be reported to the nurse or doctor.
- Instruct the home-care patient to refrain from smoking for at least 30 minutes before IV insertion to prevent vasoconstriction and ensure successful venipuncture.
- Instruct the patient to cover the IV site with a stretch bandage such as Spandage to prevent tugging at the catheter site.
- Help the patient and caregiver identify a safe place to keep supplies. Make sure they understand the recommendations for storage of IV medications since some medications require refrigeration.
- Supplies should include a biohazard container. Home health agencies will supply these containers. The nurse is responsible for returning filled boxes to his or her agency for disposal.

REVIEW QUESTIONS

1. Which of the following is the best resource for the nurse who has a question about implementation of IV therapy at a specific institution?
 - a. An experienced nurse
 - b. Institution policy
 - c. The physician
 - d. INS standards
2. Which patients have a need for IV therapy? Choose all that apply.
 - a. An 88-year-old man admitted to the hospital with dehydration
 - b. A 21-year-old woman with an eating disorder and severe weight loss
 - c. A 58-year-old woman with pneumonia that has been unresponsive to oral antibiotics
 - d. A 37-year-old man recovering from a fall and broken arm
 - e. A 4-year-old brought to the emergency room because of prolonged vomiting
 - f. A patient with fluid overload who requires fast acting diuretic therapy
3. A patient requests that an IV not be initiated in his hand. Which site is the next best choice?
 - a. Forearm
 - b. Antecubital fossa
 - c. Upper arm
 - d. Lower extremity
4. Place the steps for insertion of a peripheral IV catheter in chronological order. Use all the options.
 - a. Put on gloves
 - b. Check physician's order.
 - c. Prepare insertion site.
 - d. Label the dressing.
 - e. Wash hands.
 - f. Dilate the vein.
 - g. Document the procedure.

- h. Insert the catheter.
 - i. Stabilize the site with tape.
5. The nurse must initiate an infusion on a 21-year-old man who has a history of drug abuse, a diagnosis of septicemia, and multiple tattoos over his arms. What would be the best approach to be able to visualize and initiate a peripheral IV?
 - a. Place the arm in a dependent position.
 - b. Use a blood pressure cuff.
 - c. Use the multiple tourniquet technique.
 - d. Have another nurse hold the patient's arm.
 6. A patient receiving IV therapy via a central line develops hypotension, cyanosis, and tachycardia. The nurse notes a crack in the IV tubing. Which of the following actions should the nurse take first?
 - a. Have the RN call the physician.
 - b. Clamp the tubing and administer oxygen.
 - c. Raise the head of the bed.
 - d. Slow the infusion and lay the patient flat.
 7. Which of the following solutions is isotonic?
 - a. 0.45% NS
 - b. D5/0.2% NS
 - c. D5/0.45% NS
 - d. 0.9% NS
 8. The nurse is assessing a patient and notes a silicone catheter taped to his chest, and can feel the catheter under the skin. This type of catheter would be a:
 - a. Peripherally inserted central catheter
 - b. Implanted port
 - c. Central venous tunneled catheter
 - d. Percutaneous catheter
 9. The physician orders 5% dextrose in water at 100 mL per hour. What is the drip rate using tubing with a drop factor of 20? ___ gtt per minute
 10. A patient is to receive 1000 mL normal saline over 12 hours. How many milliliters per hour should be set on the controller? ___ mL/hour

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Green

Consider the following when assessing the patient for an appropriate venipuncture site:

1. An 18-gauge catheter should be used for blood administration whenever possible.
2. The catheter should not be inserted in the arm that has the shunt.
3. The catheter should be placed in the forearm. Hand veins are too small to accommodate the delivery of blood.

■ Mr. Rick

Your patient's IV line is likely clotted. If it has been so for a long time, it will not be salvageable. Do not flush it because doing so can dislodge the clot into the

circulation. Discontinue the IV and insert a new catheter.

■ Mrs. Gonzalez

1. The IV fluid may be leaking at the insertion site and flowing into the subcutaneous tissue, a problem known as **extravasation**.
2. Consider whether the pain could be caused by the build-up of fluid under the skin.
3. Compare the insertion site with the opposite limb. If the IV solution has infiltrated, stop the infusion, discontinue the catheter, and restart the catheter in a new site.
4. "Patient complains of pain at IV site in right arm; area is cool to touch and edematous in 4.5-cm area around site. Flow rate sluggish. Infusion discontinued; IV restarted in left arm with 22-gauge catheter. Infusing well with no signs of infiltration."

extravasation: extra—outside + vas—vessel + tion—condition

QUESTIONS TO GUIDE YOUR READING

1. What are the links in the chain of infection?
2. How can you interrupt the routes of transmission of infectious disease?
3. How can you assist the body's defense mechanisms to fight infectious disease?
4. What are the signs and symptoms of a localized versus a generalized infection?
5. What are principles of anti-infective medication administration?
6. What nursing care will you provide for a patient with an infectious disease?
7. How will you know if your nursing care has been effective?

THE INFECTIOUS PROCESS

Events leading to an infection are shown in Figure 7.1. To prevent an infection, links in the chain of events must be broken. If an infection occurs, treatment focuses on breaking the chain of infection to prevent the spread of infection to others (Box 7.1, Cultural Considerations).

A **pathogen** causes disease. When pathogenic microbes are present in the body without causing symptomatic infection, it is referred to as **colonization**. When an infection occurs without producing symptoms, it is known as a subclinical infection. Identification of a subclinical infection is made from a **host's** increased antibody level for the microbe. An infection causes signs, symptoms, and injury to the host.

Reservoir

A **reservoir** is the place in the environment where infectious agents live, multiply, and reproduce so they can be transmitted to a susceptible host. A reservoir can be animate, such as people, insects, animals, and plants, or inanimate, such as water, soil, or medical devices.

Causative Agents

Microorganisms that cause infection include **bacteria**, **viruses**, **fungi**, **protozoa**, helminths, and prions (Table 7.1). Microbes that occur naturally in or on a particular body part are known as normal **flora**. They are usually harmless, or nonpathogenic, because they do not normally produce disease in a healthy person. Normal flora are helpful to the human host. For example, intestinal flora (bacteria) assist in

FIGURE 7.1 Chain of events in the infectious process.

protozoa: proto—first + zoon—animal

Box 7.1

Cultural Considerations

One concern when caring for refugees, migrant workers, and immigrants is treating infectious conditions that jeopardize both the patient and the resident population. Some immigrants may suffer from a number of infectious such as malaria, gastrointestinal parasites, or tuberculosis. Standard precautions are a must when working with any patient.

Among the Native Americans, infectious health problems include the plague and tick fever. Many of these illnesses are due to the reservation's rodent population, which includes prairie dogs and deer mice.

Some Appalachians live in rural areas that lack electricity, plumbing, and running water, putting them at increased risk of infection. Teach all patients to thoroughly wash their hands after toileting and coming in contact with raw food or contaminated water.

The drug isoniazid (INH), used in the treatment of tuberculosis, may be metabolized differently by some ethnic and racial groups. Half of European Americans and a smaller percentage of Asian persons are slow eliminators of INH. These individuals may have high blood concentrations of this medicine, leading to harmful reactions. Carefully monitor these patients for reactions to INH.

vitamin K production, a necessary nutrient for normal blood clotting. However, if these bacteria get into another area of the body, such as the blood, they may produce disease and are then referred to as pathogens.

Bacteria

Bacteria are single-celled organisms that usually reproduce by simple cellular division. Bacteria may depend on a host or may live and reproduce outside a host. Most bacteria produce cell walls that are susceptible to antibiotics. However, bacteria can mutate in order to survive.

Bacteria are named according to their shape (spherical [coccus], rod [bacillus], and spiral [spirillum]) and classified according to their staining properties (Gram's method, acid-fast staining). Bacteria respond to stains in one of three ways: gram-positive bacteria stain purple; gram-negative bacteria lose purple stain when exposed to alcohol but stain red with a second dye; and acid-fast bacteria keep purple stain when an acid is applied.

Bacterial growth depends on oxygen, nutrition, light, temperature, and humidity. **Aerobic** bacteria, such as those found on the skin, need oxygen to live. **Anaerobic** bacteria, such as bacteria in the gastrointestinal tract, live without oxygen. Most bacteria that inhabit humans grow best at body temperature, 98.6°F (37°C).

Rod-shaped bacteria form spores that are thick walled and hard to kill. Spores remain in a resting state until favor-

TABLE 7.1 COMMON INFECTIONS

Microorganism	Type or Site of Infection
Gram-Positive Bacteria	
<i>Staphylococcus aureus</i>	Pneumonia, cellulitis, peritonitis, toxic shock
<i>Staphylococcus epidermidis</i>	Postoperative bone/joints, IV line–related phlebitis
<i>Staphylococcus pneumoniae</i>	Pneumonia, meningitis, otitis media, sinusitis, septicemia
Gram-Negative Bacteria	
<i>Escherichia coli</i>	Urinary tract, pyelonephritis, septicemia, gastroenteritis
<i>Klebsiella pneumoniae</i>	Pneumonia and wounds
<i>Legionella pneumophila</i>	Pneumonia
<i>Neisseria gonorrhoeae</i>	Gonorrhea
<i>Pseudomonas aeruginosa</i>	Wounds, urinary tract, pneumonia, IV lines
<i>Salmonella enteritidis</i>	Gastroenteritis, food poisoning
Viruses	
Herpes virus group	Cold sores/fever blisters, genital herpes
Epstein-Barr	Infectious mononucleosis
Varicella zoster	Skin (chickenpox and shingles)
Hepatitis (A, B, C, D, E)	Liver
Human immunodeficiency virus	Acquired immunodeficiency syndrome
Influenza (A, B, C)	Bronchiolitis, pneumonia
Rubella	German measles
Rubeola	Measles
Protozoa	
<i>Giardia lamblia</i>	Gastroenteritis
<i>Trichomonas vaginalis</i>	Trichomoniasis
<i>Dientamoeba fragilis</i>	Diarrhea, fever
<i>Entamoeba histolytica</i>	Amebic dysentery
<i>Toxoplasma gondii</i>	Toxoplasmosis
<i>Plasmodium falciparum</i>	Malaria
Fungi	
<i>Candida albicans</i>	Nailbed, thrush, vaginitis
<i>Histoplasma capsulatum</i>	Pneumonia

able conditions exist that allow the organism to resume normal function. Prolonged exposure to high temperature destroys spores on surgical equipment. Bleach is used in patient rooms to kill spores from *Clostridium difficile* (*C. diff*).

RICKETTSIAE. Rickettsiae are a type of bacteria that must be inside living cells to reproduce. Rickettsiae **vectors** (living organisms that transmit disease) are infected fleas, ticks, mites, and lice that bite humans. Several diseases are caused by **rickettsiae**. Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*, whose reservoirs (the places in nature where the organism usually lives and multiplies without causing disease) are rodents and dogs, is transmitted to humans by a tick bite.

Viruses

Viruses are organisms smaller than bacteria that depend on host cells to live and reproduce (see Table 7.1). Invaded host cells make more virus material. The new viral particles are

then released either by destroying the host cell or by forming small buds that break away to infect other cells.

When a virus enters a cell, it may immediately trigger disease or remain **dormant** (inactive) for years without causing illness. An example of this is *human herpesvirus 3* (varicella zoster virus), which can cause disease quickly (chickenpox) or remain dormant for years, eventually erupting in the disease called shingles. Antibiotics are not effective against viruses. Newer antiviral drugs are used to decrease symptoms caused by viruses and to decrease the viral load (the number of viral cells in the patient's blood).

Fungi

Fungi are a group of organisms that includes yeasts, molds, and mushrooms and can produce highly resistant spores (see Table 7.1). Because fungi do not contain chlorophyll, they must obtain food from living organisms or dead organic matter. Normal flora of the mouth, skin, vagina, and intestinal tract include many fungi. Most fungi are not pathogenic, and serious fungal infections are rare. Antifungal medications treat fungal infections.

Protozoa

Protozoa are single-celled parasitic organisms with flexible membranes that live in the soil and obtain nourishment from dead or decaying organic material (see Table 7.1). Protozoa infect humans through fecal-oral contamination or through ingestion of food or water contaminated with cysts or spores, through host-to-host contact, or by the bite of a mosquito or other insect that has previously bitten an infected person.

Helminths

Helminths are wormlike parasitic animals: roundworms, flatworms, tapeworms, pinworms, hookworms, and flukes. Disease transmission occurs through skin penetration of larvae or ingestion of helminth eggs. Trichinellosis (caused by the roundworm *Trichinella spiralis*) is a disease caused by eating raw or undercooked meat of pigs or wild animals that contain *Trichinella* larvae.

Prions

Prions are recently identified organisms or agents thought to be unique proteins with long incubation periods. How they reproduce is unknown. Research will shed light on these unusual organisms or protein particles, which are thought to cause mad cow disease and the human dementia known as Jakob-Creutzfeldt syndrome.

Mode of Transmission

Once the causative agent exits the reservoir, a means of transfer to a susceptible host is needed. Transmission methods for microorganisms include direct contact, indirect contact, and through the air.

Direct Contact

Direct transmission occurs through touching, biting, kissing, sexual contact, or droplet spray into the eyes or on mucous membranes while sneezing, coughing, spitting, singing, or

talking. Droplet spread is usually limited to 3 feet or less. Illnesses spread by direct transmission may include influenza, impetigo, scabies, conjunctivitis, pediculosis, herpes, *C. difficile*, and all sexually transmitted diseases, including human immunodeficiency virus (HIV). Protect yourself and your patients from direct transmission with hand washing, aseptic technique, and use of **personal protective equipment** (PPE) (gloves, surgical masks, goggles, gowns, and booties). PPE is selected and used based on the task to be performed and the isolation precautions (standard precautions and/or transmission-based precautions)

Indirect Contact

Indirect transmission is either vehicleborne or vectorborne. Vehicleborne transmission is the spread of an infectious organism by contact with a contaminated object, such as a toy, soiled bedding, dressings from a wound, surgical instruments, water, food, and biological products such as blood, serum, plasma, tissues, and organs. Vehicleborne illnesses include conjunctivitis, trichinellosis, HIV, and hepatitis A, B, C, D, and E. Vehicle transmission can be avoided through proper hand washing, thorough cleaning of the patient environment, and provision of clean water and food supplies. Vectorborne transmission is the spread of infectious organisms through a living source other than humans, such as an insect, flea, mouse, or rat. Diseases spread through vectors include malaria, plague, and Lyme disease. Vector transmission can be reduced with insect repellants, avoidance of infested areas, and rodent control.

Airborne

Airborne transmission is different from droplet transmission (see Direct Contact discussed earlier) because the particles floating in the air are much smaller, remain suspended in the air for a long time, and may travel large distances. Airborne organisms can be inhaled or deposited on the mucous membrane of a susceptible host. Measles, chickenpox, and tuberculosis are transmitted by airborne transmission. Airborne transmission is prevented with the use of high-efficiency particulate air (HEPA) respirators (also known as a tuberculosis [TB] mask). HEPA respirators filter the tiniest particles from the air, unlike surgical masks, which can allow such particles to pass into the respiratory system of a host. Institutions provide individual fit testing and training for HEPA respirator use for each health care worker.

NURSING CARE TIP

If you provide care for patients with suspected or confirmed diseases that are spread through airborne transmission, such as TB, be sure you have your own fit-tested HEPA mask to wear. Do not use other masks because they do not provide adequate protection. If you cannot obtain your own fit-tested mask, you should not enter the patient's room.

Multiple Modes of Transmission

Many diseases have multiple modes of transmission requiring a variety of protective techniques. For example, chickenpox is transmitted by direct contact, indirect contact, and airborne transmission. It is no wonder 80% to 90% of susceptible persons exposed develop the disease. Understanding the modes of transmission of a particular disease allows you to use the appropriate means of protection without using unnecessary supplies that increase costs.

Portal of Entry

To produce disease, organisms must gain entry into a susceptible host. Routes of entry into a susceptible host include the respiratory tract, skin (usually nonintact), mucous membranes, gastrointestinal tract, genitourinary tract, and placenta. Once the organism enters the host, it may lead to disease, depending on the condition of the host and many other factors, such as the **virulence** of the organism.

Susceptible Host

The body has many defense mechanisms to prevent infection, such as intact skin and mucous membranes and a functioning immune system. A breakdown in these defenses increases the possibility of infection. Factors that increase susceptibility to infection are very young age, old age, malnourishment, immunocompromise, chronic disease, stress, and invasive procedures (Box 7.2, Gerontological Issues).

Portal of Exit

The portal of exit is the route by which the infectious agent leaves the host, who has become a reservoir for infection: respiratory tract, skin, mucous membranes, gastrointestinal tract, genitourinary tract, blood, open lesions, or placenta.

Box 7.2

Gerontological Issues

Infection and Older Adults

Often an older patient may not have typical symptoms of an infection. For example, a serious bacterial infection may cause no elevation in temperature. In fact, a fever is not a common complaint or sign of infection for an older adult.

This difference among older adult patients may cause significant delay in providing appropriate treatment and care. Be alert for the following in the older adult patient, which may indicate an infection:

- Behavioral change, such as pacing or irritability.
- Masking of the symptoms of infection by a chronic disease. For example, the inflammation and pain of degenerative joint disease may make it difficult for a patient to recognize an infection in an affected joint.

THE HUMAN BODY'S DEFENSE MECHANISMS

Skin and Mucous Membranes

Intact skin and mucous membranes are the body's first line of defense against infection. Oral mucous membranes have many layers, making it difficult for organisms to enter the body. The skin has acidic (pH <7) properties that render some organisms unable to produce disease. For example, many bacteria prefer an alkaline (pH >7) environment for reproduction. There is also an abundance of normal flora that impairs the growth of pathogens both on the skin and in the gastrointestinal (GI) tract.

Cilia

Cilia are hairlike structures lining upper respiratory tract mucous membranes that protect the lungs. Cilia trap mucus, pus, dust, and foreign particles to prevent them from entering the lungs. Then the cilia push the trapped particles up to the pharynx with wavelike movements for expectoration.

Gastric Juices

Gastric juices inside the stomach are very acidic (pH 1 to 5). This acidic environment destroys most organisms that enter the stomach.

Immunoglobulins

Immunoglobulins are proteins found in serum and body fluids that may act as **antibodies** to destroy invading organisms and prevent the development of infectious disease. Antibodies are proteins that are produced by B lymphocytes when foreign **antigens** of invading cells are detected. Antigens are markers on the surface of cells that identify cells as being the body's own cells (autoantigens) or as being foreign cells (foreign antigens). Antibodies combine with specific foreign antigens on the surface of the invading organisms, such as bacteria or viruses, to control or destroy them. Antigens are neutralized or destroyed by antibodies in several ways. Antibodies can initiate destruction of the antigen, neutralize toxins released by bacteria, promote antigen clumping with the antibody, or prevent the antigen from adhering to host cells.

Leukocytes and Macrophages

Leukocytes (white blood cells) are the primary cells that protect against infection and tissue damage. There are five types of leukocytes:

- Neutrophils are phagocytic cells focusing on bacteria and small particles.
- Monocytes become macrophages and are mainly phagocytic on tissue debris and large particles.
- Lymphocytes' functions include antigen recognition and antibody production.
- Basophils respond to inflammation from injury.
- Eosinophils destroy parasites and respond in allergic reactions.

After recognizing a foreign antigen, neutrophils and macrophages engulf and digest it, a process known as **phagocytosis**. The macrophages move the antigen fragments to their surface to be recognized by T lymphocytes to further stimulate action of the immune system. Phagocytes ingest and destroy bacteria, damaged or dead cells, cellular debris, and foreign substances.

Lysozymes

Lysozymes are bactericidal enzymes present in white blood cells and most body fluids, such as tears, saliva, and sweat. These enzymes dissolve the walls of bacteria, destroying them.

Interferon

If an invading organism is a virus, white blood cells and fibroblasts release interferon (a group of antiviral proteins). Interferon aids in the destruction of infected cells and inhibits production of the virus within infected cells. Tumor cell growth may also be inhibited by interferon.

Inflammatory Response

The inflammatory response occurs as a result of any bodily injury. This response can be caused by pathogens, trauma, or other events causing injury to tissues. Infection may or may not be present.

Vascular Response

The first step of the inflammatory process is local vasodilation, which increases blood flow to the injured area. Pathogenic organisms can trigger the first step of the inflammatory process. Increased blood flow creates redness and heat at the injury. The increase in blood flow brings more plasma to the area to nourish tissue and carry waste and debris away.

Inflammatory Exudate

The second step of the inflammatory process is increased permeability of the blood vessels, which allows plasma to move out of the capillaries and into the tissues. Swelling occurs, resulting in pain from pressure on nearby nerve endings.

Phagocytosis and Purulent Exudate

The final step of the inflammatory process is the destruction of pathogenic organisms and their toxins by leukocytes. During this process, a purulent exudate (pus) may form that contains protein, cellular debris, and dead leukocytes.

Immune System

The immune system is the body's final line of defense against infection. Immune cells and lymphoid tissue work with the body's other defense mechanisms. Immune cells include lymphocytes (T cells, B cells, and natural killer cells), which have protective functions related to specific antigens. Macrophages assist T and B lymphocytes.

phagocytosis: phagein—to eat + cytos—cell + osis—condition

The lymphoid organs are the thymus, which is vital to the development of the immune system, and the bone marrow, which produces leukocytes. Other lymphoid structures include the spleen, tonsils, intestinal lymphoid tissue, and lymph nodes, where immune cells grow and whose filtering of foreign materials prevents them from entering the bloodstream. The spleen destroys old or damaged red blood cells and contains large amounts of lymphocytes.

The immune system is a finely tuned network that functions together to protect the body from invasion by pathogenic organisms. When this network breaks down, infectious disease can result.

INFECTIOUS DISEASE

General Clinical Manifestations of Infections

Localized Infection

Localized infection is caused by an increase of microbes in one area that triggers the inflammatory response. Manifestations of a local infection include pain, redness, swelling, and warmth at the site. Pain is most severe when the infection occurs in closed cavities. Redness and swelling are seen when surface structures are involved. Warmth may be felt at the site. Body temperature may rise, producing an antimicrobial effect.

Generalized Infection

Generalized infections occur when there is systemic or whole body involvement. Symptoms of generalized infection may include headache, malaise, muscle aches, fever, and anorexia. As the infection progresses, there can be an increase in fever, elevated white blood cell count, decreased blood pressure, mental confusion, tachycardia, and shock. **Sepsis** is the term used for an infection that has spread to the bloodstream.

Laboratory Assessment

Several methods are used to identify pathogens. One method is performing a microscopic examination, such as Gram's method of staining. Another method is culture and sensitivity (C&S). Organisms found in the culture specimen are grown on a laboratory plate and identified within 24 to 48 hours. A sensitivity examination is then done, which exposes any organism to many antibiotics to determine which antibiotic will be most effective for treatment.

A serum antibody test measures reaction to a certain antigen. A positive result on this test does not always mean an active infection is present. It can simply mean there has been an exposure to the antigen, so it is not as accurate as a culture.

A complete blood cell count with differential (CBC with diff) is usually obtained when an infectious disease is suspected. The five different types of leukocytes and their levels are identified. Elevations in specific leukocytes occur based on the type and severity of the pathogen.

Erythrocyte sedimentation rate (ESR, sed rate) is an early screening test for inflammation but not a definitive test for infection. During the inflammatory process, red blood cells become heavier and during the test settle to the bottom of a tube. The ESR measures in millimeters per hour the speed at which the red blood cells settle in the tube. The faster the settling, the greater the inflammation.

Other tests such as x-rays, computed tomography (CT), and magnetic resonance imaging (MRI) are helpful in identifying abscesses (walled-off infections). Skin tests diagnose infections, such as the purified protein derivative (PPD) skin test, which screens for tuberculosis. (See Chapter 31.)

Immunity

Immunity is the ability of the body to protect itself from disease. (See Chapter 17.) There are several types of immunity:

- Natural immunity occurs in species and prevents one species from contracting illnesses found in another species.
- Innate immunity is genetic, hereditary immunity is that which a person is born with.
- Acquired immunity is obtained either actively or passively through exposure to an organism, from a vaccine, or from an injection of immunoglobulins (antibodies) or is passed from mother to baby.

Types of Diseases

There are many types of infectious diseases. Those discussed are found in the chapters related to the body system they affect. For respiratory diseases such as tuberculosis, see Chapter 31; for bloodborne diseases such as HIV, see Chapter 19; for hepatitis, see Chapter 35. Mononucleosis is discussed below.

Mononucleosis

Infectious mononucleosis (referred to as mono or the kissing disease) is an infection that is usually caused by the Epstein-Barr virus (a herpesvirus). Mononucleosis is a contagious disease that anyone may develop. However, it is mainly diagnosed in young adults. Most adults have been exposed to the virus and have antibodies to it but never develop the disease. The virus remains in the body for a lifetime but rarely causes another infection.

Mononucleosis is primarily spread through person-to-person contact, mainly through saliva. Sharing utensils, food, or beverages can transmit the disease. Coughing or sneezing of small droplets of infected saliva or mucus into the air allows the virus to be inhaled by others.

The incubation period for mononucleosis is 4 to 8 weeks after exposure. Symptoms during the first 3 days include extreme fatigue, loss of appetite, and chills. Then a severe sore throat, headache, high fever, reddened throat and tonsils with a white coating, generalized lymphadenopathy (enlarged lymph nodes in two different sites other than inguinal nodes), or diarrhea occur. The spleen enlarges 50% of the time. Occasionally, a rash develops similar to the measles.

Signs and symptoms, as well as diagnostic tests, confirm mononucleosis. Lymphocyte levels are elevated. The monospot and heterophile antibody tests confirm mononucleosis.

Usually no specific treatment is needed. The illness runs its course as other viral illnesses do. Antiviral drugs are not effective. Symptoms are treated as needed with supportive care. Fatigue may last for months. Rest is important. If the spleen is enlarged, contact sports, lifting, and straining are avoided to prevent trauma and rupture. Mild inflammation of the liver or hepatitis may occur, but no treatment is usually required. Other complications are rare.

INFECTION CONTROL IN THE COMMUNITY

Many levels of organizations work closely together to control communicable diseases. The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) teach standards to prevent and control diseases and monitor disease outbreaks. Local health departments teach how to prevent and control the spread of disease. Community immunization programs have helped reduce infectious diseases.

Although requirements vary from state to state, most elementary schools require some proof of childhood immunization. Many colleges also require or recommend immunization to help control the outbreak of diseases such as measles and meningitis. In addition, educating the public about the importance of hand hygiene, immunization, clean water, safe food handling techniques, and safer sex precautions in preventing the spread of disease is essential.

Both the hospital and home health-care nurse have a responsibility to provide infection control teaching for the patient with an infection and his or her family. Such techniques may include use of disposable dishes and utensils and disposable gloves and proper disposal of contaminated items. Techniques used should be specific to the interruption of the transmission of the particular disease.

INFECTION CONTROL IN HEALTH-CARE AGENCIES

If on admission to a hospital or health-care agency a patient already has an infection, it is referred to as a community-acquired infection. An infection that develops as a result of the stay in the hospital or health-care agency is called a **nosocomial infection**. The host's condition plays a major role in whether or not an infection is acquired. Patients in the hospital are commonly debilitated, malnourished, or immunocompromised. Multiple antibiotic therapy also increases susceptibility to other types of infection and promotes the resistance of pathogens to antibiotics. Therefore, the risk of developing a nosocomial infection is very high. Some areas within an institution tend to have an increased number of nosocomial infections, such as intensive

care, neonatal, dialysis, oncology, and burn units. Patients in these areas tend to undergo more invasive procedures and are debilitated, increasing susceptibility to infection.

Several pathogens are commonly responsible for causing nosocomial infections:

- *Escherichia coli* (*E. coli*) is the most common pathogen causing nosocomial urinary tract infections. *E. coli* normally lives in the healthy intestinal tract of humans. *E. coli* can be spread by the patient, by the unwashed hands of a health-care worker, or through contaminated food and water.
- *Staphylococcus aureus* (commonly known as staph) is the most common pathogen causing nosocomial surgical wound infections and nosocomial septicemia. Staph usually lives in the nose and on the skin of healthy people. (Some highly pathogenic strains of staph are also emerging in the world.)
- *Pseudomonas aeruginosa* is the most common pathogen in nosocomial pneumonia. It is found in soil, around water, and in the health-care setting around sinks, water, irrigating solutions, and nebulizers on respiratory equipment.

The single most effective way to prevent and control the spread of infection is by effective hand hygiene. Most organisms in the institutional setting are transmitted via the hands of health-care workers. Hands *must* be washed before and after every patient contact to prevent the direct transmission of organisms (Fig. 7.2). Patients may also transmit organisms with inadequate hand washing. Teach patients the importance of hand washing after handling their own secretions. The use of gloves decreases the transmission of organisms, but CDC guidelines also require hand washing before and after glove use.

SAFETY TIP

Proper hand washing requires wetting the hands, soaping, and lathering, with at least 15 seconds of rubbing your hands together, covering all surfaces. Interlace your fingers to cleanse between them, rub your nails against your palms to clean under the nails, and then rinse your hands with fingertips pointed downward under running water. Dry your hands with clean disposable paper towels. Use the paper towel to turn off the faucet. Apply lotion to your hands to prevent drying and cracking in which infection could develop. Avoid hot water as it causes drying (CDC, 2002).

Asepsis

The concept of **asepsis** (freedom from organisms) is important for all health-care workers who have direct or indirect patient contact. For hospitalized patients, the most common sites for infectious diseases are the genitourinary tract, respiratory tract, bloodstream, and surgical wounds. Be aware

CRITICAL THINKING

Mrs. Sampson

■ Mrs. Sampson has neutropenia from chemotherapy treatments.

1. Why is hand hygiene the most important intervention you can do to help prevent infection for Mrs. Sampson?
2. What would be a priority nursing diagnosis for Mrs. Sampson?
3. What type of isolation could be beneficial to Mrs. Sampson?

Suggested answers at end of chapter.

of patients at risk of developing these infections and protect them with aseptic techniques.

Medical Asepsis

Medical asepsis is commonly referred to as clean technique. The goal is to reduce the number of pathogens or prevent the transmission of pathogens from one person to another. Frequent, proper hand hygiene is one of the best ways to achieve this goal. Gowns, gloves, masks, and protective eyewear or rooms with special ventilation may also be helpful (Fig. 7.3). Disinfectants and precautions as defined by the CDC are also crucial tools. Techniques used should be appropriate to interrupt the spread of the known pathogen. As part of medical asepsis you should keep your own body and clothing clean to prevent spread of infection to patients, yourself, and your family (Box 7.3 Guidelines to Prevent Spread of Infection to the Patient, Self, and Family).

FIGURE 7.2 Frequent hand washing by health care workers helps reduce the spread of microorganisms.

FIGURE 7.3 Gloves, gowns, masks, goggles, and face shields help prevent the spread of infection to health care workers and patients.

Surgical Asepsis

Surgical asepsis (sterile technique) refers to an item or area that is free of all microorganisms and spores. Surgical asepsis is used in surgery and to sterilize equipment. Articles can be subjected to intense heat or chemical disinfectants to destroy all organisms. The use of pressurized steam sterilizers, called autoclaves, kills even the most powerful organisms. Some equipment cannot be exposed to moist heat, so gas sterilizers are used instead. Once these articles are sterilized, they are dated, packaged, and sealed. Once a package is opened or outdated, it is no longer considered sterile. Sterile technique is rarely required in the home-care setting.

Infection Prevention Guidelines

The CDC guidelines for infection control and isolation precautions are used in hospital and health-care agency policies. CDC and agency guidelines are continuously updated and should be followed for your protection, as well as your patients'. Current CDC guidelines for isolation precautions in hospitals include two tiers of precautions: standard precautions and transmission-based precautions (Table 7.2). Visit <http://www.cdc.gov/ncidod/hip/Guide/guide.htm> for more details.

Standard Precautions

Standard precautions are used in the care of *all patients*. These precautions require you to assume that all patients are infectious regardless of their diagnosis. Standard precautions apply to blood, secretions, excretions, open skin, mucous

Box 7.3**Guidelines to Prevent Spread of Infection to the Patient, Self, and Family**

- Bathe daily and wear a clean uniform/clothing every day.
- Keep your fingernails short and do not wear acrylic nails. Both long nails and acrylic nails have been associated with spread of infection to patients and they can be colonized with harmful bacteria. Multiple studies have demonstrated that long fingernails and artificial nails harbor bacteria and have caused infections in patients that sometimes have resulted in death.
- Avoid wearing rings and bracelets that harbor organisms.
- Cleanse your stethoscope at least daily and in between patient use with alcohol. VRE bacteria have been cultured from stethoscopes in a hospital setting.
- Wash your hands between each patient contact. Hand washing is recognized as the single most important action to take to prevent spread of infection. If you are unable to use soap and water, use a nondrying alcohol hand gel, which has been shown to be effective in cleansing hands and preventing drying of the skin.
- Follow prescribed isolation precautions for your protection, as well as that of the patient.
- Remove your uniform and bathe/shower when you come home from work. This will decrease the spread of antibiotic-resistant bacteria to your home and your family. Keep your nursing shoes clean and put away from the rest of the family.

membranes, and all body fluids, excluding sweat. All patients with draining wounds or secretions of body fluids are considered infectious until an infection is confirmed or ruled out. Using gloves, gowns, masks, goggles, face shields, and, most important, hand washing helps prevent the spread of infection to health-care workers and other patients.

CRITICAL THINKING

- Which of the following patients is at greatest risk for infection and why?
1. Mr. Ashland, age 55, is hospitalized for a hernia repair. He is overweight and has adult-onset diabetes.
 2. Mrs. Burrows, age 72, is hospitalized for a broken hip. She is thin, frail, has dementia, and has undergone placement of a urinary catheter.
 3. Jackson Dunn, age 2, is hospitalized for minor surgery. Jackson is thin and small for his age.

Suggested answers at end of chapter.

Transmission-Based Precautions

Transmission-based precautions are used for patients with specific communicable diseases that can be transmitted to others. Transmission-based precautions are an additional layer of protection used in addition to standard precautions.

Prevention of Respiratory Tract Infections

Nosocomial pneumonia has been linked with the highest infection mortality rate in hospitalized patients. Patients who are at highest risk for pneumonia are those with endotracheal, nasotracheal, or tracheostomy tubes because these invasive tubes bypass the normal defenses of the upper respiratory tract. Strategies to prevent infections such as ventilator-associated pneumonia (VAP) are being “bundled” together to get health-care workers to remember to use these strategies. For more information on VAP bundles, visit <http://www.ihl.org/IHI> and put “VAP bundle” in search or visit <http://www.ihl.org/NR/rdonlyres/35B687FE-D4D0-44E5-A671-E76D74BB8D9F/0/VAP.pdf#search='canadian%20vap%20bundle'>

Prevention of Genitourinary Tract Infections

The most common hospital-acquired infection is a urinary tract infection. Patients with urinary catheters are at the greatest risk. The urinary tract is normally a sterile tract, but insertion of a catheter into the bladder may allow organisms to enter. Institutional policy on appropriate use of urinary catheters differs, and you should follow the policy of your particular institution. Appropriate uses of catheters include use in patients with urinary obstructions, neurogenic bladder conditions, and in those in shock.

Indwelling urinary catheters should be removed as soon as possible. For patients requiring long-term use of urinary catheters, intermittent catheterization is preferred because it has been shown to significantly reduce the risk of infection. Using strict aseptic technique while inserting and caring for the catheter in the health-care agency is imperative. The catheter tubing must be securely anchored to the patient’s leg, according to agency protocol, so it does not move in and out of the urethra. Movement can encourage organisms to enter the urinary tract.

The closed urinary drainage system seal should never be opened. If intermittent irrigation is ordered, sterile technique must be used to protect both ends from contamination. The drainage bag should be positioned so that it is never higher than the level of the bladder to prevent backflow of urine into the bladder, which could contaminate the sterile urinary tract. If an indwelling urinary catheter and drainage system is used long term, the catheter and the entire system should be changed regularly using sterile technique. Standards in home care differ from institutional care because patients are generally at lower risk of infection within their own environment.

All long-term indwelling urinary catheters are considered colonized, but only a few will cause infection in the patient. Remember that the most crucial point at which

TABLE 7.2 STANDARD PRECAUTIONS AND TRANSMISSION-BASED PRECAUTIONS

Standard Precautions	
Use standard precautions for all patient care. Combine standard precautions with transmission-based precautions as needed based on the patient's illness.	
Hand washing	Wash hands with nonmicrobial soap unless specially contraindicated before and after using gloves, between patients, and between procedures on same patient.
Gloves	Wear gloves before contact with any body fluids or substances.
Mask, Eye Protection, Face Shield	Use protective equipment for patient care if splashes or sprays of blood or body fluids are likely.
Gown	Wear gown to protect skin/prevent soiling of clothing for patient care if splashes or sprays of blood or body fluids are likely.
Occupational Health and Bloodborne Pathogens Patient Care Equipment	Dispose of sharps properly; do not recap needles. Clean reusable equipment before reuse. Discard single-use items properly.
Linen	Handle linen to avoid clothing contamination.
Patient Placement	Use private room for infectious patients.
Transmission-Based Precautions	
Airborne Precautions	
Examples: measles, tuberculosis, varicella (chickenpox, shingles)	
Patient placement	Provide private room with regulated air flow. Keep door closed.
Respiratory protection	Do not enter room if susceptible to measles or chickenpox unless no immune caregivers available. If susceptible, wear fit-tested N95 or HEPA respirator.
Patient transport	Limit patient transport to essential purposes. Place surgical mask on patient.
Droplet Precautions	
Examples: diphtheria (pharyngeal), <i>Haemophilus influenzae</i> (epiglottitis, meningitis, pneumonia, sepsis), influenza, mumps, mycoplasma pneumonia, <i>Neisseria meningitidis</i> (meningitis, pneumonia, sepsis), pertussis, pneumonic plague, rubella, streptococcal pneumonia	
Patient placement	Provide private room or separation of at least 3 feet between the infected patient and other patients.
Mask	Wear mask for patient care if within 3 feet of patient.
Patient transport	Limit patient transport to essential purposes. Place surgical mask on patient.
Contact Precautions	
Examples: cellulitis, <i>Clostridium difficile</i> , skin infections (diphtheria, herpes simplex virus, impetigo, pediculosis, scabies, conjunctivitis, viral hemorrhagic infections (Ebola, Lassa, or Marburg), herpes zoster	
Patient placement	Provide private room or place with patient with same infection and no other infection.
Hand washing, gloves, gown	Protect self and others from contaminated items.
Patient transport	Limit patient transport.
Patient care equipment	Dedicate the use of noncritical patient care equipment to a single patient.

Data from Public Health Service, US Department of Health and Human Services, Centers for Disease Control and Prevention, Atlanta, and Garner JS, Hospital Infection Control Practices Advisory Committee: Guideline for isolation precautions in hospitals. *Infect Control Hosp Epidemiol* 17:53, 1996; and *Am J Infect Control* 24:24, 1996
 Accessed on August 15, 2005 at http://www.cdc.gov/ncidod/hip/ISOLAT/std_prec_excerpt.htm

bacteria may enter the patient is during the insertion of the catheter, so excellent technique is required. Another point to remember is that the urinary tract is highly vascular (many blood vessels close to the surface), so that an infection in this tract can easily result in bacteremia (bacteria in the

SAFETY TIP

Catheters should be used only when necessary because of the **morbidity** and **mortality** associated with infections that develop from them.

CRITICAL THINKING

Mr. Carson

■ While working in an extended-care facility you see Mrs. Brandt, nursing assistant, wheeling Mr. Carson to activities. He has a long-term urinary catheter. The urine bag is hung on the arm of the wheelchair with a cloth partially covering it. What is your responsibility in this situation?

Suggested answers at end of chapter.

blood), which can then progress to septicemia (infection in the blood), a potentially life-threatening condition.

Prevention of Surgical Wound Infections

The initial dressing for surgical wounds is applied in the operating room using sterile aseptic technique. Postoperative orders indicate when to change the dressing. Sterile technique should be used. The wound is monitored with every dressing change for signs of infection.

Protection from Septicemia (Sepsis)

Septicemia (commonly called blood poisoning) is a blood infection with a variety of causes, including infection in another body site and contamination of invasive catheters and solutions (central lines, arterial lines, pulmonary artery catheters, urinary catheters). Insertion and care of these catheters require sterile technique and careful observation for infection signs. All solutions should be examined for expiration date, signs of contamination, cloudiness, particles, or discoloration before use. Indications of sepsis such as fever, tachypnea, tachycardia, hypotension, and elevated white blood cell count should be reported promptly to the physician for immediate treatment. Blood cultures may be ordered. Antibiotics are used to treat sepsis. An intravenous (IV) drug, drotrecogin alfa (activated) (Xigris), is available to treat severe sepsis when death is likely. Drotrecogin alfa (activated) is given for 96 hours. It is associated with a risk of bleeding. Drotrecogin alfa (activated) has reduced mortality in patients, which may be due to its anti-inflammatory effects.

ANTIBIOTIC-RESISTANT INFECTIONS

Antibiotic-resistant infections are on the rise. These types of infections result in increased health-care costs, morbidity (death), and mortality (illness). Methods to prevent these infections include not using antibiotics in animal feed, teaching patients to take all prescribed medications exactly as ordered, and avoiding the use of antibiotics for viral infections (common cold or flu). American College of Physicians/American Society of Internal Medicine guidelines suggest that most upper respiratory infections do not require antibiotic treatment. For healthy adults with the symptoms of bronchitis, sinusitis, pharyngitis, and other upper respiratory infections, over-the-counter cold symptom remedies and saltwater gargles should be used for symptom relief.

Two infections that are on the rise include methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE). For more information on antibiotic resistance, visit the World Health Organization at <http://www.who.int/csr/en/>.

Methicillin-Resistant *Staphylococcus Aureus*

A serious antibiotic-resistant infection is caused by methicillin-resistant *S. aureus* (MRSA). MRSA is difficult to treat

NURSING CARE TIP

Antibiotics are not effective against viral infections such as colds or the flu. People need to be educated that antibiotics do not work on viral infections. The misuse of antibiotics is creating antibiotic-resistant “superbugs.” People should not ask health-care providers for antibiotics to treat viral infections. Use of antibacterial products such as antibacterial soaps may also contribute to the superbug problem. Nurses play a vital role in educating people of this growing problem.

and has a high mortality rate. MRSA affects mainly the elderly and the chronically ill. Vancomycin hydrochloride, a potent and expensive antibiotic, can be used intravenously to treat MRSA. Fear exists that the bacteria will further mutate to become resistant to all currently available antibiotics. A few isolated cases of this have been documented worldwide. The risk that these resistant organisms will spread is real, which will return us to the preantibiotic days when *S. aureus* was a killer.

Vancomycin-Resistant Enterococci

Vancomycin-resistant enterococci (VRE) infections are common. Although enterococci are normal flora in the GI and female genital tracts, VRE are a new pathogenic strain. VRE are transmitted via direct or indirect contact. Patients at risk for VRE infections include those with indwelling urinary or central venous catheters, the immunocompromised or critically ill, those receiving multiple antibiotics or vancomycin therapy, surgical patients, and those with extended hospital stays. Preventive VRE measures focus on proper hand hygiene, education of health-care workers, aggressive infection-control methods, and restricting use of vancomycin. Patients with VRE should be isolated, and current CDC and institutional isolation policies should be strictly followed (Fig. 7.4). Treatment is difficult, involving combination antibiotic therapy, although VRE may also be resistant to other antibiotics.

Quinupristin/dalfopristin (Synercid) is an intravenous drug for VRE treatment. Linezolid (Zyvox) can treat both

Antibiotic-Resistant Organism Precautions

Visitors: Report to the Nurses' Station before entering the room.

1. **Private** room required.
2. **Gloves** must be worn by all hospital personnel entering room.
3. **Wash Hands** on entering and leaving room.
4. **Gowns:** required **IF** contamination of clothing is likely.
5. **Decontaminate All Equipment** used in the room before removal from the room.

FIGURE 7.4 Antibiotic-resistant organism precautions for vancomycin-resistant enterococci (VRE).

VRE and MRSA and should ideally be used only for these serious infections so that resistance does not develop. Research is ongoing to develop more antibiotics for resistant organisms, but antibiotic-resistant bacteria remain a very serious threat to the health of the world population.

THERAPEUTIC INTERVENTIONS FOR INFECTIOUS DISEASES

Treatment is begun once an infectious organism and the affected body system are identified. The type of organism and site of infection are important in selecting an appropriate medication. The drug of choice must be able to destroy (or control) the pathogen:

- Antibiotics treat bacterial infections, not viruses, fungi, helminthes, or prions.

- Antiviral medications treat viral infections, but their use is aimed at symptom control rather than cure.
- Antifungal drugs are available for fungal infections, but cure may require extended use.

Cost effectiveness is another concern when selecting a medication. Newer anti-infectives can be very expensive.

Antibiotics can be classified as either bactericidal or bacteriostatic (Table 7.3). Bactericidal agents kill bacteria, whereas bacteriostatic agents inhibit or retard bacterial growth, leaving the final destruction of the bacteria up to the infected host's immune system. Bacteriostatic agents may be less helpful for the patient who is immunocompromised.

When preparing to give an antibiotic, first ask about allergies a patient may have. Patients may have allergies to one antibiotic group that prevents the use of chemically similar drugs. Therefore, all allergies should be reported to the health-care provider.

TABLE 7.3 MEDICATIONS FOR TREATING INFECTIOUS DISEASE

Type and Examples/Uses	Nursing Implications	Patient Teaching
Bactericidal Antibiotics		
<p>Penicillins amoxicillin (Amoxil), ticarcillin (Ticar), penicillin G, ampicillin (Omnipen)</p> <ul style="list-style-type: none"> • Most effective against gram-positive organisms. 	<ul style="list-style-type: none"> • Most widely used antibiotic. • Monitor patient for allergic reaction (rash, hives, itching) or anaphylactic shock (fever, chills, trouble breathing, lower blood pressure, tight throat). Keep epinephrine available. • If signs of allergic reaction occur, stop parenteral drug and notify primary care provider immediately. • Watch for superinfection. 	<ul style="list-style-type: none"> • Review signs of allergic reactions. • Tell patient and family to stop drug and call primary care provider if allergy signs occur. • Tell patient to notify primary care provider if white patches appear in mouth or vagina becomes irritated.
<p>Cephalosporins <i>cephalothin (Keflin), cefazolin (Ancef), cefaclor (Ceclor), ceftriaxone (Rocephin)</i></p> <ul style="list-style-type: none"> • First-generation drugs are most effective against gram-positive organisms. • Second- and third-generation drugs are more effective against gram-negative organisms. 	<ul style="list-style-type: none"> • Patient with penicillin allergy may have cross allergy to cephalosporins. • Common side effects include GI disturbance, phlebitis, pain at injection site, rash, and hives. • Less common but serious side effects include kidney and liver damage and superinfection. • Monitor blood urea nitrogen, creatinine, lactic dehydrogenase, aspartate aminotransferase, and alanine aminotransferase to detect kidney or liver damage. 	<ul style="list-style-type: none"> • Tell patient to take drug on an empty stomach, 1 hour before or 2 hours after meals, to increase absorption. • Tell patient to take drug at specified intervals over 24-hour period.
<p>Aminoglycosides amikacin (Amikin), gentamicin (Garamycin), tobramycin (Nebcin)</p> <ul style="list-style-type: none"> • Used to treat gram-negative organisms. 	<ul style="list-style-type: none"> • Usually given parenterally because they are not absorbed well in GI tract. • Monitor peak and trough levels to keep drug in therapeutic range. • Assess patient's kidney function. • Check for ototoxicity (ringing in ears, deafness). • Don't mix or infuse with any other drug. 	<ul style="list-style-type: none"> • Tell patient to report signs of allergy, tinnitus, vertigo, or hearing loss. • Tell patient to obtain daily weights because weight gain may indicate kidney problems.

(Continued on following page)

TABLE 7.3 MEDICATIONS FOR TREATING INFECTIOUS DISEASE (Continued)

Type and Examples/Uses	Nursing Implications	Patient Teaching
<p>Fluoroquinolones ciprofloxacin (Cipro), levofloxacin (Levaquin), norfloxacin (Noroxin), ofloxacin (Floxin), trovafloxacin (Trovan)</p> <ul style="list-style-type: none"> Used to treat a variety of infections, such as bronchitis, bone and joint infection, pneumonia, tuberculosis, sexually transmitted disease, and urinary tract infection. 	<ul style="list-style-type: none"> Give drug on an empty stomach. Monitor liver function and report signs of dysfunction (fatal hepatitis may occur). Do not give with antacids that contain aluminum, calcium, or magnesium. 	<ul style="list-style-type: none"> Tell patient to take with a full glass of water; encourage fluids. Tell patient to report side effects: swelling of face/throat, trouble swallowing, shortness of breath, itching, hives, pain in shoulder, hands, or heel tendons. Explain that drug may cause drowsiness and increase sensitivity to light. Advise sun protection.
Bacteriostatic Antibiotics		
<p>Tetracyclines tetracycline HCl, doxycycline (Vibramycin), minocycline HCl (Minocin)</p> <ul style="list-style-type: none"> Treat most gram-positive and gram-negative organisms. 	<ul style="list-style-type: none"> Tetracycline HCl comes only in oral form. The others are usually given IV because intramuscular route leads to poor absorption. Give 1 hour before or 2 hours after meals. Do not give with milk, milk products, or antacids because they impair absorption. GI disturbances are the most common side effect. Tetracyclines increase anticoagulant activity. Monitor prothrombin time, international normalized ratio, partial prothrombin time as ordered. 	<ul style="list-style-type: none"> Suggest eating crackers and juice (but not a full meal) to reduce GI upset. Tell patient to avoid prolonged sun exposure during therapy.
<p>Erythromycin E-mycin, EES, erythromycin</p> <ul style="list-style-type: none"> A broad-spectrum antibiotic effective against many gram-negative and gram-positive organisms. 	<ul style="list-style-type: none"> Give on an empty stomach 1 hour before or 2 hours after meals. Give with a full glass of water (not with acidic fruit juices, such as orange juice or grapefruit juice). When giving drug IV, administer slowly to decrease vein irritation. 	<ul style="list-style-type: none"> Urge patient to take drug around the clock and complete entire course of treatment. Explain that gastric distress is common but not a reason to stop the drug. Suggest that patient contact primary care provider if side effects are intolerable.
<p>Sulfonamides sulfamethoxazole (Gantanol), sulfasalazine (Azulfidine), sulfisoxazole (Gantrisin), trimethoprim sulfamethoxazole (Bactrim, Septra)</p> <ul style="list-style-type: none"> Effective against most gram-positive and many gram-negative organisms. 	<ul style="list-style-type: none"> Commonly used with urinary tract infections, <i>Pneumocystis carinii</i> pneumonia, and otitis media. Common side effects include rash, pruritus, nausea, vomiting, phlebitis, signs of bleeding. IV drug should be given over 1 hour. Monitor intake and output Fluid intake should be at least 1500 mL daily. Bleeding time may increase, so use caution with anticoagulants. Phenytoin (Dilantin) toxicity may be increased. The risk of hypoglycemia may be increased. 	<ul style="list-style-type: none"> Instruct patient to take drug on an empty stomach 1 hour before or 2 hours after meals. Tell patient to take with a full glass of water; encourage fluids. Advise against prolonged exposure to the sun. Tell patient to stop drug and call primary care provider if signs of allergic reaction or bleeding occur.
Antifungal Agents		
<p>Amphotericin B</p> <ul style="list-style-type: none"> Interferes with the cell wall structure of the fungus, causing it to die. 	<ul style="list-style-type: none"> Given parenterally and reserved for life-threatening fungal infections. Monitor patient during first hour of infusion for febrile reaction. Monitor injection site often because drug is very irritating to tissues. 	<ul style="list-style-type: none"> Explain the purpose of treatment and need for long-term IV therapy. Instruct patient and family on side effects and possible discomfort at IV site.

Type and Examples/Uses	Nursing Implications	Patient Teaching
<p>Fluconazole (Diflucan)</p> <ul style="list-style-type: none"> Used to treat candidal and urinary tract infections, as well as cryptococcal meningitis. 	<ul style="list-style-type: none"> Report side effects: nausea, vomiting, diarrhea. Monitor intake and output, blood urea nitrogen (BUN), and creatinine levels for signs of kidney damage. Obtain daily weight because fluid retention follows kidney damage. Encourage 2000–3000 mL of fluid daily to help flush drug through kidneys. Can be given either parenterally or orally. Cultures are obtained before giving drug. Monitor BUN and creatinine. Use cautiously if patient has renal impairment. Monitor liver function. Monitor side effects: hepatotoxicity, nausea, vomiting, diarrhea, abdominal discomfort. 	<ul style="list-style-type: none"> Tell patient to take drug at same time each day and not to double a dose if one is missed. Teach patient and family to notify the primary provider at the first sign of yellow skin, dark urine, or pale stools (signs of liver damage).

Many antibiotics are metabolized by the liver and excreted by the kidneys. Disorders of these organs may require lower doses. Antibiotic levels fluctuate greatly depending on organ function, age, sex, health, and other factors. Antibiotic peak (highest blood level) and trough levels (lowest blood level) need to be monitored to prevent toxicity and damage to major organs.

General Principles

Nurses are responsible for administering medications correctly, including giving the correct dose and for teaching the patient the importance of taking these medications properly. Certain nursing and patient teaching responsibilities relate to *all* anti-infective medications. Consult drug references for further information before giving anti-infectives.

Nursing Responsibilities

- All patient allergies are noted, especially any documented allergy to the specific drug ordered or cross allergies to the drug ordered, and the primary care provider is notified of allergy before treatment is started.
- Monitor and report any side effects or signs of allergic response, especially anaphylactic reactions.
- Observe and report any signs of superinfection (one that occurs as a result of antibiotic use). For example, thrush may develop as antibiotics disrupt the normal flora of the GI tract.

Patient Education

- Stress to the patient and family the need to take *all* the medication exactly as prescribed. Explain that stopping treatment when the patient feels better results in potential relapse with more resistant organisms.

- Explain what signs and symptoms to watch for (allergic and nonallergic side effects) and what to do about them, especially when to call the primary care provider.

SAFETY TIP

Always review and know the normal dose of a medication before giving the medication. You are responsible for any medication you give, even if the dose was ordered incorrectly and you were following the order. If the dose is outside the normal range, do not give it. Consult with the RN, pharmacist, or supervisor who should contact the ordering physician for clarification. Always reviewing medication doses prior to giving them keeps your patient and your nursing license safe.

NURSING PROCESS

General Infections

Assessment/Data Collection

It is important to recognize the earliest signs and symptoms of infection. Early detection can help provide early treatment to prevent major complications and reduce costs. Providing emotional support to the patient is also important (Box 7.4, Patient Perspective). Patients who are prone to infection because of immunosuppression should take special precautions to prevent infection (Box 7.5, Teaching Points to Prevent Infection in the Older Adult, Debilitated, or Immunocompromised Patient).

CRITICAL THINKING

Mr. Cheevers

■ Mr. Cheevers is admitted to the hospital for IV antibiotic therapy. He states that he has no allergies. One hour after the infusion begins, you happen to meet the nursing assistant coming down the hall with a blanket. He casually says, “Mr. Cheevers is very cold. I’m bringing him a blanket. He is also restless and a bit short of breath.” What is your responsibility in this situation?

Suggested answers at end of chapter.

Nursing Diagnosis, Planning, and Implementation

Risk for infection related to external factors

EXPECTED OUTCOME: The patient remains free from symptoms of infection.

- Follow current hand hygiene guidelines *to reduce spread of infection.*
- Use standard precautions and transmission-based precautions *to prevent the transmission of organisms.*
- Observe and report signs of infection such as redness, warmth, and fever, especially for neutropenic

Box 7.4

Patient Perspective

Emotions of Chronic Infection

Eddie

It was back! I wasn’t sure I could deal with it one more time. I’ve been hospitalized four times with this same infection (cellulitis) in my leg. It feels like I’ve lost my life. I can’t count on being able to do anything and go anywhere because the infection just keeps coming back.

My left leg is now all swollen, reddened, discolored, and very painful. I can tell when I’m infected by more than the pain in the leg. I feel weak, kind of spacey, and once I passed out. I’m so sick of going into the emergency room—waiting forever to get admitted, all the IV starts and blood draws. With these infections, I’ve had a PICC (peripherally inserted central catheter) line twice. I’ve been sent home on IV antibiotics, sometimes for weeks at a time. I’ve learned how to hang my own IV antibiotics; in fact, I’ve learned much more than I ever wanted to.

My cellulitis is associated with chronic lymphedema, causing swelling in my legs. I’m working hard to keep the swelling down, so that the infection doesn’t reoccur. Wish me luck and keep giving me psychosocial support during your nursing care. I’m not sure how I will be able to deal with this much longer.

Box 7.5

Teaching Points to Prevent Infection in the Older Adult, Debilitated, or Immunocompromised Patient

- Wash your hands frequently, using proper technique.
- Avoid crowds or anyone with an infection.
- Stay well nourished because food helps keep the immune system healthy.
- Have a flu shot yearly and a pneumonia shot as recommended by your primary care provider.
- Wash raw fruits and vegetables thoroughly, cook food thoroughly, and store food safely to prevent food poisoning. (NOTE: with severe immunocompromization, raw foods, soft cheeses, and yogurt may be contraindicated.)
- If your immune system is depressed, notify your primary care provider about any elevated temperature, even in the absence of other symptoms. People with depressed immune function cannot mount the usual immune response to infection, and a low-grade fever may be the only sign of infection.

patients *as they do not have normal inflammatory response and low-grade fever is often the only sign.*

- Use oral thermometers for critically ill adults. *Oral thermometers are best practice if pulmonary artery catheters are not available for core body temperature.*
- Monitor laboratory values of white blood cell counts and cultures *as they correlate to patient’s immune function for planning care.*

Evaluation

If interventions have been successful, the patient remains free from symptoms of infection.

Imbalanced nutrition: less than body requirements related to problems eating or digesting food

EXPECTED OUTCOME: The patient maintains ideal body weight for height and weight and eats a balanced diet.

- Identify and provide foods patient enjoys with pleasant presentation *as patient will be more likely to try to eat enjoyed foods in a clean, odor-free environment.*
- Explain and ensure that a balanced diet with protein, fatty acids, and vitamins is available and should be eaten. *These nutrients are needed for healthy immune system function.*
- Monitor and document patient intake *to provide accurate nutritional assessment.*
- Provide antiemetics as ordered *to control nausea and vomiting and improve nutritional intake.*

Evaluation

If interventions have been effective, patient's body weight will be maintained within ideal body weight range and patient will eat a balanced diet. Patient will be free of signs and symptoms of infection.

Deficient knowledge related to disease process and treatment

EXPECTED OUTCOME: The patient describes therapy and carries out treatment.

- Explain infection and prevention of infectious diseases. *Patients' understanding of how infections occur helps them in controlling their risk for developing an infection.*
- Recommend responsible use of antibiotics to prevent resistant organisms.
- Explain medications, side effects, and symptoms to report to promote compliance with treatment and safe medication use.
- Teach patients how to participate in their own care and have them assist in the development of their plan of care to promote compliance with treatment.

Evaluation

If interventions have been effective, the patient will state understanding of therapy and plan and carry out treatment plan.

Respiratory Tract Infections

Assessment/Data Collection

Patients with respiratory tract infections may have a cough, a congested or runny nose, a sore throat, chest congestion, or chest pain. The throat may be reddened, or there may be white patches in the back of the throat. Lung sounds can include crackles, rhonchi, or wheezing. Ask patients if they have a productive cough and the amount, frequency, and color of the sputum. A sputum culture is obtained to identify the presence of pathogenic organisms for appropriate treatment.

Nursing Diagnosis, Planning, and Implementation

Risk for infection related to external factors

EXPECTED OUTCOME: The patient remains free from symptoms of infection.

- Encourage coughing and deep breathing to keep airways clear and prevent atelectasis.
- Provide oral care with toothbrush or suction-type toothbrush regularly to remove plaque *since Toothettes do not remove plaque, which has been found to contribute to pneumonia development.*
- Encourage fluids if not contraindicated. *Dehydration is associated with dry, sticky secretions that are difficult to cough up.*
- Provide pain relief so patient will take deep breaths.
- Elevate head of bed 30 degrees or more when a tube feeding is infusing to prevent aspiration pneumonia.
- Use sterile water rather than tap water from faucet

for oral care for immunocompromised patients to prevent nosocomial pneumonia infection.

Evaluation

If interventions have been effective, oxygen saturation will be above 90%, with report of decreased dyspnea. Respirations will be even and unlabored and patient will be free of signs and symptoms of infection.

Gastrointestinal Tract Infections

Assessment/Data Collection

The symptoms of GI tract infections may include nausea, vomiting, diarrhea, cramping, and anorexia. Patients may have frequent episodes of emesis and diarrhea and need to be monitored for signs of dehydration resulting from the loss of fluid. Stool cultures may be ordered.

Nursing Diagnosis, Planning, and Implementation

Risk for infection related to external factors

EXPECTED OUTCOME: The patient remains free from symptoms of infection.

- Encourage fluid intake to replace fluid lost during fever, vomiting, and diarrhea.
- Follow standard precautions to prevent the spread of *C. diff*, especially for older and immunocompromised patients. *C. diff does not usually cause infection in healthy adults.*

Evaluation

Patient will be free of infection and nausea, vomiting, diarrhea, cramping, anorexia, and dehydration if interventions have been successful.

Genitourinary Tract Infection

Assessment/Data Collection

Symptoms of a urinary tract infection (UTI) can include voiding urgency, frequency, burning, flank pain, change in color of urine, foul odor of urine, and confusion or change in mental status for the older adult. Monitor frequency, amount, color, and odor of the urine. Urinalysis and urine cultures may be ordered.

Nursing Diagnosis, Planning, and Implementation

Risk for infection related to external factors

EXPECTED OUTCOME: The patient remains free from symptoms of infection.

- Do not request and avoid use of urinary catheters unless no other options as patients are more likely to develop bacteremia.
- Use sterile technique for inserting urinary catheters to prevent nosocomial infections.
- Avoid contamination when emptying urinary catheter bags to prevent nosocomial infections.
- Use evidence-based facility policy for identifying and managing symptoms related to the urinary tract. *Evidence-based practice improves quality of care and reduces variability in management.*

- Standard diagnostic criteria should be used to identify, document, and communicate to physicians detailed symptoms such as fever or hematuria and not urine odor, urine color, clarity, or culture results alone *as they cannot distinguish symptomatic from asymptomatic infections and the need for medication.*
- Education of patients, residents, families, and staff should be given on evidence-based practice for UTI

identification and management *to promote appropriate practices.*

Evaluation

If interventions have been effective, patient will have normal urine output without symptoms of infection such as urgency, frequency, burning, flank pain, change in color of urine, foul odor of urine, or confusion or change in mental status.

REVIEW QUESTIONS

- Place the links in the chain of infection in their proper order of occurrence in causing an infection.
 - Portal of Entry
 - Causative Agents
 - Mode of Transmission
 - Portal of Exit
 - Reservoir
 - Susceptible Host
- Which of the following is the most important technique for the nurse to use during patient care to prevent infection transmission?
 - Wear gloves
 - Wear gown
 - Wash hands
 - Wear mask
- Which of the following nursing actions should the nurse include in the plan of care to help maintain the body's first line of defense against infection?
 - Help the patient cough and deep breathe.
 - Apply lotion to clean skin.
 - Give an antibiotic as ordered
 - Help the patient void.
- Which of the following patient temperature readings would be the priority for the LPN/LVN to report to the registered nurse?
 - Temperature 97°F (36.1°C) for older patient with hypertension
 - Temperature 98.9°F (37°C) for first day postoperative patient
 - Temperature 99.6°F (37.5°C) for patient with neutropenia
 - Temperature 100°F (37.7°C) for patient with appendicitis
- The nurse is to give a newly ordered antibiotic to a patient with a wound infection. Which of the following should the nurse do first?
 - Check all patient allergies.
 - Check the patient's temperature.
 - Change dressing and note wound appearance.
 - Give antibiotic before meal time.
- Which of the following is the most important action for the nurse to use to prevent a hospital-acquired urinary tract infection in a patient with an indwelling urinary catheter?
 - Ensure an adequate intake of IV and oral fluids.
 - Use clean technique for catheter insertion.
 - Position drainage bag higher than bladder level.
 - Maintain a closed urinary drainage system.
- Which of the following statements indicates to the nurse that the patient understands the general principles of appropriate antibiotic use?
 - "I'll take this until I start feeling better."
 - "I have pills left over from the last time I had this infection."
 - "I'll take all of this as it says to on the medication label."
 - "I take only half of a pill to reduce the cost of the pills."

1. Guideline for Hand Hygiene in Health-Care Settings MMWR October 25, 2002/51(RR16):1. CDC, 2002 accessed on 8/9/05 at <http://www.cdc.gov/mmwr/preview/mmwrhtml/r5116a1.htm>

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Sampson

1. Hand washing reduces the microorganisms on the nurse's hands to help reduce their transmission from patient to patient. This helps prevent exposure to pathogens and infection.
2. Risk for infection.
3. Reverse isolation, the goal of which is to protect the patient from exposure to organisms rather than to protect others from exposure to the patient.

■ Who Is at Greatest Risk of Infection?

1. Mr. Ashland has two risk factors: chronic disease and probably stress.
2. Mrs. Burrows has many risk factors, including old age, debilitated condition, probable malnourishment, probable stress, and an invasive procedure. This patient is at greatest risk.
3. Jackson has four risk factors: his young age, probable stress, possible malnourishment, and an invasive procedure.

■ Mr. Carson

1. Ask the nursing assistant about the urinary bag placed above the patient's bladder. Explain that the bag should always stay below the level of the bladder both for proper drainage and for infection control.
2. Assist the nursing assistant in repositioning the bag properly.
3. Let Mr. Carson's primary nurse know about the potential backflow of urine so that he can be assessed in the next few days for signs of a bladder infection.

■ Mr. Cheevers

Mr. Cheevers may be experiencing signs of allergic reaction to the medication. The fact that he has no history of allergy is no guarantee that he is not experiencing one now. He needs to be evaluated immediately, and if allergy is suspected, the IV should be stopped and the primary care provider notified. Epinephrine should be on hand to treat the patient for anaphylaxis. The primary nurse needs to be alerted to the situation in the event that it worsens. Later the nursing assistant can be instructed about the signs of allergic response.

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of shock and compensatory mechanisms?
2. What are the etiologies, signs, and symptoms of the four categories of shock?
3. What data should you collect when caring for patients with shock?
4. What are current therapeutic interventions for shock?
5. What nursing care should you provide for patients with shock?
6. How would the nurse prioritize care for a client in shock?
7. What findings would demonstrate a positive response to therapeutic interventions for shock?

Shock is a life-threatening condition. A patient in shock is in a state of circulatory collapse that results in organ damage and death without immediate treatment. Massive bleeding, overwhelming infection, severe allergic reactions, and cardiac failure are examples of conditions that may lead to shock. No matter what its source, shock is a medical emergency that requires rapid, comprehensive intervention in collaboration with the health care team.

Shock is defined as “inadequate tissue **perfusion**,” in which there is insufficient delivery of oxygen and nutrients to the body’s tissues and inadequate removal of waste products from these tissues. All body systems are affected by reduced oxygen supplies. The resulting injury to the body can be treated in the early stages of shock, but if shock is prolonged, it leads to irreversible cell damage and death. By the time blood pressure drops, cellular and tissue damage have already occurred. Therefore, it is important to identify patients at risk for shock and carefully assess them to detect early symptoms.

PATHOPHYSIOLOGY OF SHOCK

Tissue perfusion and blood pressure are maintained in the body by three mechanisms: (1) adequate blood volume, (2) an effective cardiac pump, and (3) effective blood vessels. The body is able to compensate for failure of one of these mechanisms by making a change in one or both of the other two. Shock occurs when compensatory mechanisms fail, resulting in inadequate tissue perfusion. Common causes of shock include inadequate **cardiac output** caused by heart failure, a sudden loss of blood volume resulting from hemorrhage, or a sudden decrease in peripheral vascular resistance caused by **anaphylaxis**, **sepsis**, and neurological alterations.

Metabolic and Hemodynamic Changes in Shock

When blood pressure falls, the body responds by activating the sympathetic nervous system. **Epinephrine** and **norepinephrine** are released from the adrenal medulla and increase cardiac output by causing the heart to beat faster and stronger. Blood is shunted away from the skin, kidneys, and intestines to preserve blood flow to the brain, liver, and heart. Epinephrine, cortisol, and glucagon raise blood glucose levels to supply cells with fuel. Stimulation of the renin-angiotensin-aldosterone system from decreased cardiac output causes vasoconstriction and retention of sodium and water to decrease further fluid loss. Respiratory rate increases to deliver more oxygen to the tissues. Together these compensatory responses produce the classic signs and symptoms of the initial stage of shock: **tachycardia**, **tachypnea**, restlessness, anxiety, and cool, clammy skin with

pallor. If oxygen delivery remains inadequate, signs and symptoms of progressive and irreversible shock stages are seen (Table 8.1).

CRITICAL THINKING

Classic Signs of Shock

- What is the cause and compensatory purpose of each of the classic signs of shock: tachycardia, tachypnea, **oliguria**, pallor, and cool, clammy skin?

Suggested answer at end of chapter.

LEARNING TIP

Tachycardia is a compensatory mechanism that is usually the first sign of shock. When a patient develops sustained tachycardia, it is a signal that the patient’s condition is changing. Be aware that elderly patients cannot tolerate tachycardia very long because their ability to adapt to stress is reduced.

Consider the cause of the tachycardia. For example, a surgical patient who develops tachycardia may be hemorrhaging and should be assessed for bleeding. Be aware that with internal hemorrhaging there may not be any visible signs of bleeding. Changes in vital signs may be the only evidence.

Provide prompt intervention, such as applying direct pressure to an area of hemorrhage, and implement the physician’s orders immediately.

Inadequate tissue blood flow causes an important change in cellular metabolism. When cells are deprived of oxygen, they shift to **anaerobic** metabolism to continue to receive nutrition and energy. As you may recall, anaerobic metabolism is an inefficient form of metabolism that can supply the energy needs of the cell for a few minutes only. After that, the body’s metabolic rate and temperature begin to fall as a result of reduced energy production. Anaerobic metabolism results in the production of **lactic acid** as an unwanted by-product. Unless the lactic acid can be circulated to the liver and thus removed from the bloodstream, the blood becomes increasingly acidic. **Acidosis**, which is a fall in blood pH below 7.35, is one of the classic signs of shock.

Effect on Organs and Organ Systems

Prolonged shock causes extensive damage to the organs and organ systems (Table 8.2). Inadequate blood flow results in

anaphylaxis: an—without + phylaxis—protection

tachycardia: tachy—fast + cardia—heart

tachypnea: tachy—fast + pnea—breathing

oliguria: olig—few + uria—urine

anaerobic: an—without + aerobic—presence of oxygen

acidosis: acid—sour + osis—condition

TABLE 8.1 SIGNS AND SYMPTOMS OF SHOCK STAGES

Signs and Symptoms	Stages		
	<i>Mild/Compensated Able to maintain BP and tissue perfusion</i>	<i>Moderate/Progressive Compensatory mechanisms start to fail</i>	<i>Severe Irreversible/Decompensated Do not respond to treatment Death is imminent</i>
Heart Rate	Tachycardia	Tachycardia >150 bpm	Slowing
Pulses	Bounding	Weaker, thready	Absent
Blood Pressure			
Systolic	Normal	Below 90 mm Hg In hypertensive 25% below baseline	Below 60 mm Hg
Diastolic	Normal	Decreased	Decreasing to 0
Respirations	Elevated	Tachypnea, crackles	Slowing
Depth	Deep	Shallow	Irregular, shallow
Temperature	Varies	Decreased May elevate in septic shock	Decreasing
Level of consciousness	Anxious, restless, irritable, alert, oriented, impending sense of doom	Confused, lethargy	Unconscious, comatose
Skin and Mucous Membranes	Cool, clammy, pale	Cold, moist, clammy, pale	Cyanosis, mottled, cold, clammy
Urine Output	Normal	Decreasing to less than 20 mL/hr	15 mL/hr decreasing to anuria
Bowel Sounds	Normal	Decreasing	Absent

CRITICAL THINKING

Anaerobic Metabolism

- Why is anaerobic metabolism necessary and helpful if it produces the complication of metabolic acidosis?

Suggested answer at end of chapter.

tissue **ischemia** and injury. Because blood is shunted away from the kidneys early in shock to save fluid and provide oxygen to vital organs, the kidneys commonly are injured first. The kidneys can tolerate reduced blood flow for about 1 hour before sustaining permanent damage. Cells in the kidneys die when there is a lack of oxygen and nutrients. If there is widespread damage to the kidneys, complete renal failure is likely. Renal failure resulting from inadequate blood flow to the kidneys can be prevented and treated by replacing lost fluids.

Several organs of the gastrointestinal system may be injured early in shock. Inadequate circulation to the intestines may result in injury of the mucosa and may even cause paralytic ileus. **Toxemia** may result when the body absorbs into the circulation normally occurring bacteria and endotoxins from inside the bowel. The liver may be injured both by ischemia and by toxins created by the shock state as blood is circulated through it for cleansing. Signs and symptoms of liver injury include decreased production of plasma proteins, abnormal clotting (because clotting factor production by the liver is impaired), and elevated serum levels of ammonia, bilirubin, and liver enzymes.

The immune system is also affected by shock. Many of the body's defenses become depleted from shock, leaving the body vulnerable to infection. Also, if the liver has been damaged, it is unable to assist the immune system in providing defense.

The body attempts to preserve blood supply to the heart and brain because these are vital organs that require a continuous supply of oxygen. Shock places extra demands on the heart itself, creating a situation in which the heart is in extra need of oxygen at a time when oxygen supplies are already low. When the **myocardium** receives inadequate oxygenation, cardiac output decreases and shock worsens.

TABLE 8.2 EFFECT OF SHOCK ON ORGANS AND ORGAN SYSTEMS

<i>Lungs</i>	Acute respiratory failure Acute respiratory distress syndrome
<i>Renal</i>	Renal failure
<i>Heart</i>	Dysrhythmias, myocardial ischemia, and myocardial depression
<i>Liver</i>	Abnormal clotting; decreased production of plasma proteins; elevated serum levels of ammonia, bilirubin, and liver enzymes
<i>Immune System</i>	Depletion of defense components
<i>Gastrointestinal System</i>	Mucosal injury, paralytic ileus, pancreatitis, absorption of endotoxins and bacteria
<i>Central Nervous System</i>	Ischemic damage, necrosis, brain death

The pumping ability of the heart can be further depressed by acidosis, toxins released into the blood from ischemic tissues, or ischemia-induced **dysrhythmias**. If the brain is deprived of circulation for more than 4 minutes, brain cells die from a lack of oxygen and glucose. Lengthy shock may result in brain death.

COMPLICATIONS FROM SHOCK

Acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), and multiple organ dysfunction syndrome (MODS) are three especially grave conditions that may follow a prolonged episode of shock. Patients with ARDS usually develop respiratory failure despite high levels of supplemental oxygen and mechanical ventilation. DIC results from ischemic damage to the endothelial lining of blood vessels. The formation of multiple tiny **thrombi**, microscopic debris, and depletion of tissue clotting factors cause abnormal bleeding and additional tissue damage. DIC itself may cause shock and death. MODS is a major cause of death following shock. When an organ has inadequate perfusion it fails, which may increase the rate of failure of other organs. It usually begins with respiratory failure, followed by failure of the kidneys, heart, liver, and finally cerebral and gastrointestinal function.

LEARNING TIP

To understand what *disseminated intravascular coagulation* means, define each of the words and then put the definitions together.

Disseminated = scattered or widespread

Intravascular: intra = inside + vascular = vessels

Coagulation = clotting

These definitions put together tell you that DIC is scattered, widespread clotting inside the vessels.

At first, hemorrhage does not seem reasonable in light of a clotting problem, but if you think about what is occurring, it does make sense. When many clots form throughout the body in response to stressors, few clotting factors remain available to form the clots needed to prevent hemorrhage. As a result, hemorrhage is a risk in DIC.

CLASSIFICATION OF SHOCK

The different forms of shock are classified by their cardiovascular characteristics (Table 8.3). The four shock categories are:

- **Hypovolemic** shock caused by a decrease in the circulating blood volume

- **Cardiogenic** shock caused by cardiac failure
- **Extracardiac** obstructive shock caused by a blockage of blood flow in the cardiovascular circuit outside the heart
- **Distributive** shock caused by excessive dilation of the venules and arterioles

Most cases of clinical shock show only some components of each of these categories. However, this classification system is helpful in understanding shock. The hallmark characteristic, exhibited in all forms of shock, is a decrease in blood pressure usually below the level required to provide an adequate supply of blood to the tissues.

Hypovolemic Shock

Any severe loss of body fluid may lead to hypovolemic shock. Hypovolemic shock can be caused by dehydration; internal or external hemorrhage; fluid loss from burns, vomiting, or diarrhea; or loss of intravascular fluid into the interstitium as a result of sepsis or **trauma**. Clinical signs and symptoms include pale, cool, clammy skin; tachycardia; tachypnea; flat, nondistended peripheral veins; decreased jugular vein circumference; decreased urine output; and altered mental status. The body is usually able to compensate for blood loss of less than 15% or 750 mL. The initial symptom may only be tachycardia. At 20% to 25% blood loss, tachycardia and mild to moderate **hypotension** are present. With a loss of 40% or greater (2000 mL), all clinical signs and symptoms of shock are present. Volume loss may not be the only contributing factor to hypovolemic shock, but also the patient's age, health status, and the time frame for fluid loss can be factors.

Cardiogenic Shock

Cardiogenic shock results when the heart fails as a pump. It occurs in 5% to 10% of patients with acute myocardial infarction (AMI). In most cases, approximately 40% of the myocardium must be lost to produce cardiogenic shock. Patients with cardiogenic shock have signs and symptoms similar to hypovolemic shock, except that they may display distended jugular and peripheral veins, as well as other symptoms of heart failure, such as pulmonary edema. The presence of pulmonary edema is what differentiates cardiogenic shock from other forms of shock. Other causes of cardiogenic shock include rupture of heart valves, acute **myocarditis**, end-stage heart disease, severe dysrhythmias, or traumatic injury to the heart.

Obstructive Shock

Extracardiac obstructive shock occurs when there is a blockage of blood flow in the cardiovascular circuit outside the heart. Several conditions may cause obstructive shock. **Pericardial tamponade**, which is the filling of the pericardial sac with blood, compresses the heart and limits its filling capacity. **Tension pneumothorax** compresses the heart from an abnormal collection of air in the pleural space and interferes with normal cardiac functioning. **Acute pulmonary hypertension**, a sudden abnormally elevated pressure in the pulmonary artery, increases resistance for blood

TABLE 8.3 CATEGORIES OF SHOCK

Category	Causes	Signs and Symptoms
<i>Hypovolemic Shock</i>	Any severe loss of body fluid; dehydration, internal or external hemorrhage, fluid loss from burns or from vomiting or diarrhea, or loss of intravascular fluid into the interstitium.	Tachycardia, tachypnea, hypotension, cyanosis, flat nondistended peripheral veins, decreased jugular veins, and altered mental status.
<i>Cardiogenic Shock</i>	Myocardial infarction, myocarditis, end-stage cardiomyopathy, severe dysrhythmias, valvular disease, severe electrolyte imbalance, and drug overdoses.	Dysrhythmias, labored respirations, hypotension, cyanosis, oliguria, altered mental status, possibly distended jugular and peripheral veins, and symptoms of congestive heart failure.
<i>Obstructive Shock</i>	Any block to the cardiovascular flow. Pericardial tamponade, tension pneumothorax, intrathoracic tumors, massive pulmonary emboli, and large systemic emboli.	Tachycardia, tachypnea, hypotension, cyanosis, oliguria, and altered mental status; jugular veins may be distended.
<i>Distributive Shock</i>	Any condition causing massive vasodilation of the peripheral circulation. Subcategories include anaphylactic, septic, and neurogenic shock.	See subcategories below.
<i>Anaphylactic shock</i>	Insect stings, antibiotics, anesthetics, contrast dye and blood products are typical allergens.	Tachycardia, tachypnea, hypotension, cyanosis, oliguria, and altered mental status. May also have urticaria, pruritus, angioedema, laryngeal edema, and severe bronchospasm. If conscious, may be extremely apprehensive and complain of a metallic taste.
<i>Septic shock</i>	Massive release of chemical mediators and endotoxins causes loss of vascular autoregulatory control and loss of fluid into the interstitium. Bacteria, especially gram-negative strains, protozoans, and viruses.	Early or warm phase: blood pressure, urine output, and neck veins may be normal. Skin warm and flushed with full veins. Fever usually present, although temperature may be subnormal. Late phase: tachycardia, tachypnea, hypotension, oliguria, flat jugular and peripheral veins, and cool clammy skin. Normal or subnormal temperature.
<i>Neurogenic shock</i>	Dysfunction or injury to the nervous system. Spinal cord injury, general anesthesia, fever, metabolic disturbances, and brain injuries.	Early phase: hypotension and altered mental status, bradycardia, and skin that is warm and dry. Late phase: tachycardia, tachypnea, and cool clammy skin.

flowing out the right side of the heart. All these conditions decrease cardiac output, which can lead to shock. Tumors or large emboli may also cause shock. Signs and symptoms of obstructive shock are similar to those of hypovolemic shock, except that jugular veins are usually distended.

Distributive Shock

Distributive shock occurs when peripheral vascular resistance is lost because of massive vasodilation of the peripheral circulation. Distributive shock includes anaphylactic, septic, and **neurogenic** shock.

Anaphylactic Shock

Anaphylactic shock, the most severe type of distributive shock, occurs when the body has an extreme hypersensitivity reaction to an antigen. Death from anaphylactic shock may occur in minutes. It occurs most commonly from insect stings, antibiotics (especially penicillins), shellfish, peanuts, anesthetics, contrast dye, and blood products. The signs and symptoms are similar to those seen in hypovolemic shock. Additionally, patients may have symptoms specific to allergic reactions, including **urticaria**, pruritus, wheezing, **laryngeal edema**, **angioedema**, and severe **bronchospasm**. If conscious, patients may be extremely apprehensive and short of breath, and they may complain of a metallic taste.

Septic Shock

Septic shock, the most common type of distributive shock, is caused by systemic infection and inflammation. Extensive release of chemical mediators and endotoxins causes dilation of blood vessels and loss of fluid into the interstitial space. Most cases of sepsis are caused by gram-negative bacteria, although other bacteria and viruses may be the cause. In recent years, the number of cases of gram-negative shock has been decreasing, whereas there has been an alarming increase in the number of cases of septic shock from multidrug-resistant bacteria and fungi. Septic shock is the leading cause of death among critical care patients. Predisposing conditions include trauma, diabetes mellitus, corticosteroid therapy, immunocompromise (e.g., as seen in patients with human immunodeficiency virus [HIV] and in those undergoing chemotherapy treatment for cancer), burns, malnutrition, and invasive catheters.

During the early, or warm, phase of septic shock (which may be referred to as “pink” shock), blood pressure, urine output, and neck vein size may be normal, but the skin is warm and flushed owing to vasodilation. Fever is present in the majority of patients, although some may have a subnormal temperature. Left untreated, septic shock progresses to a second phase with signs and symptoms similar to hypovolemic shock: hypotension, oliguria, tachycardia, tachyp-

nea, flat jugular and peripheral veins, and cold, clammy skin. Body temperature may be normal or subnormal.

Neurogenic Shock

Neurogenic shock occurs when dysfunction or injury to the nervous system causes extensive dilation of peripheral blood vessels. It is a rarer form of shock, occurring most commonly as a result of injury to the spinal cord (referred to as spinal shock). It occurs due to factors that either stimulate the parasympathetic nervous system or block the sympathetic nervous system. Other causes include general anesthesia, fever, metabolic disturbances, and brain contusions and concussions. Signs and symptoms include hypotension and altered mental status and, during the early phases, bradycardia and warm, dry skin. As shock progresses, however, tachycardia and cool, clammy skin develop.

THERAPEUTIC INTERVENTIONS FOR SHOCK

Because of the emergency nature of shock, the exact nature of the shock must be determined while interventions such as ventilatory and circulatory support are being implemented (Table 8.4). Life-threatening symptoms must be treated immediately (Table 8.5). Medications that are used in shock are listed in Table 8.6. The order of interventions and testing is guided by the stability of the patient. Intervention priorities are as follows:

1. Airway
2. Breathing and respiratory support
3. Cardiovascular support
4. Maintenance of circulatory volume
5. Control of bleeding if present
6. Assessment of neurological status
7. Treatment of life-threatening injuries
8. Determination and treatment of the cause of shock

Modified Trendelenburg Position

Research studies have not demonstrated that the Trendelenburg position or the modified Trendelenburg position is

TABLE 8.4 ASSESSMENT OF THE PATIENT IN SHOCK

Signs and Symptoms	Tachycardia, tachypnea, hypotension, oliguria, cyanosis, altered mental status
Diagnostic Tests	
Laboratory Tests	Complete blood count, serum osmolarity, blood chemistries, prothrombin time, partial thromboplastin time, blood typing and crossmatch, serum lactate, arterial blood gases, cardiac isoenzymes, urinalysis
Imaging	Chest x-ray, spinal films, computed tomography, echocardiogram
Monitoring	Electrocardiogram, arterial pressure monitor, central venous pressure, pulmonary artery catheter, gastric pH

TABLE 8.5 THERAPEUTIC INTERVENTIONS FOR SHOCK

Respiratory support	Oxygen (nasal cannula, face mask, non-rebreather mask, assisted ventilations with bag-valve-mask, ventilator) SpO ₂ >90%
Cardiovascular support	Venous lactic acid <2.2 mmol/L Vasopressor medication (dopamine) if fluid resuscitation not effective Revascularization of heart in cardiogenic shock via angioplasty with or without stent or fibrinolytic therapy (alteplase) Antidysrhythmics Positive inotropes
Adequate circulatory volume	1–3 L IV fluids Crystalloid fluids: normal saline (0.9% sodium chloride) or lactated Ringer's solution. 3 mL crystalloid solution for every 1 mL fluid lost Blood or blood products Urine output >30 mL/hour Hemoglobin >10 g/dL
Control of bleeding	Pressure dressings Surgical intervention
Treatment of life-threatening injuries	Surgical interventions
Determination and treatment of causes of shock	Medications Septic shock: antibiotics Cardiogenic shock: morphine, diuretics, nitrates Anaphylactic shock: epinephrine, diphenhydramine (Benadryl), methylprednisolone (Solu-Medrol), aminophylline

beneficial in improving cardiac output in shock. In fact, these positions actually can have negative effects such as compromising respirations among other effects. Although you may still see these positions used, it is important to follow valid research results for the best patient outcomes. In cardiogenic shock, any position that increases blood flow to the compromised heart increases the heart's workload. This could overwhelm or flood the heart so that it is unable to keep up with the blood volume returning to it. The result could be death.

NURSING PROCESS

Assessment/Data Collection

Assessment of the patient in shock must be carried out quickly and should always start with the ABCDs: airway, breathing, circulation, and disability.

Airway is assessed for patency and opened as necessary. A compromised airway must be treated immediately with the head-tilt/chin-lift method, an oral or nasal airway, or endotracheal intubation.

Breathing is assessed for rate, depth, and symmetry of chest movement. The patient is observed for use of accessory muscles. Lung sounds are auscultated. Crackles may be

**TABLE 8.6 MEDICATIONS USED FOR SHOCK**

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Autonomic nervous system agents <i>Alpha and beta adrenergic agents</i> Strengthens myocardial contraction and increases systolic BP and increases cardiac output	Epinephrine Dopamine Norepinephrine	IV IV IV	Nervousness Palpitations Tachycardia Tremors	Correct hypovolemia before giving medications in shock Monitor VS frequently Monitor intake and output First drug given in anaphylactic shock Give with TB syringe
Used for bronchodilation	Epinephrine	SC/IM		
<i>Beta adrenergic agent</i> Increases cardiac output in cardiogenic shock Constricts bronchial arterioles Inhibits histamine release Relieves bronchospasm in Rx of anaphylactic shock	Dobutamine	IV	Increased heart rate Anginal pain	Monitor VS frequently Monitor intake and output
Antihistamine	Benadryl	IV/PO	Drowsiness Tachycardia Dry mouth	Monitor VS Caution about activity with drowsiness
Anti-inflammatory Control of severe allergic reactions	Methylprednisilone (Solu-medrol)	IV	Side effects usually occur with long-term use	
Cogin A new class of agents that inhibits coagulation, decreases the inflammatory response, and promotes fibrinolysis in sepsis Increases survival in patients with severe sepsis	Xigris/Drotrecogin alfa	IV infusion for 96 hr	Bleeding	Contraindicated in patients with active bleeding or high risk of bleeding

IV = intravenous; PO = oral; Rx = treatment; SC = subcutaneous; VS = vital signs.

found in the patient with cardiogenic shock or in the patient who has received too much intravenous (IV) fluid. Wheezing may be present in the patient with anaphylactic shock.

Circulation is assessed with blood pressure. A narrowing pulse pressure may be present before a drop in systolic pressure and indicates a decrease in cardiac stroke volume and peripheral vasoconstriction. Peripheral pulses are palpated. Tachycardia is the first sign of shock. However, patients on medications that block the sympathetic nervous system response will not exhibit tachycardia. The pulse is assessed for quality; commonly it is weak and thready in a patient with shock. As shock progresses, the peripheral pulses become bradycardic or absent. A capillary refill greater than 3 seconds indicates inadequate circulation. Capillary refill has been found to be an unreliable indicator of shock in adults, especially elderly people. Other observations regarding circulation include distended neck veins, which may be collapsed or full; skin that may be cool, pale, and diaphoretic; presence of **cyanosis**; mucous membranes that may be pale and dry; and thirst. Rapidly scan the entire

body for evidence of bleeding or other injuries. Palpate the abdomen for signs of internal bleeding, such as a tender, distended, boardlike abdomen.

CRITICAL THINKING

Beta Blockers

■ A patient who takes a beta blocker is being monitored for septic shock. What sign of shock do you understand will not be present in a patient taking a beta blocker?

Suggested answer at end of chapter.

Disability is assessed by determining the patient's level of consciousness (LOC). A decrease in LOC indicates disability. This disability can range from lethargy to coma.

All four limbs are assessed for circulation, sensation, and mobility (CSM). Bilateral responses are compared for

NURSING CARE TIP

There is usually a loss of peripheral pulses in the patient whose systolic blood pressure has dropped below 80. If you are able to palpate radial pulses on your patient, you know that the systolic blood pressure is at least 80.

NURSING CARE TIP

To assess level of consciousness, determine if the patient is alert by asking his or her name, the date, and the location. If the patient can answer all three questions, he or she is "alert and oriented × 3 (person, place, time)."

equality. Circulation is assessed by palpating pulses for presence and quality. Sensation is determined by touching the patient's hands and feet and asking what the patient feels and if there is any numbness or tingling. Mobility (motor ability) is assessed by having the patient move all four limbs and wiggle the fingers and toes. Have the patient push with his or her feet against your hands and squeeze two of your fingers to assess strength.

A "head-to-toe" approach can follow the primary ABCD assessment. The presence, severity, and location of pain or nausea and vomiting are assessed. Bowel sounds are auscultated to determine whether they are normal, absent, hyperactive, or hypoactive. When an indwelling urinary catheter has been placed, the color of the urine and the rate of urine output are noted. Body temperature should be noted.

Nursing Diagnosis, Planning, Implementation, and Evaluation

See Table 8.7 for a summary of shock.

See Box 8.1 Nursing Care Plan for the Patient in Shock.

LEARNING TIP

Here is a saying to help you remember blood pressure effects in shock:

If they're 90/60, they're getting kinda sickly.
Say it again. If they're 90/60, they're getting kinda sickly.

CRITICAL THINKING

Mr. Hall

■ Mr. Hall, who is 55 years old, has suffered an acute myocardial infarction. He is complaining of chest pain (rated 10 out of 10 on the pain rating scale) and difficulty breathing. His SpO₂ is 89%. Crackles are heard on auscultation of breath sounds. The electrocardiogram shows an irregular and rapid heartbeat. He is restless and apprehensive.

1. Name three nursing priorities for Mr. Hall's care.
2. What type of IV fluid and rate is appropriate for Mr. Hall?
3. What signs and symptoms indicate Mr. Hall is in cardiogenic shock?

Suggested answers at end of chapter.

TABLE 8.7 SHOCK SUMMARY

Signs and symptoms	Tachycardia Tachypnea Hypotension Oliguria Cyanosis Altered mental state
Diagnostic tests	Decreased hemoglobin Increased lactic acid Decreased hematocrit in hemorrhage Increased WBC in sepsis Decreased pH in metabolic acidosis
Therapeutic interventions	Oxygen IV fluids Vasopressor medications Treat underlying cause
Complications	Acute respiratory distress syndrome (ARDS) Disseminated intravascular coagulation (DIC) Multiple organ dysfunction syndrome (MODS)
Possible nursing diagnoses	Ineffective tissue perfusion (renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) Fear

CRITICAL THINKING

Mrs. Neal

■ Mrs. Neal, who is 45 years old, came to the emergency room in severe hypovolemic shock after sustaining several bleeding wounds in an automobile accident. Her shock is resolving after receiving several transfusions and surgical repair of her injuries. She has just been admitted to the surgical unit for postoperative care.

1. What postoperative nursing assessments should be performed first?
2. Mrs. Neal's family is very alarmed by her condition. What interventions can you provide to decrease their anxiety?
3. What postoperative complications may develop in Mrs. Neal?
4. What documentation is appropriate for Mrs. Neal?

Suggested answers at end of chapter.

BOX 8.1 NURSING CARE PLAN for the Patient Experiencing Shock

Ineffective Tissue Perfusion (Renal, Cerebral, Cardiopulmonary, Gastrointestinal, Peripheral) related to hypovolemia or inadequate cardiac output or inadequate vascular tone

Expected Outcomes Patient demonstrates adequate tissue perfusion

Evaluation of Outcome Is patient's skin warm/dry, peripheral pulses present/strong? Are vital signs within patient's normal range? Are lung sounds normal, intake/output balanced, edema absent, pain/discomfort absent? Is patient alert and oriented?

Interventions

Maintain airway and provide oxygenation.

Monitor vital signs.

Monitor intake and output.

Provide adequate fluid intake.

Position patient appropriately (head elevated for patients with shortness of breath, increased intracranial pressure).

Provide quiet, restful environment.

Maintain body temperature with warmed IV fluids, room temperature, blankets.

Assess for pain and provide pain relief measures.

Change positions slowly.

Rationale

Ensures adequate oxygenation and tissue perfusion.

Changes in vital signs, which indicate change in condition, can be detected early and treated promptly.

Provides adequate cardiac output to perfuse tissues. Assesses renal function. Urine output is an indicator of renal function.

Maintains volume.

Proper positioning promotes circulation and helps prevent skin breakdown.

Conserves energy and lowers tissue oxygen demands.

Recovery is aided by normal body temperature.

Pain increases tissue demands for blood and oxygen.

Geriatric

Age-related losses of cardiovascular reflexes can result in hypotension.

Evaluation

Is SpO₂ >90%?

Is skin pink?

Are respirations between 12 and 20?

Are lung sounds clear?

Is heart rate between 60 and 100 beats per minute?

Is heart rhythm regular?

Are peripheral pulses strong?

Is systolic blood pressure (BP) >100 mm Hg?

Is patient alert and oriented × 3?

Is urinary output >30 mL/hr?

Are mucous membranes moist?

Is skin turgor < 3 seconds?

Is edema noted?

Is skin breakdown noted?

Is patient resting comfortably without anxiety?

Is body temperature within normal limits?

Is patient pain free?

Is systolic BP >100 mm Hg?

Decreased Cardiac Output related to reduced circulating blood volume

Expected Outcomes: Patient has adequate cardiac output as evidenced by vital signs and cardiac rhythm within normal limits (WNL).

Evaluation of Outcome Are blood pressure, heart rate, and cardiac rhythm within normal limits?
Are nailbeds and/or skin pink?
Is skin warm and dry?

Interventions

Monitor heart rate and cardiac rhythm with ECG and report abnormalities.
Assess skin/nailbed color, capillary refill and peripheral pulses and report abnormalities.
Give cardiovascular medications and oxygen as ordered.
Reduce myocardial oxygen demand by utilizing comfort measures to alleviate pain and anxiety, and by keeping the body at an appropriate temperature.

Rationale

Changes in heart rate and cardiac rhythm can be detected immediately and treated appropriately.
Inadequate perfusion is first evident in skin/nailbeds and peripheral pulses.
Cardiac function can be supported with medications. Supplemental oxygen increases oxygenation of heart and tissues.
Pain, anxiety, and cold all increase tissue demands for blood and oxygen, which places increased workload on the heart to supply it.

Evaluation

Is heart rate and rhythm normal?
What color and temperature is the skin/nailbeds?
Is capillary refill normal?
Are peripheral pulses present?
Is heart rate and rhythm normal?
Is body temperature within normal limits? Is the patient free of pain and anxiety?

Fear related to severity of condition and unknown outcome

Expected Outcomes Patient states fear is reduced.

Evaluation of Outcomes Does patient state fear is decreased?

Interventions

Provide explanations for procedures, the condition and its treatment.

Rationale

Knowledge allows a feeling of control and reduces fear.

Evaluation

Does patient state fear is reduced?

Deficient Knowledge related to unfamiliar condition of shock

Expected Outcomes Patient explains shock and its treatment.

Evaluation of Outcomes Can patient explain shock and how it is treated?

Interventions

Assess patient's ability to learn and identify barriers to learning.
Provide information that is most relevant to patient first.
Allow time for questions and clarification.

Rationale

For learning, the patient must be ready to learn. Barriers such as life style changes or the shock of the diagnosis may decrease learning.
Giving necessary information first meets patient's immediate needs.
Clarification ensures accurate information is learned.

Evaluation

Is patient alert and stable?
Does patient indicate willingness to learn?
Does patient express concerns about condition?
Does patient state understanding of important information?
Does the patient state accurate information?

REVIEW QUESTIONS

- Which of the following mechanisms does the body use to compensate for shock?
 - Peripheral nervous system depression
 - Central nervous system depression
 - Sympathetic nervous system stimulation
 - Parasympathetic nervous system stimulation
- Which of the following findings would the nurse recognize as specifically occurring with anaphylactic shock?
 - Wheezing
 - Hypotension
 - Tachycardia
 - Oliguria
- Which of the following conditions causes the decreased level of consciousness commonly found in patients experiencing shock?
 - Severe pain
 - Endotoxins
 - Cerebral edema
 - Cerebral hypoxia
- Which of the following nursing diagnoses is most appropriate to include in the plan of care for a patient experiencing shock?
 - Fatigue
 - Ineffective tissue perfusion
 - Ineffective health maintenance
 - Hopelessness
- A patient who is found lying in a pool of blood from a leg incision that has opened is restless and confused. The nurse calls for help and takes vital signs. Which of the following treatments for shock would the nurse anticipate would be ordered first?
 - IV fluids
 - Oxygen
 - Vasopressor medications
 - Antibiotics
- Which patient would be a priority for the nurse to see?
 - A patient who was in a motor vehicle accident, blood pressure 140/80, pulse 98, respirations 22
 - A patient who had chest pain with blood pressure 108/68, pulse 84, respirations 16
 - A patient who slipped and fell with blood pressure 112/74, pulse 68, respirations 14
 - A patient who is one day post op, blood pressure 90/58, pulse 118, respirations 24
- Which of the following findings would indicate to the nurse that therapeutic interventions are effective in shock?
 - Heart rate 110
 - SpO₂ 89%
 - Systolic blood pressure 108
 - Respiratory rate 22
- Place in correct order of occurrence systolic blood pressure progression through the three stages of shock beginning with mild, moderate, and severe. Use all options.
 - Below 60 mm Hg
 - Normal
 - Below 90 mm Hg

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Classic Signs of Shock*

Tachycardia is caused by decreased cardiac output and reduced tissue oxygenation. Its purpose is to increase cardiac output and oxygen delivery by causing more heart beats to pump out blood from the heart.

Tachypnea is caused by decreased tissue oxygenation. Its purpose is to increase respirations so more oxygen is available for delivery to tissues.

Oliguria is caused by a reduced blood flow to the kidneys. Its purpose as a compensatory mechanism is

to conserve as much fluid as possible to help maintain a normal blood pressure.

Pallor is caused by reduced blood volume or flow.

When pallor results from compensation, it is due to peripheral vasoconstriction that occurs to shunt blood volume to the vital organs.

Cool, clammy skin is the result of decreased blood flow to the skin and the release of moisture (sweat) from the skin. The sympathetic nervous system causes these compensatory mechanisms; peripheral vasoconstriction shunts blood to the vital organs, and sweating cools the body in anticipation of the fight or flight response, which generates body heat when it occurs.

■ **Anaerobic Metabolism**

Anaerobic metabolism is the source of nutrition and energy for the cell that prevents cellular death when oxygen is not available. It is a short-term compensatory mechanism to save the cell until oxygen becomes available again.

■ **Beta Blockers**

Tachycardia will not be present. Beta blockers block the response of the sympathetic nervous system, which is activated in shock.

■ **Mr. Hall**

1. Nursing priorities for Mr. Hall include relief of chest pain and anxiety, stabilization of cardiac rhythm and vital signs, and adequate tissue oxygenation.
2. Because Mr. Hall's lung sounds reveal crackles, indicating fluid in the lungs, he should not be given IV fluids. He should have an IV access to give IV medications as needed. He already has too much fluid for his heart to handle, and giving him IV fluids could be life threatening.

3. Signs of cardiogenic shock include decreased blood pressure; increased heart and respiratory rates; cyanosis; decreased urine output; cool, pale skin; and decreased mental status.

■ **Mrs. Neal**

1. Assessment of respiratory status and cardiovascular status, inspection of surgical wounds for bleeding, assessment of mental status, and need for pain relief should be performed first.
2. Explain the cause of shock and all interventions, rationales, and desired outcomes. Keep the environment calm, provide for privacy, and answer all questions in a matter-of-fact and reassuring manner. Allow Mrs. Neal's family to visit.
3. Unrelieved pain, bleeding, infection, and respiratory complications are possible.
4. Airway: rate, depth, regularity of respirations; breath sounds, SpO₂. Vital signs: cardiac rhythm, quality of pulses, skin color, blood pressure, body temperature. Urine output: oral and IV intake, fluid balance. Pain: measures to relieve pain and evaluation of those measures. Dressings: any bleeding. Bowel sounds.

QUESTIONS TO GUIDE YOUR READING

1. How is pain defined?
2. What are the common myths and barriers to the effective management of pain?
3. What are the differences between addiction, physical dependence, and tolerance?
4. What is current knowledge of the basic physiology of the pain response?
5. What are characteristics that help to define acute, chronic nonmalignant, and cancer pain?
6. What should be included in a basic pain assessment?
7. How is the World Health Organization analgesic ladder used for the treatment of pain?
8. What are the three classes of analgesics and their uses?
9. What are commonly used pain medication treatment modalities and their appropriate use?
10. How and when are nondrug pain management techniques utilized?
11. How does ethical decision making play a role in the care of the patient in pain?

THE PAIN PUZZLE

Pain is the most common reason patients seek medical advice. However, despite the widespread nature of the problem, pain is often untreated or undertreated. The care of patients with pain is challenging and requires a systematic approach to assessment and treatment.

Decisions about pain management require careful assessment of the patient's condition and attention to the ethical principles that influence patient care. Providing information and giving the patient choices helps maintain the patients autonomy. Just as risks, benefits, and alternatives to surgery and anesthesia are discussed with the patient, so should pain management options be discussed in the process of obtaining informed consent. Nurses often worry about overmedicating patients, thinking that they are “doing good” (beneficence) or “doing no harm” (nonmaleficence) by withholding medication from a patient they do not believe is in pain (Box 9.1 Ethical Consideration). It is important to learn as much as you can about pain and pain management so you can effectively advocate for your patients, assist with patient education, and provide appropriate resources.

The Joint Commission for Accreditation of Healthcare Organizations (JCAHO) published pain management standards in 2000 and began assessing the management of pain in hospitals and other health-care organizations based on these standards in January 2001. These standards support the importance of the appropriate and effective management of pain. They address assessment and the safe pharmacological management of pain, as well as patient and family teaching, postoperative pain, management of opioid-induced side

effects, discharge planning, and process improvement. These guidelines are available through the [JCAHO.org website](http://www.jcaho.org).

For more information on pain management, visit the following Web sites. For some sites, it may be necessary to type “pain” in the search window.

<http://www.iasp-pain.org>

<http://www.jcaho.org>

<http://www.who.org>

Cultural differences must be considered when planning care for the patient in pain. People from various cultures have different ways of expressing pain (Box 9.2 Cultural Considerations). Some may be dramatic and emotional; others tend to be stoic and quiet. Knowledge of widely accepted information about different ethnic and cultural groups can be useful in understanding a patient's experience and what care might be considered acceptable. It is important, however, to assess a patient's pain care needs individually and not make assumptions based on culture or ethnicity alone.

Because of the importance of controlling health-care costs, the entire health team must provide care in the most cost-effective manner possible while continuing to provide the best quality of care. Effective pain management can help reach those goals by enhancing comfort, minimizing side effects of **opioids** and complications related to inadequate pain control, and reducing the lengths of hospital stays.

(Text continued on page 125)

Box 9.1

Ethical Consideration—Controlling Pain

A patient was admitted from home to the medical unit 2 days after his 83rd birthday with a diagnosis of metastatic cancer of the pancreas. He had several full-course treatments of chemotherapy and radiation during the previous year with only temporary remissions of the disease. His condition deteriorated rapidly during the previous month, and his family was no longer able to care for him. The patient's physician expected him to die within a few weeks and admitted him to the hospital, primarily for pain control. On admission, the physician ordered morphine sulfate (MS) 5 mg IV to be given every 2 hours around the clock.

Although this seemed like a relatively large dose of a strong opioid medication to be given this frequently, the patient tolerated the treatment for the first 36 hours, and reported a significant reduction in his pain. On the third morning after his admission, he was difficult to arouse for his morning vital signs and breakfast. When his nurse, Kathy, finally did manage to awaken him, he was disoriented, his blood pressure was 82/50, and his respirations were shal-

low and 10/min. He still complained of generalized pain and asked for more medication.

Kathy did not give the patient his scheduled 0800 dose of MS. She phoned the physician and reported her assessment of the patient, expressing her belief that continuing the medication at the previously prescribed dose and frequency would be fatal to this patient. The physician, who had been up most of the night with an emergency patient, told her that the patient was dying and that she should administer the medication immediately. In this situation:

- What are Kathy's ethical obligations in this case (to self, patient, and community)?
- How should she weigh the risks and benefits of providing adequate pain medication given the possible side effect of hastening the patient's death?
- If Kathy has a moral objection to carrying out a physician's order, what are her options?
- How can Kathy find a way to start meaningful dialogue about such issues with the physician?

Box 9.2

Cultural Considerations

The pain experience may differ between and among individuals of differing cultural, ethnic, or religious groups. Remember that individuals within groups can vary, and not all fit the general descriptions provided below. (See Chapter 3.)

Culture	Expression and Meaning of Pain	Patient Preferences	Assessment	Interventions
Native American	Frequently do not request pain medicine and are undertreated. May not realize that they can ask for pain medicine. Many believe pain is something that must be endured. May describe pain in general terms such as “not feeling good.” The word for pain varies according to the tribal language.	Many prefer traditional herbal medicines. May complain to family member or visitor, who relays message to caregiver.	Frequently ask patient and family members or visitors if patient has pain. Observe for nonverbal clues of pain.	Explain that the control of pain can promote healing. Offer pain medicine as needed. Allow adequate time for response; silence is valued. Maintain a calm, relaxing environment. Incorporate traditional practices for pain relief if not harmful.
European American	Strong sense of stoicism, especially in men. Fear of being dependent may decrease use of pain medicine. Many have fear of addiction. May continue to work and carry out daily activities and minimize pain.	May prefer relaxation and distractions as means of pain control.	Observe for nonverbal signs of pain. Use visual analog or numerical pain scales to assess severity of pain.	Encourage use of pain medicine as needed. Incorporate distraction and relaxation techniques.
African American	Usually openly and publicly display pain, but this is highly variable. Many, especially the elderly, fear that medication may be addictive. Many believe that suffering and pain are inevitable and should be endured.	May focus on spirituality and religious beliefs to endure pain. Prayers and the laying on of hands are thought to relieve pain if the client has enough faith.	Observe for verbal and nonverbal expressions of pain. Use of pain scales is helpful.	Offer pain medication as needed. Allow meditation and prayer along with pain medication. Support patient’s spiritual practices.
Hispanic American	Puerto Ricans tend to be expressive of pain and discomfort. Moaning, groaning, and crying are culturally accepted ways of dealing with and reducing pain. Mexicans may bear pain stoically because it is “God’s will.” Many feel that pain and suffering are a consequence of immoral behavior. For men, expressing pain shows weakness. The Spanish word for pain is <i>dolar</i> .	Prefer oral or intravenous medication for pain. Heat, herbal teas, and prayer are used to manage pain.	Visual analog and numerical scales may be helpful. Observe and compare verbal and nonverbal behaviors indicating pain.	Do not censor verbal expression of pain. Incorporate traditional practices as permitted. For individuals who are stoical with pain, encourage pain medicine frequently. Explain that pain control can hasten healing.

Culture	Expression and Meaning of Pain	Patient Preferences	Assessment	Interventions
Asian American	Chinese and Koreans tend to be stoical, and describe pain in terms of diverse body symptoms instead of locally. Filipinos may view pain as a part of living an honorable life. Some view this as an opportunity to reach a fuller life and to atone for past transgressions. Frequently stoic and tolerate pain to a high degree. Some moan as an expression of pain. For asians, bearing pain is a virtue and a matter of family honor. Some, especially older individuals, may fear addiction.	Prefer oral or intravenous pain medications. May like warm compresses. For Koreans, intramuscular injections may be seen as an invasion of privacy. Vietnamese maintain self-control as a means of pain relief.	Observe for nonverbal signs of pain. Vietnamese may not understand numerical scale of rating pain. Observing facial expression may provide a good indicator of pain.	Incorporate traditional healing methods as much as possible. Offer and encourage pain medicines to promote healing.
Arab American	See pain as something to be controlled. May express pain openly to family with elaborate verbal expressions, less so with caregivers. May use terms such as fire, hot, and cold.	Intramuscular or intravenous usually preferred over oral medications.	Compare verbal and nonverbal characteristics of pain to determine degree of pain.	Engage family to help with distraction and relaxation techniques. Administer medication promptly.

It is not possible to record a patient's pain on a machine or measure it as with a blood or urine sample. It is difficult to objectively gauge the effect of a nursing intervention on pain, whether the intervention is medication or nondrug therapy. Pain and its treatment can be likened to a difficult puzzle that requires many pieces to solve.

In this chapter, the many challenges of pain assessment and treatment are discussed. Some of the tools needed to effectively deal with these challenges are presented. Common myths and barriers that continue to affect nursing practice are clarified.

DEFINITIONS OF PAIN

According to Margo McCaffery, a well-known consultant in the care of patients with pain, "Pain is whatever the experiencing person says it is, existing whenever the experiencing person says it does."¹ This is a reminder to nurses to accept the patient's report of pain.

In 1979, pain was defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory

and emotional experience associated with actual or potential tissue damage or described in terms of such damage."² This definition indicates that pain is complex, and is not only physical but has emotional and other components as well.

Why does it exist? Pain is a protective mechanism or a warning. Pain in the presence of injury may help to prevent further injury. Consider the patient who experiences a fracture and holds it still to prevent further damage or a child who touches a hot stove and pulls his or her hand away before a serious burn occurs.

Why is untreated or undertreated pain a bad thing? Complications can occur when pain is experienced. The body produces a stress response in the presence of pain during which harmful substances are released from injured tissue. Reactions include breakdown of tissue, increased metabolic rate, impaired immune function, and negative emotions. In addition, pain prevents the patient from participating in self-care activities such as walking, deep breathing, and coughing. Consider the patient who has had chest surgery and then has to cough and deep breathe. It hurts! Because he or she has pain, the patient tries not to cough, turn, or even move. Retained pulmonary secretions and

pneumonia can develop. If the patient does not move around, return of bowel function is delayed and an ileus can result. When pain is well controlled, complications can be avoided and patients are able to do what they need to do to get well and go home from the hospital or continue with recovery activities. The concept of “balanced analgesia” (see Options for Treatment below) emphasizes pain relief and control of adverse effects by combining analgesics from different classes of medications rather than using opioids alone.

Suffering often accompanies pain, but not all pain has the element of suffering. Suffering can exist without pain and pain without suffering. Suffering represents a threat to one’s self-image or life. According to the latest cancer pain guidelines from the Agency for Health Care Research and Quality (AHCQRQ), suffering is defined as the state of severe distress associated with events that threaten the intactness of the person.³ Pain can be a constant reminder for patients with cancer that they have a life-threatening illness. Suffering can often be relieved if patients believe that their pain can be relieved.

MYTHS AND BARRIERS TO EFFECTIVE PAIN MANAGEMENT

Treatment of patients in pain is influenced by a number of factors, including the nurse’s personal experiences with pain. Why are some patients not believed when they report pain? Why do some nurses and other health-care team members insist that patients behave a certain way before they are believed? Common myths about pain may impair the nurse’s ability to be objective about pain and create barriers to effective treatment. Because there is no objective measure for pain, nurses may rely on what is comfortable rather than what has been proven to be effective.

Myth: A person who is laughing and talking is not in pain.

Fact: A person in pain is likely to use laughing and talking as a form of distraction. This can be very effective in the management of pain, especially when used in conjunction with appropriate drug therapies. Patients may be more easily distracted when they have visitors and may ask for pain medication as soon as their family or significant other goes home.

Myth: If morphine is given too early to the patient with cancer pain, it will not work when the patient really needs it, toward the end, when the pain is worse.

Fact: Morphine is an opioid **agonist**. Opioid doses can be escalated (titrated upward) indefinitely as needed as the patient’s pain increases. There is no **ceiling effect**, or maximum effective dose. Side effects such as sedation or clinically significant respiratory depression may temporarily limit the dose or the rate at which the dose can be increased.

Myth: Respiratory depression is common in patients receiving opioid pain medications.

Fact: Respiratory depression is uncommon in patients receiving opioid pain medications. If patients are

monitored carefully when they are at risk, such as with the first dose of an opioid or when a dose is increased, respiratory depression is preventable. A patient’s respiratory status and level of sedation (LOS) should be routinely monitored using an LOS scale.

Myth: Pain medication is more effective when given by injection.

Fact: Intramuscular (IM) injections are not recommended because they are painful, have unreliable absorption from the muscle, and have a lag time to peak effect and rapid falloff compared with oral administration. Oral administration is the first choice if possible; the intravenous (IV) route has the most rapid onset of action and is the preferred route for postoperative administration.

Myth: Teenagers are more likely to become addicted than older patients.

Fact: **Addiction** to opioids is very uncommon in all age groups when taken for pain by patients without a prior drug abuse history.

MORE PAIN-RELATED DEFINITIONS

Nurses often express concern about patients who require large amounts of pain medication or know exactly when their next dose of pain medication is due. Nurses may say that such patients are addicted or that they are “clock watchers,” but do we really know what that means? Patients are expected to be informed about their medications and involved in their care, but when they know when their medications are due, we may become suspicious. In truth, if a patient is watching the clock, the most likely reason is because he or she is in pain. The most common reason that patients ask for more pain medicine is because they have increased pain. It is important to understand the differences between **addiction**, **physical dependence**, and **tolerance**. When talking with patients and teaching them about their medications, it is important to help them understand these differences as well. Addiction is something many patients fear.

CRITICAL THINKING

Mrs. Smithers and Mr. Barnett

■ Mrs. Smithers had an abdominal hysterectomy and is sitting up in bed the morning after surgery, putting on her makeup. On morning rounds she is smiling but reports that her pain is at 6 on a scale of 0 to 10. Mr. Barnett has just been transferred from the surgical intensive care unit the day after surgery for multiple injuries. He is moaning and reports his pain at 6 on a scale of 0 to 10. Which of these patients is really having as much pain as they say they are? How can you make that judgment?

Suggested answers at end of chapter.

Tolerance simply means that it takes a larger dose to provide the same level of pain relief. Physical dependence is a physiological phenomenon that most people experience after a few weeks of continuous opioid use. If an opioid is abruptly discontinued after a few weeks of use, the patient may experience a withdrawal syndrome, exhibiting symptoms such as sweating, tearing, runny nose, restlessness, irritability, tremors, dilated pupils, sleeplessness, nausea, vomiting, and diarrhea. These symptoms can be prevented by slowly weaning a patient from an opioid rather than stopping it suddenly.

Psychological dependence is a better term for addiction and is defined as a pattern of compulsive drug use characterized by a continued craving for an opioid and the need to use the opioid for effects other than pain relief. The patient who is psychologically dependent continues to use the drug despite harmful effects.

Pseudoaddiction has been described in patients who are receiving opioid doses that are too low or spaced too far apart to relieve their pain, and certain behavioral characteristics resembling psychological dependence, such as drug-seeking behaviors, have developed. The difference is, in the patient with this phenomenon, the drug seeking behaviors cease when the pain is relieved.

MECHANISMS OF PAIN TRANSMISSION

Many theories of how pain is transmitted are described in the literature. The specificity theory, developed by Descartes in 1644, proposed that body trauma sends a message directly to the brain, causing a sort of “bell” to ring, prompting a response from the brain. In 1965, Melzack and Wall proposed the gate control theory, which describes the dorsal horn of the spinal cord as a gate, allowing impulses to go through when there is a pain stimulus and closing the gate

when those impulses are inhibited. The gate control theory stimulated massive research on the physiology of pain and is still considered in research.

Much more is known about the transmission of pain today. **Endorphins** are endogenous (naturally occurring) chemicals that act like opioids to inhibit pain impulses in the spinal cord and brain. Unfortunately, they degrade too quickly to be considered effective **analgesics**. Endorphins are the chemicals that stimulate the long-distance runner’s “high.” **Enkephalins** are one type of endorphin.

Pain is transmitted through the dorsal horn of the spinal cord and other points in the central nervous system to higher centers of the brain with the influence of chemicals known as neurotransmitters, which are released from damaged tissue. These chemicals include **prostaglandins**, substance P, and others. Many treatments and analgesics are designed, based on known principles, to inhibit the release of these chemicals at different points along the pain pathway. It is also now understood that men and women respond differently to painful stimuli and to pain management interventions.

Mechanisms of pain transmission are **nociceptive** and **neuropathic**. **Nociception** refers to the body’s normal or physiological reaction to noxious stimuli, such as tissue damage, with the release of pain-producing substances. Nociceptive pain in the visceral organs may be referred to other parts of the body (Fig. 9.1). **Neuropathic**, or nonphysiologic, pain is not usually localized, and it may spread to involve other areas along the nerve pathway.

TYPES OF PAIN

Pain is often categorized according to whether it is acute, cancer related, or chronic nonmalignant. Acute pain is des-

FIGURE 9.1 Sites of referred pain.

pseudoaddiction: pseudo—false + addiction—psychological dependence

nociceptive: noci—pain + ceptive—reception

neuropathic: neuro—nerves + pathy—disease, suffering

cribed as pain that follows injury to the body, prompting an inflammatory response, and subsides as healing takes place. It may be associated with short-term, objective, physical signs such as increased heart rate and elevated blood pressure. Examples of acute pain include pain related to fractures, burns, or other trauma.

Cancer pain may be acute, chronic, or intermittent and often has a definable cause such as tumor invasion or neuropathy caused by the cancer treatment.

Chronic nonmalignant pain persists beyond the time when healing usually takes place, such as low back pain, the pain accompanying arthritis, and phantom limb pain. Chronic nonmalignant pain may have nociceptive as well as neuropathic components and may require a variety of medications and nondrug treatments. Because of the body's ability to adapt, patients with chronic nonmalignant pain or chronic cancer pain may not appear to be in pain. The physiological responses that accompany acute pain, such as elevated heart rate and blood pressure, cannot be sustained without harm to the body, so the body adapts and the vital signs return to normal. The nurse must guard against labeling these patients as **malingers** (pretending to be in pain) or drug seeking.

OPTIONS FOR TREATMENT OF PAIN

Analgesics

Medications that relieve pain are called analgesics. Analgesics are the largest pieces of the pain management puzzle. There are three main classes of analgesics: opioids, nonopioids, and **adjuvants**. Opioids are classified by their ability to bind to opioid receptors in the brain and spinal cord, as well as other areas of the body, inhibiting the perception of pain. Nonopioids include nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen (Tylenol). Adjuvants include categories of drugs that were originally developed for a different purpose but have been found to have pain-relieving properties in certain painful conditions.

Nonopioids

Nonopioids are generally the first class of drugs used for treatment of pain. They can be useful for acute and chronic pain from a variety of causes, such as surgery, trauma, arthritis, and cancer. These medications are limited in their use because they have a ceiling effect to analgesia. A ceiling effect indicates that there is a dose beyond which there is no improvement in the **analgesic** effect and there may be an increase in adverse effects. When used in combination with opioids, care must be taken to ensure that the dose of the nonopioid drug does not exceed the maximum safe dose for a 24-hour period. For example, if a patient receiving two acetaminophen with hydrocodone (Vicodin) tablets every 4 hours continues to experience pain, the dose cannot be increased because of the potential toxic effects of the aceta-

TABLE 9.1 ADVERSE EFFECTS OF NONOPIOIDS

Drug	Adverse Effects
NSAIDs (including aspirin)	Gastrointestinal (GI) irritation and bleeding Inhibition of platelet aggregation, increasing risk of GI bleeding Renal insufficiency in some patients, especially the elderly Patients with asthma at risk for hypersensitive reactions
Acetaminophen	Necrosis of the liver with overdose

minophen (Table 9.1). Nonopioids do not produce tolerance or physical dependence. Most do have antipyretic (fever-reducing) effects. This class of drugs works primarily at the site of injury, or peripherally, rather than in the central nervous system as opioids do. NSAIDs block the synthesis of prostaglandin, one of many chemicals necessary for pain transmission. In general, it is helpful to include a nonopioid in any analgesic regimen, even if the pain is severe enough to require the addition of an opioid. See Table 9.2 for examples of nonopioid analgesics.

Opioids

Opioids are drugs that have actions similar to morphine. They are added to nonopioids for pain that cannot be managed effectively by nonopioids alone. Opioids are classified as full agonists, partial agonists, or mixed agonists and **antagonists**. Full agonists have a complete response at the opioid receptor site; the partial agonist has a lesser response. The mixed agonist and antagonist activates one type of opioid receptor while blocking another.

Opioids alone have no ceiling effect to analgesia. Doses can safely be increased to treat increasing pain if the patient's respiratory status and level of sedation are stable. See Box 9.3 (Common Adverse Effects of Opioids) for adverse effects of opioids. Controlled-release opioids such as oxycodone (Oxycontin) and morphine (MS Contin) are effective for prolonged, continuous pain.

Controlled- or time-release medication should never be crushed, but always taken whole. Whenever a controlled-release preparation is used, it is important to have an immediate-release medication available for **breakthrough** pain, such as oral morphine solution (OMS) or oxycodone (Oxy-IR).

Morphine is the drug of choice for the treatment of moderate to severe pain. It is the drug used as a standard against which all other analgesics are compared. (See Table 9.3 for **equianalgesic** doses of medications.) Morphine is long acting (4 to 5 hours) and available in many forms, making it convenient, as well as affordable, for the patient. It has a slower onset than many other opioid agonists.

equianalgesic: equi—equal + analgesic—relieving pain

TABLE 9.2 ANALGESIC AGENTS

Medication Class/ Action	Drug Examples	Route	Common Side Effects	Nursing Implications
Salicylates Peripherally acting analgesics; reduce pain, fever, inflammation	Aspirin	PO, PR	Tinnitus, GI upset and bleeding, renal impairment	Give with food. Decreases platelet aggregation, so watch for bleeding.
NSAIDS Peripherally acting analgesics; reduce pain, fever, inflammation	Ibuprofen (Motrin) Ketorolac (Toradol) Naproxen (Naprosyn)	PO PO, IM, IV PO	GI upset and bleeding, renal impairment	Give with food. Decrease platelet aggregation, so watch for bleeding.
Second-Generation NSAIDS COX-2 inhibitors; reduce pain and inflammation, no effect on platelet aggregation	Celecoxib (Celebrex)	PO	Abdominal pain, renal impairment, GI upset and bleeding, but less risk for bleeding than 1 st generation NSAIDS.	Rofecoxib (Vioxx) and Valdecoxib (Bextra) have been removed from the market owing to increased risk for MI and stroke. Research is ongoing to determine if all COX-2 inhibitors have this effect.
Acetaminophen Relieves pain and fever; no anti-inflammatory or antiplatelet effect	Acetaminophen (Tylenol)	PO, PR	Liver toxicity and failure	Maximum safe dose is 4 g per day.
Opioids Bind to opioid receptors in the CNS to alter perception of pain.	Codeine (Tylenol #3 is acetaminophen with codeine) Fentanyl (Sublimaze, Duragesic) Hydromorphone (Dilaudid) Meperidine (Demerol) Methadone (Dolophine) Morphine Oxycodone (Vicodin is acetaminophen with hydrocodone)	PO, PR, IM, SQ, IV, Epidural PO, IV, IM, Patch PO, PR, IV, IM PO, IV, IM, SQ PO, IM, SQ PO, IM, SQ, IV PO	Respiratory depression, sedation, hypotension, constipation	Monitor vital signs, level of sedation, and respiratory status. Encourage fluids and fiber to prevent constipation. Avoid use of meperidine in elderly.

TABLE 9.3 EQUIANALGESIC CHART*

Drug	Parenteral (IM/IV/SQ)	Oral Dose	Conversion Factor (Parenteral to PO)
Morphine	10 mg	30 mg	3
Codeine	130 mg	200 mg NR	1.5
Hydromorphone (Dilaudid)	1.5 mg	7.5 mg	5
Methadone (Dolophine)	10 mg	20 mg	2
Meperidine (Demerol)	75 mg	300 mg NR	4

NR = Not recommended at that dose.

*Approximate doses of medications in milligrams to equal same amount of pain relief.

Source: Adapted from McCaffery, M: Pain: Assessment and Use of Analgesics (conference). Fall 1996.

Hydromorphone (Dilaudid) is commonly used for moderate to severe pain as well. It is shorter acting than morphine and has a somewhat faster onset. It is a good option for pain management in most patients

Meperidine (Demerol), also an opioid agonist, should be reserved for healthy patients requiring opioids for a short period or for those who have unusual reactions or allergic responses to other opioids. When broken down in the body, it produces a toxic metabolite called normeperidine. Normeperidine is a cerebral irritant that can cause adverse effects ranging from dysphoria and irritable mood to seizures. Normeperidine has a long half-life even in healthy patients, so those with impaired renal function are at increased risk. Meperidine use should be avoided in patients over the age of 65, in those with impaired renal function, and in those receiving monoamine oxidase inhibitor (MAOI) antidepressants. Additionally, the effective dose of

SAFETY TIP

It is important to monitor a patient's level of sedation and respiratory status whenever administering opioids. Increased sedation, decreased respiratory effort, and constricted pupils can be signs of opioid overdose. Careful monitoring and dosage adjustments of opioids can prevent opioid-induced respiratory depression.

oral meperidine is three to four times the parenteral dose, and is not recommended.

Fentanyl (Sublimaze, Duragesic) can be administered parenterally, intraspinally, or by **transdermal** patch (Duragesic patch). Fentanyl is commonly used intravenously with anesthesia for surgery and also for relief of postoperative pain via the intravenous route. **Patient-controlled analgesia** (PCA) or epidural route (discussed later in this chapter) IV fentanyl is very short acting and must be administered more frequently than other opioids to maintain an effective level of analgesia. The fentanyl patch is useful for the patient with stable cancer pain and requires dosing only every 3 days.

Methadone (Dolophine) is a potent analgesic that has a longer duration of action than morphine. It has a very long half-life and accumulates in the body with continued dosing. Dosing intervals may be lengthened after pain relief has been achieved. Methadone is well absorbed from the gastrointestinal tract and is very effective when given orally at

doses similar to the parenteral dose. Methadone is also used in drug treatment programs during detoxification from heroin and other opioids. Patients on methadone maintenance can present a unique challenge when admitted to the hospital. It is important to continue the maintenance dose even if additional pain medications are required after surgery or trauma. See Table 9.2 for examples of opioids.

Opioid Antagonists

Naloxone (Narcan) is a pure opioid antagonist that counteracts, or antagonizes, the effect of opioids. It is often used in the emergency department setting for treatment of opioid overdose. Caution must be used when naloxone is given to a patient receiving opioids for the treatment of pain. If too much naloxone is given too fast, it can reverse not only the respiratory depression and sedation but the analgesia as well.

Some antagonists are shorter acting than the opioid that is being used. If the antagonist is given because of respiratory depression, the dose may need to be repeated because its effect may wear off before that of the opioid.

Some analgesics are classified as combined agonist and antagonist. These drugs bind with some opioid receptors and block others. The most commonly used agonist-antagonist drugs are butorphanol (Stadol) and nalbuphine (Nubain).

How does this information translate into nursing practice? Consider, for example, a patient who is taking sustained-release morphine every 12 hours to control metastatic bone pain and is experiencing breakthrough pain between doses. You observe that butorphanol has been ordered for pain by another doctor and administer it. The butorphanol will antagonize, or counteract, the effects of the morphine, and the patient may develop acute pain. It is important to be informed about the actions of all drugs that are administered and to be aware of possible drug interactions that may interfere with patient care.

Agonist-antagonist drugs are also used sometimes to counteract opioid adverse effects. Nalbuphine (Nubain) can be used to treat itching and nausea that may accompany the administration of opioids. A smaller dose can be given so that the analgesia is not reversed completely along with the reversal of the adverse effect.

Analgesic Adjuvants

Adjuvants are classes of medications that may potentiate the effects of opioids or nonopioids, have analgesic activity themselves, or counteract unwanted effects of other analgesics. Adjuvants are especially important when treating pain that does not respond well to traditional analgesics alone. Examples of adjuvants are steroids, benzodiazepines, antidepressants, and anticonvulsants.

Steroids can be used to treat a variety of pain conditions, including acute and chronic cancer-related pain. They may be used as part of actual cancer treatment because of their toxicity to some cancer cells, or they may reduce pain by decreasing inflammation and the resultant compression of healthy tissues. Their use is standard emergency practice in the treatment of suspected spinal cord compression. Patients with pain caused by malignant lesions pressing on

CRITICAL THINKING

Mrs. Shepard

■ Mrs. Shepard is 92 years old and has undergone an open cholecystectomy. Her continuous epidural infusion of analgesic has been discontinued. The physician has ordered oral acetaminophen with hydrocodone every 3 to 4 hours as required for pain. This is her second postoperative day, and she refuses to get out of bed because her pain is 7 on a scale of 0 to 10.

The medication record shows that Mrs. Shepard has not received any pain medication since the continuous epidural infusion was stopped 3 hours ago.

1. Why is Mrs. Shepard in so much pain?
2. What complications can occur as a result of her pain?
3. Each analgesic tablet contains 500 mg of acetaminophen and 5 mg hydrocodone. The maximum daily dose of acetaminophen is 4 g. If she takes one tablet every 3 hours, is her dose safe?
4. What can be done to relieve her pain and better prevent it in the future?

Suggested answers at end of chapter.

nerves such as the brachial or lumbosacral plexus may receive large doses of steroids.

Benzodiazepines such as midazolam (Versed) or diazepam (Valium) are effective for the treatment of anxiety or muscle spasms associated with pain. These drugs do not provide pain relief except in the treatment of muscle spasms. Benzodiazepines may cause sedation, which limits the amount of opioid that may be safely given.

Tricyclic antidepressants such as amitriptyline, imipramine, desipramine, and doxepin have been shown to relieve pain related to neuropathy and other painful nerve-related conditions. These medications must be taken for days to weeks before they are fully effective, and patients must be instructed to continue the medications even if they seem ineffective at first. Additional benefits of this class of medications may include mood elevation and improved ability to sleep.

Anticonvulsants such as carbamazepine (Tegretol) and gabapentin (Neurontin) are often used to relieve the sharp or cutting pain caused by peripheral nerve syndromes. Again, these medications must be taken regularly before full benefit is realized.

Stimulants such as methylphenidate hydrochloride (Ritalin) or caffeine-containing medications may be used to counteract the sedating effects of opioids in some patients.

A “balanced analgesia” approach should be used, combining analgesics and adjuvants from different classes to minimize opioid adverse effects, such as nausea and vomiting or sedation (Box 9.3, Common Adverse Effects of Opioids) while maximizing pain relief. For example, an opioid and a nonopioid given together can provide pain relief with an overall lower dose of each medication than if they were given alone. Because these drugs have different mechanisms of action and different adverse effects, it is possible to give lower doses of opioids providing an “opioid sparing” effect. If doses can be reduced in this manner additional, sedating medications such as antiemetics and antihistamines may be avoided.

World Health Organization Analgesic Ladder

In 1990, the World Health Organization (WHO) developed the WHO analgesic ladder, which involves choosing among three levels of treatments based on intensity of pain (Fig.

Box 9.3

Common Adverse Effects of Opioids

Sedation
Respiratory depression*
Constipation
Nausea, vomiting
Itching
Constricted pupils*

*These effects are not common, but they alert the nurse to possible overdose.

FIGURE 9.2 World Health Organization three-step analgesic ladder.

9.2). The ladder, which helps direct the interventions required when using medications to treat pain, was developed for the treatment of cancer pain but can be used when treating other types of pain as well.

When experiencing mild pain (level I on the WHO ladder), the patient can usually sleep, perform activities of daily living, and even work. The first level of the ladder addresses the use of nonopioid analgesics. When pain is unrelieved by maximum around the clock (ATC) dosing, the treatment moves up the ladder to level II (mild to moderate pain) and adds an opioid analgesic. The patient with mild to moderate pain may not be able to sleep or may have trouble working and staying focused. If pain increases beyond that which is controlled by the level II analgesics, it is time to move on to level III. At this level, the pain is moderate to severe and is affecting the quality of the patient’s life, and he or she may not be able to perform activities of daily living. At any level, an adjuvant analgesic may be appropriate.

Analgesics should be given on an ATC basis to prevent breakthrough pain, especially for cancer and chronic non-malignant pain. For patients experiencing surgical or traumatic pain, analgesics should be given ATC until the pain decreases to a level that allows medications to be given as required (e.g., prn, such as prior to physical therapy). When using the WHO ladder, it is important to keep in mind that it is not necessary to start at level I if the patient is having severe pain. Analgesics from level III on the WHO ladder may be the starting point for some patients.

Other Interventions

Other pain treatments include the use of radiation therapy or antineoplastic chemotherapy to help shrink tumors that are

causing pain for a patient with cancer. Chemotherapy is also used for treating pain associated with connective tissue disorders such as rheumatoid arthritis or systemic lupus erythematosus. Bowel regimens, laxatives, enemas, or antigas medication to decrease abdominal fullness may also be considered pain treatments. In patients with osteoporosis, drugs that result in calcium uptake by the bones can aid in pain relief. These may include hormonal agents and medications that decrease calcium resorption from bone.

The IV administration of strontium-89 chloride by a qualified physician helps ease the bone pain of some patients with metastatic bone cancer. It is most effective for patients who have hormone-related cancers, such as cancer of the breast or prostate.

Lidocaine/prilocaine (EMLA, a eutectic mixture of local anesthetics) cream is a topical local anesthetic that decreases pain associated with procedures such as venipunctures and lumbar punctures. It is most effective if left in place for 1 hour before the procedure and covered with a semipermeable membrane dressing such as Tegaderm or Opsite before the needle stick. EMLA and tetracaine gel are effective topical local anesthetics and safe for use in children. A lidocaine patch is available for patients with post-herpetic nerve pain.

Placebos

Use of placebos involves the administration of an inactive substitute such as normal saline in place of an active medication. In the past, placebos were sometimes given in an attempt to determine whether a patient's pain was "real." This is unethical and inappropriate unless the patient has given written consent. The use of placebos is a denial of the patient's report of pain. If a placebo is ordered for a patient, discuss concerns with the physician and nurse supervisor. Placebos are used in drug studies (clinical trials) to compare a new drug with an inactive substance. In studies, patients are informed that they may be receiving a placebo.

Routes for Medication Administration

Analgesics can be administered by almost any route. The oral route is desired in most instances because it is easy and painless for the patient and can be used at home. See Table 9.4 for a comparison of the various routes.

Nondrug Therapies

Nondrug treatments are usually classified as cognitive-behavioral interventions or physical agents. The goals of these two groups of treatments are different. Cognitive-behavioral interventions can help patients understand and cope with pain and take an active part in its assessment and control. The goals of physical agents may include providing comfort, correcting physical dysfunction, altering physiological response, and reducing fear that might be associated with immobility. Nondrug therapies should be used in conjunction with drug therapies and are not expected to relieve pain alone.

Cognitive-Behavioral Interventions

Included in this group are interventions such as educational information, relaxation exercises, guided imagery, distraction (e.g., music, television), and biofeedback. These treatments require extra time for detailed instruction and demonstration. The use of these modalities must be acceptable to the patient to be useful.

Providing patients with educational information about what to expect and how patients can participate in their own care has been shown to decrease patients' reports of postoperative pain and analgesic use. Relaxation can be accomplished through a variety of methods. The patient may prefer a relaxation exercise with a script that can be practiced and used the same way each time or simply the use of a favorite piece of music that allows a state of muscle relaxation and freedom from anxiety. Guided imagery uses the patient's imagination to take the patient away from the pain to a favorite place, such as a beach in Tahiti. The success of guided imagery does not mean that the pain is in any way imaginary. The use of distraction is commonly used by patients to focus their attention on something other than the pain. Patients watch a favorite television program or laugh with visitors when they are in pain. When the program is over or the visitors leave, the patient may notice the pain again and ask for a dose of pain medication.

Biofeedback is sometimes used in chronic pain programs to show patients how to teach their bodies to respond to different signals. Biofeedback has been very useful in patients with migraine headaches. When patients experience the aura that many migraine sufferers get before the headache, they begin the exercise that relaxes them and prevents the migraine.

Physical Agents

Physical agents can contribute directly to the patient's comfort. Examples of physical agents include applications of heat or cold, massage, exercise, immobilization, and transcutaneous electrical nerve stimulation (TENS).

The application of heat to sore muscles and joints is effective for pain relief. Heat works to increase circulation, induce muscle relaxation, and decrease inflammation when applied to a painful area. Heat can be applied using dry or moist packs or wraps or in a bath or whirlpool. Heat is contraindicated in conditions that would be worsened by its use, such as in an area of trauma, because of the possibility of increased swelling caused by vasodilation. To prevent burns, heat should not be applied over areas of decreased sensation.

Cold can reduce swelling, bleeding, and pain when used to treat a new injury. Cold can be applied by a variety of methods, such as cold wraps and cold packs, as well as localized ice massage. Patients often choose heat over cold if they have the choice. Cold is better tolerated over a small area. Alternating heat and cold therapies is most effective if not contraindicated.

Massage and exercise are used to stretch and regain muscle and tendon length, and to relax muscles. Massage pressure can be superficial or deep. It is important that

TABLE 9.4 ROUTES FOR ANALGESIC ADMINISTRATION

Route	Uses	Advantages	Disadvantages	Nursing Considerations
Oral	Preferred route in most cases	Convenient, inexpensive	Slower onset than IV	Can provide consistent blood levels when given ATC
Rectal	May be used to provide local or systemic pain relief	Can be used when patient is unable to take oral medication	May be difficult for patient or family to self-administer	Some oral preparations can be given rectally
Transdermal patch	Chronic pain	Easy to apply; delivers pain relief for three days without patch change.	12-hour delay before effective drug level reached, and delay in excreting once removed. Patient must be closely monitored and alternative routes may be needed when starting and stopping therapy.	May be less effective in smokers owing to circulatory alterations. Absorption may be erratic. Absorption may be increased with fever. Use caution not to touch medication when applying. Follow drug manufacturer's instructions for administration.
Intramuscular	Acute pain	Rapid pain relief	Painful	Use only if other routes cannot be used.
Intravenous	Preferred route for postoperative and chronic cancer pain for patients who cannot tolerate oral route.	Provides rapid relief; continuous infusion provides steady drug level	Difficult to use in home care setting; requires training.	Follow drug manufacturer instructions for administration.
Patient controlled Intravenous	Used to allow patient control over administration schedule	Patient can simply push a button to administer a dose of opioid	Requires special training. Pump must be programmed correctly.	An hourly limit and lockout interval are programmed into the pump to prevent the patient from accidentally overdosing. Teach patient and family that only the patient should push the button.
Subcutaneous	May be used if IV route is problematic	Can deliver effective pain relief	Injection may be painful	May be effective for treatment of chronic cancer pain
Intraspinal (epidural or subarachnoid)	Catheter into epidural or subarachnoid space may be used for traumatic injuries or chronic pain unrelieved by other methods; may also be used for orthopedic procedures.	May be able to control pain with lower doses of opioid because relief is delivered closer to site of pain. Fewer systemic side effects.	Requires single or continuous injection in back; may be associated with intense itching.	Steroids may be administered with opioid to reduce pain by treating inflammation.

massage is acceptable and not offensive to the patient. Immobilization is used following a variety of orthopedic procedures, as well as fractures and other injuries worsened by movement.

Physical agents are readily available, inexpensive, and require little preparation or instruction. But always remember, it is important to use nondrug treatments to enhance appropriate drug treatments, not as a substitute.

NURSING PROCESS

Assessment/Data Collection

Accurate assessment of pain is essential to effective treatment. Without appropriate assessment, it is not possible to

intervene in a way that meets the patient's needs. The American Pain Society recommends that nurses consider pain the "fifth vital sign."⁴ That way it will be routinely assessed whenever other vital signs are assessed. The WHAT'S UP? format found in Chapter 1 can assist you in performing a complete and effective assessment (Table 9.5). Following are some additional key points for assessing pain and putting together more pieces of the pain puzzle.

Accept the Patient's Report of Pain

Pain is what the patient says it is, not what the nurse or physician thinks it should be. When a member of the health-care team distrusts the patient's report of pain, the patient can usually sense that he or she is not believed. The patient may compensate by either underreporting pain or, less com-

TABLE 9.5 WHAT'S UP? FORMAT FOR ASSESSMENT OF PAIN

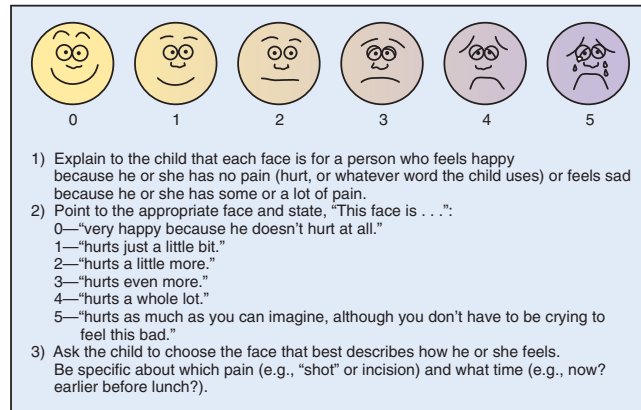

W—Where is the pain? Be specific. Use drawing of body if necessary.
H—How does the pain feel? Is it shooting, burning, dull, sharp?
A—Aggravating and alleviating factors. What makes the pain better? Worse?
T—Timing. When did the pain start? Is it intermittent? Continuous?
S—Severity. How bad is the pain on a 0 to 10 (0 to 5; faces) scale
U—Useful other data. Are you experiencing any other symptoms associated with the pain or pain treatment? Itching, nausea, sedation, constipation?
P—Perception. What is the patient's perception of what caused the pain?

monly, anxiously overreporting. Patients may try to hide their pain for fear of being thought of as a complainer or drug seeker.

Obtain a Pain History

Information is obtained from the patient about the pain he or she is experiencing. Allowing the patient to describe the pain in his or her own words helps establish a trust relationship between you and the patient. This is also the time to discover the effects the pain is having on the patient's quality of life. Does the pain prevent the patient from eating, sleeping, or participating in work or family activities? Are there adverse effects such as nausea and vomiting or constipation that need to be addressed? Emotional and spiritual distress and coping abilities should be assessed. Ask the patient about how he or she has coped with pain previously and what treatment measures have been effective in the past as well as those that have not been effective. A thorough history is essential so you can individualize pain interventions to fit the patient's needs.

A variety of tools are available to assist in accurate and complete pain assessment. You should become familiar with the tool used in your setting and use it consistently. It is of utmost importance that all health-care personnel caring for the patient use the same pain rating scale, whether it is a numerical scale (e.g., 0 to 5 or 0 to 10), a visual analog scale (Fig. 9.3), or the Wong-Baker faces scale (Fig. 9.4). Whatever scale is used, it must be one that has been validated with research. The faces scale was developed for use in children, but has also been shown to be a valid instrument

**FIGURE 9.3** Pain scale.**FIGURE 9.4** Wong-Baker faces. (From Wong, DL: Whaley & Wong's *Essentials of Pediatric Nursing*, ed. 5. Mosby, St. Louis, 1997.)

for use in the elderly. Some scales are cute and interesting but may not be valid or even useful. The best tools are simple and easy to use. Longer questionnaires, although valid, require more time and may cause distress for the patient in acute pain but may be helpful when doing a complete pain history (Fig. 9.5). A scale should also be used to monitor the patient's level of sedation following opioid administration (Fig. 9.6). Any unexpected decrease in the patient's level of consciousness should be reported promptly to the registered nurse (RN) or physician.

It is important to use the patient's own descriptions and words when taking the pain history, such as *aching*, *knifelike*, or *throbbing*. This is also true when the patient is experiencing neuropathic (non-physiological) pain, which can be difficult to define. Terms commonly used to describe neuropathic pain include *burning*, *shocklike*, and *tingling*.

Do a Complete Physical Assessment

A good physical assessment is necessary to determine the effect of the pain and pain treatments on the body. It helps identify all the pain sites and helps you to prioritize the seemingly overwhelming task of helping the patient achieve acceptable pain relief and good quality of life. As discussed previously, the patient with acute pain may exhibit signs such as grimacing and moaning or elevated pulse and blood pressure, but these signs cannot be relied on to "prove" that the patient is in pain. The only reliable source of pain assessment is the patient's self-report (Box 9.4, Gerontological Issues).

Nursing Diagnosis, Planning, and Implementation

See Box 9.5, Nursing Care Plan for the Patient in Pain. Some additional principles to consider during planning and implementation follow.

Set Goals with the Patient

Establish a pain control goal during the planning phase. The patient must be asked to determine an acceptable level of

pain if complete freedom from pain is not possible. Education is important when helping the patient set a realistic pain control goal. Although a goal of zero pain is desirable, it may not be possible or safe. On the other hand, a patient may choose a pain goal of 6 but be unable to get out of bed and do other recovery activities. Patients should also identify activity goals. After surgery, goals may include the ability to ambulate and sleep without pain. For patients with chronic pain, the goals may be different. For example, if a patient with terminal cancer wants to be able to attend her granddaughter's wedding, you can assist the patient in reaching that goal. She can be taught to reserve energy that day for the activity that is most important to her. Instructing her in optimal timing of her pain medication will also assist her in reaching a good comfort level for the activity.

Allow the Patient as Much Control as Possible

Pain can bring forth feelings of helplessness and hopelessness. Giving patients pain management options allows them to maintain some control. It is also the nurse's responsibility to teach patients about the goals of pain management and why it is an important part of care. If patients understand

Box 9.4

Gerontological Issues

The older patient may have different manifestations of pain than a younger patient. Older patients who are confused may be unable to tell you that they are feeling pain. Consider incidents of restlessness and confusion as possible signs of pain. Pulling at dressings, tugging at IV sites, and trying to climb over the side rails to get out of bed can also be symptoms of discomfort. Any change in the patient's behavior may be indicative of discomfort. Remember to take more time when assessing pain in the older patient as they may need more time to process what you are asking.

You can anticipate pain and provide relief measures to prevent severe pain. A trial dose of pain medication may help to determine if the patient's behavior is because of pain. Pain medications and basic comfort care can be administered routinely if pain is likely. Nagging achiness in hands and feet is often noted as a reason for decreased activity, inability to sleep, and altered functional ability. A hand or foot massage using lotion and gentle massage strokes is often a very relaxing comfort measure.

Opioid analgesic doses may need to be decreased initially as they tend to work longer and stronger in the older patient.

Box 9.5 NURSING CARE PLAN for the Patient in Pain

Nursing Diagnosis: Pain

Expected Outcomes: Pain is at a level that is acceptable to the patient. Patient is able to participate in activities that are important to him or her.

Evaluation of Outcomes: Is pain at a level that is acceptable to the patient? Is the patient able to participate in activities that he or she has identified as important?

Intervention

Assess pain based on patient report. Use the WHAT'S UP format.

Teach the patient to use a pain rating scale. Use the same scale consistently.

Determine with patient what is an acceptable pain level.

Rationale

Patient's pain is defined as what the patient says it is, when the patient says it is occurring.

A rating scale is the most reliable method for assessing pain severity.

Only the patient can decide what pain level is acceptable.

Evaluation

Does the patient verbalize his or her pain?

Does the patient use verbal or non-verbal messages that imply trust in nurse's belief of pain report?

Does the patient understand the use of the scale and use it to report pain?

Is the patient's pain at an acceptable level?

Intervention

Assess whether pain is acute, chronic, or both.

Assess need for and offer emotional and spiritual support for the experience of pain and suffering.

Give analgesics before pain becomes severe. For moderate to severe pain, give analgesics ATC.

Combine opioid and nonopioid analgesics as ordered.

Assess for pain relief approximately 1 hour after administration of oral analgesics, or 30 minutes after IV analgesics.

Observe for anticipated adverse effects of pain medication.

If opioids are being used, assess for respiratory depression and level of sedation at regular intervals.

Institute measures to prevent constipation: 8 to 10 glasses of fluid daily (unless contraindicated), fiber in meals, fiber or bulk laxatives, and exercise as tolerated.

Teach patient alternative (nondrug) pain relief interventions, such as relaxation and distraction, to be used with medication.

Assess whether patient is taking pain medications appropriately, and if not, assess reasons. Instruct in how to manage pain interventions.

Rationale

Acute and chronic pain may present differently and may require different interventions.

Pain, as well as disease processes, can be accompanied by feelings of powerlessness and distress.

Severe pain is more difficult to relieve.

Balanced analgesia provides optimum pain relief with fewer side effects.

If pain is not relieved, additional measures will be needed.

Many pain medications cause nausea and constipation. The nausea usually subsides after several days, but the constipation does not.

High doses or sudden increases in doses of an opioid can result in respiratory depression and increased sedation.

A common side effect of opioids is constipation.

Alternative interventions can help the patient feel in control and may help reduce the perception of pain.

Pain medications must be taken appropriately to be effective.

Evaluation

Has acute versus chronic pain been identified? Are treatments appropriate?

Does the patient appear emotional, angry, or withdrawn? Does the patient have difficulty making decisions? Is the patient-nurse relationship therapeutic?

Is analgesic schedule effective?

Is the analgesic combination effective?

Does patient report acceptable level of relief?

Are adverse effects occurring? Can they be managed? Does medication regimen need to be adjusted?

Is the patient's respiratory rate greater than 8 per minute or above the parameter ordered by the physician? Is the patient alert and oriented?

Are the patient's bowels moving according to his or her usual pattern?

Does the patient use alternative interventions effectively?

Is the patient able to manage the pain control regimen? Are adjustments necessary?

that the health care provider's goals and theirs are the same, they are likely to cooperate with and contribute to the pain management plan.

Understand that Pain Affects the Whole Family

It is important to include the whole family in the plan. Understanding family dynamics helps the nurse in implementing an effective pain management plan. Cultural influences are also important to consider (see Chapter 3). It is difficult for family members to see loved ones in pain.

Including them in the planning helps them feel that they can help make the patient more comfortable. (See Home Health Hints.)

Pain is Exhausting

Pain may keep the patient from sleeping. This cycle of sleeplessness and pain must be interrupted to help the patient. The need for adequate rest must not be ignored. This is often an ongoing problem for the patient with chronic nonmalignant pain or chronic cancer pain, and it is perhaps

more difficult to manage. The patient must get at least 4 to 6 hours of uninterrupted sleep to be relaxed enough to break the cycle. Controlled-release opioids may help maintain pain relief, allowing the patient to sleep. If controlled-release medications are not used, it may be necessary to wake a patient to administer pain medication so that the pain does not get out of control. The addition of a sedative may be necessary to allow the patient to sleep.

A Team Approach to Pain Management

A plan must be developed using an interdisciplinary approach, including the patient and family, the nurse, and the physician. Other team members, such as the occupational and physical therapist, chaplain, social worker, and pharmacist, should be included as appropriate. Communication is the important link allowing the team to be effective in creating a plan that works for the patient. Plans must be individualized to meet the special needs of each patient and vary greatly depending on the characteristics of pain the patient is experiencing and the effect on the patient.

Patient Education

Patients must be informed about the medications they are taking for pain management so they can take an active role in their care. Patients informed about the goals of pain management are more likely to report unrelieved pain so that they can receive prompt and effective treatment. Goals include a satisfactory comfort level with minimal side effects and complications of pain and its treatment, as well as a reduced period of recovery.

CRITICAL THINKING

Mr. Sebastian

■ Mr. Sebastian is a 75-year-old man who has been diagnosed with lung cancer and is anxious about leaving the hospital to return home following a thoracotomy. The nursing assessment reveals the need for home health care for dressing changes and teaching about the medications he will need at home. While in the hospital, Mr. Sebastian has required 5 mg of morphine IV every 4 hours around the clock.

1. The morphine is available in syringes prefilled with morphine grains 1/6 per mL. How many milliliters should the nurse administer?
2. What discharge instructions must be given to Mr. Sebastian and his wife before sending him home?
3. How might his pain be managed at home to prevent unnecessary readmissions to the hospital?

Suggested answers at end of chapter.

CRITICAL THINKING

Mrs. Zales

■ Mrs. Zales, a 32-year-old woman, was admitted for a hysterectomy after being treated for painful endometriosis for 12 months. After her surgery she had a PCA pump with hydromorphone, which was effective in relieving her pain. Forty-eight hours after surgery the surgeon discontinued the PCA pump and ordered oral hydrocodone with acetaminophen. It was ineffective, so an order for hydromorphone, 2 to 4 mg orally every 3 to 4 hours as needed, was added. The nurses gave only one dose of the hydromorphone, then, thinking that her pain should be lessening, switched Mrs. Zales back to the hydrocodone with acetaminophen. By the next morning she was in severe pain, and the on-call physician ordered IM meperidine and promethazine (Phenergan). Mrs. Zales's discharge was delayed until her pain could be controlled.

What do you think happened? How could the delayed discharge have been avoided?

Suggested answers at end of chapter.

CRITICAL THINKING

Ms. Jackson

■ Ms. Jackson had abdominal surgery 2 days ago. She has been receiving morphine via IV PCA at an average of 2.5 mg per hour for the last 6 hours. She rates her pain at 3 on a scale of 0 to 10. She is to be discharged today. Her physician has ordered codeine 30 mg with acetaminophen (Tylenol with codeine No. 3), 1 or 2 tablets every 4 hours as needed for pain at home.

Will Ms. Jackson be comfortable at home? Why or why not?

Suggested answers at end of chapter.

NURSING CARE TIP

Many medication interventions are available for the treatment of pain. Whenever possible, administer analgesics by the mouth, by the WHO ladder, and by the clock.

ETHICAL CONSIDERATION DISCUSSION

This is a complex case. Not only are we looking at professional ethical obligations as dictated by her regulatory body; we have to consider Kathy's personal values. There may be a conflict. Kathy may believe that life is valuable and worth preserving at any cost, and that the administration of a medication that will shorten life or even precipitate a death cannot be an activity that she can become involved in. Her beliefs may prohibit her from taking many jobs where end of life issues are part of daily routine (such as abortion clinics, palliative care units, long-term care units, and emergency rooms).

If Kathy has moral objections to administering what she considers to be a lethal dose of medication, she should seek out her supervisor in order to explain her difficulty with the order. She may be able to withdraw from assisting with or performing procedures that are against her personal moral values. This task can be undertaken by a nurse who has no moral objections, provided that there is a nurse available. The supervisor may choose to administer the medication himself or herself, or to pursue alternate outcomes, such as con-

tacting the palliative care team or an alternate physician if possible. Kathy might consider talking with the physician or forming a group on the unit to discuss the issues and develop some unit guidelines for such cases.

Situations like this are an everyday occurrence. A nurse should assess the work environment before committing to work on a unit. Kathy may be able to inform her supervisor and colleagues that under certain circumstances, she will not participate in a treatment regimen and will need to rely upon the team to support that decision and assist with finding alternate methods of delivering care. She should recognize, however, that sometimes there is no one else available to administer medications or perform procedures. At that point, she would have to think carefully about her professional obligations; that is, to whom does she owe the primary obligation . . . to the patient or to her own moral code? And what is that obligation? In the end, if Kathy is unable to function effectively on this unit, she may need to seek employment elsewhere.

It is important to provide the patient with information about a drug's common adverse effects, the frequency of the dose and its duration of action, and potential drug-drug and food-drug interactions if indicated. There are many special considerations for medications such as control release oral agents and transdermal patches; care must be taken to include these in the education plan for the patient using these medications at home. Drug-specific instructions are found in drug handbooks. Education must be presented at a level that the patient can understand. Informed patients use their medications more effectively and safely.

Evaluation

The final phase of the nursing process is evaluation. Once the plan of care has been implemented, evaluate whether the patient's goals have been met. Has the patient's identified goal for an acceptable level of pain been met? How were the pain treatments tolerated? Was the patient able to participate in activities that he or she identified as important? The plan should be continuously updated based on the evaluation.

Home Health Hints

- Emotional or spiritual distress and fear related to dependence on family caregivers may alter the patient's perception or report of pain. Some patients may feel pain more intensely because of the influence of fear, and others may underreport if they are trying to protect family members.
- Several alternative measures are easily taught to patients and caregivers in the home. For example, ice can be made in paper cups and used for a cold massage of a painful area.
- Medical massage therapy is growing in popularity for the treatment of chronic pain. Remember a physician's order might be necessary for this type of treatment. Discuss this option with the registered nurse, patient, and caregiver to help identify if this intervention is appropriate for your patient.

REVIEW QUESTIONS

- A patient is walking up and down the hall and visiting with other patients. He is laughing and joking. He approaches the nurse's station, asks for his pain shot, and reports that his pain is 6 on a scale of 0 to 10. Based on McCaffery's definition of pain, which of the following assumptions by the nurse is most likely correct?
 - The patient is not really in pain but just wants his medication.
 - The patient is having pain at a level of 6 on a scale of 0 to 10.
 - The patient is in minimal pain and should receive a pill instead of a shot.
 - The patient is in pain but does not need his pain medication yet.
- A patient with terminal cancer has been requiring 5 mg of IV morphine every 1 to 2 hours to control pain, yet is engrossed in a movie on television and appears to be in no pain. Which of the following explanations of this behavior is most likely correct?
 - Denial of pain is common in patients with cancer.
 - The cancer treatment is working and the pain is improving.
 - The patient is hiding the pain in order to finish watching the movie undisturbed.
 - Distraction can be an effective treatment for pain when used with appropriate drug treatments.
- Which patient is exhibiting tolerance to opioid analgesics?
 - The patient who requests opioid analgesics frequently because of severe acute pain.
 - The patient who refuses opioid analgesics because of fear of addiction.
 - The patient who needs increasing doses of opioids to achieve the same level of pain relief.
 - The patient who requests opioid analgesics even when not in pain in order to feel euphoric.
- A patient has incisional pain following total hip replacement surgery. Which of the following types of pain is the patient experiencing?
 - Nociceptive/physiological
 - Neuropathic/nonphysiological
 - Chronic nonmalignant
- With which type of pain is the patient least likely to present with outward signs such as moaning or changes in vital signs?
 - Acute pain
 - Chronic nonmalignant pain
 - Cancer pain
- Which of the following methods is the most reliable way to assess a patient's pain?
 - Ask the patient to describe the pain.
 - Observe the patient for physical signs of pain such as moaning or grimacing.
 - Ask the patient to rate his or her pain using a valid assessment scale.
 - Ask a family member to rate the patient's pain.
- According to the World Health Organization analgesic ladder, at what point in a patient's pain experience is it appropriate to use adjuvant treatments? Choose all answers that are correct.
 - In addition to analgesics for early, mild pain
 - As an alternative to analgesics for moderate to severe pain
 - In addition to analgesics for pain that is persistent despite treatment
 - In addition to analgesics for pain that is growing increasingly more severe
- A patient is hospitalized following a motor vehicle accident. He has multiple orthopedic injuries and is in acute pain. He has an order for morphine 6 mg IV every 4 hours as needed. He can also have a nonopioid oral analgesic every 4 hours as needed. In order to reduce the risk of adverse effects and maintain an acceptable level of sedation and pain control, which of the following analgesic schedules will be most effective?
 - Offer the opioid every 4 hours.
 - Tell him to put on his light when he feels pain, and give the drugs immediately when he requests them.
 - Give both the IV opioid and the PO nonopioid every 4 hours ATC.
 - Alternate the IV analgesic with the nonopioid oral analgesic.
- Mr. Lawrence is an 88-year-old man admitted with a broken hip after a fall. He has an order for meperidine 50 to 75 mg IM q4–6hr prn pain. As his nurse, which of the following actions should you take?
 - Give the meperidine every 4 hours ATC.
 - Offer the meperidine every 6 hours because you know that his liver and kidney function may be diminished.
 - Administer an NSAID with the meperidine for added pain relief.
 - Talk to the RN or physician about getting an order for a different analgesic.
- A patient is started on gabapentin (Neurontin) 300 mg by mouth three times daily for chronic nerve pain related to diabetic neuropathy. Which instruction should the nurse provide?
 - "Take the medication at the first sign of any pain, up to three times daily."

- b. "Take one capsule every eight hours continuously to keep the pain under control."
 - c. "Take the medication only when you need it, to prevent becoming addicted."
 - d. "Take one capsule three times a day, then discontinue it when the pain is under control."
11. A nurse receives an order to administer 1 mL of sterile normal saline IM to a patient suspected of opioid abuse. Which response by the nurse is appropriate first?
- a. Administer the saline and carefully document the patient's response in the medical record.
 - b. Administer the saline but inform the patient exactly what it is and why it was ordered.
 - c. Refuse to administer the medication and inform the physician that the order is inappropriate.
 - d. Share concerns about the order with the supervisor and explain why the nurse cannot in good conscience administer the saline.
12. A nurse needs to administer morphine 10 mg IM. It is supplied as grains 1/4 per mL. How many milliliters should the nurse prepare for injection?
_____ mL

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ **Smithers and Barnett**

It is important to accept both patients' pain reports. Assessment should be based on what the patient says rather than what is observed. Each patient copes with his or her pain in a unique way, and the nurse cannot judge whether one is in more pain than the other.

■ **Mrs. Shepard**

1. Pain medication is most effective when given on a routine schedule around the clock to avoid breakthrough pain. Mrs. Shepard's epidural infusion should continue to relieve her pain for a time, up to several hours after it is discontinued, depending on the medication used. The oral medication is most effective when given at the time the epidural is stopped so that it is taking effect as the epidural effects wear off. See Box 9.4 (Gerontological Issues) for special considerations for the older patient.
2. Pain prevents patients from moving freely. Postoperative complications such as retained pulmonary secretions and ileus can occur when patients are immobile. Effective pain management can help prevent these complications.
3. If she takes a dose every 3 hours, then she will receive eight doses in 24 hours: $500\text{ mg} \times 8 = 4000\text{ mg}$ or 4 g, which is the maximum safe dose. Recall that elderly patients metabolize and excrete medications more slowly than younger patients. If she will need the hydrocodone/acetaminophen more than a few days, it would be wise to consult with the physi-

cian about giving the opioid and acetaminophen separately.

4. Mrs. Shepard should be instructed what her role will be when her pain management regimen is altered. Does she have to ask for the pain medication or will it just be brought to her? Patient and family education is vital to success in management of a patient's pain.

■ **Mr. Sebastian**

1.

5 mg	1 grain	1 mL	=	0.5 mL
	60 mg	grains 1/6		
2. Home instruction regarding ATC administration of pain medication is indicated, as well as effects and side effects to report. He will also need to implement measures to prevent constipation.
3. MS Contin, a long-acting form of morphine, may be an option for Mr. Sebastian, along with an immediate-release preparation for breakthrough pain. Also, information about what to do and who to contact if pain becomes unmanageable is necessary to help prevent readmissions to the hospital.

■ **Mrs. Zales**

Mrs. Zales was probably tolerant to opioids because of her need for medication for chronic pain over the last year. For this reason, she needed more medication than a nontolerant patient who does not usually use opioids. Also, the belief that promethazine and other phenothiazines potentiate opioids is a myth. They do cause increased levels of sedation and may limit the amount

(Continued on following page)

of opioid that can be given safely. IM injections are not recommended because they are painful, absorption is not predictable, and there is a delay between injection and relief. Nurses often base the treatment of a patient's pain on what they usually do or what they think should be effective rather than on sound pain management practices and principles. A more rational approach to Mrs. Zales would have been regular pain assessment with ATC treatment until pain began to subside. If her pain level had been better controlled, she might have been discharged on oral analgesics without the delay.

■ ***Ms. Jackson***

Using an equianalgesic conversion, we can determine whether Ms. Jackson is likely to have good pain relief

based on her requirement with the PCA. Her current pain level of 3 shows that the morphine has been effective. Remember that the pump keeps a history of what the patient uses, which is the best indicator of what the patient needs. Ms. Jackson has used 15 mg of morphine during the past 6 hours. An equianalgesic dose of Tylenol with codeine No. 3 would be almost 200 mg of codeine, but only 30 to 60 mg has been ordered. In addition, if Ms. Jackson takes enough Tylenol with codeine No. 3 to get 200 mg of codeine, she will receive a dangerous dose of both the codeine and the acetaminophen. The physician needs to be contacted for different analgesic orders.

REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY OF CELLS

Cells are the smallest living structural and functional subunits of the body. Although human cells vary in size, shape, and certain metabolic activities, they have many characteristics in common.

Cell Structure

Human cells have a cell membrane, cytosol, cell organelles, and, with the exception of mature red blood cells, a nucleus. In the mature red blood cell, the nucleus has been lost. Each cell structure has a specific and vital function. The cell membrane forms the outer boundary of the cell and is made up of phospholipids, proteins, and cholesterol. Proteins serve four different purposes: (1) Some are channels or transporters to permit movement of materials, (2) some are enzymes catalyzing reactions, (3) some are receptor sites for hormones to trigger a cell's activity, and (4) some are antigens to identify the cell as belonging in the body.

A cell membrane is selectively permeable, meaning that not all substances pass through equally. The lipids in the

membrane permit the diffusion of lipid-soluble materials into or out of the cell. Materials may enter or leave a cell in a variety of ways, such as diffusion, osmosis, active transport, pinocytosis, and phagocytosis.

Cytosol and Cell Organelles

Cytosol is a watery solution of minerals, gases, and organic molecules that is found between the cell membrane and the nucleus. Chemical reactions (such as the synthesis of adenosine triphosphate [ATP] in glycolysis) take place in the cytosol. Cell organelles are subcellular structures with specific functions, which are shown in Figure 10.1. Many cell organelles are found in the cytosol.

Nucleus

The nucleus of a cell is surrounded by a double-layered nuclear membrane with many pores. Inside the nucleus are one or more nucleoli and the chromosomes of the cell.

A nucleolus is a small sphere made of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein. The nucleoli form a type of RNA called ribosomal RNA, which is part of the cell organelle called the ribosome and is involved in protein synthesis.

FIGURE 10.1 Schematic diagram of a typical human cell. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. F.A. Davis, Philadelphia, 2003.)

The nucleus is the control center of the cell because it contains the chromosomes. The 46 chromosomes of a human cell are made of DNA and protein. DNA is the genetic code for the characteristics and activities of the cell. Specific regions of DNA are called genes; a gene is the code for one protein. Not all the genes in any cell are active—only those relative few needed for the proteins to carry out their specific functions. These proteins may be structural, such as the collagen of connective tissue, or functional, such as the hemoglobin of red blood cells. Important functional proteins are the enzymes that catalyze the specific reactions characteristic of each type of cell.

Genetic Code and Protein Synthesis

The genetic code of DNA is the code for the amino acid sequences needed to synthesize a cell's proteins (Fig. 10.2). A complementary copy of the DNA's gene is made by a molecule called messenger RNA (mRNA). The mRNA then moves to the cytoplasm of the cell and attaches to the ribosomes. Transfer RNA (tRNA) molecules bring the necessary amino acids to the proper places on the mRNA molecule, and enzymes of the ribosomes catalyze the formation of peptide bonds to link the amino acids into the primary structure of a protein.

As with any complex process, mistakes are possible. Should there be a mistake in the DNA code, the process of protein synthesis may go on anyway, but the resulting protein will not function normally; this is the basis for genetic diseases. DNA mistakes acquired during life are called mutations. A mutation is any change in the DNA code. Ultraviolet rays or exposure to certain chemicals may cause structural changes in the DNA code. These changes may kill the affected cells or may irreversibly alter their function. Such altered cells may become **malignant**, being unable to function normally but very active; this is the basis of some forms of **cancer**.

Mitosis

Mitosis is the process by which a cell reproduces itself. One cell, after its 46 chromosomes have duplicated themselves, divides into two cells, each with a membrane, cytoplasm, and organelles from the original cell and a complete set of chromosomes. Mitosis is necessary for the growth of the body and the replacement of dead or damaged cells. Some cells are capable of mitosis and others are not. Cells of the epidermis of the skin undergo mitosis continuously to replace the superficial cells that are constantly worn off the skin surface. The same is true of cells that line the stomach

FIGURE 10.2 Schematic diagram of the process of protein synthesis. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. FA. Davis, Philadelphia, 2003.)

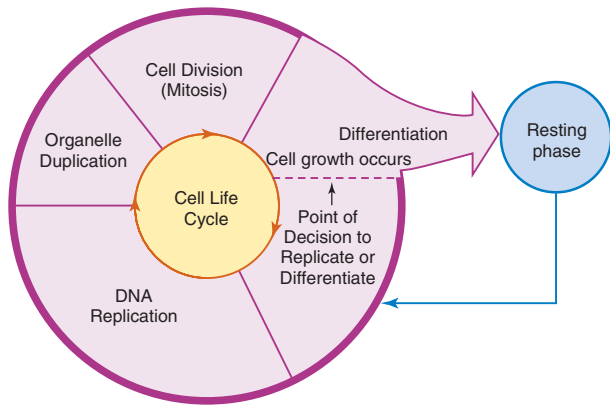

FIGURE 10.3 Cell cycle.

and intestines. Cells in the red bone marrow also divide frequently; red blood cells have a fixed life span (about 120 days) and must be replaced. Some cells seem to be capable of only a limited number of divisions, and when that limit has been reached, the cells die and are not replaced.

Other cells do not undergo mitosis to any great extent after birth. Nerve cells (neurons) are unable to divide (except for in the hippocampus), and muscle cells have very limited mitotic capability. When such cells are lost through injury or disease, the loss of their function in the individual is usually permanent.

Cell Cycle

The cell cycle involves a series of changes through which a cell progresses, starting from the time it develops until it reproduces itself. The duration of the cell's life, the time it takes for mitosis to occur, the growth ratio (percentage of cycling cells), the frequency of cell loss, and the doubling time (time for a **tumor** to double its size) are important concepts related to tumor growth and treatment strategies.

Cells can occupy three places in the cell cycle: cells that are actively dividing, cells that leave the cycle after a certain point and die, and cells that temporarily leave the cycle and remain inactive until reentry into the cycle. Inactive cells continue to synthesize RNA and protein (Fig. 10.3).

Cells and Tissues

A tissue is a group of cells with similar structure and functions. The four groups of human tissues are epithelial, connective, muscle, and nervous tissue

Epithelial tissues form coverings and linings throughout the body. Often the cells are capable of mitosis, and damage to the tissue may be repaired. The healing of a cut to the skin is a typical example. Epithelial tissue also forms glands.

There are many types of connective tissues with varied functions. For example, blood is a connective tissue involved in the transportation of materials throughout the body. Fibrous connective tissue, made mostly of the protein collagen, forms strong membranes such as those around muscles, attaching structures such as ligaments and tendons and the dermis of the skin. Bone and cartilage support connective tissues. Adipose connective tissue stores fat as

potential energy. Many kinds of connective tissue cells are capable of mitosis.

There are three kinds of muscle tissue: skeletal muscle, smooth muscle, and cardiac muscle. Skeletal muscle tissue makes up the voluntary muscles attached to the skeleton. Smooth muscle is found in viscera such as the stomach and intestines, the walls of arteries and veins, the walls of the bronchial tubes, and the uterus. Cardiac muscle forms the walls of the heart. As mentioned, the cells of muscle tissue have little ability to reproduce themselves.

Nervous tissue is made of neurons and supporting neuroglial cells. Although mature neurons are not capable of mitosis, many neuroglia are capable. It is the neuroglia, not neurons, that usually form the tumors that develop in the central nervous system.

INTRODUCTION TO CANCER CONCEPTS

Oncology is the branch of medicine dealing with tumors. Oncology nursing is also called cancer nursing; it is an important component of medical-surgical nursing care. See Box 10.1 Cancer Resources. Cancer is second only to heart disease in mortality rates in the United States. The American Cancer Society reports that an estimated 10 million Americans alive today have a history of cancer.

Early accounts of cancer date back to the 17th century B.C. Documentation of the benefits of early cancer detection and its impact on treatment exist from the beginning of the 19th century. Today, microscopic technology and genetic engineering provide physicians with a better understanding of tumor growth and cell activity and a means for early cancer detection and intervention.

Benign Tumors

Cells that reproduce abnormally result in **neoplasms**, or tumors. *Neoplasm* is a term that combines the Greek word *neo*, meaning “new,” and *plasia*, meaning “growth,” to suggest new tissue growth. The new growth results in enlargement of tissue and the formation of an abnormal mass. Not all neoplasms contain cancer cells; however, a neoplastic cell is responsible for producing a tumor and shows a lively growing cell. A neoplastic growth is very difficult to detect until it contains about 500 cells and is approximately 1 cm.

A **benign** tumor is defined as a cluster of cells that is not normal to the body but is noncancerous. Benign tumors grow more slowly and have cells that are the same as the original tissue. An organ containing a benign tumor usually continues to function normally.

Cancer

Cancer is a group of cells that grows out of control, taking over the function of the affected organ. Cancer cells are described as poorly constructed, loosely formed, and with-

oncology: onco—mass + logy—word, reason

neoplasm: neo—new + plasm—form

out organization. An organ with a cancerous tumor eventually ceases to function. A simplistic definition is “confused cell.” *Malignant*, a term often used as a synonym for cancer, is defined as a growth that resists treatment and tends to worsen and threaten death. A comparison of benign and malignant tumors is found in Table 10.1.

**LEARNING TIP**

Cancer is not contagious.

Pathophysiology

Cancer is not one disease, but many diseases with different causes, manifestations, treatments, and prognoses. There are more than 100 different types of cancer caused by mutation of cellular genes. Cancer takes on the characteristics of the cell it mutates and then takes on characteristics of the mutation. Growth-regulating signals in the cell’s surrounding environment are ignored as the abnormal cell growth increases. Normal cells are limited to about 50 to 60 divisions before they die. Cancer cells do not have a division limit and are considered immortal.

The progression from a normal cell to a malignant cell follows a pattern of mutation, defective division and abnormal growth cycles, and defective cell communication. Cell mutation occurs when a sudden change affects the chromosomes, causing the new cell to differ from the parent. The malignant cell’s enzymes destroy the glue-like substance found between normal cells, which disrupts the transfer of information used for normal cell structure.

Cancer cells also lack **contact inhibition**. This is a property of normal cells in which contact by the cell with another cell or tissue signals cells to stop dividing. Since cancer cells do not possess contact inhibition, they continue to divide and invade surrounding tissues.

Etiology

Cancer cell growth and reproduction involves a two-step process. The first step in cancer growth is called initiation. Initiation causes an alteration in the genetic structure of the cell (DNA). Cell alteration is associated with exposure to a **carcinogen**. The cellular change primes the cell to become cancerous.

Promotion is the second type of cancer cell growth. It occurs after repeated exposure to carcinogens causes the initiated cells to mutate. During the promotion step, a tumor forms from mutated cell reproduction.

A healthy immune system can often destroy cancer cells before they replicate and become a tumor. It is important to remember that any substance that weakens or alters the immune system puts the individual at risk for cell mutation. Medical researchers support the theory that cancer is a symptom of a weakened immune system.

Risk Factors

Increased risk of cancer is linked to many environmental factors. An evaluation of cancer begins with assessment of well-known risk factors such as specific viruses; exposure to radiation, chemicals, and irritants; genetics; diet; and general immunity. Certain racial and ethnic groups also are at higher risk for some types of cancer (Box 10.2 Cultural Considerations).

carcinogen: karkinos—cancer; crab + genesis—birth

TABLE 10.1 BENIGN AND MALIGNANT TUMORS

	Benign	Malignant
<i>Growth Rate</i>	Typically slow expansion	Often rapid with cell numbers doubling normal cell growth; malignant cells infiltrate surrounding tissue
<i>Cell Features</i>	Typical of the tissue of origin	Atypical in varying degrees of the tissue or origin; altered cell membrane; contains tumor-specific antigens
<i>Tissue Damage</i>	Minor	Often causes necrosis and ulceration of tissue
<i>Metastasis</i>	Not seen; remains localized at site of origin	Often spreads to form tumors in other parts of the body
<i>Recurrence after Treatment</i>	Seldom recurs after surgical removal	Recurrence can be seen after surgical removal and following radiation and chemotherapy
<i>Related Terminology</i>	Hyperplasia, polyp, and benign neoplasia	Cancer, malignancy, and malignant neoplasia
<i>Prognosis</i>	Not injurious unless location causes pressure or obstruction to vital organs	Death if uncontrolled

VIRUSES. Certain viruses, such as the **oncoviruses** (RNA-type viruses), are linked to cancer in humans. Retrovirus is an enzyme produced by RNA tumor viruses and is found in human leukemia cells.

The Epstein-Barr virus (EBV), which causes infectious mononucleosis, is also associated with Burkitt's lymphoma. Herpes simplex virus 2 has been associated with cervical and penile cancers. Papillomavirus, associated with genital warts, is considered one cause of cervical cancer in women. Chronic hepatitis B is linked with liver cancer.

RADIATION. There is an increased incidence of cancer in persons exposed to prolonged or large amounts of radiation.

oncovirus: onco—mass + virus

Ionizing radiation involving ultraviolet rays such as sunlight, x-rays, and alpha, beta, and gamma rays plays a major role in promoting leukemia and skin cancers, primarily melanomas.

Persons exposed to radioactive materials in large doses, such as a radiation leak or an atomic bomb, are at risk for leukemia and breast, bone, lung, and thyroid cancer. Controlled **radiation therapy** is used to treat cancer patients by destroying rapidly dividing cancer cells. Radiation can also damage normal cells. The decision to use radiation is made after careful evaluation of the tumor's location and vulnerability to other treatments.

CHEMICALS. Chemicals are present in air, water, soil, food, drugs, and tobacco smoke. Chemical carcinogens are

Box 10.2

Cultural Considerations

Many racial and ethnic groups in the United States have high rates of cancer. Although risk factors for the development of specific cancers are similar, barriers to prevention and nursing strategies to reduce risk factors vary among ethnicities.

Europeans

Foreign-born and first-generation white men from Norway, Sweden, and Germany have an increased risk of stomach cancer. This suggests an interrelation among ethnic, geographical, and dietary risk factors as the cause of this high incidence of stomach cancer. Assessing for these data among these populations may assist in the diagnostic process.

Recent Eastern European immigrants may be a risk for thyroid cancer and leukemia because of the current industrial pollution and radiation exposure from the Chernobyl nuclear disaster in the former USSR in 1986. Some contamination occurred in Estonia, Latvia, Lithuania, and Poland. This may constitute a health hazard and may affect both recent immigrants and visitors to these countries. It is essential that health-care providers carefully screen individuals for these cancers.

African Americans

Cancer sites among African Americans include the prostate, breast, lung, colon, rectum, cervix, pancreas, and esophagus. Because African Americans are overrepresented in the working class, they experience increased exposure to hazardous occupations. For example, African American men are at a higher risk for developing cancer related to their high representation in the steel and tire industries and in factories manufacturing chemicals and pesticides. They have the highest overall cancer rate, the highest overall mortality rate, and their 5-year survival rate is 30% lower than that of European

Americans. In general, African Americans report later for treatment than European Americans. Colon tumors are deeper within African Americans, making detection on digital examination more difficult. Poverty, a diet high in fat and low in fiber, and lower levels of thiamine, riboflavin, vitamins A and C, and iron may increase cancer risk among African Americans. Additionally, cigarette smoking, inner city living with pollution, obesity, and alcohol consumption increase African Americans' risk for developing cancer.

Lack of medical care access acts as a barrier to prevention among African Americans. Survival, not prevention, is the priority for some. Additional barriers include a lack of cancer risk teaching and detection in some African American communities, lack of health insurance, and little stigma attached to alcohol consumption and smoking. Strong family ties encourage seeking health care from family members before professionals.

Primary strategies for cancer prevention and increasing survival among African Americans include using African American professionals as speakers in community activities, using church-based information dissemination, providing forums in African American communities, and addressing smoking advertisements in African American communities. Additional strategies include involving granny healers and ministers, changing food preparation practices and amounts rather than changing cultural food habits, involving extended family members in educational campaigns, and using high-profile African Americans such as sports leaders and actors in media campaigns.

Hispanics

Hispanic populations in the United States have an increased incidence for some types of cancer. Cervical cancer is increased among Central and South American women. Pancreatic, liver, and gall-bladder cancer is increased among Mexican Americans. Many Mexican Americans are less aware of the early warning signs of cancer; many are more fearful of getting cancer than the general public; and many work in mining, factories using chemicals, and farming using pesticides.

Barriers to preventive health care among many Hispanics include high poverty rates, low educational rates, a preference for health-care providers who understand Spanish, a preference for health-care information presented in Spanish, a delay in seeking treatments for symptoms, and using lay healers as a first choice in health care. Additionally, many have a fear of surgical intervention with a body cavity left open to air and have decreased access to health care. For some, an undocumented immigration status creates a fear of reprisal.

Nursing approaches effective among Hispanics include educating lay healers regarding cancer prevention and early warning signs of cancer, using bilingual health-care providers, using Hispanic health-care providers whenever available, using respected Hispanic community leaders in educational programs, presenting videos in Spanish using Hispanic actors, educating the entire family because of close family networks, and connecting with Hispanic community churches, restaurants, and stores. Additionally, the nurse can use the 1-800-4-CANCER telephone number for Spanish translation and counseling, become involved with Hispanic community movements, and provide information in community and regional Hispanic newspapers and community publications.

Asians and Pacific Islanders

Cervical, liver, lung, stomach, multiple myeloma, esophageal, pancreatic, and nasopharyngeal cancer are higher among Chinese Americans. Chinese American women have a 20% higher rate of pancreatic cancer. High rates of stomach and liver cancer in Korea predispose recent immigrants to these conditions. Thus, the nurse needs to assess and teach newer immigrants regarding these types of cancer.

High rates of stomach, breast, colon, and rectal cancer common among Japanese people may be related to the high sodium content of the Japanese diet, a genetic predisposition, consumption of salted fish and contaminated grain, hepatitis B, smoking, vitamin A deficiency, low vitamin C intake, chronic esophagitis, and pulmonary sequelae of cigarette smoking. Barriers to prevention include the following: prevention models are not native to their culture; there may be a lack of trust in Western medicine; they have decreased access to health care; some are unable to speak the English language; and for some, an undocumented immigration status creates a fear of reprisal.

Nursing approaches to improve cancer risk prevention among Asians and Pacific Islanders include education about prevention versus acute care practice, educating native healers, involvement in community with respected native leaders, videos and literature in native language, and incorporating native healing practices such as traditional Chinese medicine.

Native Americans

Native American populations have an increased risk for skin, pancreatic, gallbladder, liver, and prostate cancer. Risk factors for the development of cancer include obesity, a diet high in fat, high rates of alcohol consumption, and high rates of smoking. Barriers to prevention include a lack of Native American health-care providers, health care providers' unfamiliarity with Native American cultures, lack of financial resources, and a lack of integration of Native American healing practices into prevention practices. Nursing approaches to decrease cancer risk prevention among Native American populations include the following: incorporate prevention into Native American healing practices; educate Native American lay healers regarding cancer prevention practices; work with tribal community leaders; respect modesty, gender roles, and tribal customs; work with the Indian Health Service and Bureau of Indian Affairs; encourage traditional customs of physical fitness and exercise; and encourage dietary portion control and healthy food preparation practices instead of changing cultural food habits.

implicated as triggering mechanisms in malignant tumor development. Length of exposure time and degree of exposure intensity to chemical carcinogens are associated with risk for cancer development.

Smoking accounts for 87% of lung cancer worldwide.¹ Chemical agents, such as those in tobacco, are more toxic when used with alcohol. Alcohol and tobacco are the most frequent causes of cancers of the mouth and throat. Chemicals used in manufacturing, such as vinyl chloride, are associated with liver cancer.

IRRITANTS. Chronic irritation or inflammation caused by irritants such as snuff or pipe smoke often cause cancer in local areas. Nevi (moles) that are chronically irritated by clothing, especially clothing contaminated by chemical residue, may become malignant. Asbestos found in temperature and sound insulation has been proven to cause a particularly destructive type of lung cancer.

GENETICS. Genetics plays a large part in cancer formation. Certain breast cancers are linked to a specific gene mutation.

Skin and colon cancers have a genetic tendency. People with Down's syndrome (a chromosomal abnormality) have a higher risk of developing acute leukemia.

DIET. Diet is a large factor in both cause and prevention of malignancies. People who eat high-fat, low-fiber diets are more prone to develop colon cancers. Diets high in fiber reduce the risk of colon cancer. High-fat diets are linked to breast cancer in women and prostate cancer in men. Consumption of large amounts of pickled, smoked, and char-broiled foods has been linked with esophageal and stomach cancers. A diet low in vitamins A, C, and E is associated with cancers of the lungs, esophagus, mouth, larynx, cervix, and breast.

HORMONES. Hormonal agents that disturb the balance of the body may also promote cancer. Long-term use of the female hormone estrogen is associated with cancer of the breast, uterus, ovaries, cervix, and vagina. It has been found that children born of mothers who took diethylstilbestrol (DES) during pregnancy have an increased incidence of reproductive cancers. DES is a synthetic hormone with estrogenlike properties used in the past to prevent miscarriage.

Tumors of the breast and uterus are tested for estrogen or progesterone influence. If a breast tumor is malignant, the tumor is tested and treatment varies depending on whether it is positive for estrogen or progesterone dependence.

IMMUNE FACTORS. A healthy immune system destroys mutant cells quickly on formation. An individual with altered immunity is more susceptible to cancer formation when exposed to small amounts of carcinogens compared with someone with a healthy immune system. Immune system suppression allows malignant cells to develop in large numbers.

Altered immunity is noted in persons with chronic illness and stress. An increased risk of cancer follows a traumatic, stressful period in life, such as the loss of a mate or a job. Failure to decrease stress productively contributes to a higher incidence of chronic illnesses. Thus, a cycle of stress, illness, and increased cancer risk develops. Individuals with acquired immunodeficiency syndrome (AIDS) have a compromised immune system and an increased risk for certain cancers. A decline in the immune system is also noted as the body ages. A weaker immune system contributes to chronic illnesses and cancers associated with the elderly population.

Cancer Classification

Cancers are identified by the tissue affected, speed of cell growth, cell appearance, and location. Neoplasms occurring in the epithelial cells are called carcinomas. Carcinoma is

LEARNING TIP

An individual's cancer risk is viewed as the balance between exposure and susceptibility to carcinogens.

FIGURE 10.4 Adenocarcinoma of the caecum. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

the most common type of cancer and includes cells of the skin, gastrointestinal system, and lungs (Figs. 10.4 and 10.5). Cancer cells affecting connective tissue, including fat, the sheath that contains nerves, cartilage, muscle, and bone, are called sarcomas. *Leukemia* is the term used to describe the abnormal growth of white blood cells. Cancers involving cells of the lymphatic system, lymph nodes, and spleen are called lymphomas. See Table 10.2 for cancer types based on origin.

Spread of Cancer

Neoplastic cells that remain in one area are considered localized, or **in situ**, cancers. These tumors may be difficult to visualize on clinical examination and are detected through microscopic cell examination. In situ tumors are often removed surgically and require no further treatment. **Metastasis** is the term used to describe the spread of the tumor from the primary site into separate and distant areas.

Metastasis is the stage at which cancer cells acquire invasive behavior characteristics and cause the surrounding tissue to change (Fig. 10.6). Metastasis occurs primarily because cancer cells break away more easily than normal cells and can survive for a time independently from other cells. There are three steps in the formation of a metastasis.

FIGURE 10.5 Lung cancer. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

in situ: in—in + situ—position

metastasis: meta—beyond + stasis—stand

TABLE 10.2 TUMOR DESCRIPTION

Tumor Type	Character	Origin
Fibroma	Benign	Connective tissue
Lipoma	Benign	Fat tissue
Carcinoma	Cancerous	Tissue of the skin, glands, and digestive, urinary, and respiratory tract linings
Sarcoma	Cancerous	Connective tissue, including bone and muscle
Leukemia	Cancerous	Blood, plasma cells, and bone marrow
Lymphoma	Cancerous	Lymph tissue
Melanoma	Cancerous	Skin cells

Cancer cells are able to (1) invade blood or lymph vessels, (2) move by mechanical means, and (3) lodge and grow in a new location.

Metastatic tumors carry with them the cell characteristics of the original or primary tumor site. As a result, surgeons are able to determine the original tumor site based on metastatic cell characteristics. For example, lung tissue found in the brain suggests a primary lung tumor with metastasis to brain tissue. Common sites of metastasis are the lungs, liver, bones, and brain.

Incidence of Cancer

Cancer affects all age groups, although the incidence is higher in people ages 60 to 69. The second highest age group is ages 70 to 79. Men have a higher incidence of cancer than women. Cancer in people over age 60 is thought to occur from a combination of exposure to carcinogens and weakening of the body's immune system.

Some cancers, such as Wilms's tumor of the kidney and acute lymphocytic leukemia, occur more commonly in young people. The cause of tumors in young people is not well understood, but genetic predisposition tends to be a major factor.

FIGURE 10.6 Invasive metastasis to skin area following mastectomy for breast cancer. (Photo courtesy Dinesh Patel, MD. Medical Oncology, Internal Medicine, Zanesville, OH.)

The most common type of cancer in adults is skin cancer; it is also considered to be the most preventable. Exposure to ultraviolet radiation (sunlight) increases the risk of skin cancer. Wearing protective clothing and sunscreen can greatly reduce the risk of skin cancer.

Lung cancer is responsible for the highest mortality rate in both men and women and also is commonly preventable. Cigarette smoking is the main cause, along with air pollution and exposure to chemical agents.

Men have a high incidence of prostate cancer between ages 60 and 79. Cancer of the colon and rectum has been linked to the consumption of high-fat, low-fiber diets and ranks as the third highest cancer in men.

The highest incidence of cancer in women is in the lungs, and the second highest is in the breast. Women with a family history of breast cancer have a greater risk than those with no family history. Commercial testing for the oncogene linked with breast cancer is available and marketed for high-risk women, especially those in the Ashkenazi Jewish population. Genetic testing is done through genetic counseling programs, and the cost ranges from \$700 to \$2400, depending on the geographical region. See Figure 10.7 for estimated new cancer cases and deaths for 2005.

Mortality Rates

Cancer survival rates have improved over the past 30 years, and since the 1990s the number of cancer deaths has decreased for both men and women. A 5-year period is used to monitor cancer patients' progress following diagnosis and treatment. Survival statistics are based on persons living 5 years in remission. Remission is considered to have occurred when all signs and symptoms of cancer have disappeared, even though there still may be cancer in the body.

For more information about cancer incidence and mortality data, visit the National Cancer Institute website at <http://www.nci.nih.gov> or the National Coalition for Cancer Survivorship website at <http://www.cansearch.org>.

Detection and Prevention

Nurses play an important role in preventing and detecting cancer. You can help educate patients about risk factors, self-examination, and cancer screening programs. Early diagnosis and treatment provide time to stop the progression of cancer.

EARLY DETECTION. An annual physical examination helps medical personnel detect the seven warning signals of cancer promoted by the American Cancer Society. The warning signals can be remembered with the mnemonic CAUTION:

- Change in bowel or bladder habits
- A sore that fails to heal
- Unusual bleeding or discharge
- Thickening or lump in breast or other tissue
- Indigestion or swallowing difficulties
- Obvious change in wart or mole
- Nagging cough or hoarseness

*Excludes basal and squamous cell skin cancers and in situ carcinoma except urinary bladder.

Note: Percentages may not total 100% due to rounding.

FIGURE 10.7 Estimated new cancer cases and deaths by sex, United States, 2005. (*Cancer Facts and Figures*, American Cancer Society, 2005.) <http://www.cancer.org/downloads/STT/CAFF2005f4PWSecured.pdf>, page 10.

The American Cancer Society² recommends monthly breast self-examination after puberty for both men and women, and monthly self-testicular examination for men (see Chapter 41 for information on how to do self-examinations).

Mammography (a specific x-ray of breast tissue used to detect a mass too small for palpation) is recommended annually in women after age 40. However, if a woman is at risk for breast cancer because of family history, the frequency of screening should be discussed with her doctor. Routine pelvic examinations no longer have a recommended frequency. This is a matter to be discussed between a woman and her doctor. Initial Papanicolaou testing (Pap smear) is currently recommended to begin no later than age 21. If a woman has three normal results in a row, screening can be done every 2 to 3 years unless there are risk factors present. Once a woman is past the age of 70 and has had three normal Pap tests in a row within the past 10 years, she can choose to stop screening. Cytological examination of cervical cells increases the chance of diagnosing cervical cancer in situ.

The American Cancer Society recommends one of the following five options to screen for colorectal cancer, beginning at age 50:

1. An annual stool test for blood
2. A flexible sigmoidoscopy every 5 years

3. A yearly stool test for blood and flexible sigmoidoscopy every 5 years
4. A double-contrast barium enema every 5 years
5. A colonoscopy every 10 years

Option 3 is preferred. Screening should begin earlier and take place more frequently in high-risk people.

Screening for prostate cancer is important for men beginning around age 50. Digital rectal examination and prostate-specific antigen (PSA) blood testing is recommended annually for men older than 50 who have a life expectancy of at least 10 years and for younger men who are at higher risk. See Box 10.3 Gerontological Issues for specific screening recommendations for older adults.

GENETIC TESTING. Currently, much attention is directed toward genetic testing and identification of persons at risk for cancer. Genetic testing technology poses both legal and ethical questions concerning confidentiality and insurance cost issues. The cooperation of family members is important because genetic testing is done after a family member has been diagnosed with cancer. Family members may experience a variety of emotions surrounding the increased risk for themselves and their guilt over the role they may have played in increasing the risk for their children.

HEALTHY LIFESTYLE. Promotion of healthy lifestyles, including proper diet and exercise, helps strengthen the

Box 10.3

Gerontological Issues

Screening Guidelines

Use the following American Cancer Society guidelines for older adults

Colorectal cancer:

- Sigmoidoscopy, every 5 years, and/or
- Fecal occult blood test yearly, or
- Double contrast barium enema every 5 years, or
- Colonoscopy every 10 years

Breast cancer:

- Breast self-examination monthly
- Breast clinical examination yearly
- Mammogram yearly

Prostate cancer:

- Prostate exam (digital rectal exam) yearly
- Prostatic surface antigen yearly

immune system and reduce cancer risk. The American Cancer Society promotes smoking cessation campaigns and supports the effort by stating that smoking is the most preventable cause of death from lung cancer. Second-hand smoke contributes to an increased risk of lung cancer in nonsmokers as well.

PROTECTANT FOODS. There has been a lot of attention in the news in areas of diet and cancer risk. This is an area where much research is being done. The American Cancer Society does provide information about diet and cancer. This includes discussion about folic acid, omega-3 fatty acids, and antioxidants, to name a few. A diet poor in folic acid can lead to development of cancers of the colon and breast. It is recommended that folic acid is best obtained by eating fruits, vegetables, and enriched grain products.

People who ingest a high saturated fat diet are at a greater risk of obesity, which can be a risk factor for some types of cancer. However, ingestion of omega-3 fatty acids in animals has been studied and shown to suppress the incidence of certain cancers. These findings are being researched for application in humans. Foods rich in omega-3 fatty acids include fish.

Eating antioxidant-rich foods like vegetables and fruits has been shown to have some effect on lowering the risk of cancer. Antioxidants include vitamins C and E, selenium, and carotenoids. However, no study has yet confirmed that this same effect could come from ingesting supplements containing antioxidants.

Most research points to the benefit of eating a balanced diet rather than using supplements to prevent cancer (Box 10.4 Nutrition Notes).

VACCINES. Preventive cancer vaccines are being developed for cancers associated with specific viruses. At present, most cancer vaccines are therapeutic rather than prophylactic and are used to stimulate the patient's immune

Box 10.4

Nutrition Notes

Reducing Cancer Risk

Encourage patients to consume these foods:

- Fruits and vegetables, especially those rich in vitamin C or carotene
- Cruciferous vegetables (cabbage, broccoli, Brussels sprouts)
- Whole grains
- Grilled meats that have been
 - Precooked in a microwave oven.
 - Marinated but basted only with fresh marinade, not that used to steep raw meat

Encourage patients to limit these foods:

- Excessive meat, especially when smoked, salted, charbroiled, or cooked at high temperatures
- Excessive fat (more than 30% of daily calories)
- Excessive calories
- Alcohol

system to destroy cancer cells. Vaccine therapy for malignant melanoma and lymphoma is being tested.

Diagnosis of Cancer

A diagnosis of cancer can be a very frightening experience (Box 10.5 Patient Perspective). Often people try to mask symptoms because they are so frightened of the disease. A careful and thorough assessment of the patient's present and past medical and surgical histories and pertinent family history should be obtained. A complete physical examination provides both objective and subjective data. The most conclusive information about the health of tissue is acquired by examining cell activity through biopsy.

BIOPSY. Accurate identification of a cancer can be done only by **biopsy** (surgical removal of tissue cells). Microscopic examination of a piece of suspected tissue or aspirated body fluid can confirm the presence of mutant cells. A biopsy is commonly done in a physician's office or outpatient surgery department.

Incisional biopsy is an invasive procedure that involves the surgical removal of a small amount of tissue for inspection. Tissue can also be removed during endoscopic procedures (insertion of a tube to observe the inside of a hollow organ or cavity), such as a lung biopsy done during bronchoscopy. Excisional biopsy is used to remove an entire tissue mass. Needle aspiration biopsy involves insertion of a needle into tissue for fluid or tissue aspiration (Fig. 10.8). This procedure is less invasive than incisional or excisional biopsy. Transcutaneous aspiration involves the insertion of a fine needle into tissue such as breast, prostate, or salivary gland and is used for diagnosing metastatic cancers. Frozen section biopsy provides immediate evaluation of the tissue sample during a surgical procedure. By freezing the

Box 10.5

Patient Perspective

Robyn

I am a 43-year-old woman with three children and in the prime of my life, at least I thought. That was before I was diagnosed with cancer in my left breast. I was breast-feeding at the time I felt the lump and, although I went for a biopsy, I felt sure the lump resulted from a blocked milk duct or fibroid cyst. But, unbelievably, the biopsy came back positive for cancer. My whole life flipped upside down. I was devastated.

I was scheduled for surgery within a week, and my emotions were in complete turmoil. I felt nauseated all the time, vomited almost every morning, and had diarrhea daily. My stomach felt like it had a pot of bees inside. I never cried so much in my life. Thinking about all the tests, the surgery, and the untold ways my life could be affected made me a nervous wreck. Finally, I got down on my knees and turned this whole crisis over to God. I couldn't handle it anymore, so I asked God to give me peace, and I placed all my trust and faith in Him. It worked, and I was finally able to get control and face this thing head on.

As I went for further testing, the nurses and technicians I met were all very helpful and informative. Some actually broke down with me because they had endured this same disease. We would hold each other and then exchange phone numbers just to “talk” if I needed it. It was very encouraging to know these women had made it through, and I could too.

The surgery went smoothly, and I was released the next day. There wasn't much discomfort, and I felt good physically. The nerve was removed and a scar runs from the center of my chest down under my armpit. I was able to return to work in 3 weeks. The doctor gave me a prescription for a prosthesis as soon as the drains were removed and I began healing. We went to a specialty place to be fitted, and, although the prosthesis was nothing like the real thing, I looked normal and it helped to build my confidence.

The impact on my family was one of complete bewilderment because I had no family history of this type of cancer. Everyone tried to help with positive sentiments like we caught it early, breast cancer has a high cure rate, periodic follow-up can keep you cancer free, and so on. My husband and children supported and comforted me. I tried to focus on them because I want to be there for them when they graduate, get married, etc. My mother and sister helped get me to all my appointments and filled my prescriptions.

Chemo was advised as a follow-up treatment, and

I was scheduled for four rounds, one every 3 weeks. This was undoubtedly the worst thing I have ever endured. Not even giving birth can compare to the way chemo makes you feel. I had a very bad experience the first round and was extremely sick and unable to eat for 5 days. I wondered why I didn't just die from the cancer because I felt that this was killing me. Before the second round, I told the doctor how violently ill I'd been and she adjusted the dosages of some of the drugs. I was very groggy; although I didn't vomit, I still wasn't feeling myself. For the third round, they changed a medication and I withstood the side effects a lot better—although I was still nauseated, light-headed, fatigued, and unable to focus, eat, or taste anything. At times, it was hard just to put one foot in front of the other. They prepared me for the loss of my hair, but you really don't know how hard that is until it starts coming out in globs. Not just the loss, but then you have such a long time to wait for it to grow back. When the chemo is over, it's hard to look back and feel the way you did then, but when you look in the mirror and your hair is still gone, it's a hard reminder.

All through being diagnosed and dealing with breast cancer I have felt a tremendous outpouring of love and caring, not only from my immediate family but also from my church family. I was never so well taken care of. All the hugs, cards, calls, food, and flowers brought to the house encouraged me tremendously. It makes it a little easier to cope when you know you have so many people who care and are concerned enough to take time out of their daily lives to give you support.

I'm lucky because my sister is an RN and prepared me for many of the side effects and difficulties. She also was there to help ask questions and get information from other survivors that kept me in a positive frame of mind. I know that without her help and God's grace and peace my recovery would not have been so easy. Looking back I can't really feel all those terrible emotions and symptoms, but I still am afraid of the unknown. It is not easy when it is you and not someone else this happens to.

Now that I'm through the worst part of this, I take positive steps every day to enjoy the little things in life. I feel that the more you keep involved in everyday activities and become educated about the disease and its treatments, the easier it is to deal with. I am taking a drug called tamoxifen now and will be for 5 years. Two of the side effects are hot flashes and sweats. If this is all I have to deal with, however, praise God. My prognosis is very good, and I am expecting a complete cure because I am a survivor.

FIGURE 10.8 Fine-needle breast biopsy. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

tissue sample for microscopic examination, a quick analysis is possible, which helps direct the remainder of the surgical procedure. Frozen section biopsy is especially useful in the diagnosis and surgical intervention of breast cancer.

Stereotactic biopsy is a safe and efficient procedure for evaluating lesions in the brain and breast. The procedure is done by a specially trained radiologist. The biopsy site must be firmly immobilized. The lesion is scanned for location, and a small incision is made for easy insertion of a small fiberoptic instrument (Fig. 10.9). Stereotactic biopsy of the brain involves a local anesthetic because a small hole in the skull is made. Breast stereotactic biopsy uses pressure exerted by a mammogram machine to secure the breast; anesthesia may not be necessary.

LABORATORY TESTS. Blood, serum, and urine tests are important in establishing baseline values and general health status. Laboratory values are used with other assessment findings. An elevated white blood cell (WBC) count is

FIGURE 10.9 Stereotactic biopsy of a brain lesion. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

expected if the patient has evidence of infection; however, an increase in WBCs without infection raises suspicion of leukemia. Fifty percent of patients with liver cancer have increased levels of bilirubin, alkaline phosphatase, and glutamic-oxaloacetic transaminase.

Bone marrow aspiration is done to learn the number, size, and shape of red and white blood cells and platelets. Bone marrow aspiration is a major tool for diagnosis of leukemia. (See Chapter 27 for a description of this test and related nursing care.)

Tumor markers, also called biochemical markers, are proteins, antigens, genes, hormones, and enzymes produced and secreted by tumor cells. Tumor markers help confirm a diagnosis of cancer, detect cancer origin, monitor the effect of cancer therapy, and determine cancer remission. Some examples of tumor markers include the following:

- Prostatic acid phosphatase (PAP)—high levels noted in prostate cancer
- PSA—elevated levels associated with prostate cancer
- Cancer antigen (CA) 15-3—elevated levels noted in breast cancer; useful in monitoring patient response to therapy for metastatic breast cancer
- CA 125—increased levels in ovarian, cervical, liver, and pancreatic cancers
- CA 19-9—used to diagnose and evaluate colorectal, pancreatic, and hepatobiliary cancers
- Alpha-fetoprotein (AFP)—elevated in hepatocellular cancer
- Carcinoembryonic antigen (CEA)—increased levels suggest tumor activity

CYTOLOGICAL STUDY. Cytology is the study of the formation, structure, and function of cells. Cytological diagnosis of cancer is obtained primarily through Pap smears of cells shed from a mucous membrane (e.g., cervical or oral smear). Test results are based on the degree of cell abnormality. Normal results reflect no cellular changes. Slight cellular changes are considered normal, with a possible link to abnormal cells seen in infection. Significant cellular changes reflect a higher probability of precancerous or cancerous activity. Infection causes cellular changes and contributes to an increase in abnormal cells detected.

RADIOLOGICAL PROCEDURES. X-ray examination is a valuable diagnostic tool in detecting cancer of the bones and hollow organs. Routine chest x-ray examination is one diagnostic test used in detecting lung cancer. Mammography is a reliable and noninvasive low-radiation x-ray procedure for detecting breast masses (Fig. 10.10). Breast tissue is compressed to allow better visualization of the soft tissue. You must alert patients that soft tissue compression causes a degree of discomfort, but the compression is necessary to obtain an accurate picture. Assure the patient that the discomfort is brief. See Chapter 41 for more information on mammography.

Contrast media x-ray studies are used to detect abnormalities of bone and the gastrointestinal and urinary sys-

FIGURE 10.10 Mammogram. (Photo courtesy Dinesh Patel, MD. Medical Oncology, Internal Medicine, Zanesville, OH.)

tems. Contrast media can be given by various methods. Barium is given orally for visualization of the esophagus and stomach or rectally for visualization of the colon (e.g., a barium enema). Intravenous injection of contrast media is used for lung and brain scans.

Computed tomography (CT) provides a three-dimensional, cross-sectional, computerized picture of the body. CT scans are important in the diagnosis and staging of malignancies and can detect minor variations in tissue thickness. The use of a contrast medium enhances the accuracy of an abdominal CT scan. CT scans are also used to improve the accuracy of inserting a fine needle for biopsy.

NUCLEAR IMAGING PROCEDURES. Nuclear medicine imaging involves camera imaging of organs or tissues containing radioactive media. Radioactive compounds are given intravenously or by ingestion. These studies are highly sensitive and can detect sites of abnormal cell growth months before changes are seen on an x-ray.

Positron emission tomography (PET) scanning provides information about cellular biochemical and metabolic activity. Patients are given biochemical compounds, and images are made of the tissue through gamma-camera tomography. PET scans have been useful in brain imaging as well as the detection of the spread of cancers of the lung, ovaries, colon, rectum, and breast.

ULTRASOND PROCEDURES. Ultrasonography uses high-frequency sound waves to provide images of deep soft-tissue structures in the body. The procedure is noninvasive and does not use x-rays. Echoes from high-frequency sound waves outline tissue density and masses. This technology helps detect tumors of the pelvis and breast. Ultrasound may also be used to distinguish between benign and malignant breast tumors.

MAGNETIC RESONANCE IMAGING. Magnetic resonance imaging (MRI) creates sectional images of the body. MRI can be done with or without contrast dye and does not use radiation. The patient is placed in a cylinder-shaped

magnetic field. The magnetic field aligns the nuclei of body cells in one direction. The magnetized cells are then excited by radiofrequency pulses. Images are made as cell nuclei change their alignment. MRI is valuable in the detection, localization, and staging of malignant tumors in the central nervous system, spine, head, and musculoskeletal system. MRI cannot be used in patients with pacemakers, implanted pumps, surgical clips, metal knees or hips, or in some cases tattooed eyeliner because metals are attracted by the magnet.

ENDOSCOPIC PROCEDURES. An endoscopic examination allows the direct visualization of a body cavity or opening. The procedure involves the insertion of a flexible endoscope containing fiberoptic glass bundles that transmit light and can produce an image. Endoscopy enables the surgeon to biopsy abnormal tissue and is used to detect lesions of the throat, esophagus, stomach, colon, and lungs.

Oral endoscopic procedures require patient preparation to reduce the risk of aspirating stomach secretions. The patient is given nothing to eat or drink before and immediately after the examination. A local anesthetic is used during the examination to anesthetize the throat. Following the procedure, oral food and fluids are withheld until the gag reflex returns to prevent aspiration. The gag reflex is assessed by touching a cotton-tipped swab to the back of the throat to stimulate the reflex after the procedure.

Staging and Grading

Tumor staging is used to determine the stage of solid-tumor masses, providing valuable information to guide treatment plans. Tumor staging is important in the development of an international system that can compare statistics among cancer centers. The most common system used for staging tumors is the tumor, node, metastasis (TNM) system.

This staging system classifies solid tumors by size and tissue involvement. TNM stages are T0 (no tumor), Tis (tumor in situ), and T1 through T4 (progressive increase in tumor size or involvement). Extent of lymph node involvement ranges from N0, no nodes, to N4, a large amount of lymph node involvement. Metastasis is described as M0, no metastasis, to M1, metastasis to some area (Table 10.3).

There is also a rating or grading system to define the cell types of tumors. Tumors are classified according to the percentage of cells that are differentiated (mature). If the tissue of a neoplastic tumor closely resembles normal tissue, it is called well differentiated. A poorly differentiated tumor is a malignant neoplasm that contains some normal cells, but most of the cells are abnormal. The better defined or differentiated the tumor, the easier it is to treat.

Treatment for Cancer

There are three main types of treatment for cancer: surgery, radiation therapy, and **chemotherapy**. To find out more about cancer treatment options, visit the American Cancer Society website at <http://www.cancer.org>.

chemotherapy: chemo—chemistry + therapy—treatment

TABLE 10.3 TUMOR, NODE, METASTASIS CLASSIFICATION, STAGING, AND TISSUE INVOLVEMENT

Classification	Staging	Tissue Involvement
Primary tumor (T) T _{is}	Stage I	Tumor in situ; indicates no invasion of other tissues
T ₁ , T ₂ , T ₃ , T ₄	Stage II	Ranges indicate progressive increase in tumor size with local metastasis
Regional lymph node involvement (N) N ₀ N ₁ , N ₂ , N ₃ ,	No nodes Stage III	Metastasis to regional lymph nodes
Metastasis (M) M ₀ M ₁	No metastasis Stage IV	Distant metastasis

SURGERY. Surgery can be curative when it is possible to remove the entire tumor. Skin cancers and well-defined tumors without metastasis can be removed without any additional intervention. Other tumors may be removed as much as possible, with follow-up chemotherapy or radiation to treat the remaining tumor cells.

Prophylactic surgery is used to remove moles or lesions that have the potential to become malignant. Colon polyps are often removed to prevent malignancies from developing, especially if the polyps are considered premalignant. An extreme example of prophylactic surgery is a woman who elects to have a mastectomy (surgical removal of the breast) because of a high incidence of breast cancer in her family.

Surgery may also be done for **palliation** (symptom control). Surgical removal of tissue to reduce the size of the tumor mass is helpful, especially if the tumor is compressing nerves or blocking the passage of body fluids. The goals of palliative surgery are to increase comfort and quality of life.

Reconstructive surgery can be done for cosmetic enhancement or for return of function of a body part. Facial reconstruction is important for a patient's self-image after removal of head or neck tumors. Women can elect to have breast reconstruction after mastectomy.

Surgical intervention for cancer treatment is typically not an emergency intervention, which allows patients and medical personnel time for planning. Autologous blood donation (blood donated by the patient before surgery) has become popular and reduces the risk of exposure to blood-borne infections. The American Red Cross and many hospitals have programs specifically designed for autologous blood donation and accept donations from 30 days to 72 hours before surgery.

You can play a major role in reducing the patient's fears about postoperative pain. Patient-controlled analgesia (PCA) provides patients with some control over their pain.

Therapies such as deep relaxation, imagery, and hypnosis can be used with traditional pain control measures.

It is important to encourage patients to express and discuss their fears. Patients with a limited understanding of cancer may fear that tissues will not heal postoperatively. Provide information about wound care, including dressing changes and drainage tubes, to increase the patient's knowledge base and sense of control. Visual aids concerning tumor site and surgical procedures are valuable teaching tools.

Patients who are undernourished are poor surgical candidates and require intervention such as enteral or parenteral nutrition before and after surgery. Patients with cancer are also at increased risk for postoperative deep vein thrombosis (DVT). Preoperative teaching includes the importance of leg movement, early ambulation, wearing antiembolism stockings, and recognizing symptoms of DVT, such as calf pain or a cramping sensation in the calf muscle when the foot is dorsiflexed.

RADIATION. Radiation is used commonly in the treatment of cancer for control or palliation, or it can be curative if the disease is localized. The decision to use radiation is commonly based on cancer site and size. Radiation destroys cancer cells by affecting cell structure and the cell environment. It is used in fractionated (divided) doses to prevent destructive side effects; however, side effects can occur in the area being treated because of damage to normal cells.

The size of a large tumor can be decreased with radiation before surgery, making surgical intervention more effective and less dangerous. Palliative radiation is used to reduce the size of a large cancerous lesion and consequently reduce pressure and pain. Radioisotopes inserted into cancerous tissue during surgery help destroy the cancerous cells without removing the organ.

Nursing Care of the Patient Receiving Radiation Treatment. Symptoms of tissue reaction to radiation treatment can be expected about 10 to 14 days after the start of the treatment program and continue up to 2 weeks after treatment is completed. Typical reactions and appropriate nursing interventions include the following:

- **Fatigue.** Encourage the patient to nap frequently and prioritize activities. Reassure the patient that the feeling will go away when the treatments are completed.
- **Nausea, vomiting, and anorexia.** Encourage the patient to take prescribed medication for nausea and vomiting. Anorexia can be eased by giving small amounts of high-carbohydrate, high-protein foods and avoiding foods high in fiber.
- **Mucositis** (inflammation of the mucous membranes, especially of the mouth and throat). Encourage the patient to avoid irritants such as smoking, alcohol, acidic food or drinks, extremely

anorexia: an—not + orexis—appetite

mucositis: muco—mucous (membrane) + itis—inflammation

hot or cold foods and drinks, and commercial mouthwash. Advise the patient to perform mouth care before meals and every 3 to 4 hours. A neutral mouthwash is appropriate and can be made by using 1 ounce of diphenhydramine hydrochloride (Benadryl) elixir diluted in 1 quart of water or normal saline solution. Agents that coat the mouth, such as Maalox, are sometimes used. Lidocaine hydrochloride 2% viscous has an anesthetic effect on the mouth and throat.

- **Xerostomia** (dry mouth). Encourage frequent mouth care. Saliva substitute is available over-the-counter and is helpful, especially at night when patients complain of a choking sensation from extreme dryness.
- **Skin reactions.** These can vary from mild redness to moist **desquamation** similar to a second-degree burn. Skin surfaces that are especially warm and moist, such as the groin, perineum, and axillae, have poor tolerance to radiation. Prophylactic skin care includes keeping skin dry; keeping it free from irritants, such as powder, lotions, deodorants, and restrictive clothing; and protecting it against exposure to direct sunlight. Irradiated skin can be fragile during treatment. It is important to wash these areas gently with mild soap and water, rinse well, and pat dry. The skin may have markings and tattoos to delineate the treatment field. Take care not to wash off the markings.
- **Bone marrow depression.** This reaction occurs with both radiation and chemotherapy. Weekly blood cell counts are done to detect low levels of WBCs, red blood cells, and platelets. Transfusions of whole blood, platelets, or other blood components may be necessary.

xerostomia: xero—dry + stoma—mouth

Safety Considerations. Radiation may be administered externally or internally. External radiation is given by a trained medical specialist in a designated area in the hospital or clinic. Internal radiation is administered to patients admitted to a health-care facility.

Safety guidelines must be followed when caring for a patient with radioactive materials implanted into tissue or body cavities or administered orally or intravenously because the patient will be radioactive. Nursing responsibilities include knowledge about the following:

- Radiation source being used
- Method of administration
- Start of treatment
- Length of treatment
- Prescribed nursing precautions

Personnel involved with radiation therapy must recognize the three primary factors in radiation protection: time, distance, and shielding. These three factors depend on the type of radiation used. *Time* involves the time spent administering care, *distance* involves the amount of space between the radioisotope and the nurse, and *shielding* involves the use of a barrier such as a lead apron.

You must work efficiently when caring for patients who are receiving radioisotopes that are releasing gamma rays. Your exposure to radiation is proportionate to the time spent and the distance from the radiation source. For example, you will receive less exposure standing at the foot of the bed of a patient with radioisotopes inserted into the head than if you stand at the head of the bed (Fig. 10.11). Time and distance are used to protect the nurse, visitors, and other personnel.

It is important to teach the patient and family members the reason nursing care focuses on providing only essential care. Speedy nursing encounters and visitor restrictions are better accepted and less likely to promote feelings of isolation when patients understand the reasons behind them.

FIGURE 10.11 Radiation distancing. Nurse B receives less radiation than Nurse A, and Nurse C receives less radiation than Nurse B.

Drainage from the site of a radioactive colloid injection is considered radioactive, and the physician must be informed immediately. Dressings contaminated with radioactive seepage must be removed with long-handled forceps. Radioactive materials must never be touched with unprotected hands; shielding is required to prevent exposure to radiation. Contamination from radioisotope applicators or interstitial implants cannot occur when the capsule is intact; contamination occurs when the capsule is broken.

SAFETY TIP

Remember to use the principles of time, distance, and shielding to protect yourself from radiation exposure.

CHEMOTHERAPY. Chemotherapy is chemical therapy that uses **cytotoxic** drugs to treat cancer. Cytotoxic drugs can be used for cure, control, or palliation of cancerous tumors and are described according to how they affect cell activity. For example, alkylating agents bind with DNA to stop the production of RNA; antimetabolites substitute for nutrients or enzymes in the cell life cycle; mitotic inhibitors interfere with cell division; antibiotics inhibit DNA and RNA synthesis; and hormonal agents alter the hormonal structure of the body. Chemotherapy is usually more effective when multiple drugs are given in multiple doses. Examples of specific drugs and their adverse effects are provided in Table 10.4.

The effects of chemotherapy are systemic unless used topically for skin lesions. Chemotherapy is used preoperatively to shrink tumors and postoperatively to treat residual tumors. Factors influencing the effectiveness of chemotherapy are tumor type, available chemotherapeutic drugs, and genetics.

Combination Chemotherapy. Combination chemotherapy means that two or more antineoplastic agents are used together to treat a particular type of cancer. This can expose a larger number of cells at different points in the cell cycle to more than one kind of chemotherapy. Combining drugs also decreases the side effects of therapy and decreases the possibility of the tumor becoming resistant to the therapy.

In order for drugs to be combined this way, there are several criteria that need to be met. These include being effective when used alone to treat certain cancers and having different toxicities that would limit their use. For example, if three drugs that are all cardiotoxic are given, the patient is more likely to develop cardiotoxicity. Patients are still monitored for toxic effects from the treatment as well as improvement in their status.

Routes of Administration. Chemotherapy may be given via oral, intramuscular, intravenous, or topical routes. The

cytotoxic: cyto—cell + toxic—poison

dosage of medication is regulated by the size of the individual and the toxicities of the drug. The administration of intravenous chemotherapeutic agents requires specialized training and knowledge of antineoplastic drugs.

Vesicant drugs are given only by the intravenous route. These drugs cause blistering of tissue that eventually leads to necrosis if they infiltrate, or leak out of the blood vessel, into soft tissue (Fig. 10.12). Skin grafts may be necessary if tissue damage is extensive.

Central Lines. Central lines are intravenous catheters that terminate in the superior vena cava near the right atrium of the heart. This is a large vessel that allows for dilution of vesicant drugs and reduces the risk of infiltration. Central lines may be external, with the distal end of the catheter exiting the skin, or internal, with the distal catheter ending in an implanted port. See Chapter 6 for additional information on central lines.

Side Effects. Toxicities in patients receiving chemotherapy vary according to the medications given; however, some general side effects are commonly associated with chemotherapeutic drugs. Fast-growing epithelial cells, such as those of the hair, blood, skin, and gastrointestinal tract, are generally affected by both chemotherapy and radiation.

Hematologic System. Chemotherapy is toxic to the bone marrow, which is where the blood cells are produced. Numbers of blood cells (especially white cells) drop after approximately 7 to 14 days, depending on the drug. This time period when the cell counts are lowest is called the **nadir**. This is then the time when patients are most at risk for developing complications. Patients may develop low white blood cell counts (**leukopenia**), increasing their susceptibility to infection and sepsis. A reduction in platelets (**thrombocytopenia**) increases the risk of bruising and bleeding and can require platelet transfusions. Increased risk

(Continued on page 162)

LEARNING TIP

When assessing patients with possible side effects of chemotherapy and radiation, use the mnemonic BITES:

- B**—Bleeding suggests low platelet count.
- I**—Infection suggests low WBC count and a risk for infection.
- T**—Tiredness suggests anemia.
- E**—Emesis places the patient at risk for altered nutrition and fluid and electrolyte imbalance.
- S**—Skin changes may be evidence of radiation reaction or skin breakdown.

vesicant: vesicate—to blister

leukopenia: leuko—white cells + penia—lack

thrombocytopenia: thrombo—clot + cyte—cell + penia—lack

TABLE 10.4 CHEMOTHERAPY MEDICATIONS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antitumor Antibiotics				
Damage cells' DNA and the ability to make DNA and RNA	Bleomycin (Blenoxane)	IM or IV	Fever, chills, cough, shortness of breath; in severe cases, pulmonary fibrosis, pain at the tumor site, anaphylaxis	Observe for changes in respiratory status related to pulmonary toxicity. Observe for anaphylaxis.
	Doxorubicin (Adriamycin)	IV	Red urine, nausea and vomiting, alopecia, cardiac damage	This drug is a vesicant and should be given through a running IV or a central line if it is a continuous infusion. Monitor cardiac status. Lifetime dose is 550 mg/m ² .
	Mitoxantrone (Novantrone)	IV	Headache, dyspnea, diarrhea, nausea, vomiting, stomatitis, alopecia, fever, bone marrow suppression, allergic reactions from itching to angioedema	Urine may be a blue-green color for 24 hours after the dose is given. Monitor WBC and platelet count prior to each dose. Observe for signs of allergic reaction. Teach patient signs of bleeding.
Antimetabolites				
Resemble normal metabolites needed for cell function. Once they can trick the cell into gaining entry, cell division becomes impaired.	Capecitabine (Xeloda)	PO	Bone marrow depression, nausea, vomiting, stomatitis, hand and foot syndrome	Monitor WBC and platelet count throughout therapy. Teach the patient signs of infection and bleeding. Teach the patient about mouth care. Drug should be taken after a meal with plenty of water. Teach the patient about hand and foot syndrome and to notify MD if it should occur.
	Cytabine (Cytosar)	IV	Fever, chills, unusual bleeding or bruising, sore throat, tiredness, nausea and vomiting	Monitor CBC prior to each dose. Instruct the patient of signs of infection or bleeding. Instruct patient to call MD for any temperature increases greater than 37.8°C (100.0°F).
	Fluorouracil (5-FU)	IV	Diarrhea, loss of appetite, alopecia, nausea and vomiting, skin sensitivity, stomatitis	Monitor CBC prior to dose. Nadir occurs in 10–14 days. Instruct about mouth care.
	Gemcitabine (Gemzar)	IV	Dyspnea, edema, nausea, vomiting, diarrhea, stomatitis, hamaturia, alopecia, bone marrow suppression	Monitor CBC prior to each dose. Premedicate with antiemetics. Instruct patient to report any flu like symptoms to MD.
Alkylating Agents				
Cause the DNA strands to bind together and prevent the cell from dividing.	Carmustine (BCNU)	IV	Fever and chills, nausea and vomiting, pulmonary toxicity, vision changes	This drug is an irritant. The patient may have pain at the injection site from the drug. Nadir occurs in 3–5 weeks. Monitor labs prior to each dose. Monitor respiratory status.
	Cisplatin (Platinol)	IV	Ototoxicity, fever and chills, tinnitus, nausea and vomiting	Monitor neurological status, renal function studies. Premedicate with antiemetics. Monitor for signs of anaphylaxis. Nadir occurs in 2–3 weeks; monitor CBC prior to each dose.
	Cyclophosphamide (Cytoxan)	IV, PO	Nausea and vomiting, hematuria, alopecia, bone marrow depression	Monitor CBC prior to each dose. Monitor BUN and creatinine. Teach the patient to drink at least 3 L of fluid a day and to void every 2 hours. This drug requires hydration prior to and after drug is given. Oral form should be taken early in the morning so that the drug does not build up in the bladder during the night.
	Ifosfamide (Ifex)	IV	CNS toxicity, nausea, vomiting, hemorrhagic cystitis, alopecia	Monitor urine for blood. This drug requires hydration before and after each dose. Premedicate with antiemetics. Monitor CBC.

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antimitotic Agents				
Come from plant sources. Prevent mitosis from occurring in the cell and then cells cannot divide.	Docetaxel (Taxotere)	IV	Fatigue, edema, nausea and vomiting, stomatitis, anemia, thrombocytopenia, myalgia, alopecia, hypersensitivity, anaphylaxis, bone marrow depression, neuropathy	Patient must take dexamethasone starting 1 day prior to the scheduled chemotherapy to prevent hypersensitivity. Monitor CBC. Nadir occurs on day 7. Monitor weight. Monitor skin for changes. Monitor for changes in neurological status from baseline.
	Paclitaxel (Taxol)	IV	Nausea, vomiting, myalgia, cardiac toxicities, hypersensitivity or anaphylaxis, neuropathy, alopecia, stomatitis, hypotension	Premedicate with antiemetic and dexamethasone. Monitor for signs of hypersensitivity. Monitor CBC and platelet counts. Monitor neurological status for changes from baseline. Teach the patient about mouth care. Monitor vital signs for changes.
	Vincristine (Oncovin)	IV	Constipation, difficulty walking, tingling in fingers and toes	This drug is a vesicant and should be given through a running IV. Assess for neuropathies or changes in neurological status from baseline. Monitor CBC, platelets.
	Vinorelbine (Navelbine)	IV	Fatigue, constipation, nausea, alopecia, bone marrow suppression, neuropathy, nausea, vomiting, stomatitis	This drug is a vesicant. When giving through a running IV, use the port closest to the IV bag rather than the patient. Monitor CBC prior to each dose. Nadir occurs in 7–10 days. Teach patient signs of infection and bleeding. Monitor neurological status and changes from baseline. Teach the patient about mouth care.
Topoisomerase Inhibitors				
Inhibit topoisomerase (the enzyme needed for DNA to copy) and cause cell death.	Etoposide (VP-16)	IV	Nausea and vomiting, alopecia, numbness and tingling in fingers and toes, bone marrow depression	Premedicate for nausea. Nadir occurs in 10–14 days; monitor CBC prior to each cycle. Monitor neurological status and changes from baseline.
	Irinotecan (Camptosar)	IV	Dizziness, headache, insomnia, dyspnea, edema, nausea, vomiting, diarrhea, stomatitis, alopecia, bone marrow suppression, weight loss	Teach measures to control diarrhea and to notify MD if it occurs. Monitor CBC prior to each dose.
	Topotecan (Hycamtin)	IV	Headache, dyspnea, nausea, vomiting, diarrhea, hair loss, bone marrow suppression	Monitor CBC. Premedicate for nausea.
Hormones				
	Tamoxifen (Nolvadex)	PO	Hot flashes, weight gain, nausea, bone pain	Anticoagulants increase the PT. Instruct the patient not to take antacids within 2 hours of taking tamoxifen. May cause bony pain but the discomfort is temporary.
Miscellaneous Agents				
Work by interfering with enzyme systems or metabolic pathways in the cells	Hydroxyurea (Hydrea)	PO	Fever and chills, sore throat, drowsiness, diarrhea, nausea and vomiting	Monitor WBC. Monitor metabolic panel for signs of tumor lysis syndrome. Monitor neurological status and changes from baseline.
	Procarbazine (Matulane)	PO	Bone marrow depression, MAO inhibitor, drowsiness, nausea and vomiting, peripheral neuropathy	Monitor CBC prior to each cycle. Premedicate as needed for nausea. Monitor neurological status and changes from baseline.
	Thalidomide (Thalomid)	PO	Birth defects, peripheral neuropathy, drowsiness, rash, constipation, neutropenia	Pregnancy test done before beginning therapy. CONTRAINDICATED IN PREGNANCY. Monitor neurological status and changes from baseline. Teach patient to report any rash to MD. Instruct about measures to prevent constipation. Monitor CBC throughout therapy.

CBC = complete blood count; CNS = Central nervous system; GI = gastrointestinal; IM = intramuscular; IV = intravenous; MAO = monoamine oxidase inhibitor; PT = prothrombin time.

FIGURE 10.12 Necrosis of skin tissue resulting from administration of a vesicant chemotherapy drug. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, OH.)

of **anemia** occurs with the reduction of red blood cells and may require blood transfusions. See Table 10.5 for medications that can be used to stimulate production of these cells.

Gastrointestinal System. The gastrointestinal tract is susceptible to the toxicity of chemotherapy drugs. Patients often become nauseated and vomit or experience diarrhea. **Stomatitis** is a common complaint and is discussed under side effects of radiation. These side effects can be controlled with medication.

Hair. Alopecia, or hair loss, is common with many (but not all) chemotherapeutic drugs. This is a temporary condition, and growth of the new hair usually starts when the chemotherapeutic medication is stopped. Alopecia involves the entire body and includes eyebrows, eyelashes, and axillary and pubic hair. Hair regrowth may be of different color or texture than the original hair. It is not uncommon for individuals who originally had straight hair to regrow curly hair.

Reproductive System. The effects of chemotherapy or radiation can cause temporary or permanent alterations of the reproductive system. Occasionally, patients are rendered sterile because of the treatment. Issues concerning fertility should be discussed with the patient before treatment. Measures such as freezing ova and the use of sperm banks provide options for the patient and his or her partner.

Neurological System. Drugs may affect the neurological system. An adverse reaction to vincristine is neurotoxicity, which may result in tingling or numbness in the extremities and in severe cases may cause footdrop from muscle weakness.

anemia: an—not + emia—blood

stomatitis: stoma—mouth + itis—inflammation

Less common complications include renal toxicities, such as pain and burning on urination, and hematuria. Doxorubicin (Adriamycin) has been associated with permanent heart damage, and bleomycin can cause pulmonary fibrosis.

Severe toxic side effects can be controlled by carefully limiting the amount of medication given and constantly monitoring the patient for complications.

New Treatments Being Researched

New therapies for cancer are constantly being researched. Hyperthermia has been used with radiation and chemotherapy. It has been beneficial in some types of cancer but is seldom used except in investigational studies.

Biological response modifiers (such as interferons) are drugs used to stimulate the immune system. These drugs are used commonly for specific types of cancer and have produced some beneficial results. They are also being used in many investigational studies. Go to www.cancer.gov for information on current clinical trials.

NURSING PROCESS FOR THE PATIENT WITH CANCER

Assessment/Data Collection

Patients with cancer are assessed for many different problems associated with cancer and its treatment. Thorough assessment will assist the health team to build a plan of care relevant to the patient's needs.

Monitor laboratory studies. The normal platelet level is 150,000 to 300,000/mm³. Potential for bleeding exists when the platelet count is 50,000; risk for spontaneous bleeding occurs when the count is less than 20,000. Monitor the white blood cell count for risk for infection and the red cell count for anemia.

Monitor the patient's weight and note complaints of nausea, changes in taste, vomiting, and diarrhea related to either the disease or treatment. Monitor oral mucosa for lesions or inflammation. Also monitor for signs of dehydration. Box 10.6 (Nutrition Notes) presents criteria for determining whether a patient needs nutritional support.

Psychosocial issues related to cancer are as varied as the persons afflicted with the disease. You can help the patient explore perceptions about quality of life. Culture and age affect cancer perceptions (e.g., in a culture in which life expectancy is short, possible death from cancer in the later years is not a significant threat). Assess the patient's ability to cope and what coping strategies have been effective in the past. Determine what information the patient has received and understands about his or her disease and prognosis.

Assess the roles of the patient and caregiver in the family. Be aware of whether the caregiver is able to be at home or whether he or she must work outside the home and care for the patient. Isolation can be either self-imposed or imposed by friends and family, as terminal illness issues are confronted. It can be very frustrating to see a loved one decline with cancer; often people say they are "afraid of say-

TABLE 10.5 COLONY-STIMULATING FACTORS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Granulocyte Colony-Stimulating Factor (G-CSF) Stimulates proliferation of stem cells into granulocytes (neutrophils).	Filgrastim (Neupogen) Pegfilgrastim (Neulasta)	IV, SC	Bone pain	Monitor CBC. Teach self-administration of SC medication if to be given at home.
Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF) Stimulates proliferation of stem cells into neutrophils, monocytes, macrophages, and eosinophils.	Sargramostim (Leukine)	IV, SC	Headache, itching, rash, bone or joint pain, muscle ache, dyspnea	Monitor vital signs and respiratory status during IV infusion. Monitor CBC. Teach self-administration of SC medication if to be given at home.
Erythropoietin Stimulates proliferation of stem cells into red blood cells.	Epoetin alfa (Epoen, Procrit)	IV, SC	Hypertension, seizure	Monitor blood pressure and hematocrit. Teach self-administration of SC medication if to be given at home.
Interleukin-11 Stimulates production of platelets.	Oprelvekin (Neumega)	SC	Dizziness, weakness, conjunctival hemorrhage, dyspnea, cough, pleural effusion, dysrhythmia, edema, syncope, anorexia, constipation, diarrhea, vomiting, alopecia, rash, bone and muscle pain, chills, fever, infection, pain	Monitor for fluid retention. Monitor CBC, platelet count. Teach self-administration of SC medication if to be given at home.

ing or doing the wrong thing” so they “just stay away.” Listen for cues from patients expressing self-blame, anger, or depression. It is important to recognize signs of depression and suicidal tendencies.

Assess for fatigue and anxiety in the patient being treated for cancer. A decline in sexual desire is not uncommon during cancer treatment. Assess for anxiety about sexual intercourse, including fears concerning contracting cancer from the patient and fears that sexual intercourse will make the cancer worse.

Assess the patient’s feelings about any actual or perceived change in appearance due to surgery, radiation, or chemotherapy.

Nursing Diagnosis, Planning, and Implementation

See Box 10.7 Nursing Care Plan for the Patient with Cancer for top nursing care priorities. Additional nursing diagnoses are presented below. Also see Box 10.8 Cancer Survivor’s Bill of Rights.

Ineffective protection related to thrombocytopenia associated with chemotherapy and radiation

EXPECTED OUTCOME: The patient will be free of bleeding.

- Monitor platelet counts. *Platelet count of <50,000 indicates potential for bleeding*
- Teach self-administration of oprelvekin (Neumega) as ordered. *Oprelvekin stimulates production of platelets.*
- Test all urine and stool for occult blood *to detect the presence of blood.*
- Avoid giving intramuscular, subcutaneous, or rectal medications. *Medications given via invasive routes can cause bleeding.*
- Apply pressure for at least 5 minutes to venipuncture or injection sites. *Pressure for a longer time*

(Text continued on page 166)

Box 10.6

Nutrition Notes

Assessing the Need for Nutritional Support

Intensive nutritional support may not benefit all cancer patients because the tumor interferes with the patient’s utilization of nutrients. Clinical judgment is required to analyze the patient’s needs and expected response. In general, if any of the following findings are present, you should talk with the dietitian or physician about the need for nutritional support.

- Weight 5 kg (11 lb) below a healthy body weight
- Serum albumin less than 3 g/dL
- Location of cancer (head and neck, gastrointestinal system)

Box 10.7 NURSING CARE PLAN for the Patient with Cancer

Nursing Diagnosis: Risk For Ineffective Coping Related to the Diagnosis and Treatment of Cancer as Evidenced by Behaviors Such as Denial, Isolation, Anxiety, and Depression

Expected Outcomes Patient will cope effectively as evidenced by identifying stressors related to illness and treatment; communicating needs, concerns, and fears; and use of appropriate resources to support coping.

Evaluation of Outcomes Is patient able to identify stressors and communicate concerns? Does patient effectively draw upon past coping mechanism? Does patient have and appropriately use support systems?

Interventions

Assess effective coping mechanisms used in the past and currently available to the patient.

Use active listening skills to encourage the patient to express feelings and fears.

Assess the meaning of quality of life to the patient.

Assess for suicide risks.

Explore outlets that promote feelings of personal achievement.

Promote the use of humor.

Rationale

Coping mechanisms that worked in the past may be helpful again, and the nurse can support appropriate choices.

The patient must identify fears to be able to cope effectively with them.

Once identified, the nurse can assist the patient to achieve quality-of-life goals.

A patient who feels hopeless may be at risk for suicide.

Personal achievement promotes self-esteem.

Humor can be both distracting and therapeutic.

Evaluation

Is the patient able to identify and draw on past coping mechanisms?

Does the patient identify fears and concerns?

Is the patient able to identify the meaning of quality of life? Are there ways the nurse can assist the patient to reach quality-of-life goals?

Is the patient at risk? Are suicide precautions necessary?

Does the patient have creative outlets that promote feelings of achievement? Can the nurse assist in implementing these activities?

Does the patient use humor? Does it provide temporary distraction from concerns?

Nursing Diagnosis: Pain Related to Tissue Injury from Disease Process and Treatment

Expected Outcomes Patient will be pain free as evidenced by patient statement of comfort on pain scale.

Evaluation of Outcome Does patient state pain is controlled?

Interventions

Assess the patient's pain including onset, location, duration, character, and aggravating and alleviating factors.

Ask patient to rate pain on a scale from 0 to 10 (0 = absence of pain; 10 = worst pain).

Monitor pain relief every 2 to 4 hours.

Administer analgesics as ordered, ATC.

Educate patient on use of PCA.

Rationale

Assessment provides direction for the treatment plan.

A pain rating should guide treatment and evaluate effectiveness of treatment.

Alternative medications may be necessary for breakthrough pain.

Using an ATC schedule prevents pain from becoming severe.

PCA allows the patient to be in control of own pain relief.

Evaluation

Is assessment complete and used to guide treatment?

Does patient use pain assessment scale effectively? Is patient in pain?

Is PCA or epidural analgesic effective?

Is patient's pain kept under control at all times?

Does PCA keep patient pain free and able to participate in desired activities?

Interventions

Monitor level of sedation and respiratory status if opioid dose is increased.

Explain and encourage use of relaxation techniques and other complementary techniques.

Use nonpharmacological interventions once the pain is controlled with medications.

Rationale

Patients who receive long-term opioid therapy develop a tolerance to the depressant effects of opioids.

Relaxation techniques can reduce pain intensity by reducing skeletal muscle tension.

Nonpharmacological interventions supplement but do not replace analgesics.

Evaluation

Is patient alert with respiratory rate between 12 and 20?

Does patient use relaxation techniques effectively?

Does patient use nonpharmacological interventions? Do they help?

Nursing Diagnosis: Risk for infection related to diminished immunity and bone marrow suppression as a result of chemotherapy or radiation

Expected Outcomes The patient will be free and safe from infection as evidenced by being afebrile and stating self-care measures to protect from infection. Signs and symptoms of infection are identified and treated early.

Evaluation of Outcome Are signs and symptoms of infection absent? If present, are they reported quickly? Can the patient identify self-care measures for preventing infection?

Interventions

Monitor body temperature every 4 hours.

Monitor white blood cell count daily.

Assess for signs of inflammation or drainage at potential infection sites such as old aspirate sites, venipuncture sites, oral and rectal mucosae, perineal area, axillae, incisions, pierced earlobes, under breasts, and between toes.

Monitor for signs of respiratory infection such as sore throat, cough, shortness of breath, and sputum production.

Monitor for signs of urinary tract infection including burning, pain, urgency, blood in urine.

Teach administration of G-CSF or GM-CSF as ordered.

Use good hand washing technique before interaction with the patient.

Limit visitors to only healthy adults.

Keep fresh flowers and potted plants out of the patient's room.

Rationale

Elevated body temperature is an early sign of infection.

For the neutropenic patient, the WBC will not be elevated. Neutropenia is risk factor for infection.

Intact skin is the first line of defense against invading microorganisms.

Nosocomial pneumonia has a high mortality and morbidity rate.

GU tract is the most common site for nosocomial infection.

These medications help the body produce more white blood cells. The patient may need to administer it subcutaneously at home.

Appropriate hand hygiene can reduce the transmission of antimicrobial organisms.

Viral infection in an immunosuppressed patient has a high mortality rate.

Aspergillus is a fungus found in soil and water and can cause pneumonia.

Evaluation

What is the patient's temperature?

Is the white cell count 5000 to 10,000/mm³?

Are there any sites that need special care to maintain skin integrity?

Are signs of respiratory infection present?

Are signs of urinary tract infection present?

Does patient demonstrate correct self-administration? Is white count improving?

Are you careful with your hand washing? Have you also instructed the patient, family, and nursing assistants about careful hand washing?

Are the patient and family aware of visiting restrictions and rationale? Is there a sign on the door reminding visitors?

Is the room free from potential sources of infection?

Box 10.8**Cancer Survivor's Bill of Rights**

The American Cancer Society promotes the following Survivor's Bill of Rights to promote cancer care.

1. Survivors have the right to assurance of lifelong medical care, as needed. The physicians and other professionals involved in their care should continue their constant efforts to be:
 - sensitive to the cancer survivor's lifestyle choices and need for self-esteem and dignity;
 - careful, no matter how long their patients have survived, to take symptoms seriously, and not dismiss aches and pains, for fear of recurrence is a normal part of survivorship;
 - informative and open, providing survivors with as much or as little candid medical information as they wish, and encouraging their informed participation in their own care;
 - knowledgeable about counseling resources, and willing to refer survivors and their families as appropriate for emotional support and therapy, which will improve the quality of individual lives.
2. Survivors will have the right to the pursuit of happiness. This means they have the right:
 - to talk with their families and friends about their cancer experience if they wish, but to refuse to discuss if that is their choice and not to be expected to be more upbeat or less blue than anyone else;
 - to be free of the stigma of cancer as a "dread disease" in all social relations;
 - to be free of blame for having gotten the disease and of guilt for having survived it.
3. In the workplace, survivors have the right to equal job opportunities. They have the right:
 - to apply for jobs worthy of their skills, and for which they are trained and experienced;
 - to be hired, promoted, and accepted on return to work, according to their individual abilities and qualifications, and not according to "cancer" or "disability" stereotypes;
 - to privacy about their medical histories.
4. Every effort should be made to assure all survivors adequate health insurance, whether public or private. This includes:
 - survivors have the right to be included in group coverage at the place of employment;
 - physicians, counselors, and other professionals must keep themselves and survivors informed and up to date on available group or individual health policy options;
 - social policy makers, both in government and in the private sector, must seek to broaden insurance programs like Medicare to include diagnostic procedures and treatment to help prevent recurrence and lessen survivor anxiety.

Source: From Cancer Survivor's Bill of Rights, American Cancer Society.

is needed at sites of invasive procedures to stop bleeding.

- Teach the patient about gentle mouth care including no flossing, a soft toothbrush, and wearing properly fitting dentures *to help prevent trauma and bleeding.*
- Avoid trauma to rectal tissue by avoiding rectal temperatures and enemas. Teach importance of avoiding anal intercourse. *Trauma to rectal tissue can cause bleeding to occur.*
- Instruct the patient not to take any salicylates or nonsteroidal anti-inflammatory medications *because they can interfere with platelet functions and cause bleeding in the GI tract.*
- Observe for bruising, petechiae, bleeding gums, tarry stools, and black emesis. *These are signs of bleeding.*
- Advise the patient to use an electric razor *to decrease trauma that could result in bleeding.*
- Teach the patient to avoid blowing his or her nose or inserting objects into the nose *to reduce trauma to nasal mucosa to prevent spontaneous bleeding.*

- Teach the patient to avoid intercourse for the duration of the thrombocytopenia *to decrease the probability of bleeding after intercourse.*

Nutrition, imbalanced: less than body requirements related to anorexia, nausea, or vomiting associated with disease, pain, and treatment

EXPECTED OUTCOME: The patient will have adequate caloric intake adequate to meet body requirements and balanced intake and output, as evidenced by stable weight and albumin $\geq 3\text{g/dL}$.

- Monitor food and fluid intake and output every 8 hours. *This will provide objective data for the amount of nutrients and fluids taken in.*
- Weigh the patient daily. *Weight is an objective measurement to determine if intake is adequate enough to maintain weight.*
- Consult a dietitian for dietary supplements. *Dietitians can calculate the calories needed for adequate nutrition and make recommendations for supplements.*
- Consult with the physician for medications to con-

Box 10.9

Nutrition Notes

Treating Problems Related to Nutrition

Try these ideas if a cancer patient has problems with eating.

Early Satiety and Anorexia

- Select nutrient-dense foods. For example, fortify puddings and milkshakes with dry skim milk powder.
- Encourage appropriate exercise.
- Present food attractively.
- Remove covers from food containers away from the bedside if strong odors annoy the patient.
- Offer small, frequent meals.
- Encourage family to provide home-cooked food.
- If meals are rejected, offer 1 oz of a complete nutritional supplement every hour.

Bitter or Metallic Taste

- Cook in glass containers in a microwave oven.
- Serve food cold or at room temperature.
- See if the patient prefers eggs, fish, poultry, and dairy products to beef and pork.
- Experiment with sauces and seasonings. Sweet sauces and marinades may improve the palatability of meats.

Local Oral Effects

- Ulcerations—Offer soft, mild foods; cream sauces, gravies, and dressings for lubrication; cold foods for numbing; and straws for liquids. Avoid hot items, salty or spicy foods, and acidic juices. If an anesthetic mouthwash is prescribed, caution the patient to chew carefully to avoid biting the lips, tongue, or cheeks.
- Dry mouth—Offer frequent sips of water or artificial saliva. Lubricate with gravies, butter, margarine, milk, cream, or bouillon. Sugarless hard candy, chewing gum, or popsicles may stimulate saliva production.

- Dysphagia—Teach the patient to make swallowing a conscious act (inhale, swallow, exhale) and to experiment with head position. Offer foods with a smooth, even consistency. Thick liquids are easier to swallow than thin. Encourage dunking breads in a beverage to soften.

Nausea and Vomiting

- Administer antiemetics on a regular prophylactic schedule.
- Suggest dry crackers.
- Offer liquids between instead of with meals to reduce stomach volume and low-fat meals to facilitate stomach emptying.
- Instruct the patient to chew thoroughly, eat slowly, and rest afterward.
- Arrange meal schedule to take advantage of times when patient feels better.
- Avoid serving favorite foods when the patient is nauseous to avoid an association between those foods and vomiting.

Diarrhea

- Suggest a low-residue diet. (Citro-1 and Enlive are clear liquid nearly complete nutritional supplements.)
- Try a lactose-free diet for temporary lactose intolerance.
- Propose pectin-containing foods (apples, strawberries, citrus fruits) to absorb water in the bowel.
- Recommend active cultures of yogurt to repopulate intestine.

Altered Immune Response

- Restrict fresh fruits and vegetables that cannot be peeled or adequately disinfected.
- Consider avoiding yogurt to prevent translocation of the bacteria to the bloodstream.

trol nausea, vomiting, and diarrhea. *If these symptoms are controlled, then the patient is better able to eat.*

- Keep the environment free of strong odors, such as disinfectants, perfumes, deodorizers, and body wastes. *Strong odors can induce nausea.*
- Provide room-temperature or cold foods and clear liquids. *These foods have fewer odors and may be more comfortable for the patient to eat.*
- Offer sour foods such as hard candy and lemon. *These may help control nausea.*

- Encourage listening to music or doing relaxation exercises. *These may provide distraction from pain and nausea.*
- Add nutmeg to foods. *Nutmeg may help slow down motility of the gastrointestinal tract and decrease the risk of nausea and vomiting.*
- Provide mouth care before meals. *Oral care allows for a better taste in the mouth, and saliva is necessary for digestion of food.*
- Provide small, high-calorie meals. *Smaller, more frequent meals prevent the patient from feeling full and wanting to vomit.*

- Administer pain medication before meals to help reduce the impact of pain on the appetite.
- Instruct the patient to avoid fluids with meals to prevent premature feelings of fullness.
- Teach the patient to avoid exercise before meals. *If the patient is fatigued, he or she will not have the energy to eat and digest food.*

See Box 10.9 (Nutrition Notes) for additional nutrition interventions.

Deficient self-care related to weakness and fatigue

EXPECTED OUTCOME: The patient will perform self-care activities to optimal potential.

- Assess what self-care activities the patient can do independently (bathing, grooming, feeding, toileting, ambulating). *By assessing what the patient can do independently, you can develop goals and interventions appropriate for this patient.*
- Teach self-administration of epoetin alfa as ordered. *Epoetin alfa stimulates production of red cells and can help fatigue related to anemia.*
- Identify and include the patient's strengths in self-care activities to help increase the patient's independence.
- Provide the tools necessary for the patient to assist with his or her own bathing, grooming, feeding, toileting, and ambulation. Physical and occupational therapy departments may be able to help identify assistive devices. *Adaptive and assistive devices can promote independence.*
- Teach the patient about options available for when he or she is no longer able to care for his or her own needs. *Support from other sources will help the patient conserve energy. Planning ahead can help reduce anxiety.*
- Instruct family members in how to assist in daily care. *Allowing family to assist in the daily care will promote their role as caregiver.*
- Consult home health-care or hospice nurses to assist with care needs upon discharge from the acute setting. *Support from these sources will assist the patient to maintain dignity when independence is no longer possible.*

Anticipatory grieving related to potential disease outcome

EXPECTED OUTCOME: The patient will be able to express feelings of guilt, anger, or sorrow and to share anticipated needs related to end-of-life care.

- Use therapeutic communication techniques to ask open-ended questions like, "What are your thoughts and fears?" *This can assist the patient to identify concerns, and also help the nurse to individualize nursing care.*

- Actively listen to the patient's grief. *Being present for the patient and just listening helps the patient communicate needs and fears.*
- Encourage family members to spend time with the patient to make end-of-life decisions. *More people would rather rely on family and friends than physicians to make end-of-life decisions.*
- Ask the patient about end-of-life decisions. Provide information as needed. *Knowing what a dying patient wants will help the nurse to develop the end-of-life care plan.*
- Contact the patient's minister or clergy if the patient agrees. *Religious beliefs can influence the patient's and/or family's grieving process.*
- Help the patient build memories by assisting to write letters, plan his or her funeral, or write an obituary. *These are ways to nurture the patient's relationship with family and to leave a memento behind.*

Caregiver role strain related to patient care and anticipated outcome

EXPECTED OUTCOME: The caregiver will identify resources available to assist in providing care for the patient.

- Observe the caregiver's ability to provide care for the patient. *The nurse needs to know if the caregiver will be able to handle the care needs.*
- Assist the caregiver to identify supports available to them. *Assistance to the caregiver can provide a break and decrease the risk of depression in the caregiver.*
- Instruct the caregiver in the resources available in the community. *Support groups can help the caregiver by providing an outlet for sharing their concerns and providing support.*
- Consult the multidisciplinary team to provide the services needed at time of discharge. *Preparing the caregiver for discharge needs/care with the proper resources will help the caregiver feel empowered to deliver the care.*

EXPECTED OUTCOME: Caregivers will maintain their physical and psychological health.

- Observe for signs of depression in the caregiver and intervene to help them cope. *The caregiver can develop a weakened immune system secondary to stress and depression.*
- Arrange for respite for the caregiver or encourage the caregiver to utilize this service. *Respite care can provide a break for the caregiver if they are willing to try it.*
- Encourage the caregiver to grieve over the patient. *Caregivers will grieve for the loved one's loss of function or role in the family.*

- Assist the caregiver with ways to decrease stress. *Encouraging caregivers to take the time to care for themselves will leave them with the energy they need to continue providing the care.*
- Actively listen to the caregiver's concerns. *Listening to the concerns of the caregiver can assist the nurse in assessing how well the caregiver is able to cope, and help in planning care.*

Social isolation related to changing relationships

EXPECTED OUTCOME: The patient will be able to identify feelings of isolation.

- Observe the patient for signs of barriers to social interaction such as incontinence, and lack of transportation, money, or support system. *Why a patient feels isolated can vary from one person to another but knowing the reason can help the nurse plan appropriate interventions.*
- Discuss causes of perceived or actual isolation. *How the patient is dealing with the illness will have an impact on how he or she manages the illness.*
- Listen to the patient describe reasons for isolation. *Listening and being present are ways to show caring.*

EXPECTED OUTCOME: The patient will be able to participate in chosen activities.

- Promote opportunities for the patient to interact socially such as mealtimes or therapy sessions. *The patient will feel less isolated if given an opportunity to participate in diversional activities.*
- Provide positive reinforcement to the patient when he or she initiates conversation with others. *Positive feedback by the nurse can impact the patient's sense of confidence.*
- Provide information about support groups and encourage the patient to contact these individuals. *Support groups can help the patient cope better with stressful events in their life.*

Ineffective sexuality pattern related to change in body functions

EXPECTED OUTCOME: The patient will have knowledge about limitations or changes in sexual activity during cancer treatment.

- Provide a private environment so that the patient feels comfortable discussing issues of sexuality. *Privacy is necessary so that there is a comfort level for the patient to express concerns.*
- Assess what the patient understands about sexuality during cancer treatment. *This discussion can clear up any misinformation the patient and partner may have regarding sexuality during therapy.*
- Encourage the patient to discuss concerns about

sexuality with his or her partner. *Communication is a key component of emotional intimacy.*

- Stress to the patient that cancer cannot be passed from person to person through sexual intimacy. *Cancer is not contagious.*
- Instruct the patient that sexual activity is usually safe during and after cancer treatment. *Sexual activity does not necessarily hurt the patient.*
- Advise the patient to abstain from sexual intercourse while his or her blood count is low to prevent the risk of secondary infections and bleeding. *A low WBC can put the patient at risk for infection. A low platelet count can put the patient at risk for bleeding.*
- Discuss with the patient that closeness and intimacy may still be desired even if sexual intercourse is not. *Closeness and touching are ways to be intimate without intercourse.*
- Instruct the patient and partner that pain during intercourse can be related to surgery or treatment and to take pain medication prior to sexual intercourse. *Pain medication prior to intercourse can make the patient more comfortable.*

Disturbed body image related to cancer and its treatment (e.g., surgical procedures such as an ostomy or loss of hair associated with chemotherapy)

EXPECTED OUTCOME: The patient will be able to accept the changes in body image resulting from cancer and its treatment.

- Allow the patient to discuss feelings of anger or depression and confirm that these feelings are normal when adjusting to body changes. *A patient may be better able to cope with body changes if he or she can talk about feelings and understand that the feelings are normal.*
- Encourage the patient to select a wig prior to hair loss. *Selecting a wig before the hair loss occurs allows the patient to find one resembling his or her own hair color and style.*
- Encourage the patient to provide own care to ostomy site or surgical wound when ready. *Encouragement and education about self-care will promote independence.*
- Provide resources such as Reach to Recovery (www.cancer.org, type in Reach to Recovery) and Look Good . . . Feel Better support groups (www.lookgoodfeelbetter.org/). *Support groups provide a forum for patients to share their experiences with others experiencing the same types of changes.*
- Provide information about community assistance/financial aid for programs or services. *Social workers can assist with community resources that can provide equipment or supplies for the patient.*

Evaluation

If the interventions have been effective, the patient does not experience any unusual bleeding or bruising. The patient and family are knowledgeable about risk factors associated with bleeding and about signs of bleeding to report promptly.

The patient is nourished and maintains weight within his or her normal limits. The patient maximizes his potential for self-care activities. The patient and caregiver have knowledge of available resources to assist with self-care activities in the home setting. Caregivers have the knowledge to be able to provide care for the patient. The patient is able to openly discuss feelings, and is able to spend time with family and loved ones to resolve any issues.

If interventions have been effective, the caregiver is able to utilize resources in the community to assist with the care of the patient, and maintain her or his own physical and psychological health while caring for the patient. The patient is able to discuss feelings of isolation and seek out activities to participate in. The patient maintains a healthy sexuality and is able to discuss feelings openly and honestly with her or his partner.

The patient is able to openly discuss concerns regarding body changes and is able to maintain control of his or her body. The patient has knowledge of community resources and support groups to assist with needs related to body image.

CRITICAL THINKING

Mrs. Jones

■ Mrs. Jones is admitted to your unit following a simple mastectomy for breast cancer. The tumor was staged as a T2, N0, M0. Estrogen and progesterone receptors were negative. A bone scan was negative for metastasis. She is scheduled for four chemotherapy treatments, 3 weeks apart. The medications prescribed are high doses of doxorubicin (Adriamycin) and cyclophosphamide (Cytosan). A central line is inserted for chemotherapy.

1. What does the staging of Mrs. Jones's tumor mean?
2. What major side effects of her medications should you look for?
3. Why was a central line inserted?
4. What nursing diagnoses are appropriate for Mrs. Jones?

Suggested answers at end of chapter.

HOSPICE CARE OF THE PATIENT WITH CANCER

Patients who are considered terminal and have a life expectancy of 6 months or less are eligible for hospice care, which provides humanistic care for dying people and their

families. The dying person is provided care in a home or homelike setting that promotes comfort and quality of life until death. Hospice care is offered as an inpatient or outpatient service (see Home Health Hints at the end of the chapter).

Inpatient services are used for symptom control and respite care for the family. Family and pets may be allowed to stay with the patient. Hospice care deals with the family in crisis and continues for up to 1 year after the patient dies, with follow-up counseling, listening, nurturing, and referrals.

Outpatient care is given in the home with family members providing the primary care. Support care is given by the hospice staff. Medications and supplies are furnished by the hospice service. At home, the patient can enjoy loved ones, pets, plants, music, and other personal possessions for as long as possible. See Chapter 16 Nursing Care of Patients at the End of Life for more information.

ONCOLOGICAL EMERGENCIES

Superior Vena Cava Syndrome

Superior vena cava syndrome (SVCS) occurs in patients with lung cancer when the tumor or enlarged lymph nodes block the circulation in the vena cava. This results in edema of the head and neck and may lead to seizures. Radiation therapy can be used to shrink the tumor and allow for circulation to resume naturally. Nursing interventions for the patient with SVCS include removing rings and restrictive clothing, avoiding taking blood pressure and venipunctures in the upper extremities, and elevating the head of the bed to decrease feeling of dyspnea.

Spinal Cord Compression

Spinal cord compression may develop in patients with bone metastasis when the bones collapse. This is a very painful problem and requires pain management while radiation is given to relieve the symptoms. Patients may develop some motor loss when this occurs. Often a myelogram or bone scan is used for diagnosis. Nursing care includes providing a safe environment, assistance with activity, and monitoring for changes in neurological status.

Hypercalcemia

Hypercalcemia occurs when the serum calcium level exceeds 11 mg/dL. Hypercalcemia is associated with the release of calcium into the blood from bone deterioration, or from ectopic secretion of parathyroid hormone by a tumor. It is common in patients with bone metastasis, especially metastasis from breast cancer. It can be treated with intravenous medication and hydration to lower the calcium levels. Nursing care includes monitoring intake and output, pain control, and changes in pulse rate and rhythm.

Pericardial Effusion/Cardiac Tamponade

Pericardial effusion, or cardiac tamponade, is a condition usually caused by direct invasion of the cancer, causing the pericardial sac to fill with fluid. Treatment involves draining the fluid from the heart sac by pericardiocentesis and using sclerosing agents to keep the pericardial sac from refilling with fluid. Nursing care for the patient with cardiac tamponade includes monitoring respiratory status, keeping the head of the bed elevated for maximum lung expansion, monitoring vital signs, monitoring intake and output, and assessing for edema.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) involves an abnormal activation of the clot formation and fibrin mechanisms of the blood, resulting in the consumption of coagulation factors and platelets. Patients with DIC are at high risk for thrombus formation, infarctions, and bleeding. Treatment includes fresh frozen plasma and cryoprecipitates with heparin. Nursing interventions in the care of the patient with DIC include monitoring for bleeding, monitoring vital signs, assessing skin for signs of bleeding, accurate intake and output, and monitoring for changes in mental status.

Home Health Hints

- The home health or hospice nurse helps manage cancer pain in the home. Intramuscular dosing of pain medication should be avoided because of pain associated with injections and the burden this places on the caregiver. Oral or intravenous analgesics are preferred. For moderate to severe pain, medication dosing should be around-the-clock with prn doses for breakthrough pain.
- The nurse should anticipate constipation from opioid administration and treat prophylactically.
- Some patients are fearful about taking prescribed pain medications. Instruct them on the importance of taking the medications as ordered by the physician. It is important for the patient and caregiver to understand that it is easier to maintain pain relief than to try to gain control of and treat severe pain.
- Home health nurses are in key positions for making timely referrals for hospice care. Eligible clients are those who have a life expectancy of 6 months or less, have a desire for supportive care rather than continued treatments, and have a friend or relative who is willing to coordinate the care.

REVIEW QUESTIONS

- Which of the following is the hereditary material of cells?
 - Protein in the ribosomes
 - DNA in the chromosomes
 - RNA in the nucleus
 - Ribosomes in the cytoplasm
- A patient asks, “How do malignant tumors differ from benign tumors?” Which of the following statements by the nurse is most accurate? Select all that apply.
 - Malignant tumors invade surrounding cells and tissues.
 - Malignant tumors are generally encapsulated.
 - Malignant tumors remain localized.
 - Cells in malignant tumors stop dividing prematurely.
 - Cells in malignant tumors lack contact inhibition.
 - Malignant tumors have defective cell communication.
- A patient has received vinorelbine (Navelbine) on day 1 of treatment. The nadir will occur in approximately 10 days. The patient is at greatest risk for which of the following complications at day 10?
 - Infection
 - Hair loss
 - Diarrhea
 - Myalgia
- A female patient is starting on doxorubicin (Adriamycin). Which of the following nursing interventions will be most helpful as the patient plans for hair loss?
 - Obtain a prescription for a hair growth product.
 - Massage her scalp to increase circulation and delay hair loss.
 - Teach her to apply ice to her scalp to prevent hair loss.
 - Help her choose a wig before her hair loss begins.
- Which of the following nursing actions is best before administering pain medication for cancer pain?
 - Assess the patient’s anxiety level.
 - Assess the patient’s understanding of the side effects of pain medication.
 - Determine the patient’s pain tolerance.
 - Assess the success of past pain management measures.

6. The nurse notes that a patient undergoing treatment for bone cancer is having difficulty walking. For which oncologic emergency should the patient be assessed?
 - a. Tumor lysis syndrome
 - b. Hypercalcemia
 - c. Spinal cord compression
 - d. Superior vena cava syndrome
7. A patient receiving radiation therapy has reddened skin over the treated area. How will the nurse know if nursing interventions have been effective?
 - a. The patient will be able to describe a proper skin care regimen.
 - b. The nurse will keep the skin clean and dry.
 - c. The patient's skin will remain intact without breakdown or infection.
 - d. The nurse will report the reddened area to the physician.
8. Which patient will benefit from hospice care?
 - a. A patient who has liver cancer and is expected to live 4 to 6 weeks.
 - b. A patient who is having multiple side effects from aggressive chemotherapy.
 - c. A patient who is trying to make a decision about whether to have surgery that could cure his cancer but may risk serious loss of function.
 - d. A patient who requires large doses of morphine to control pain related to his cancer and radiation treatment.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Jones

1. Mrs. Jones's tumor is beginning to invade surrounding tissue. There is no lymph node involvement and no metastasis.
2. Doxorubicin is commonly associated with red urine. Cyclophosphamide can cause blood in the urine. Both medications can cause nausea, vomiting, and alopecia. Both are vesicants.
3. Because the drugs are vesicants, it is important to inject them into a large vein.
4. Many diagnoses are appropriate, including acute pain related to surgical incision, disturbed body image related to alopecia and loss of a breast, imbalanced nutrition related to nausea and vomiting, risk for injury related to medication side effects, and deficient knowledge about cancer treatment and management of side effects.

Nursing Care of Patients Having Surgery

QUESTIONS TO GUIDE YOUR READING

1. What are factors that influence surgical outcomes?
2. What is your role in each perioperative phase?
3. What is your role in obtaining informed patient consent?
4. How would you enhance learning for the elderly preoperative patient?
5. What are some nursing interventions for common postoperative patient needs?
6. How will you know if your nursing interventions have been effective?
7. What are signs and symptoms of common postoperative complications?
8. What are the criteria for ambulatory discharge?
9. What is the role of the home health nurse in caring for postoperative patients?

Surgery is the use of instruments during an operation to treat injuries, diseases, and deformities.

Surgical procedures are named according to (1) the involved body organ, part, or location and (2) the suffix that describes what is done during the procedure (Table 11.1).

Physicians who perform surgery include **surgeons** or other physicians trained to do certain surgical procedures. Laser and scope technology continue to lead to new procedures that offer less risk, less invasion, faster recovery, and reduced hospitalization or ambulatory surgery. Robotic surgery is a newer area being explored. Today, surgery is a safe, effective treatment option because of medications such as antibiotics and anesthetics that allow a quicker recovery.

SAFETY TIP

A national partnership, the Surgical Care Improvement Project—A National Quality partnership (SCIP), began in 2005. The SCIP's goal is to improve the safety of surgical care by reducing postoperative complications by 25% by the year 2010. The partnership was developed by the Centers for Medicare & Medicaid Services (CMS) and the Centers for Disease Control and Prevention (CDC), and over 30 other national organizations are part of the partnership.

The four high-incidence and high-cost areas being examined by the SCIP are surgical site infections (SSIs), deep vein thrombosis (DVT), postoperative ventilator-related pneumonia, and adverse cardiac events. Methods for preventing SSIs include giving prophylactic antibiotics within 1 hour prior to surgery and controlling perioperative serum glucose during major cardiac procedures. DVT can be prevented by administering appropriate perioperative anticoagulants for those at risk. Examples of ways to prevent postoperative pneumonia are elevating the head of bed greater than or equal to 30 degrees for major postoperative surgical patients on a ventilator, if not contraindicated. Avoiding adverse cardiac events includes giving beta blockers during the perioperative period to eligible major noncardiac surgical patients and to surgical patients who have coronary artery disease. Look for updates on the committee's work at www.medqic.org/SCIP/

SURGERY URGENCY LEVELS

Surgery is scheduled based on the urgency required for a successful outcome for the patient (Table 11.2). *Emergency*, or *immediate*, surgery is needed when life or limb is suddenly threatened and any delay in surgery would jeopardize

TABLE 11.1 SURGICAL PROCEDURE SUFFIXES

Suffix	Meaning	Word-Building Examples
-ectomy	Removal by cutting	crani (skull) + ectomy = craniectomy appen (appendix) + ectomy = appendectomy
-orrhaphy	Suture of or repair	colo (colon) + orrhaphy = colorrhaphy herni (hernia) + orrhaphy = herniorrhaphy
-oscopy	Looking into	colon (intestine) + oscopy = colonoscopy gastr (stomach) + oscopy = gastroscopy
-ostomy	Formation of a permanent artificial opening	ureter + ostomy = ureterostomy colo (colon) + ostomy = colostomy
-otomy	Incision or cutting into	oust (bone) + otomy = osteotomy thoro (thorax) + otomy = thoractomy
-plasty	Formation or repair	oto (ear) + plasty = otoplasty mamm (breast) + plasty = mammoplasty

the patient's life or limb. Examples of the need for emergency surgery are ruptured aortic aneurysm, ruptured appendix, traumatic limb amputation, or loss of pulse due to an extremity emboli. *Urgent surgery* is the need for an operation within 24 to 30 hours. Examples of this are fracture repair or an infected gallbladder. *Elective surgery* is that which can be planned and scheduled without any immediate time constraints. Examples of this are joint replacement, hernia repair, or skin lesion removal. *Optional surgery*, such as cosmetic surgery, is done at the request of the patient.

PURPOSES OF SURGERY

Surgery is done for several reasons (see Table 11.2). *Preventive surgery* removes tissue before it causes a problem as in mole or polyp removal to prevent cancer development. *Diagnostic*, or *exploratory*, surgery takes tissue samples for study to make a diagnosis, uses scopes to look into areas of the body, or involves an incision to open an area of the body for examination. Examples of this surgery are a biopsy or exploratory laparotomy performed with a scope or incision. *Curative surgery* involves the removal of diseased or abnormal tissue as in an inflamed appendix, tumor, or a benign cyst or the repair of defects such as hernias or cleft palate. *Palliative surgery* is done when an underlying condition cannot be corrected but symptoms need to be alleviated. Examples of this are removal of part of a tumor that is causing pain or pressure, a rhizotomy which cuts a nerve root to relieve pain, insertion of a gastrostomy tube (feeding tube

TABLE 11.2 SURGERY URGENCY LEVEL AND PURPOSES

Urgency Level		
Type	Definition	Examples
Emergent	Immediate surgery needed to save life or limb	Ruptured aortic aneurysm or appendix, traumatic limb amputation, loss of extremity pulse from emboli
Urgent	Surgery needed within 24–30 hours	Fracture repair, infected gallbladder
Elective	Planned/scheduled, with no time requirements	Joint replacement, hernia repair, skin lesion removal
Purposes of Surgery		
Aesthetic	Requested by patient for improvement	Blepharoplasty, breast augmentation
Diagnostic	To obtain tissue samples, make an incision, or use a scope to make a diagnosis	Biopsy
Exploratory	Confirmation or measurement of extent of condition	Exploratory laparotomy
Preventive	Removal of tissue before it causes a problem	Mole or polyp removal
Curative	Removal of diseased or abnormal tissue	Inflamed appendix, tumor, benign cyst
Reconstructive	Correction of defects of body parts	Scar repair, total knee replacement
Palliative	Alleviation of symptoms without curing disease	Rhizotomy (cuts nerve root to relieve pain), partial tumor removal to relieve pain or pressure, gastrostomy tube for swallowing problem

inserted into the stomach through the abdominal wall) to provide tube feedings for a patient with swallowing problems, or formation of a colostomy (opening of the colon through the abdominal wall for fecal elimination) for an incurable bowel obstruction. *Cosmetic*, or *reconstructive*, surgery is done to improve appearance as in a face lift or mammoplasty, or to correct defects as in repair of scars.

PERIOPERATIVE PHASES

There are three phases in the surgical process: **preoperative**, **intraoperative**, and **postoperative**. These phases together are referred to as **perioperative**, which is the time before, during, and after surgery. Each of the perioperative surgical phases has a defined time frame in which specific events related to surgery occur (Table 11.3).

TABLE 11.3 PERIOPERATIVE SURGICAL PHASES

Perioperative	All three phases surrounding and during surgery
Preoperative	Begins with decision for surgery and ends with transfer to the operating room
Intraoperative	Begins with transfer to operating room and ends with admission to postanesthesia care unit (PACU)
Postoperative	Begins with admission to PACU and continues until recovery is complete

PREOPERATIVE PHASE

Your primary roles as a licensed practical nurse/licensed vocational nurse (LPN/LVN) in the preoperative phase are to:

- Assist in data collection for developing the patient's plan of care.
- Reinforce explanations and instructions given to the patient and family by the physician and registered nurse (RN).
- Provide emotional and psychological support for patients and their families.

Families of patients experience anxiety during surgery. You can help reduce the family's anxiety so that they are less anxious and able to assist the patient during recovery.

Other health team members assist in preparing the patient for surgery. The physician obtains a medical history, performs a physical examination, and orders diagnostic testing. Registered nurses perform a baseline preoperative assessment, provide explanations and instructions, offer patients and families emotional and psychological support to ease anxiety, develop a plan of care, and then verify the patient's name, surgical site (along with the patient), allergies, and related information when the patient arrives in the surgical area.

Factors Influencing Surgical Outcomes

When preparing a patient for surgery and assisting in the development of a nursing care plan, the goal is to identify and implement actions that reduce surgical risk factors. Preoperative care focuses on helping the patient achieve the best possible surgical outcome by being in the healthiest possible condition for surgery.

Emotional Responses

The word *surgery* causes a common emotional reaction in patients and their families. You need to be aware of these reactions to assist the patient in coping with them. If any of the patient's fears are extreme, such as a fear of dying or not waking up after surgery, the physician should be informed.

Surgical patients may experience various fears related to **anesthesia**: possible brain damage, feeling sensation during surgery, feeling loss of control, or a fear of not waking up. The patient should discuss these concerns with the

anesthesiologist. Listening to music or using guided imagery before surgery may reduce a patient's anxiety and help to calm the patient.

It is normal for patients to be concerned about pain. During surgery, the anesthesia provider gives medications to control pain. Nurses give prescribed analgesics for pain relief after surgery. Complementary techniques can also be used to help reduce pain, such as guided imagery or focused breathing.

Changes in body image may be a great fear for some patients. The thought of disfigurement, mutilation, bleeding, or having a scar causes great anxiety for some patients. Allow them to discuss these fears.

Age

Surgery can be a positive experience that promotes quality of life for many elderly patients. For healthy older patients, age

alone does not mean that they are at greater surgical risk. Complications can occur, however, related to previous health status, immobilization occurring from surgery, normal aging changes reducing the effectiveness of deep breathing and coughing, and the effects of administered medications (Box 11.1 Gerontological Issues). Older patients may require a longer time to recover from anesthetic agents because of aging changes in drug metabolism and elimination.

Hydration and Nutrition

A normal fluid and electrolyte balance decreases complications. Patients should be well nourished to adequately heal and recover from surgery (Box 11.2 Nutrition Notes). Higher levels of protein (tissue repair and healing), vitamin C (collagen formation), and zinc (tissue growth, skin integrity, and cell-mediated immunity) are required. Obese or underweight patients may not heal as well and may have complications.

Box 11.1

Gerontological Issues

Surgical Considerations for the Older Adult

Older adults usually have limited physiological reserve, resulting in decreased ability to compensate for changes that occur during surgery. There is increased risk for hemorrhage, anemia, fluid/electrolyte imbalance, and infection. Increased risk for complications is secondary to age-related loss of blood vessel elasticity and decreased cardiac, respiratory, and renal reserves. Nursing interventions should be aimed at these age-related changes before, during, and after the surgical procedure to help reduce complications.

Preoperatively:

- Reassure the patient and family.
- Pad bony prominences to protect against pressure ulcers and muscle and bone discomfort.
- Teach what to expect before, during, and after surgery, diet changes, description and length of surgical procedure, activities in the recovery room, pain management, coughing and deep breathing exercises, procedures, and treatments (e.g., dressings, catheters).
- Ensure preoperative screening: blood work, radiographic studies, nutritional assessments, pulmonary function tests, electrocardiogram.

Intraoperatively:

- Assess patient for hypothermia (cool temperature in operating room, medications that slow metabolism).
- Assess patient for hypoxia (older adult may exhibit restlessness).
- Assess patient for hemorrhage.
- Assess patient's output (urine, drainage, bleeding, emesis).

Postoperatively:

Pain Control—Provide adequate pain relief so required postoperative activities, such as deep breathing, coughing, position changes, and exercise, can be performed more effectively.

Respiratory Function—Reduce respiratory complications by encouraging deep breathing and coughing:

- Do deep breathing and coughing after pain medication has begun to take effect because this will increase the older patient's ability to take deeper breaths. Assess the patient carefully when giving narcotic analgesics because they may cause respiratory depression.
- Use a pillow and instruct the patient to hold it firmly over abdominal or chest incisions to support the incision. Taking a deep breath increases chest expansion, as well as abdominal pressure, which may pull or stretch an incision.
- Older adults perform deep breathing and coughing exercises better if the nurse performs the exercises with them. For example, say the following: "Let's take a deep breath in through the nose, hold it and count to three, then slowly blow it out completely through the mouth. When you blow the air out, shape your lips like they are going to whistle. Great, let's do it again."

Mobility—Encourage mobility through the following nursing actions and observations:

- Use pillows to support the patient's body alignment; assist the patient to ambulate as soon as possible after surgery; and regularly help the patient with passive or active range of motion exercises, along with flexion and extension exercises, for legs and feet.
- Monitor for unilateral swelling of the leg and calf or groin pain, which may indicate deep vein thrombosis,

a risk related to venous pooling in the lower extremities. This risk is increased with postoperative inactivity.

- Assist the patient to change position at least every 2 hours. If patients lay in one position too long, pressure ulcers can develop. When tissues are compressed between bones and the bed surface, blood supply is reduced to the tissue and cells begin to die. This results in painful open wounds.

Bowel Function—Assess bowel sounds. It is common for patients to feel bloated after surgery. Increasing activity, such as walking—not just sitting in a chair—stimulates peristaltic action of the bowel. This helps expel flatus and reduce discomfort.

Urinary Function—Be aware of the following aspects of urinary function:

- It is common for individuals to have difficulty emptying their bladder after surgery. Patients who are sleeping but restless should be evaluated for bladder distention. It is often difficult to void on a bed pan or in a urinal in a supine position.

- Older men with an enlarged prostate may have even greater difficulty voiding if they have received medications that have urinary retention side effects.
- Assisting patients to sit or stand to use urinals, use a bedside commode, or ambulate to the bathroom promotes bladder emptying and helps avoid the use of urinary catheters.
- Measure urine output that is voided or from a catheter. Note the color and odor of the urine. Older adults are prone to dehydration, and this provides an indication of their hydration status for intervention.

Delirium—Perform the following nursing actions to minimize delirium:

- Monitor level of consciousness routinely. Provide a calm environment and orient patients to their environment. Restraints should not be used because they can worsen delirium.
- Recognize that urinary catheter presence can contribute to delirium, so methods to avoid the need for a catheter should be tried.

Obese patients have more respiratory problems and wound healing difficulties, such as delayed healing and wound **dehiscence** (opening of the incision). Emaciated individuals may have more infections and delayed wound healing because they lack the nutrients needed for tissue healing.

Smoking and Alcohol

Tobacco and alcohol use increases the surgical patient's risks. Smoking thickens and increases the amount of lung secretions and reduces the action of cilia that remove the

secretions. Patients should be encouraged to avoid smoking for 24 hours before surgery or 3 to 4 weeks before surgery if they have a chronic lung disorder. Not smoking increases the action of the lungs' defense mechanisms and makes more hemoglobin available to carry oxygen during surgery. It also improves wound healing. Visit <http://www.surgeon-general.gov/tobacco/hospital.htm> for more information on smoking cessation.

Long-term alcohol use may cause nutritional deficiencies and liver damage, which can create bleeding problems,

Box 11.2

Nutrition Notes

Screening and Nourishing the Preoperative Patient

Mild to severe malnutrition affected 39% of patients undergoing gastrointestinal or orthopedic surgical procedures, but only about two-thirds of them received nutritional support and just 59% of the patients even had a weight recorded on their charts.¹ Patients with low serum albumin levels had more complications and slower recoveries from elective gastrointestinal surgery than patients with higher levels.²

Before elective surgery, the patient may have time to correct some nutritional deficiencies. Many patients are instructed to lose weight to reduce the risk of surgery. If they are anemic, an iron preparation can be administered. At least 2 to 3 weeks are required for objective evidence of the effectiveness of nutritional therapy. Before surgery on the gastrointestinal tract, a low-residue diet may be given for 2 to 3 days to minimize the feces in the bowel.

Preoperative fasting times have been reduced in recent years so that in many cases clear liquids may be consumed up to 2 hours before anesthesia, breast milk 4 hours, infant formula or a light meal 6 hours, and a regular meal 8 hours.³ Clinical judgment is required regardless of the guidelines, which specifically exempt patients with gastromotility or metabolic disorders, those with potential airway problems, and women in labor.

Many botanical products sold in the United States over-the-counter as nutritional supplements profoundly affect body systems during surgery. So many people are taking botanical products that the American Society of Anesthesiologists⁴ issued a warning to consumers of herbal medicine to stop taking the products 2 to 3 weeks before scheduled surgery. Possible interactions cited were an unintended deepening of anesthesia and problems with bleeding and blood pressure.

fluid volume imbalances, and drug metabolism alterations. In addition, alcohol interacts with medications and should be avoided before surgery.

Diseases

Chronic disorders may increase the patient's surgical risk unless they are well controlled. A preoperative assessment and clearance for surgery by the patient's physician may be needed. For diabetics, the stress of surgery can alter blood glucose levels. Patients with chronic lung disorders may have pulmonary complications from anesthesia. To help prepare patients with lung disorders for surgery, show them how to deep breathe and cough and use an incentive spirometer (Fig. 11.1).

Preadmission Surgical Patient Assessment

Nonemergent surgical patients have either a preadmission phone call or face-to-face interview with RNs in the preadmission testing (PAT) department. Patients have reduced anxiety and better understanding with prescreening.⁵ The interview process includes a health history, identification of risk factors, patient and family teaching, discharge planning, and necessary referrals to social work, support groups, and educational programs. Laboratory tests, electrocardiograms (ECGs), chest x-rays, and other diagnostic testing are done based on the patient's needs. A urine or serum pregnancy test as appropriate for female patients may be done to prevent fetal exposure to anesthetics. Health information and diagnostic testing results are reviewed by anesthesia providers and interventions are ordered for abnormalities. Then a plan of care is developed.

Federal law says patients must be asked before surgery if they have a signed advance directive to place in the medical record. An advance directive (e.g., health-care durable power of attorney or living will) indicates a person's wishes

for medical care if they become unable to speak for themselves. If there is no advance directive, written information on advance directives are provided. A health-care power of attorney allows patients to place someone of their own choosing, such as a relative or friend, in control of their medical decisions if they are unable to make them. A living will instructs the physician when to provide, withhold, or withdraw treatment that prolongs life and specifies types of treatment the patient wishes, such as comfort care only.

Preoperative Routines

Preoperative teaching provides information about common surgical preparation procedures and routines:

- Date and time of admission and surgery
- Admission procedures: arrive about 2 hours before surgery to allow preparation time
- Length of stay, items to bring and wear
- Recovery after surgery
- Family information: where to wait during surgery and who communicates patient's status to them
- Discharge criteria: if after outpatient surgery, a responsible adult must take the patient home

PREOPERATIVE INSTRUCTIONS. To reduce the risk of aspiration when anesthesia is started, as well as postoperative nausea and vomiting, the anesthesiologist orders fluid and food restrictions. The patient is told when to stop fluid and food intake (NPO), usually after midnight the night before surgery. If surgery is scheduled for the afternoon, clear liquids in the early morning may be allowed by the anesthesiologist. Patients may brush their teeth or rinse their mouth if no water is swallowed. Cancellation of surgery may result if the patient has not been NPO as ordered.

Any medications the patient is to take the morning of surgery, with an ounce of water, are explained. Special preparations, such as an enema, are also described. For abdominal or intestinal surgery, enemas are ordered to empty the bowel in order to reduce fecal contamination preoperatively and straining or distention postoperatively.

Instructions for postoperative care are given before surgery so the patient is alert when being taught and has time to learn. Patients should be told that active participation in postoperative care aids in their recovery. Teach patients how to report their pain level using a pain rating scale (such as a 0 [none] to 10 [severe] rating scale, a color-based rating scale, or a scale using pictures of faces showing varying degrees of frowning or smiling that indicate a certain pain level) so that prompt pain relief can be provided (see Chapter 9). Pain relief methods are described, such as analgesic injections, an epidural catheter, or patient-controlled analgesia (PCA). Anticipated dressings, tubes, casts, or special equipment, such as a continuous passive motion machine for total knee replacement, are also described. If needed, crutches are fitted to the patient, and their proper use is explained and demonstrated.

Postoperative exercises are taught to decrease complications. They include deep breathing and coughing, use of incentive spirometry, leg exercises, turning, and how to get

FIGURE 11.1 An incentive spirometer aids lung expansion.

out of bed. After an exercise is taught, the patient should perform a return demonstration so understanding and ability to perform the exercise correctly can be evaluated.

Deep breathing helps prevent the development of **atelectasis** (collapse of the lung caused by hypoventilation or mucous obstruction preventing some alveoli from opening and being fully ventilated) by expanding and ventilating the lungs. The patient is taught to sit up, exhale fully, take in a deep breath through the nose, hold the breath and count to three, and then exhale completely through the mouth. The patient is told to repeat this hourly while awake, in sets of five, for 24 to 48 hours postoperatively.

Incentive spirometry may also be ordered postoperatively to prevent atelectasis by increasing lung volume, alveoli expansion, and venous return. (see Fig. 11.1). Any patient can benefit from incentive spirometry, especially the elderly and those at increased risk for developing lung complications. The spirometer stays at the patient's bedside for hourly use while awake. Offer the spirometer to the patient each hour to ensure that it is used. Teach patients to do the following:

- Sit upright, at 45 degrees minimum, if possible.
- Take two normal breaths. Place mouthpiece of spirometer in mouth.
- Inhale until target, designated by spirometer light or rising ball, is reached, and hold breath for 3 to 5 seconds.
- Exhale completely.
- Perform 10 sets of breaths each hour.

Coughing moves secretions to prevent pneumonia. Teach patients how to cough effectively (Table 11.4). Give pain medication before coughing and offer reassurance that coughing should not harm the incision. Several sets of coughing are performed, if not contraindicated by the patient's condition (such as hernia repair or head injury), every 1 to 2 hours while the patient is awake.

Leg exercises, if not contraindicated, improve circulation and help prevent complications related to stasis of blood, such as emboli formation. Patients are told to lie down, raise the leg, bend it at the knee, flex the foot, extend the leg, and lower it to the bed. Each leg is exercised in sets of five. Foot circles are also done every hour while awake. Teach the patient to raise a leg slightly off the bed with toes pointed. Draw a circle in the air with the great toe, rotating to the right four times, then to the left. Repeat this five times and then do the same with the other foot.

Patients are taught that turning from side to side in bed is aided by bending the leg that is to be on top and placing a pillow between the legs to support the top leg. They are told, unless contraindicated, to use the bed rail to pull themselves over to the side. They are encouraged to deep breathe while turning instead of holding their breath to promote comfort.

To reduce the strain on the incision and to make it easier for patients to get out of bed, patients are instructed to turn to their side without pillows between their knees. Then

TABLE 11.4 TEACHING PATIENTS COUGHING TECHNIQUES

Procedure	Rationale
Have patient sit up and lean forward.	Promotes lung expansion and ability to generate forceful cough
Show patient how to splint incision with hands, pillow, or blanket.	Reduces incision pressure so it does not feel as if incision is opening
Have patient inhale and exhale deeply three times through mouth.	Helps expand lungs
Have patient take in deep breath and cough out the breath forcefully with three short coughs using diaphragmatic muscles. Take in quick deep breath through mouth, cough deeply, and deep breathe.	Generates forceful cough and expands lungs to help move secretions

they should place their hands flat against the bed and push up while swinging their legs out of bed and into a sitting position. Patients should be told to sit for a few minutes after changing position to avoid dizziness and falling. They should also deep breathe while sitting up to promote lung expansion.

DIAGNOSTIC TESTING. Patient preoperative diagnostic testing is based on the patient's age, medical history, assessment findings, and institutional protocols (Table 11.5). Abnormal findings are reported to the physician.

Preoperative Patient Admission

Upon admission for surgery, subjective and objective patient data are collected (Table 11.6). Ensure that patients have their contact lenses, glasses, or hearing aids for accurate communication. During the interview, note the patient's emotional reaction to surgery. If the patient is anxious, explore the cause of the anxiety and allow the patient to express concerns. Anxiety is a feeling of apprehension or uneasiness resulting from the uncertainties and risks associated with surgery, while fear, a feeling of dread from a source known to the patient, is an extreme reaction to surgery.

Nursing Process for Preoperative Patients Nursing Assessment/Data Collection

SUBJECTIVE DATA. During data collection, it is important to ask the patient if there have been any personal or family problems with anesthesia. A rare hereditary muscle disease, malignant hyperthermia, can predispose the patient to a serious life-threatening reaction to certain anesthetic agents (discussed later). Prior surgeries are also recorded.

MEDICATIONS. All medications (herbs and over-the-counter, prescription, and recreational drugs) that the patient takes must be reviewed. Alterations in drug dosages and routes of administration may be required. You should ensure

atelectasis: ateles—imperfect + ektasis—expansion

TABLE 11.5 PREOPERATIVE DIAGNOSTIC TESTS

Diagnostic Test	Purpose
Chest x-ray	Detect pulmonary and cardiac abnormalities
Oxygen saturation	Obtain baseline level and detect abnormality
Serum Tests	
Arterial blood gases	Obtain baseline levels and detect pH and oxygenation abnormalities
Bleeding time	Detect prolonged bleeding problem
Blood urea nitrogen	Detect kidney problem
Creatinine	Detect kidney problem
Complete blood cell count	Detect anemia, infection, clotting problem
Electrolytes	Detect potassium, sodium, chloride imbalances
Fasting blood glucose	Detect abnormalities, monitor diabetes control
Pregnancy	Detect early, unknown pregnancy
Partial thromboplastin time	Detect clotting problem
INR, prothrombin time	Detect clotting problem, monitor warfarin therapy
Type and cross match	Identify blood type to match blood for possible transfusion
Urine Tests	
Pregnancy	Detect early, unknown pregnancy
Urinalysis	Detect infection, abnormalities

INR = International normalized ratio.

that the patient clearly understands all medication instructions. For example, patients taking an anticoagulant such as warfarin (Coumadin) may be told by their physician to decrease or stop it several days before surgery to avoid bleeding problems during surgery. Many herbs can interfere with medications used during surgery or increase bleeding times. Patients may be instructed to stop certain herbs several days or weeks before surgery.

Diabetic patients on insulin are usually given instructions by the physician to either hold their insulin or take half of their normal dose of insulin the day of surgery. On the day of surgery, blood glucose monitoring may be done every 4 hours or as ordered to ensure that blood glucose levels are maintained within a desired range.

Patients on chronic oral steroid therapy cannot abruptly stop their medication even though they are told to take nothing by mouth (NPO) before or after surgery. Serious complications, such as circulatory collapse, can develop if steroids are stopped abruptly. The physician should order a patient's steroid therapy to be given by a parenteral route if the patient is NPO, so that it is not interrupted. You should ensure that the steroid therapy is ordered and continued for the patient via an alternate route.

Patients should be asked about the use of drugs such as cocaine, marijuana, or opioids because these drugs can interact with anesthesia or other medications. To obtain honest, accurate information, patients should be told of this potential

TABLE 11.6 NURSING ASSESSMENT OF THE PREOPERATIVE PATIENT

Subjective Data: Health History Questions

Demographic information: Name, age, marital status, occupation, roles?

History of condition for which surgery is scheduled: Why are you having surgery?

Medical history: Any allergies, acute or chronic conditions, current medications, pain, or prior hospitalizations?

Surgical history: Any reactions or problems with anesthesia? Previous surgeries?

Tobacco use: How much do you smoke? Pack-year history (number of packs per day × number of years)?

Alcohol use: How often do you drink alcohol? How much?

Coping techniques: How do you usually cope with stressful situations? Support systems?

Family history: Hereditary conditions, diabetes, cardiovascular, anesthesia problems?

Female patients: Date of last menses and obstetrical information?

Objective Data: Body System Review

Vital signs, oxygen saturation

Height and weight

Emotional status: calm, anxious, tearful, affect

Neurological: ability to follow instructions

Skin: color, warmth, bruises, lesions, turgor, dryness, mucous membranes

Respiratory: infection: cough; breath sounds; chronic obstructive pulmonary disease; respiratory rate, pattern, and effort; barrel chest

Cardiovascular: angina, myocardial infarction, heart failure, hypertension, valvular heart disease, mitral valve prolapse, heart rate and rhythm, peripheral pulses, edema, jugular vein distention

Gastrointestinal: bowel sounds, date of last bowel movement, abdominal distention, firmness, ostomy

Musculoskeletal: deformities, weakness, decreased range of motion, crepitation, gait, artificial limbs, prostheses.

interaction. Information and questions should be stated in a nonjudgmental manner. For example, you should ask, "How much alcohol do you drink daily or weekly?" instead of "Do you drink alcohol?" The first statement assumes that people drink alcohol. This allows the patient who does not drink to indicate none and the patient who does to state an amount rather than having to say yes and then give an amount upon further questioning. More accurate responses are given because this approach is viewed more positively by the patient who consumes alcohol. Another example would be to ask the patient, "What roles do drugs or alcohol play in your life?"

OBJECTIVE DATA. A physical assessment of body systems is performed. This information can highlight risk factors for surgery, determine the type of anesthesia to be used, and assist in planning interventions to reduce risk factors. A cough, cold, or fever is reported to the physician because surgery may be delayed until the patient recovers from an acute infection. Dentures, bridges, capped teeth, and loose teeth are documented because they can become dislodged during intubation (insertion of endotracheal breathing tube) for general anesthesia, causing complications.

Nursing Diagnosis, Planning, and Interventions

Anxiety or fear related to potential change in body image, hospitalization, pain, loss of control, and uncertainties surrounding surgery.

EXPECTED OUTCOME: Patient will state reduced anxiety or fear.

- Inform patients about procedures and surgical routines, *which helps reduce anxiety.*
- Allow patients to express their concerns to *allow inaccurate information to be corrected.*
- If patients express extreme anxiety or fear, inform the physician *as complications or even death could result. When fear is excessive, the physician may reschedule the surgery until the patient is better able to cope.*

Deficient knowledge related to lack of prior experience with surgical routines and procedures

EXPECTED OUTCOME: Patient will demonstrate understanding of surgical information and routines.

- Patient anxiety levels should be considered when providing explanations *as learning can be affected by high anxiety levels.*
- Identify knowledge deficiencies with the patient *so that he or she is motivated to learn.*
- Reinforce information provided prior to admission and new information to patients *to promote informed choice and increase self-care abilities. Teaching is caring in action and empowers patients to be a participant in their care.*
- Include the patient's family or caregivers in teaching sessions *so they can assist the patient through the surgical experience.*
- Use a variety of teaching methods (discussion, written materials and instructions, models, and videos) *to allow for different learning styles and to reinforce learning.*
- Individualize explanations *so the patient is not overwhelmed.*
- Use teaching methods that adapt to aging changes that may affect learning. *Box 11.3 Gerontological Issues describes methods to provide a positive learning experience for the elderly patient.*
- Document teaching and patient understanding.

Evaluation

The goal of decreased anxiety is achieved if the patient states and demonstrates that anxiety is relieved. If the patient is able to learn during teaching sessions, anxiety is not a barrier to learning.

The goal for correcting deficient knowledge is reached if the patient states understanding of the information presented and accurately performs return demonstrations of presented information.

Preoperative Consent

Before performing surgery, it is the physician's responsibility to obtain voluntary, written, informed consent from the

Box 11.3

Gerontological Issues

Considerations for Elderly Patient Teaching Sessions

Environmental considerations:

- Comfortable: anxiety free, quiet, appropriate temperature
- Correctly lit: small, intense lighting with nonglare, soft white light (not fluorescent)
- Private: no distractions, no background noise, turn off pagers

Presentation considerations:

- Assess readiness to learn.
- Assess comfort and safety needs.
- Use past experience and relate to new learning.
- Base learning on assessment data and current knowledge base.
- Use simple, understandable words and avoid medical jargon.
- Use legible audiovisual materials: large print, black print on white nonglare paper.
- If using colors, remember that older adults see red, orange, and yellow best; blue, violet, and green are more difficult to see.
- Perform ongoing assessment of energy level of patient.
- Answer questions as they occur.

Presenter considerations:

- Have positive attitude and belief in self-care promotion for older adults.
- Earn trust by being viewed as credible, positive role model.
- Maintain professional appearance.
- Use knowledge of aging changes in presentation:
 - Speak slowly in low tone.
 - Sit near patient for best visibility.
 - Ensure that prostheses are in place: glasses, hearing aids.
 - Allow patient increased response time and use memory aids such as pictures or diagrams.
 - Use touch appropriately to convey caring.
- Teach most important information first.
- Present one idea at a time.
- Provide instruction using multiple senses (vision and hearing).
- Provide repetition.
- Ask for feedback to ensure comprehension.
- Provide feedback and positive reinforcement.

patient. The consent gives legal permission for the surgery and has two purposes. It protects the patient from unauthorized procedures, and it protects the physician, anesthesiologist, hospital, and hospital employees from claims of

performing unauthorized procedures. A signed consent is needed for all invasive procedures, anesthesia, blood administration, and radiation or cobalt therapy.

Informed consent involves three elements:

1. The physician must tell the patient in understandable terms about the diagnosis, the proposed treatment and who will perform it, the likely outcome, possible risks and complications of treatment, alternative treatments, and the prognosis without treatment. If the patient has questions before signing the consent, the physician must be contacted to provide further explanation to the patient. It is not within the nurse's scope of practice to provide this information.
2. The consent must be signed before analgesics or sedatives are given because patients must demonstrate that they are informed and understand the surgery.
3. Consent must be given voluntarily. No persuasion or threats can be used to influence the patient. The patient can withdraw consent at any time, even after the consent form has been signed.

To ensure that patients are truly informed prior to signing a consent, in some institutions patients must take and pass a knowledge quiz, which can be given verbally. If they do not pass the quiz, then further explanation is required by the physician. Additionally, in the surgical holding area, patients verbally reconfirm. They are asked, "Do you still remember what you were told about your surgery?"

It is often your role to obtain and witness the patient's or authorized person's signature on the consent form (Fig. 11.2). You should ensure that the person signing the consent form understands its meaning and that it is being signed voluntarily. If the patient is unable to read, the entire consent must be read to the patient before it is signed. Patients are unable to give consent if they are unconscious, are mentally incompetent, are minors, or have received analgesics or

FIGURE 11.2 Nurse is witnessing signature of patient on surgical consent.

drugs that alter central nervous system function within time frames specified by agency policy. Consent may be obtained in any of these cases from parents, next of kin, or legal guardians.

NURSING CARE TIP

Witnessing a Consent

As the patient's advocate you should ensure, before the consent is signed, that the patient is informed about the surgery and has no further questions for the physician.

If the patient does have questions, the consent should not be signed and the physician should be contacted to answer the patient's questions.

Your signature as a witness on a consent form indicates that you observed the informed patient or patient's authorized representative voluntarily sign the consent form. It does not mean that you informed the patient about the surgical procedure; that is the responsibility of the physician.

In a medical emergency, the patient may not be able to give consent. In this case, the next of kin or legal guardian may give telephone consent, or a court order can be obtained. If time does not permit this, the physician documents the need for treatment in the chart as necessary to save the patient's life or avoid serious harm, according to state law and institutional policy.

Preparation for Surgery

Preoperative Checklist

A preoperative checklist is usually completed and signed by the nurse (per agency policy) before the patient is transported from the unit to surgery (Fig. 11.3). The checklist provides guidance for preoperative preparation of the patient:

- An identification band is placed on the patient. A hospital gown is given to the patient to wear. Underwear is removed, depending on the type of surgery.
- Vital signs are taken and recorded as baseline information and to assess patient status.
- Makeup, nail polish, and artificial nails (if applicable) are removed to allow assessment of natural color and pulse oximetry for oxygenation status during surgery.
- Removal of hair pins, wigs, and jewelry prevents loss or injury. Rings such as wedding rings are taped in place if the patient does not want to take them off, except if the ring is on the operative side (arm or chest surgery), as edema may occur.
- Dentures, contact lenses, and prostheses are removed to prevent injury. Some patients are concerned about body image and do not want family

- members to see them without dentures or makeup. Remove dentures after the family goes to the waiting room and insert them before the family sees the patient postoperatively.
- Glasses and hearing aids go with patients to surgery if they are unable to communicate without them. Label them with the patient's name and document where they go.
 - All orders, diagnostic test results, consents, and history and physical (required on the chart) are reviewed for completion and documented on the checklist.

- Patient valuables are recorded and given to a family member or locked up per institutional policy by the nurse.
- Antiembolism devices are applied if ordered.
- Patients are asked to void before sedating preoperative medications are given, unless a urinary catheter is present, to prevent injury to the bladder during surgery.

Preoperative Medications

The final preparation before surgery is giving preoperative medications at the time ordered, usually 1 hour before, or on

TABLE 11.7 PREOPERATIVE MEDICATIONS

Category	Medication	Purpose
Narcotics	Morphine sulfate Fentanyl (Sublimaze) Meperidine (Demerol)	Analgesia; enhancement of postoperative pain relief
Antianxiety and sedative hypnotics	Diazepam (Valium) Hydroxyzine hydrochloride (Vistaril) Lorazepam (Ativan) Midazolam (Versed) Phenobarbital sodium (Luminal sodium)	Sedation; anxiety reduction
Anticholinergic	Atropine sulfate Glycopyrrolate (Robinul) Scopolamine hydrobromide	Secretion reduction
Antiemetic	Droperidol (Inapsine) Ondansetron (Zofran) Metoclopramide (Reglan) Promethazine hydrochloride (Phenergan)	Control nausea and vomiting; may be effective into the postoperative period
Histamine (H ₂) antagonist	Cimetidine (Tagamet) Famotidine (Pepcid) Ranitidine (Zantac)	Reduction of acidic gastric secretions in case aspiration occurs either silently or with vomiting.
Alkalinizing agent	Sodium citrate and citric acid (Bicitra)	Prevention of an asthmalike attack, pneumonitis, pulmonary edema, or severe hypoxia
Antibiotic	Cefazolin (Ancef) Cefoxitin (Cefotan) Ampicillin (Omnipen)	Prevention of postoperative infection

call to surgery (surgery calls to instruct that it is time to give the drugs) (Table 11.7). All medications administered are documented. The bed rails are raised for safety and the patient is instructed not to get up alone after medications are given.

Transfer to Surgery

When the surgery department is ready, the patient is taken to the surgical holding area on a stretcher (Fig. 11.4). The patient's chart, inhaler medications for those with asthma, and glasses or hearing aids also go to the surgical holding area. The patient can be accompanied by family members.

During surgery, the family waits in the surgical waiting area, which is a communication center where the family is kept informed regarding the patient's status. The physician

calls the family there when surgery is over. Families may be given beepers so that they can walk outside or to other areas of the hospital and still be reached.

After Transfer

After the patient goes to surgery, prepare the patient's room and necessary equipment so it is ready for the patient's return (Table 11.8).

INTRAOPERATIVE PHASE

When the patient is transferred to the operating table, the next phase of the perioperative period, the intraoperative phase, begins (Fig. 11.5). Surgery may take place in a hospital operating room (OR) or free-standing ambulatory or outpatient surgical centers (Fig. 11.6). Additionally, surgery is performed in physician's offices, cardiac catheterization laboratories, radiology centers, emergency rooms, and specialized units that perform endoscopy procedures.

The OR team members must perform a sterile surgical hand scrub to reduce the amount of microorganisms on their hands and arms. An antimicrobial soap scrub is used to reduce the chances of microorganism contamination. Jewelry (e.g., watches, rings, bracelets) is also removed. Fingernails are kept short and clean. Artificial nails and colored nail polish are not permitted. Gloves are worn by the OR team to keep the surgical field sterile.

The OR is designed to enhance **aseptic** technique. Clean and contaminated areas are separated. Special ventilation systems control dust and prevent air from flowing into

FIGURE 11.4 Surgical holding area.

TABLE 11.8 POSTOPERATIVE PATIENT HOSPITAL ROOM PREPARATION

After patient transfer to surgery, the nurse should prepare the patient's room for the patient's postoperative care needs to be ready for patient's return from the postanesthesia care unit.

Preparation	Rationale
	Bed
Bed linens should be clean and are changed if used before surgery by patient.	Reduces contamination of surgical wound
Place disposable, absorbent, waterproof pads on bottom sheet if drainage is expected.	Protects linen from wetness and soiling so a patient in pain does not have to be disturbed for linen change.
Apply lift sheet on bed of patient needing assistance with repositioning.	Makes lifting and turning easier for patient and nurse.
Have extra blankets available.	Patient may be cold or have a low temperature.
Fanfold top cover to end of bed or to side of bed away from patient transfer side.	Bed ready to receive patient on transfer from cart to bed. Allows covers to be easily pulled up over patient.
Obtain extra pillows as needed for positioning, elevating extremities, splinting during coughing.	Pillows help maintain position when patient is turned, elevate operative extremities for comfort and swelling reduction, or splint an incision during coughing.
	Equipment
Obtain IV pole.	Surgical patients have IV infusions postoperatively.
Have emesis basin at bedside.	Nausea or vomiting may occur, especially after movement during transfer.
Have tissues and washcloths in room.	Promotes comfort: washing face or a cool cloth on forehead.
Have urinal or bedpan available in room.	Patients may be unable to get out of bed for first voiding.
Prepare suction setup for tracheostomy, nasogastric tube, or drains as ordered.	Suction may be ordered related to surgical procedures: Sterile suction: tracheostomy Nasogastric tube: thoracic, abdominal, gastrointestinal surgery T-tube: cholecystectomy
Have oxygen set up as needed.	After tracheostomy, patients wear humidified oxygen mask.
Obtain special equipment as indicated by the surgical procedure.	Institutional policy and physician orders may require specialized equipment. Examples: Jaw surgery: suction, wire cutters, tracheostomy tray Tracheostomy: suction, extra tracheostomy set, tracheostomy care supplies Transurethral resection of prostate: irrigation supplies.
Have vital sign equipment available.	Promotes ability to promptly obtain vital signs.
	Documentation Forms
Obtain agency postoperative documentation forms and place in room	Promotes timely and accurate documentation of patient data.

IV = Intravenous.

FIGURE 11.5 Operating room. Anesthesia equipment is on the left.

the OR from hallways. The temperature and humidity in the room are controlled to discourage bacterial growth. Everyone entering the OR wears surgical scrubs, shoe covers, caps, masks, and goggles to protect the patient from infection and themselves from bloodborne pathogens. Traffic in and out of the OR is limited. Strong disinfectants are used to clean the OR after each surgical case, and instruments are sterilized.

Before the patient arrives in surgery, a nursing plan of care is developed from preadmission assessment data. The OR is prepared based on the plan of care (Box 11.4 Nursing Care Plan). Attention is given to safety needs of the patient. Special needs are addressed, such as a tall patient's need for longer table length or an elderly patient's positioning needs resulting from osteoporosis. A surgical case cart containing sterile instruments required for the patient's case is prepared

FIGURE 11.6 Operating room in use. Anesthesia is on the right.

ahead of time. Items such as needles and sponges are counted before surgery and again before closure of the incision to account for all of them and ensure that none has been left in the patient. To ensure safety, electrical equipment is checked for proper functioning.

Health-Care Team Member Roles

- Physician (medical doctor [MD], doctor of osteopathy [DO], oral surgeon, or podiatrist)
- Surgical (first) assistant: assists the physician and is either another physician, a specially trained registered nurse, or a physician's assistant

Box 11.4

Intraoperative Nursing Diagnoses and Expected Outcome

- Risk for perioperative-positioning injury related to positioning, chemicals, electrical equipment, and effect of being anesthetized

Free from injury

- Risk for impaired skin integrity related to chemicals, positioning, and immobility

Skin integrity is maintained

- Risk for deficient fluid volume related to NPO status and blood loss

Maintains blood pressure, pulse, and urine output within normal limits

- Risk for infection related to incision and invasive procedures

Is free of symptoms of infection

- Pain related to positioning, incision, and surgical procedure

Reports pain is relieved to satisfactory level

- Anesthesiologist: physician who specializes in anesthesia and supervises certified registered nurse anesthetists in the operating room
- Certified registered nurse anesthetist (CRNA): registered nurse trained and certified in the administration of anesthesia, usually at the master's degree level
- Registered nurse (RN): circulates in OR; roles include being patient's advocate, planning care, protecting patient safety, monitoring patient positioning, checking vital signs and making patient assessment, reducing patient's anxiety, monitoring sterility during surgery, preparing skin before incision, managing equipment such as by making sponge counts, documenting the procedure, and aiding health team communications
- Surgical (second assistant) technician: assists physician (may be an RN, LPN/LVN, or surgical technologist)

Patient Arrival in Surgery

The nurse greets the patient; verifies the patient's name, age, allergies, surgeon performing the surgery, informed consent, surgical procedure (right site, especially right or left when applicable), and medical history; answers questions; and alleviates anxiety. The patient is introduced to the anesthesiologist and CRNA, who also verify patient information and explain the type of anesthesia that is to be used. All surgical patients have intravenous (IV) fluids started. The patient may also receive prophylactic antibiotics. Taking a time out for everyone to stop and verify correct patient information can prevent adverse events.

SAFETY TIP

Eliminate wrong-site, wrong-patient, wrong-procedure surgery.

Create and use a preoperative verification process, such as a checklist, to confirm that appropriate documents (e.g., medical records, imaging studies) are available.

Implement a process to mark the surgical site and involve the patient in the marking process.

(2006 National Patient Safety Goals from www.jcaho.org)

As a patient enters the OR, he or she should be told what to expect:

- "The room may feel cool, but you can request extra blankets."
- "There is a lot of equipment in the room, including a table and large, bright overhead lights."

- “Several health-care team members will introduce themselves to you.”
- “Your physician will greet you.”

The patient is assisted onto the operating table, and a safety strap is carefully applied. Monitoring equipment is applied and readings recorded. Then the anesthesia provider begins anesthesia. When the anesthesia provider gives permission, the patient is carefully positioned to prevent pressure points that could cause tissue or nerve damage. Any necessary tubes that are not already in place, such as a nasogastric tube or urinary catheter, are inserted by the RN.

Patient allergies are rechecked. If the patient requires body hair removal, dry shaving with a safety razor should be avoided because of the potential for microabrasions and colonization by microorganisms. Hair should be removed with electric clippers or a depilatory, which is less harmful to the skin. Then a skin prepping solution that the patient is not allergic to, such as povidone-iodine, is used to cleanse the skin. (This may be done in preop holding or in surgery depending on the institution.) A large area surrounding the operative site is scrubbed to allow for extension of the incision. The scrub is completed in a circular motion from inside to outer edge. If an allergic reaction to the solution occurs, it can cause skin redness and blistering wherever the solution was used. After the skin is scrubbed, a sterile drape is applied with the incisional area left exposed.

SAFETY TIP

Improve the safety of using medications.

Label all medications, medication containers (e.g., syringes, medicine cups, basins), or other solutions on and off the sterile field in perioperative and other procedural settings.

(2006 National Patient Safety Goals from www.jcaho.org)

Anesthesia

Anesthesia is used for surgery to prevent pain and allow the procedure to be done safely. The type of anesthesia and the anesthetic agents are ordered by the anesthesia provider with input from the patient and physician (Box 11.5 Cultural Considerations).

There are two types of anesthesia: general and local (regional). General anesthesia (GA) causes the patient to lose sensation, consciousness, and reflexes. GA acts directly on the central nervous system. Local anesthesia blocks nerve impulses along the nerve where it is injected, resulting in the loss of sensation to a region of the body without the loss of consciousness.

General Anesthesia

General anesthesia is commonly given by an IV or inhalation route. GA is chosen when patients are anxious or do not

Box 11.5

Cultural Considerations

Care of the Patient Having Surgery

Chinese people show a greater increase in heart rate in response to atropine than Caucasian persons. Thus, the nurse needs to carefully monitor the pulse after atropine is given as a preoperative medication. Additionally, Chinese people are more sensitive to the sedative effects of diazepam (Valium) and require lower doses. Thus, the nurse needs to carefully monitor the Chinese patient for untoward effects of diazepam (Valium).

want local anesthesia, when the surgical procedure will take a long time and there is a need for muscle relaxation, or when the patient is unable to cooperate, as in head injury, muscle disorders, or impaired cognitive function.

INTRAVENOUS AGENTS. To begin most general anesthesia, the patient is induced (which means, anesthesia is caused) with a short-acting IV agent that provides a rapid, smooth **induction** (the period from when the anesthetic is first given until full anesthesia is reached). Because these agents last only a few minutes, they are used along with inhalation agents, which maintain anesthesia during surgery. After induction, the patient is intubated with an endotracheal (ET) tube to provide mechanical ventilation and anesthesia (Fig. 11.7).

INHALATION AGENTS. Maintenance of anesthesia is accomplished by using inhalation agents. These agents are delivered, controlled, and excreted through mechanical ventilation. Inhalation agents and the ET tube can be

FIGURE 11.7 Endotracheal tube with cuff inflated.

induction: inductio—to lead in

irritating to the respiratory tract. Complications that can occur from their use include laryngospasm (sudden violent contraction of the vocal cords), laryngeal edema, irritated throat, or injury to the vocal cords. When the tube is removed, the nurse should closely monitor the patient and be prepared to provide respiratory support and assist with reintubation if complications arise.

ADJUNCT AGENTS. An **adjunct** agent is a medication used along with the primary anesthetic agents. These medications can include narcotics to control pain, muscle relaxers to avoid movement of muscles during surgery, antiemetics to control nausea or vomiting, and sedatives to supplement anesthesia.

SAFETY TIP

Reduce the risk of surgical fires.

Educate staff, including operating licensed independent practitioners and anesthesia providers, about how to control heat sources and manage fuels, and establish guidelines to minimize oxygen concentration under drapes.

(2006 National Patient Safety Goals from www.jcaho.org)

Malignant Hyperthermia

Malignant hyperthermia (MH) is a rare hereditary muscular disease that can be triggered by some types of general anesthetic agents. Obtaining a history of anesthetic problems in the patient or family members can help detect the potential for development of this condition so that precautions can be taken. Those with a history of heat stroke are at increased risk for MH. A muscle biopsy can also diagnose this problem. Patients with this condition can undergo surgery safely with careful planning and choice of anesthetic agents by the anesthesia provider.

In MH, there is increased metabolism in muscles, which produces a very high fever and muscle rigidity, as well as tachycardia, tachypnea, hypertension, dysrhythmias, hyperkalemia, metabolic and respiratory acidosis, and cyanosis. MH is life threatening, so immediate treatment is required or death results. Surgery is stopped and anesthesia discontinued immediately. Oxygen at 100% is given. The patient must be cooled with ice and infusions of iced solutions. Dantrolene sodium (Dantrium), a muscle relaxant that relieves the muscle spasms, is the most effective medication for treating malignant hyperthermia. Dantrolene sodium is kept readily available in the OR and administered according to the treatment protocol of the Malignant Hyperthermia Association of the United States. For more information about malignant hyperthermia, visit www.mhaus.org.

Local (Regional) Anesthesia

Local anesthesia is selected when the patient is not anxious, can tolerate the local agent, and is not required by the sur-

gical procedure to be unconscious or relaxed. It is a good choice for some outpatient procedures or when the patient has not been NPO. The anesthesia provider, or sometimes the physician, administers local anesthesia.

Local anesthetic agents may include bupivacaine hydrochloride (Marcaine), lidocaine (Xylocaine), and dibucaine (Nupercainal). Topical administration places the agent directly on the surgical area. Local infiltration is achieved by injecting the medication into the tissue where the incision is to be made. A regional block is done by injecting the local agent along a nerve that carries impulses in the region where anesthesia is desired. There are several types of regional blocks. A nerve block is the injection of a nerve at a specific point. A Bier block is done by placing a tourniquet on an extremity to remove the blood and then injecting the local agent into the extremity. A field block is a series of injections surrounding the surgical area. A spinal or epidural block is injection of a local agent into an area around the spinal nerves.

SPINAL AND EPIDURAL BLOCKS. Injection of a local agent into the subarachnoid space produces spinal block (Fig. 11.8). Epidural block occurs when the local agent is injected into the epidural space. Spinal and epidural blocks are used mainly for lower extremity and lower abdominal surgery. Both motor and sensory function is blocked. The patient must be carefully monitored for complications. Hypotension results from sympathetic blockade causing vasodilation, which reduces venous return to the heart and therefore reduces cardiac output. Respiratory depression results if the block travels too far upward. As the block

FIGURE 11.8 Injection of spinal anesthesia. (A) Epidural anesthesia. (B) Epidural catheter. (C) Spinal anesthesia.

wears off, patients feel as if their legs are very heavy and numb. This is normal, and reassurance should be offered to the patient that this type of feeling does not last after the block wears off.

Complications. A postdural puncture headache may occur in 10% to 40% of patients caused by leakage of cerebrospinal fluid (CSF) from the needle hole in the dura that does not close when the needle is withdrawn. The use of a small-gauge spinal needle (less than 25 gauge) helps prevent headaches. Photophobia or double vision may also be present. Postanesthesia orders usually include methods to help reduce the pain of a headache, including positioning the patient flat and forcing fluids.

If a spinal headache develops, it may be severe and can last for weeks. Lying flat and prone (on abdomen) may help relieve the pain of the headache. Adequate fluid intake and analgesics may be ordered, and steroids may be helpful. If the headache continues, a blood patch treatment can be used to stop the CSF leakage. This treatment can be done by the anesthesiologist at the bedside or in the postanesthesia care unit (PACU). To create a blood patch, approximately 10 mL of the patient's own blood is injected into the epidural space at the previous puncture site. The injected blood forms a clot that "patches" the dural hole to prevent further CSF leakage. Pain relief should occur quickly if the patch is successful. Blood patch treatment can be repeated.

Conscious Sedation

Conscious sedation (sometimes called twilight sleep) is purposeful, minimal sedation that does not cause the complete loss of consciousness during selected medical, dental, or diagnostic procedures. Medications such as sedatives, hypnotics, and opioids are given to produce conscious sedation. Selection of patients who are eligible for conscious sedation is based on the procedure, the patient's general health, patient preference, and physician preference. Examples of short procedures for which conscious sedation is used are dental procedures, endoscopy (EGDs or colonoscopy), cardiac catheterization, cardioversion, and closed fracture reduction. During conscious sedation, patients are comfortable, respond purposefully, and maintain their own patent airway. Medications are ordered by the physician and usually administration by a specially trained registered nurse, as defined by agency and state scope of nursing practice.

A signed informed consent is obtained. Then an IV for medications and fluids is inserted before the procedure. Patient monitoring is done every 5 minutes to check vital signs, electrocardiogram, and oxygen saturation. Changes are reported to the physician. Oxygen may be given by nasal cannula or mask. Emergency equipment (e.g., airway suction, defibrillator, drugs) is on standby, according to advanced cardiac life support (ACLS) protocols.

After the procedure, the patient awakens easily and quickly. The patient is monitored every 15 to 30 minutes for response to the procedure and the drugs until the patient is fully awake and stable. The patient is ready for discharge when vital signs return to baseline and are stable, oral fluids

are retained, he or she has voided (if applicable), and written and oral discharge teaching is given to both the patient and the responsible adult to whom the patient is being discharged. The responsible adult and the patient must sign the instructions. Instructions include the following: an adult must drive the patient home and provide a safe environment; the patient must not and will not drive or operate heavy machinery or sign legal documents for 24 hours.

LEARNING TIP

In comparison with general anesthesia, conscious sedation:

- Is less invasive.
- Requires less medication.
- Causes less depression of the cardiovascular and respiratory systems.
- Allows the patient to more quickly return to a wakeful state.

Transfer from Surgery

When surgery is completed and anesthesia stopped, the patient is stabilized for transfer. After local anesthesia, the patient may return directly to a nursing unit. After general and spinal anesthesia, the patient goes to the PACU or, in some cases, the intensive care unit (ICU).

Patient safety, which is always a priority, is an important concern at this time. The patient is never left alone. Ensuring a patent airway and preventing falls and injury from uncontrolled movements are priorities. The anesthesia provider and OR nurses transfer the patient to the PACU and monitor the patient until the perianesthesia nurse is able to receive the report and assume care of the patient. This begins the final patient perioperative phase, the postoperative period.

SAFETY TIP

Improve the effectiveness of communication among caregivers.

Implement a standardized approach to "hand off" communications, including an opportunity to ask and respond to questions. (2006 National Patient Safety Goals from www.jcaho.org)

POSTOPERATIVE PHASE

The postoperative phase begins when the patient is admitted to the PACU or a nursing unit and ends with the patient's postoperative evaluation in the physician's office (Fig. 11.9). The family is updated on the patient's status by the physician as the patient is admitted to the PACU.

FIGURE 11.9 Postanesthesia care unit.

Admission to the Postanesthesia Care Unit

The postanesthesia nurse's goal is to promote safe recovery from anesthesia. The nurse's role in the PACU begins by receiving a patient report from the OR nurse and anesthesia provider. When the patient is admitted to the PACU, an admission assessment is done. The priority areas of patient assessment are the following:

- Respiratory status and patency of airway
- Vital signs including SaO_2
- Level of consciousness and responsiveness
- Surgical site incision/dressing/drainage tubes
- Pain level and pain management

Oxygen by nasal cannula or mask is given if the patient has had general anesthesia, or as ordered. Some patients who are still intubated may require mechanical ventilation. Continuous monitoring is done on all patients for ECG, pulse oximetry, and blood pressure measurements. The surgical site incision or dressing is assessed. Drainage and **hematoma** formation are documented and reported. Urinary catheter, drains, and nasogastric tubes are checked for function and patency as applicable.

The patient's body temperature is measured on admission to the PACU, and then blankets heated in blanket warmers are applied. If the patient's temperature is below normal, a warming blanket that can be set to a desired temperature is applied. Body temperature may be decreased as a result of a cool OR environment, anesthesia, cool IV solutions, and incisional openings, which allow heat loss. Patient recovery is aided by avoiding a decrease in body temperature during surgery. Using forced warm air before surgery to warm the patient, rather than warm blankets, has been shown to maintain body temperature best upon arrival in the PACU. Be aware that the elderly (and infants) are at increased risk of **hypothermia**. Temperature is measured again before PACU discharge because a normal body temperature is usually one of the discharge criteria.

hematoma: heimatós—blood + oma—tumor

Shivering may occur from anesthesia or as a result of being cold. It is important to control shivering because it increases oxygen consumption 400% to 500%. Meperidine (Demerol) is effective in relieving shivering when anesthesia is the cause. If the patient is cold, raising the body temperature is helpful to decrease shivering. It is important to provide supplemental O_2 during the episode of shivering and until the SaO_2 is normal.

See Box 11.6 Perianesthesia Nursing Responsibilities.

It is essential for nurses to wash their hands between patients in the PACU. Vital signs and assessment are done at least every 5 to 15 minutes, IV fluid infusion is maintained, and IV analgesics are given for pain as needed. Antiemetics are administered for nausea or vomiting. Deep breathing and coughing, if not contraindicated by the surgical procedure, are encouraged. Coughing increases pressure, which could cause harm to some surgical areas. Surgical procedures that prohibit coughing include hernia repair; eye, ear, intracranial, jaw, and plastic surgery. If the patient is no longer NPO, ice chips or sips of water may be offered when the patient is fully awake to promote comfort for a dry mouth. If ordered, postoperative therapies such as patient-controlled analgesia (PCA), which allows patients to administer their own pain medication (see Chapter 9), or continuous passive motion machines for joint replacement surgeries are begun in the PACU.

Nursing Process for Postoperative Patients in PACU

Various postoperative complications may occur in the PACU or later in the postoperative phase. The causes of these complications may be the surgical procedure, anesthesia, blood and fluid loss, immobility, unrelieved pain, or other diseases the patient may have. Nursing care focuses on preventing, detecting, and caring for these complications.

Respiratory Function

ASSESSMENT/DATA COLLECTION. Normal respiratory function can be altered in the immediate postoperative period by airway obstruction, hypoventilation, secretions, laryngospasm, or decreased swallowing and cough reflexes.

Box 11.6

Perianesthesia Nursing Responsibilities

- Airway maintenance
- Vital signs
- Respiratory assessment
- Neurological assessment
- Surgical site status
- General assessment
- Patient safety
- Monitoring anaesthetic effects
- Pain relief
- Assessing PACU discharge readiness

Respiratory function assessment includes respiratory rate, depth, ease, and pattern. Breath sounds, chest symmetry, accessory muscle use, and sputum are also observed.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Ineffective breathing pattern related to anesthesia, pain, and analgesic/sedative medications

EXPECTED OUTCOME: Patients will maintain normal SaO_2 levels.

- Maintain oxygen therapy as ordered on all general anesthesia patients. *Hypoventilation can be an effect of anesthesia medications or analgesics, decreased level of consciousness, or an incision in the thorax causing painful respirations.*
- Encourage deep breathing to expand the lungs.
- Give analgesics carefully to promote deep breathing but avoid respiratory depression.
- Maintain CPAP/BiPap as needed for those with sleep apnea. *Patients with sleep apnea may bring their CPAP/BiPap machines with them for use.*
- Report respiratory depression to the anesthesiologist for prompt treatment

Ineffective airway clearance related to obstruction, anesthesia medications, and secretions

EXPECTED OUTCOME: Patients will have patent airway at all times.

- Ensure that patients maintain a patent airway as airway obstruction is usually caused from relaxed muscles allowing tongue to block the pharynx in patients who have a decreased level of consciousness.
- Use jaw-thrust method to manually open patient's airway if patient has snoring respirations and has not completely emerged from anesthesia.

Risk for aspiration related to depressed cough and gag reflexes and reduced level of consciousness

EXPECTED OUTCOME: Patients will have clear lung sounds.

- Position patients on their side, unless contraindicated, to protect airway until they are awake.
- Have suction equipment always available to clear secretions or emesis.

EVALUATION. The goal for ineffective airway clearance and aspiration is achieved if the patient's airway remains patent and lung sounds remain clear. The goal for ineffective breathing pattern is met if the patient's respiratory rate is within normal limits, no dyspnea is reported, and arterial blood gases are within normal limits.

Cardiovascular Function

ASSESSMENT/DATA COLLECTION. Alterations in cardiovascular function can include hypotension, dysrhythmias, and hypertension. Hypotension can be the result of blood and fluid volume loss or cardiac abnormalities. Shock can result from significant blood and fluid volume loss or from sepsis (see Chapter 8). Dysrhythmias may occur from hypoxia,

altered potassium or magnesium levels, hypothermia, pain, stress, or cardiac disease. New-onset hypertension can develop from pain, a full bladder, or respiratory distress. Cardiovascular function assessment includes heart rate, blood pressure, ECG, and skin temperature, color, and moistness. Vital signs are compared with baseline readings to determine if they are normal. Tachycardia, hypotension, pale skin color, cool, clammy skin, and decreased urine output indicate hypovolemic shock, which requires reporting and prompt treatment.

Nursing Diagnosis, Planning, and Implementation Deficient fluid volume related to blood and fluid loss or NPO status

EXPECTED OUTCOME: Patients will maintain blood pressure, pulse, and urine output within normal limits.

- Check dressings and incisions for color and amount of drainage to detect fluid loss.
- Maintain IV fluids at ordered rate to replace lost fluids but avoid fluid overload.
- Monitor intake and output to detect imbalances.

EVALUATION. The goal for deficient fluid volume is met if vital signs and urine output are within normal limits.

NURSING CARE TIP

Tachycardia: An Early Warning Sign

Tachycardia is a compensatory mechanism designed to provide adequate delivery of oxygen in times of altered function. It is usually the earliest warning sign that an abnormality is occurring. It should be a red flag to assess the patient and ask yourself what this particular patient is likely to be experiencing that is compromising oxygenation, allowing you to begin prompt treatment.

PATIENT CONDITION	POSSIBLE CAUSES OF COMPROMISED OXYGENATION
Postoperative patient	Hemorrhage, respiratory depression, pain
Myocardial infarction patient	Cardiogenic shock, pain
Respiratory patient	Respiratory distress
Trauma patient	Hemorrhage, severe pain

Neurological Function

Until its effects wear off, anesthesia can alter neurological function. Patients may arrive in the PACU awake, arousable, or sleeping. If patients are sleeping, they should become more alert during their stay in the PACU. As emergence from anesthesia occurs, patients may become wild or agitated for a short period. This is referred to as emergence delirium. During this time it is important to provide safety measures

such as side rails and restraints with restraint protocols followed to protect IV lines and keep endotracheal tubes in place. Once resolved, the patient returns to a calm state and has no recollection of the episode. Movement, sensations, and perceptions may also be altered by anesthesia. Movement is the first function to return after spinal anesthesia.

For geriatric patients, it is important to review their history to understand if they have any cognitive or neurological deficits. Confused patients may be agitated or frightened when they awaken. It is helpful to know how caregivers normally communicate with the patient. You should understand that the patient may not be able to report pain or follow commands. If possible, it may be helpful to have a familiar relative or caregiver with the patient in the PACU to calm him and help him communicate. You should watch for nonverbal pain cues such as moaning, grimacing, rubbing an area, and restlessness. If patients have limited movements or sensations before surgery, you should know this to obtain an accurate assessment of anesthetic effects.

ASSESSMENT/DATA COLLECTION. A neurological assessment includes level of consciousness; orientation to person, place, time and event; pupil size and reaction to light; and motor and sensory function.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Disturbed sensory perception related to decreased level of consciousness, amnesiac effects of anesthesia, or spinal anesthesia

EXPECTED OUTCOME: Patients will maintain safety and be free from injury.

- All patient data are verified until patients are awake and can communicate *to prevent errors.*
- Maintain patients' safety with side rails and extremities positioned in proper alignment and protected *until patients are fully awake or extremity movement and sensation return following spinal anesthesia.*
- Tubes, dressings, and IVs are secured and observed *to prevent dislodgement.*
- Provide orientation explanations as patients awaken and repeat until amnesiac anesthesia effects are no longer present. Examples of explanations include: "Mr. Smith, surgery is over; you are in the recovery room." "Your family is waiting for you and knows you are in the recovery room." "The doctor spoke with your family and told them how you are doing."

EVALUATION. The goal for disturbed sensory perception is met if the patient remains free from injury.

Pain

ASSESSMENT/DATA COLLECTION. If patients are awake, they are asked to rate the presence of pain using a scale, such as 0 to 10, a pain scale using color, or pictures that rate pain. The location and character of the pain are documented. When patients are not fully awake, vital signs and nonverbal indications of pain should be monitored. Nonverbal indications of pain can include abnormal vital signs, restlessness, moaning, grimacing, rubbing, or pulling at specific areas or equipment.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Pain related to tissue damage (mechanical [incision])

EXPECTED OUTCOME: The patient will report that pain is relieved at a satisfactory level.

- Monitor patient pain *as pain may result from surgical procedure, movement, deep breathing, anxiety, full bladder, positioning during surgery, nasogastric tubes, catheters, IVs, ET tubes, or prior medical conditions such as arthritis, cancer, or back pain.*
- Give IV narcotic analgesics promptly *for their rapid onset.*
- Begin PCA as ordered, *as it is started in PACU.*
- Reposition the patient, provide warmth, and empty full bladder *to help alleviate pain.*
- Play music in PACU, such as nature sounds or music by Mozart, dim lights, and reduce room noise *to help alleviate pain.*

EVALUATION. The goal for pain is met if patients report a decreased level of pain that is satisfactory to them. For example, the patient reports pain of 10 on a scale of 0 to 10. You medicate the patient, and 30 minutes later the patient rates pain as 2 on a scale of 0 to 10. The patient indicates that 2 is an acceptable pain level, so the goal is achieved.

Family Visitation

Family visitation in the PACU has been shown to be helpful to patients and their families. Allowing family visitation varies by hospital. Patients and families should be educated about the expectations for family visitation to keep it safe for the patient. During visitation, confidentiality of all patients must be ensured according to HIPAA (Health Insurance Portability and Accountability Act of 1996). Some patients do not want the surgical procedure revealed to their spouse or any family members.

Discharge from the Postanesthesia Care Unit

The length of stay in the PACU if the patient remains stable is normally about 1 hour. A postanesthesia recovery scale is used to score the patient's readiness to be discharged. The scale rates categories such as respiration, oxygen saturation, level of consciousness, activity, and circulation. The anesthesiologist discharges the patient for transfer to a nursing unit or home when discharge criteria are met (Table 11.9). The patient may be transferred to the ICU if patient status and/or frequent or invasive monitoring is needed.

Transfer to Nursing Unit

The perianesthesia nurse gives a report of the patient's condition to the unit nurse when the patient is transferred to the nursing unit. The patient is moved into bed on the nursing unit with assistance to prevent dislodging IVs, tubes, drains, or dressings. After patients are placed in bed, the following safety interventions are performed:

- The bed is placed in its lowest position, with the side rails raised.

TABLE 11.9 DISCHARGE CRITERIA FOR POSTANESTHESIA CARE UNIT OR AMBULATORY SURGERY

Vital signs stable
Patient awake or at baseline level of consciousness
Drainage or bleeding not excessive
Respiratory function not depressed
Oxygen saturation above 90%
Additional Criteria for Ambulatory Surgery
No nausea or vomiting
No IV narcotics within last 30 minutes
Voided if required by surgical procedure or ordered
Is ambulatory or has baseline mobility
Understands discharge instructions
Provides means of contact for follow-up telephone assessment
Released to responsible adult

- The nurse's call button is placed within easy patient reach and answered promptly.
- Patients are instructed that they should be assisted with ambulation when they get up.

When patients get up postoperatively, especially for the first time, they may be weak or dizzy. One or two health-care workers should assist the patient and allow the patient to dangle before standing (Fig. 11.10). These precautions can help prevent falls.

Nursing Process for Postoperative Patients

A complete patient assessment is performed after transfer to the nursing unit. Respiratory status, vital signs (including temperature), level of consciousness, surgical site, dressings, and pain assessment are noted. IV site, patency, and IV solution and infusion rate are assessed and monitored. Nasogastric tubes are hooked to suction or clamped as ordered. Drains and catheters are positioned to promote proper functioning.

FIGURE 11.10 Postoperative patient dangling.

After discharge from the PACU, interventions to promote recovery include monitoring for complications (respiratory depression, hemorrhage, and shock), providing postoperative care, educating patients and their significant others, making necessary referrals, and providing home health care (Box 11.7 Nursing Care Plan for the Postoperative Patient).

Respiratory Function

ASSESSMENT/DATA COLLECTION. Regular monitoring of the patient's respiratory rate, depth, and effort and breath sounds as well as cough strength (if not contraindicated by the type of surgery, such as hernia repair or eye, ear, intracranial, jaw, or plastic surgery) should be done. Postoperative patients are at risk for developing atelectasis and pneumonia. They may have a weak cough as a result of being drowsy from anesthesia or analgesics. If fine crackles are heard in the lung bases, the patient should be encouraged to deep breathe or cough. Afterward you should listen again to see if the crackles have cleared. If the patient's airway is compromised, immediate action is taken to support the airway and the physician is notified.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Ineffective breathing pattern related to pain and analgesic medications

EXPECTED OUTCOME: Patients will maintain normal SpO_2 levels and normal arterial blood gases.

- Maintain oxygen therapy as ordered on all general anesthesia patients. *Hypoventilation can be an effect of anesthesia medications or analgesics, or an incision in the thorax causing painful respirations.*
- Encourage deep breathing to expand the lungs.
- Give analgesics as needed to promote deep breathing so the patient does not guard against deep respirations or coughing especially if incision is near the diaphragm.

Ineffective airway clearance related to ineffective cough and secretion retention

EXPECTED OUTCOME: Patients will have patent airway and clear breath sounds at all times.

- Deep breathing and coughing is encouraged every hour while the patient is awake, especially through the first postoperative day. *Retained secretions can lead to mucous plugs that block bronchioles, causing alveoli to collapse and atelectasis. Infection can develop from the stasis of mucus, resulting in pneumonia.*
- Place incentive spirometer within patient's reach and encourage hourly use while awake to prevent atelectasis.
- Turn patient at least every 2 hours to help expand the lungs and move secretions.
- Ambulate patient as soon as possible as immobility decreases movement of secretions.

EVALUATION. If the patient's breath sounds are clear and arterial blood gases remain normal, the goals are met.

BOX 11.7 NURSING CARE PLAN for the Postoperative Patient

Nursing Diagnosis: Ineffective airway clearance related to ineffective cough and secretion retention

Expected Outcome Patient maintains a patent airway at all times. Breath sounds remain clear.

Evaluation Of Outcomes Is patient able to clear own secretions? Are breath sounds clear?

Interventions

Monitor breath sound.

Encourage deep breathing and coughing and use of incentive spirometer hourly while awake.

Ensure that patient's pain is relieved before activity.

Encourage movement by turning every 2 hours and ambulating as able.

Rationale

Abnormal breath sounds such as crackles or wheezes can indicate retained secretions.

Lung expansion helps prevent atelectasis and keeps lungs clear of secretions.

Movement can cause or increase pain.

Movement promotes lung expansion and movement of secretions.

Evaluation

Are breath sounds clear?

Does patient perform breathing and coughing and use incentive spirometer?

Does patient state pain is controlled before activity?

Is patient moving?

Nursing Diagnosis: Pain related to surgery, nausea, and vomiting

Expected Outcome Patient reports that pain management relieves pain satisfactorily and describes pain management plan.

Evaluation of Outcomes Does patient report satisfactory pain relief? Is patient able to describe pain management plan?

Intervention

Assess pain using rating scale such as 0 to 10.

Provide analgesics prn.

Provide antiemetics prn.

Position patient comfortably.

Rationale

Self-report is the most reliable indicator of pain.

Analgesics relieve pain.

Antiemetics relieve nausea and vomiting.

Incisions, drains, tubing, equipment, and bed rest can cause discomfort, which positioning can relieve.

Geriatric

When assessing pain speak clearly and slowly so elderly patient can hear.

Assess elderly patients' pain level regularly, observing nonverbal pain cues (restlessness, grimacing, moaning), especially for those cognitively impaired.

If elderly patient does not hear or misunderstands, pain may not be reported accurately to ensure appropriate intervention provided.

The pain of elderly patients is often underreported and undertreated, especially if cognitively impaired, and noting nonverbal cues can aid in pain treatment.

Evaluation

Does patient report pain using scale?

Is patient's pain less after medication?

Is patient's nausea and vomiting less after medication?

Does patient report positioning is comfortable?

Does patient hear and report pain and relief accurately using pain scale?

Are nonverbal cues present in elderly patients, especially those cognitively impaired?

Nursing Diagnosis: Risk for infection related to inadequate primary defenses from surgical wound

Expected Outcome Patient remains free from infection.

Evaluation of Outcomes Does patient remain free from infection?

Intervention

Observe incision for signs and symptoms of infection.
Monitor drainage and maintain drains.
Maintain sterile technique for dressing changes.

Rationale

Redness, warmth, fever, and swelling indicate infection.
Drains remove fluid from the surgical site to prevent infection development.
Sterile technique reduces infection development.

Evaluation

Are signs and symptoms of infection present?
Are drainage amount and color normal for procedure?
Is incision free of signs and symptoms of infection?

Circulatory Function

ASSESSMENT/DATA COLLECTION. Monitor the patient’s circulatory status to detect and prevent hemorrhage, shock, and thrombophlebitis. Vital signs, SaO₂ and skin temperature, color, and moistness are observed and compared with baseline data and abnormal trends noted. Institutional policy is followed for frequency of patient vital sign monitoring. The incision or dressing is checked for drainage or hematoma formation. Drainage may leak down the patient’s side and pool underneath the patient. While wearing gloves, feel underneath the patient or turn the patient to check for bleeding. Report any signs of hemorrhage or shock promptly.

The lower extremities of surgical patients are observed. Tenderness or pain in the calf may be the first indication of a deep vein thrombosis. Leg swelling, warmth, and redness, as well as fever, may also be present. Bilateral calf and thigh measurement is done daily if thrombophlebitis is suspected or diagnosed. Peripheral pulses and capillary refill are also checked.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Deficient fluid volume related to blood and fluid loss or NPO status

EXPECTED OUTCOME: Maintain blood pressure and pulse within normal limits.

- Monitor dressings, incisions, drains, and tubes for color and amount of drainage and report bright red drainage or excessive drainage amounts immediately.
- Monitor intake and output to detect imbalances.
- IV fluids are maintained at the ordered rate to maintain fluid volume.

Ineffective tissue perfusion: peripheral or pulmonary related to interruption of blood flow during surgery, dehydration, and use of leg straps.

EXPECTED OUTCOME: Maintain normal tissue perfusion.

- Encourage leg exercises hourly while the patient is awake to prevent venous stasis and thrombosis.
- Assist with early postoperative ambulation as ordered to prevent thrombosis.
- Apply knee-length or thigh-length antiembolism

elastic stockings or intermittent pneumatic compression as ordered to help prevent stasis of blood (Fig. 11.11).

- Give low-dose heparin, low molecular weight heparin (enoxaparin [Lovenox]), warfarin, and plasma expanders such as dextran 40 and dextran 70 as ordered to reduce clot formation.
- Avoid pressure under the knee from pillows, rolled blankets, or prolonged bending of the knee and elevate legs to help prevent venous stasis.

EVALUATION. The goal for deficient fluid volume is met if vital signs and urine output are within normal limits. The goal for ineffective tissue perfusion is met if tissue blood flow remains normal.

Postoperative Pain

Pain is common after surgery, although each patient’s pain experience varies. In addition to incisional pain, painful muscle spasms can occur. Nausea and vomiting, ambulation, coughing, deep breathing, and anxiety can cause discomfort and increase postoperative pain. Unrelieved pain has negative physiological effects. It also impairs deep breathing and coughing and hinders early ambulation, which may increase

FIGURE 11.11 Postoperative patient wearing A-V Impulse System foot pump. The foot pump is used to prevent deep vein thrombosis, reduce pain and edema, and enhance arterial blood flow (Kendall, Mansfield, MA).

CRITICAL THINKING

Mrs. Owens

■ Mrs. Owens returned from a bowel resection 2 days ago. She is receiving 1000 mL of 0.9% normal saline over 10 hours.

1. As you monitor the patient you understand that the IV pump rate would be set at what rate?
2. How many milliliters should the nurse record as intake for 12 hours?

■ Intake and output for 12 hours:

Intake:

One 8-ounce (oz) cup of coffee

4 oz orange juice

6 oz of tomato soup

$\frac{3}{4}$ cup Jello

Two cups of water

1200 mL of 0.9% normal saline IV

Output:

1700 mL of urine

Suggested answers at end of chapter.

complications, length of hospital stay, and health-care costs. Nurses should understand that providing pain relief not only reduces suffering, it also has positive benefits for a quicker recovery. It is important for nurses to stay informed of advances in pain management and ensure that they make pain relief a priority in providing patient care. (See Chapter 9.)

ASSESSMENT/DATA COLLECTION. Nurses must be proactive and diligent in their provision of pain relief. Anticipating postoperative patients' pain by regularly monitoring their pain levels instead of waiting until it is the time for the next dose of pain medication is essential to provide quality nursing care for pain relief.

Pain is not a normal part of aging. Careful assessment of older patients' unique aging changes, chronic diseases, and pain relief needs is required to appropriately treat their postoperative pain. Cognitively impaired adults are at risk for undertreatment of their postoperative pain. You must ensure that you assess and treat pain for these patients. Pain rating scales are available for use with those who are cognitively impaired so that you can determine if they are experiencing pain.

If patients are not fully awake on transfer, vital signs and nonverbal indications of pain should be monitored. Nonverbal indicators of pain may include abnormal vital signs (usually elevated blood pressure, although hypotension can occur in some patients), restlessness, moaning, grimacing, and rubbing or pulling at specific body areas or equipment. Patients who are awake are asked the location of the pain, to rate the presence of pain, and to describe the pain quality, such as sharp, aching, throbbing, or burning, which is then documented.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Pain related to tissue damage from surgery, muscle spasms, nausea, or vomiting

EXPECTED OUTCOME: The patient reports pain relief at a satisfactory level using pain rating scale.

- Monitor pain using pain rating scale of 0 to 10.
- Provide medications promptly as ordered to relieve symptoms.
- Understand appropriate timing intervals for IV to IM doses of analgesics as IV analgesics usually have a shorter duration than IM analgesics so that patients do not wait and suffer needlessly.
- Reposition patient to promote comfort.

EVALUATION. Thirty minutes after pain medication is given, patients are asked to rate their pain level. If patients are sleeping at this time, allow them to sleep. When they awaken, ask them to rate their pain level. The goal for pain is met when patients report a decreased level of pain that is satisfactory to them. If the patient does not report satisfactory pain relief, the physician should be promptly notified of the inadequate pain relief.

NURSING CARE TIPS

- For the first dose of an IM analgesic, patients in pain should not have to wait the ordered time interval of the IM dose after an intravenous analgesic dose (i.e., 3 hours if the IM order is morphine 10 mg IM q3h prn). Having to wait when the IV analgesic is no longer effective can cause needless pain.
- Patient controlled analgesia (PCA) may be started in the PACU. The patient's ability to use PCA, the patient's response to the medication, and the relief obtained from it are monitored. If PCA is not effective or if side effects occur, the physician should be notified.
- Comfortable positioning, warming the patient, and relieving a patient's full bladder can also alleviate pain. Attention to environmental factors such as bright overhead lighting, excessive noise or visitors, and extreme room temperatures also helps promote comfort.
- Antiemetics should be given as ordered to relieve the discomfort of nausea and vomiting. If vomiting occurs, patients should be turned onto one side to aid emesis removal and prevent aspiration. A nasogastric tube may be ordered to help control vomiting.

CRITICAL THINKING

Mrs. Wood

■ Mrs. Wood returns to the surgical unit after a hysterectomy. Her postoperative vital signs and assessment findings are normal. Mrs. Wood rates her pain level, and you note that she moans occasionally, repeatedly moves her legs, and pulls at her covers near her abdominal incision. She is drowsy but says it hurts. In the PACU, she received 10 mg of morphine IV 55 minutes ago. Morphine 5 to 10 mg IM is ordered every 3 hours as needed.

1. What nonverbal pain cues does Mrs. Wood display?
2. How should you document Mrs. Wood's pain?
3. What action should you take to relieve Mrs. Wood's pain?
4. When should you next monitor Mrs. Wood's pain level?
5. If Mrs. Wood indicates that her pain is unrelieved after 30 minutes, what action should you take?
6. You are to give Mrs. Wood morphine 8 mg IM now. You have available morphine 10 mg/mL. How many milliliters will you give?

Suggested answers at end of chapter.

Urinary Function

ASSESSMENT/DATA COLLECTION. Monitor the patient's urinary status to ensure normal function is maintained after anesthesia administration. If the patient has a urinary catheter, the amount, color, and consistency of the urine are noted. Otherwise, monitor for the patient's first postoperative voiding to prevent bladder distention. Patients should void within 8 hours of their last voiding. For patients having urinary or gynecological procedures, the patient may need to void within 4 to 6 hours to prevent increased pressure on the surgical site. Catheterization may be necessary if the patient is unable to void. After outpatient surgery, patients may be required to void before being discharged.

If patients report the inability to void, the bladder is palpated for distention or a bladder volume measurement is done, which determines the amount of urine in the bladder. You should be aware that restlessness can be caused by discomfort from a full bladder. A distended bladder requires intervention to empty it. Efforts are made to promote voiding before inserting a urinary catheter because of the risk of infection.

The body's stress response to the surgical experience stimulates the sympathetic nervous system ("fight or flight" response), which saves fluid by reducing urine output. Therefore, initially urine output may be reduced and concentrated. Then it should gradually increase, becoming less concentrated and lighter in color.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Urinary retention related to surgery, pain, anesthesia, altered positioning

EXPECTED OUTCOME: Patient completely and regularly empties her bladder.

- Measure and record output on postoperative patients, especially those undergoing major procedures or urological surgery, older patients, and those with an IV or urinary catheter *to detect urinary elimination problems.*
- Report urinary output less than 30 mL in 1 hour from urinary catheter *as this is minimum acceptable output.*
- Recognize that patients voiding small, frequent amounts (30 to 50 mL every 20 to 30 minutes) or dribble may have retention overflow and may not be emptying their bladder. *This is not normal and may require catheterization to empty the bladder and prevent complications.*
- Patients should be assisted to the bathroom or bedside commode, and men should be allowed to stand or sit to void if possible *to promote voiding.*
- If bedpans are used, they should be warmed *to prevent reflexive sphincter tightening.*
- For patient who is unable to void, techniques to promote voiding should be used before catheterization: running water, pouring warm water over a female patient's perineum, or drinking a hot beverage *may stimulate voiding.*
- Provide privacy after safety is ensured *to promote voiding.*
- Have patients place their feet solidly on the floor *to relax the pelvic muscles to aid voiding.*
- Notify physician if patient is uncomfortable, has a distended bladder, or has not voided within the specified time frame *for treatment orders.*

EVALUATION. The goal for urinary retention is met if the patient is able to void without pain or complications.

Surgical Wound Care

A wound is a break in the skin. When a wound occurs, it disrupts the integrity of the skin, giving bacteria an entry point into the body. Wounds can be clean or dirty. Clean wounds are surgical wounds that are not infected. Contaminated wounds include accidental wounds or surgical incisions exposed to gastrointestinal (GI) contents or unsterile conditions. Infected wounds and dirty wounds contain microorganisms from trauma, ruptured organs, or infection. Necrotic and infected tissue is removed before infected wounds are closed. This is known as **debridement**.

An incision is a wound made by a physician with a sharp instrument such as a scalpel. A puncture wound has a small opening and may be made with a scalpel to insert a tube or drain. Incisions are closed with sutures, staples (Fig. 11.12), or surgical glue, which is painless and produces less scarring. As the wound heals, sutures or staples are removed

FIGURE 11.12 A stapled incision. (A) Note wound edges not approximated at arrows. (B) Arrows indicate puncture sites where drains were inserted.

in 7 to 10 days, and Steri-Strips may be applied to continue supporting the wound as it heals.

WOUND HEALING. Wound healing occurs in phases (Table 11.10). Wounds can heal by first intention, second intention, and third intention (Fig. 11.13). The edges of the wound are approximated with staples or sutures with first-intention healing. This usually results in minimal scarring. With healing by second intention, the wound is usually left open and allowed to heal by granulation. Scarring is usually extensive with prolonged healing. With healing by third intention, an infected wound is left open until there is no evidence of infection and the wound is then surgically closed.

WOUND COMPLICATIONS. Wound problems can include hematoma, infection, dehiscence, and **evisceration**. A hematoma occurs from bleeding in the wound and into the tissue around the wound. A clot forms from the bleeding. If the clot is large with swelling, the clot may need to be removed by the physician.

Infected wounds may be warm, reddened, and tender and have **purulent** (pus) drainage. The drainage may have a foul odor. A fever and elevated white blood cell (WBC) count may be present. Antibiotics are used to treat the infection.

TABLE 11.10 WOUND HEALING PHASES

Phase	Time Frame	Wound Healing	Patient Effect
I	Incision to 2nd postoperative day	Inflammatory response	Fever, malaise
II	Third to 14th postoperative day	Granulation tissue forms	Feeling better
III	3rd to 6th postoperative week	Collagen deposited	Raised scar formed
IV	Months to 1 year	Collagen deposited	Flat, thin scar

evisceration: e—out + viscera—body organs

Dehiscence and evisceration are serious wound complications (Fig. 11.14). Wound dehiscence is the sudden bursting open of a wound's edges, which may be preceded by an increase in serosanguineous drainage. Evisceration is the viscera spilling out of the abdomen. Dehiscence and evisceration often occur with abdominal incisions in patients who are malnourished, obese, elderly, or who have poor wound healing. Supporting the wound during coughing and other activities that pull on the incision or applying an abdominal binder on patients who are at risk help prevent dehiscence and evisceration. When evisceration occurs, the patient may have pain and vomiting and may report that "something let loose" or "gave way."

If dehiscence or evisceration occurs, place the patient in low Fowler's position with flexed knees. Cover the wound with sterile dressings or towels moistened with warm sterile normal saline. Notify the physician immediately of this surgical emergency. Apply gentle pressure over the wound and keep the patient still and calm. Monitor vital signs for evidence of shock (e.g., tachycardia, tachypnea, dyspnea, hypotension). IV fluids are infused as ordered. Prepare the patient for immediate surgery to close the wound.

For dehiscenced surgical incisions that resist healing, a newer device, vacuum-assisted closure (VAC), is available to aid in healing the incision. The device can be used on other types of wounds. Wound closure is aided by application of local negative pressure to wound edges by VAC.

ASSESSMENT/DATA COLLECTION. Drains. Drains are inserted into wounds during surgery to prevent accumulation of blood, lymph, or necrotic tissue in wounds that can lead to infection or delayed healing. Drains may work by gravity or suction. Penrose drains are open, soft, flat, rubberlike drains that carry drainage out of the wound. Moderate **serosanguineous** drainage is expected from a Penrose drain and may require frequent dressing changes. Examples of drains that use suction to gently enhance drainage include the Jackson-Pratt, Hemovac, and Mini-Snyder Hemovac. These drains are closed systems that may require periodic emptying and reapplication of the suction by compressing the drain. Output is recorded when the drainage is emptied. The amount of drainage expected varies with the type of surgery. Specialized drainage systems allow the autotransfusion of drainage containing blood back to the patient to maintain hemoglobin levels without the risks associated with blood transfusions, such as transfusion reactions or transmission of infections.

Dressings. Dressings protect the wound, absorb drainage, prevent contamination from body fluids, provide comfort, and apply pressure to reduce swelling or bleeding as in a pressure dressing. The initial dressing is applied in surgery and then is usually removed by the physician approximately 24 hours postoperatively. If drainage appears on the initial

serosanguineous: sero—whey + sanguineous—bloody

FIGURE 11.13 Wound Healing. (A) Primary intention. Wound healing occurs in a clean wound, such as a surgical wound, whose edges are approximated typically with staples or sutures. Healing occurs quickly with slight scarring. (B) Secondary intention. Large irregular or infected wounds are left open to allow healing to occur from the inside out. Pressure ulcers or chronic wounds are often treated this way. Large scarring occurs with lengthy healing time. (C) Tertiary intention. Infected or contaminated wound is left open for a brief time period until wound is clean. Granulation tissue fills in for some wound healing and then edges are approximated and closed surgically. Wider scarring occurs.

dressing, reinforce it with another dressing, according to physician orders or institution policy.

After the initial dressing is removed, if the wound is dry and the edges intact (approximated), the physician may not order the dressing to be replaced. This allows easy observation of the wound and avoidance of applying tape to the skin. Draining wounds are dressed with several layers that are changed as needed. When the old dressing is removed, it should be done carefully to prevent dislodging of tubes or drains. The condition of the wound is documented with each dressing change. It is normal for the incision to be puffy and red from the inflammatory response. The surrounding skin should be the patient's normal color and temperature. Correct tape application over the dressing is done by gently laying the tape over the dressing and applying even pressure on each side of the wound. Pressure

should not be applied on top of the wound by pulling on the tape from one side of the wound to the other side.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Impaired skin integrity related to surgical incision

EXPECTED OUTCOME: Regain skin integrity.

- Monitor skin color and temperature and report changes.
- Monitor dressings and note drainage color, amount, and consistency. *Surgical wound drainage initially is sanguineous (red) and changes to serosanguineous (pink) and then serous (pale yellow) after a few hours to days.*
- Report drainage that is bright red, remains sanguineous after a few hours, or is profuse promptly

FIGURE 11.14 (A) Wound dehiscence. (B) Wound evisceration.

to the physician *because the patient may be hemorrhaging.*

- Use standard precautions when changing dressings to protect yourself.

EVALUATION. The goal for impaired skin integrity is met if the patient's wound heals and skin integrity is regained without complications.

Gastrointestinal Function

Nutritional intake and bowel functioning can be affected by surgery and anesthesia. Application of NPO status and undergoing bowel preparation often occur preoperatively. Postoperatively, intestinal handling during surgery, the need to rest the GI tract following a procedure, immobility, lack of peristalsis, and complications such as nausea and vomiting, paralytic ileus (from peristalsis stopping), constipation, or obstruction can interfere with normal GI function.

ASSESSMENT/DATA COLLECTION. Postoperatively, bowel sounds are auscultated every 4 hours. Normally, 5 to 30 bowel sounds are heard per minute. Bowel sounds can be absent, hypoactive, normal, or hyperactive. The abdomen is checked to see if it is soft or firm and flat or distended. When the patient begins passing flatus or stool, document it. Any abnormal findings are reported to the physician.

After abdominal surgery, peristalsis and bowel sounds usually stop for 24 to 72 hours. Flatus is usually absent for 24 to 72 hours postoperatively. Patients do not have bowel movements until peristalsis returns. The patient is kept NPO until flatus and bowel sounds return or as ordered by the physician. The patient's abdominal girth is measured if distention occurs. If a paralytic ileus develops, abdominal distention, absent bowel sounds, and pain may result. As ordered, a nasogastric tube can be used to decompress the GI tract until peristalsis returns. Drainage from the decompression tube is observed for amount, color, and consistency.

Intake and output are measured. Removal of gastric secretions can cause electrolyte imbalances. Signs and symptoms of electrolyte imbalance can include new-onset confusion or weakness, which should be reported.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. **Imbalanced nutrition: less than body requirements related to NPO, pain, nausea**

EXPECTED OUTCOME: The patient will resume normal dietary intake and maintain weight within normal limits.

- Maintain IV fluids, total parenteral nutrition, or enteral feedings *until the patient can resume a normal dietary intake* (Box 11.8 Nutrition Notes).
- Give antiemetics as ordered *for nausea and vomiting.*
- Give water and clear liquids at first as ordered, then advance diet to soft and finally solid foods *to promote tolerance.*

Constipation related to decreased peristalsis, immobility, altered diet, narcotic side effect

EXPECTED OUTCOME: The patient will return to normal bowel elimination patterns and report freedom from gas pains and constipation.

- Encourage early ambulation and exercise *to promote restoration of GI functioning.*
- If gas pains occur, encourage ambulation, have patient lie prone, and pull the knees up to the chest *to relieve pain.*
- Provide stool softeners or laxatives as ordered.
- Monitor elimination and record.

EVALUATION. The goal for imbalanced nutrition: less than body requirements is met if patients are able to maintain their baseline weight and resume a normal dietary intake. The goal for constipation is met if patients are free from discomfort and establish a regular bowel elimination pattern.

NURSING CARE TIP

Most IV solutions do not provide enough nutrients or calories to prevent malnutrition. The primary purpose of most IV fluids is to provide hydration. A 1000-mL IV solution containing 5% dextrose provides only about 170 calories. This does not meet an adult's daily caloric needs, especially if healing is occurring. You should ensure that early consideration of other nutritional methods is made to meet the patient's dietary needs.

Mobility

ASSESSMENT/DATA COLLECTION. It is important for the patient to move as much as possible to prevent complications and promote healing. Pain, incisions, tubes, drains, dressings, and other equipment may make movement

Box 11.8

Nutrition Notes

Nourishing the Postoperative Patient

After surgery, intravenous 5% glucose in water is commonly prescribed. Two liters of this solution contain only 340 calories, which is insufficient to meet the patient's energy needs but enough to prevent ketosis from breakdown of adipose tissue. Previously well-nourished adults generally have nutrient reserves for 3 to 4 days of semistarvation. To prevent excessive muscle protein from being used for energy, adequate nourishment should be delivered to the patient within 3 days. Complete nutrition is available in clear liquid formulations such as Citrotein and Enlive.

To avoid abdominal distension, oral feedings are delayed until peristalsis returns, as evidenced by the patient's passing flatus or the health-care worker's auscultating bowel sounds. Patients usually progress from clear liquids to a regular diet as soon as possible. If "diet as tolerated" is prescribed, the patient should be asked what sounds good. Sometimes a full dinner when the patient doesn't feel well "turns off" the appetite. After gastrointestinal surgery, oral food and fluids are deferred longer than with other surgeries to allow healing. When particular amounts are prescribed, those limits should be strictly implemented to preserve the suture lines. One other precaution is often taken after surgery on the mouth and throat: After tonsillectomy, for example, no red liquids are given so that bleeding can be seen and vomitus is not mistaken for blood.

Specific nutrients necessary for healing are as follows:

- Vitamin C for collagen formation
- Vitamin K for blood clotting
- Zinc for tissue growth, skin integrity, and cell-mediated immunity
- Protein for controlling fluid balance and edema and for manufacturing antibodies and white blood cells, as well as for building scar tissue

difficult. You should determine the patient's ability to move in bed, to get out of bed, and to walk. Pain levels that may interfere with movement are assessed. The patient's tolerance to activity is observed. Understanding of how to perform exercises is noted.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. Impaired physical mobility related to surgery, decreased strength, and movement restriction

EXPECTED OUTCOME: The patient's goals are to resume normal physical activity.

- Position patient in bed. Pillows can be used to support the body in good alignment.

- Turn at least every 2 hours, alternating from supine to side-to-side if not contraindicated.
- Encourage patients to move themselves to increase circulation and promote lung expansion.
- Encourage hourly exercises (deep breathing, range of motion of all joints, and isometric exercises of the abdominal, gluteal, and leg muscles) while awake in bed if ambulation is not possible to prevent complications.
- Perform passive joint range of motion if the patient is unable to do active range of motion.
- Raise head of the bed slowly to allow the circulatory system to adjust to the position change.
- Lower head of bed if patients report dizziness or feeling faint.
- Dangle patient on the side of the bed in preparation for ambulation (see Fig. 11.10).
- If dangling tolerated, ambulate: Before getting up, patients should pedal their feet to "wake up" the muscles controlling the arteries. To rise, they should keep their eyes forward and move slowly until they feel adjusted to being up. Usually the patient ambulates a short distance the first time and increases the distance as tolerated. One or two health-care workers should assist the patient and use a gait (walking) belt for safety. Walkers with wheels and seats may also be used for support and for resting if the patient becomes dizzy or tired. If patients feel faint or dizzy or their vital signs change, they should be assisted back to bed. A wheelchair may be needed to transport them safely back to their room.

EVALUATION. The goal for impaired physical mobility is met if patients are able to increase ambulation and resume normal activities.

Postoperative Patient Discharge

Discharge planning begins in preadmission testing and continues after admission to ensure that the patient is ready for a timely discharge. When the patient meets discharge criteria, the physician discharges the patient from either the ambulatory setting or the hospital.

Ambulatory Surgery

DISCHARGE CRITERIA. Generally, the patient can be considered a candidate for discharge 1 hour after surgery if clinical discharge criteria or the PACU discharge scoring system are met (see Table 11.9). Clinical discharge criteria include stable vital signs, no bleeding, no nausea or vomiting, and controlled pain that is not severe. Depending on the type of surgical procedure, such as urological, gynecological, or hernia surgery, the patient may be required to void before discharge. The patient should be able to sit up without dizziness before discharge. Patients meeting discharge criteria are discharged by the physician and released to a responsible adult. Patients are not permitted to drive themselves home because of the effects of anesthesia and medications they have received.

DISCHARGE INSTRUCTIONS. Patients and their families are given written discharge instructions before discharge. Elderly patients should have a caregiver participate in the discharge instruction session to understand what observations to make and what to do if complications develop. The instruction form is signed by the patient or an authorized representative to indicate understanding. Prescriptions and a copy of the instructions, to provide a reference for later, are sent with the patient. The patient is encouraged to rest for 24 to 48 hours. The patient is to avoid operating machinery, driving, drinking alcoholic beverages, and making major decisions for 24 hours because the effects of undergoing surgery can alter energy levels and thinking ability. The physician orders any fluid, dietary, activity, or work restrictions.

Patients are taught wound care, medication information (including side effects), and signs and symptoms of complications to report to the physician. Phone numbers for the physician, surgical facility, and emergency care are provided. Patients are informed of the date for their follow-up visit to the physician and told to call and make an appointment.

Inpatient Surgery

DISCHARGE CRITERIA. The physician determines the patient's readiness for discharge from the hospital. Postoperative lengths of stay vary based on the surgical procedure and the patient's individual needs. Before discharge, a complete assessment of the patient is performed and documented.

DISCHARGE INSTRUCTIONS. All necessary teaching is completed before discharge (Fig. 11.15). Patients and their families are given prescriptions and a copy of written instructions that are signed by the patient to indicate understanding before discharge. If more teaching or reinforcement is needed, a referral to a home health nurse can be requested.

The physician orders any fluid, dietary, activity, or work restrictions. Patients are taught wound care, medication information (including side effects), and signs and symptoms of complications to report to the physician.

FIGURE 11.15 Nurse providing discharge teaching to patient.

Patients are informed of the date for their follow-up visit to the physician.

Home Health Care

The role of the home health nurse is to assist the patient in the recovery process (Home Health Hints).

A referral to the home health nurse is made when the patient requires the following:

- Continued assistance with skilled nursing interventions, such as wound care, IV medications, or ostomy care
- Additional teaching to be able to perform self-care, such as diabetic teaching for a patient with newly diagnosed diabetes or ostomy care
- Assessment of the recovery process
- Assistance needed because of weakness, lack of social support, or development of complications; care provided in the home is adapted to the patient's resources and environment to facilitate compliance

Home health-care workers can include assistants who help with activities of daily living and household chores, LPNs/LVNs who provide basic nursing care, and registered nurses who perform patient assessments, teaching, and complex nursing care. The frequency of visits is determined by the patient's needs.

Home Health Hints

After a patient comes home from surgery, the home care nurse can help give direction to the family to prepare the room where the patient will be staying:

- It is helpful if the room can be on the same floor with the bathroom, kitchen, and living space.
- If an extended recovery period or illness is expected, the den or living room might be considered as the

primary living space to provide room for equipment and make companionship easier. The patient can see activity in the home and be included in family activity. Also, caregivers can be more attentive to the patient's needs and save countless footsteps.

- Special equipment may be needed, including the following:

- For the patient on bedrest, a hospital bed with full side rails helps with a variety of position changes and better height for the caregiver.
 - Draw sheets made of folded twin sheets are needed, as well as extra pillows for positioning.
 - A bedside stand is needed for personal and toilet articles.
 - A bedside commode can be placed near the bed if the patient cannot walk to the bathroom. A bedpan or urinal may be needed. A functional female urinal is easier to use than a bedpan.
 - A flexible tube with a shower head that connects to the bathtub faucet is convenient and allows the patient more independence in bathing.
 - Installation of grab bars and tub stools and skid-proofing of a shower or tub are important safety measures to help prevent falls.
 - If the patient is eligible for insurance coverage for durable medical equipment, a physician's order must be obtained.
- It is helpful for caregivers to keep a notebook in the hospital and continue it at home. Treatments, medicines, observations, procedures, doctor and nurse visits, instructions, and therapies with dates and times can be recorded. This helps prevent confusion, prepares the next caregiver, and affords better organization of time and resources for everyone. It can also be nice to see who visited the patient.
- Families of patients recovering from surgery should provide items to keep the patient occupied and comfortable: talking books, inspirational reading material, pictures, and their favorite pajamas, robe and slippers, and coverlet.

REVIEW QUESTIONS

Multiple response item. Select all that apply.

1. Which of the following nursing actions would reduce surgical risk factors for preoperative patients?
 - a. Playing music
 - b. Avoiding discussion of fears
 - c. Reinforcing pain control methods
 - d. Showing use of incentive spirometer
 - e. Encouraging smoking cessation 8 hours before surgery
2. Which of the following is the patient care role for the LPN/LVN in the preoperative phase?
 - a. Assisting in data collection
 - b. Explaining the surgical procedure
 - c. Obtaining preoperative orders
 - d. Providing informed consent

Multiple response item. Select all that apply.

3. Which of the following is within the LPN/LVN's scope of practice related to the patient providing consent for surgery?
 - a. Obtaining informed consent
 - b. Providing informed consent
 - c. Answering surgical procedure questions
 - d. Requesting patient questions be referred to physician
 - e. Witnessing the patient's signature on the consent
 - f. Reading the consent to a patient prior to signing
4. When teaching the elderly preoperative patient, which of the following is a teaching strategy that improves learning?
 - a. Sit near a window with bright sunlight

- b. Use large black-on-white printed materials
- c. Sit beside patient
- d. Use blue and green materials

Multiple response item. Select all that apply.

5. Which of the following interventions would help prevent atelectasis in a postoperative patient?
 - a. Coughing and deep breathing
 - b. Holding breath while moving
 - c. Restricting fluids
 - d. Leg exercises
 - e. Pain control
 - f. Ambulation
6. Which of the following would the nurse evaluate as indicating that the postoperative patient's diet can be resumed, as ordered?
 - a. Absence of flatus
 - b. Bowel sounds every 8 seconds
 - c. Excessive thirst
 - d. Absent bowel sounds
7. Which of the following findings would the nurse recognize as being the earliest indicator of hemorrhage or shock that should be reported to the physician?
 - a. Tachycardia
 - b. Polyuria
 - c. Nausea
 - d. Fever

8. Which of the following is a criterion the nurse uses to determine patient readiness for discharge from ambulatory surgery?
- Ability to drive an automobile
 - Ability to ambulate 50 feet
 - Being pain free
 - Absence of nausea or vomiting

Fill in the blank with the correct answer

9. What is the role of the home health nurse in caring for postoperative patients?
-

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Owens

- 100 mL per hour. IV pumps are always set to deliver the amount of milliliters per hour. Divide the total volume of 1000 mL \times the total time of 10 hours = 100 mL per hour.
- Intake = 2400 mL.
To calculate this:
Remember your conversions:
30 mL = 1 oz
1 cup = 8 oz (don't supersize the cup!)
Calculations:
1 8-oz ounce cup of coffee = $1 \times 8 \times 30 = 240$ mL
4 oz orange juice = $4 \times 30 = 120$ mL
6 oz of tomato soup = $6 \times 30 = 180$ mL
 $\frac{3}{4}$ cup jello = $\frac{3}{4} \times 8 \times 30 = 180$ mL
2 cups of water = $2 \times 8 \times 30 = 480$ mL
1200 mL of 0.9 normal saline IV
The patient's output does not impact the intake total so it is not used for this calculation.

■ Mrs. Wood

- Moaning occasionally, moving legs restlessly, and pulling covers near abdominal incision are nonverbal pain cues.
- Document pain levels by actual observations: occasional moaning, restless leg movements, and pulling of covers near abdominal incision. By patient's statement: "It hurts." Because Mrs. Wood is too drowsy to use the pain scale, other data are used. When Mrs. Wood is more awake, explanation of the pain scale should be reinforced and used.

- Review pain medication orders to determine if analgesics can be given. Noting that an IV analgesic was given 50 minutes ago and the IM analgesic is ordered every 3 hours, you should request that the physician or pharmacist be consulted to determine appropriate time intervals. If the consultation indicates it is time to give the analgesic, verify that vital signs are still stable and then give the analgesic. You should also consider other pain relief measures such as patient warmth, positioning, or environmental issues such as bright lighting, room temperature, and noise.
- After administration of the analgesic, Mrs. Wood's pain level should be assessed in at least 30 minutes to determine pain relief. If Mrs. Wood is asleep, she should not be awakened unless you determine it is necessary. Nonverbal cues should be observed and respirations counted and documented. If no indication of pain is noted, Mrs. Wood's pain level should be monitored by you at least hourly or as needed.
- Document pain level on scale of 0 to 10 and have the physician notified of inadequate pain relief. The patient should not have to wait the 3-hour interval in pain. Consider providing other pain relief measures while the physician is being notified.
- Try unit analysis for solving mathematical calculations. It is easy to understand and our students say it is a great method after they try it.

Unit Analysis Method:

$$\frac{8 \text{ milligrams}}{10 \text{ milligrams}} \mid \frac{1 \text{ milliliter}}{10} = 8 = 0.8 \text{ milliliter}$$

QUESTIONS TO GUIDE YOUR READING

1. What are the components of the primary survey?
2. What interventions would you use for a trauma victim?
3. What are the symptoms of inhalation injury?
4. What are the stages of hypothermia and hyperthermia?
5. What are priorities of care for poison overdose?
6. What is your role in crisis situations and psychiatric emergencies?
7. What is your role in identifying a bioterrorist attack or disaster response?

The ability to recognize an emergent condition, prioritize, and provide quick assessments and interventions is essential in nursing. In emergent situations, initial assessment and intervention is guided by the ABCDs of the primary survey. The primary survey of the patient's airway, breathing, and circulation and disability allows recognition, prioritization, and treatment of life-threatening situations. The secondary survey, a rapid head-to-toe assessment, identifies additional serious injuries throughout the body. This chapter presents specific emergent conditions with application of the nursing process.

Upon arrival in the Emergency Department, most patients are triaged by the registered nurse (RN). During the triage process, the RN evaluates the patient's complaint, asks appropriate questions that help to develop a differential diagnosis, and performs a rapid assessment of the patient (Fig. 12.1).

PRIMARY SURVEY

To recognize life-threatening conditions and determine priorities of care, an initial assessment of the patient's airway, breathing, circulation, and disability is conducted. This process is known as the primary survey. The components of the primary survey are listed in Table 12.1.

A—Airway

The airway is the most important component of the primary survey. The neck should not be hyperextended, flexed, or rotated until spinal injury is ruled out because any movement may worsen an existing cervical spine injury (Fig. 12.2). The airway is inspected for obstruction, including loose teeth, foreign objects, bleeding, and vomitus. Next, any visible airway obstructions are removed using suction.

Airway adjuncts, such as nasopharyngeal or oropharyngeal airways, may be used to keep the airway open.

FIGURE 12.1 Triage nurse evaluating patient who has just arrived in emergency room

TABLE 12.1 COMPONENTS OF THE PRIMARY SURVEY

A	Airway
B	Breathing
C	Circulation
D	Disability/Central Nervous System

When additional airway support and mechanical ventilation are required, advanced airway adjuncts, such as endotracheal intubation or cricothyroidotomy, may be performed by specially trained emergency personnel or physicians.

B—Breathing

After the patency of the airway is ensured, the patient is assessed for spontaneous breathing and respiratory rate and depth. The nurse observes whether the patient's chest rises and falls spontaneously and auscultates for breath sounds bilaterally. If the patient is not breathing, interventions are conducted before proceeding. The patient may be ventilated with a mouth-to-face mask or a bag-valve-face mask. Endotracheal intubation is the preferred method of maintaining an airway in an unconscious patient because it ensures airway patency and protects the lungs from aspiration.

FIGURE 12.2 (A) Chin lift maneuver is used to open the airway. (B) Jaw thrust maneuver is used to open the airway if the patient may have a head or neck injury.

C—Circulation

The carotid pulse is palpated for quality and rate. The skin is inspected for color and temperature. External bleeding is controlled by external pressure and elevation when possible. Any life-threatening conditions that may compromise circulation are assessed and interventions provided before proceeding. Other conditions that may compromise circulation include internal bleeding, **shock** resulting from hemorrhage, or major burns. Large-gauge intravenous (IV) cannulas (16 or 18 gauge) are initiated for fluid resuscitation. If the patient does not have a pulse, cardiopulmonary resuscitation must be initiated. If a pulse can be palpated, vital signs are taken and recorded.

D—Disability/Central Nervous System

To detect serious central nervous system injury, a brief neurological assessment is conducted to determine the level of consciousness, which may range from alert (A) and responds to verbal stimuli (V) to responds to painful stimuli (P) or unresponsive (U). To assess response to painful stimuli, a painful stimulus is applied, such as rubbing the sternum, pressing a pen against the base of the nail, or applying periorbital pressure. The patient is observed for the response to the pain, and the response is recorded. Movement of all extremities is also assessed.

SECONDARY SURVEY

For victims of severe trauma, a secondary survey is conducted. This assessment identifies areas of medical or injury problems that are not immediately life threatening but require treatment. Major body areas that may sustain serious injury, such as the head, spine, chest, abdomen, and musculoskeletal system, are quickly examined to detect additional injuries (Table 12.2). To adequately perform a head-to-toe assessment, the patient's clothing is removed. Each major body area is inspected and palpated for deformity, bruising, opens wounds, bleeding, and pain.

SHOCK

Shock is a condition of acute peripheral circulatory failure, causing inadequate and progressively failing tissue perfusion. (See Chapter 8.) During the initial phases of shock, compensatory adjustments allow the body to adapt to the circulatory changes. Eventually, however, these compensatory mechanisms fail and cellular perfusion decreases, causing cell death. There are four types of shock: **hypovolemic**, **cardiogenic**, **obstructive**, and **distributive**. Hypovolemic shock signs and symptoms are caused by a decrease in the circulating blood volume. Cardiogenic shock signs and symptoms result from cardiac failure. Obstructive shock caused by a blockage of blood flow in the cardiovascular circuit outside the heart results in signs and symptoms of reduced blood flow and oxygenation. Distributive shock

TABLE 12.2 COMPONENTS OF THE SECONDARY SURVEY

Head	Inspect for lacerations, bleeding from orifices. Check pupil size and response to light. Are pupils equal in size?
Chest	Auscultate for breath sounds in all lung fields. Inspect for lacerations, wounds, foreign bodies.
Abdomen	Auscultate for bowel sounds in all four quadrants. Palpate for areas of tenderness and rigidity.
Extremities	Inspect for lacerations, wounds, foreign bodies. Inspect for lacerations, wounds, and foreign bodies. Inspect for injuries and deformities. Note areas of tenderness. Palpate for pulses. Evaluate temperature and capillary refill and compare the left to the right extremities.

caused by excessive dilation of the venules and arterioles causes signs and symptoms of decreased blood pressure. Therapeutic interventions for shock are listed in Box 12.1 Guiding Principles for Treating Shock.

ANAPHYLAXIS

Anaphylaxis is a severe allergic reaction. The reaction may occur suddenly after initial contact with an allergen or after any subsequent exposure. Signs and symptoms result from a massive release of chemical mediators from mast cells and basophils throughout the body. Chemical mediators lead to vasodilation and capillary leaking that results in hypotension and eventually vascular collapse. See Box 12.2 Signs and Symptoms of an Allergic Reaction.

Pathophysiology

Anaphylactic shock is a form of distributive shock. There is no loss of blood, but there is excessive vasodilation. Bronchials constrict, and air movement into the lungs

Box 12.1

Guiding Principles for Treating Shock

- Maintain an open airway and give oxygen as ordered.
- Control external bleeding by direct pressure.
- Keep the patient supine if possible.
- Accurately record vital signs.
- Give IV fluids as ordered.
- Give the patient nothing to eat or drink until surgery is ruled out.

anaphylaxis: an—without + phylaxis—protection

Box 12.2**Signs and Symptoms of an Allergic Reaction**

- Generalized itching and burning
- Urticaria (hives)
- Swelling about the lips and tongue
- Dyspnea
- Bronchospasm and wheezing
- Chest tightness and cough
- Anxiety
- Hypotension

becomes increasingly difficult. Increased fluid and mucus are secreted into the bronchial passages. Fluid in the air passages and constricted bronchi cause wheezing. The body is rapidly deprived of needed oxygen by this respiratory system reaction. Signs of severe anaphylaxis include hypotension due to vasodilation, decreased level of consciousness due to decreased oxygenation, and respiratory distress with stridor and cyanosis due to airway constriction and fluid. One of the increasing causes of anaphylactic shock is latex allergy reaction. This type of allergy is on the rise among health-care workers as a result of repeated exposure to health-care products such as latex gloves. Using latex-free products limits exposure and reduces the risk of developing this type of allergy.

Nursing Process for the Patient Experiencing Shock or Anaphylaxis**Assessment/Data Collection**

When assessing a patient at risk for shock, be aware of the signs and symptoms common to all types of shock (Box 12.3). It is important to note the patient's initial level of consciousness and monitor the patient for any subsequent changes. A progressive decline in level of consciousness indicates an urgent need for intervention. Pulses indicate the strength of the heart's contractions. Because a pulse is an immediate indicator of the patient's condition, it should be taken frequently during any emergency condition. Changes

Box 12.3**Common Signs and Symptoms of Shock**

- Restlessness and anxiety
- Weak, rapid, thready pulse
- Cold and clammy skin
- Pale skin color
- Shallow, rapid, labored breathing
- Gradually and steadily falling blood pressure
- Alteration in consciousness in severe shock state
- Thirst

in blood pressure may also indicate changes in blood volume. Blood pressure changes can occur rapidly but usually not as swiftly as pulse changes.

Skin temperature and color changes may be seen with shock. Severe blood loss activates the “fight-or-flight” response in the sympathetic nervous system, which causes the skin to become cool and clammy. This occurs when peripheral blood vessels constrict to shunt blood to vital organs. Skin color depends on the presence of circulating blood in the vessels of the skin. Pale, white, or ashen skin indicates insufficient circulation. In patients with deeply pigmented skin, color changes may be apparent in the nailbeds, conjunctiva of the eye, or mucous membranes of the mouth.

Capillary refill is checked on nailbeds to evaluate arterial circulation to an extremity. The nailbed is compressed to produce blanching (lighter color change), released, and the seconds counted until color returns to the blanched area. Normally, nail color should return within 3 seconds after the pressure is released. Patients in shock may have delayed or absent capillary refill.

**LEARNING TIP**

Gently squeeze and release your own nailbed. Do you see the color change? Count the seconds until the color returns. That is your capillary refill time.

Nursing Diagnoses, Planning, and Implementation

Ineffective tissue perfusion: cerebral and multiple organs related to decreased circulating blood volume secondary to internal and/or external bleeding

EXPECTED OUTCOME: *The patient's bleeding will be controlled to maintain vital signs within limits normal for the individual.*

- Apply direct pressure to external bleeding site *to stop the flow of blood and allow normal coagulation to occur.*
- Elevate bleeding extremity and combine with direct pressure *to help stop venous bleeding.*
- When direct pressure and elevation do not control hemorrhage, pressure-point control should be attempted (Fig. 12.3). *The chosen artery for pressure-point control must be proximal to the injury site and must be over a bony structure.*
- Monitor vital signs continually, record, and report to the physician *to identify early changes in vital signs indicative of progressing shock.*
- Elevate legs to heart level *to promote venous return to the heart* (contraindicated in cardiogenic shock).
- Use a blanket *to help keep the patient from getting cold; however, the patient also should not be allowed to overheat because this causes peripheral*

FIGURE 12.3 Arterial pressure points to control bleeding.

blood vessels to dilate, which draws blood away from vital organs.

- Monitor IV fluids as ordered to increase circulating volume.

Ineffective breathing pattern related to airway constriction

EXPECTED OUTCOME: The patient will maintain respiratory rate within normal limits and experience improved gas exchange in the lungs and normal arterial blood gases.

- Administer oxygen as ordered using appropriate method which will deliver the maximum amount of oxygen necessary to maintain the pulse oximetry at 92% or greater.
- Administer epinephrine as ordered. *Epinephrine is the drug of choice for treating anaphylaxis and is administered to the adult as a dose of epinephrine 0.2 to 0.5 mg of a 1:1000 solution given subcutaneously. Injections can be repeated every 10 to 15 minutes until the desired effect is achieved or significant side effects occur.*
- Give antihistamines as ordered to control the allergic rash and pruritus.
- Steroids are given in gradually tapered doses to prevent return of symptoms.

Evaluation

If interventions have been effective, the blood pressure will improve to within normal limits for the individual patient, the patient will demonstrate a strong pulse; warm, dry skin; and be less anxious.

The patient should show an immediate reversal of shock symptoms. Breathing is easy, and blood pressure and pulse return to the normal range. Breath sounds become clear, and hives and pruritus subside.

MAJOR TRAUMA

Major trauma is the fifth leading cause of death in the United States. It mainly affects persons under age 36. Young men

have the highest overall incidence of traumatic injury. Victims of major trauma may receive injury to an isolated vital organ or to multiple body systems.

Mechanism of Injury

When assessing a victim of major trauma, it is important to determine the mechanism of injury (Box 12.4 Gerontological Issues). Injuries are classified as either penetrating or blunt. Penetrating, or open, injuries may be caused by any sharp object, such as broken glass or a knife, or by projectiles traveling at high speed, such as bullets or fragments from an explosion. In blunt, or closed, injuries the skin surface is intact. The injury from blunt trauma usually

Box 12.4

Gerontological Issues

Injuries and Older Adults

Older adults are at a high risk for falls that put them at risk for bruises, abrasions, cuts, and fractures. Nurses who initially assess older adults with injuries requiring treatment must ask questions and perform assessments that would identify if the patient is a victim of abuse or neglect.

Injuries Caused by Falls Versus Battery or Assault

Any unexplained bruises, burns, abrasions, cuts, fractures, evidence of old injuries or bruises, burns, and cuts that are in different stages of healing suggest abuse. The pattern of an injury can also suggest abuse—for example, cigarette burns in areas covered with clothing; bruises or friction burns in a ring around the neck, ankles, or wrists; welts, burns, or bruises in the outline of a hand or belt buckle; multiple similar injuries in an area, such as whip marks across the buttocks or back of the legs; defensive injury pattern of bruising; and trauma to the hands and forearms.

Injuries related to falls have a predictable injury pattern related to the history and report of the fall. When an older adult falls there is bruising of the hands and knees caused when the person attempts to break the fall. Additional bruising or injuries to the front of the body, arms, and head could be caused by hitting furniture or other items during the fall. Skin tears on the arms are common with a fall. Often, a friend or family member sees the older adult starting to fall and tries to steady the person by grabbing the area, tearing the skin. Ask questions to be sure that the report of the fall incident is consistent with the presenting injuries.

Any form of abuse or suspicion of abuse must be reported to the state agency that investigates reports of suspected abuse. It is not the nurse's responsibility to prove that there has been abuse or neglect, only to report incidents or cases of possible abuse.

extends beyond the point of impact to surrounding and underlying structures. For example, a blow to the chest may cause a fracture of several ribs that in turn may cause blunt trauma (such as a laceration or hematoma) to the spleen.

Damage caused by a gunshot wound and the trajectory of the bullet depends on the projectile mass, the type of tissue struck, the striking velocity, and the range. Entrance wounds are round or oval and may be surrounded by an **abrasion** rim. Powder burns are visible if the firearm was discharged at close range. Documentation of these wounds should include a clear description of their appearance but should not include the words *entry* or *exit*. Patients with gunshot wounds near the level of the diaphragm should be evaluated for both abdominal and thoracic injuries.

Surface Trauma

Surface trauma includes any injury that does not break the skin (closed wound) and any open wound in which the skin surface is broken. Types of closed wounds include contusions (bruising) and hematomas (collection of blood under the skin). Types of open wounds include **abrasions, lacerations, avulsions, amputations, and punctures**.

Abrasions are a scratching of the epidermal and dermal layers of the skin. They bleed very little but can be extremely painful because of inflamed nerve endings. Dirt may be ground into abrasions and can increase the risk of infection when large areas of skin are involved.

Puncture wounds result from sharp, narrow objects such as knives, nails, or high-velocity bullets. They can often be deceptive because the entrance wound may be small with little or no bleeding. It is difficult to estimate the extent of damage to underlying organs as a result. Puncture wounds usually do not bleed profusely unless they are located in the chest or abdomen.

Lacerations are open wounds resulting from snagging or tearing of tissue. Skin tissue may be partly or completely torn away. They vary in depth and may be irregular in shape. Lacerations can cause significant bleeding if blood vessels or arteries are involved.

Avulsions involve a full-thickness skin loss in which wound edges cannot be approximated. This type of injury is often seen in machine operators, or in lawn mower and power tool accidents.

An amputation is a partial or complete severing of a body part. In cases of complete amputation, the arteries usually spasm and retract into the tissue, resulting in less bleeding than does a partial amputation, in which the lacerated arteries continue to bleed.

If the patient has sustained an amputation, bleeding is controlled with direct pressure and elevation. A tourniquet is applied only as a last resort. If a tourniquet is necessary, it should be made of wide material such as a blood pressure cuff, which is less damaging to nerves and blood vessels. A dressing is applied to the amputated extremity, which is referred to as the stump. The stump is covered with sterile saline-moistened gauze followed by dry gauze, which is held in place with an elastic bandage for pressure. Amputated parts are taken to the hospital with the patient for

possible reattachment. At the hospital, the amputated part is rinsed with saline solution, wrapped in sterile gauze, and placed in a sealed plastic bag, which is then placed in a mixture of ice and ice water.

For a patient with an injury caused by an impaled object, it is imperative that the object not be removed unless it is obstructing the airway. Removing an impaled object may cause additional trauma and uncontrollable internal bleeding. Impaled objects are never cut off, broken off, or shortened unless transportation to the emergency department is otherwise impossible. A bulky dressing is applied around the object to stabilize it and reduce motion.

Tetanus

Tetanus is a disease caused by the bacillus *Clostridium tetani*, which enters the body through an open wound. Tetanus causes seizures, muscle spasms, stiffness of the jaw, coma, and death. Tetanus vaccinations should begin at 2 months of age and be followed by a series of pediatric immunizations until age 15. Thereafter, booster vaccinations are recommended every 10 years in the absence of an open wound.

Head Trauma

Sharp blows to the head can cause shifting of intracranial contents and lead to brain tissue contusion. The pathophysiology of head trauma can be divided into two phases. The first phase is the initial injury that occurs at the time of the accident and cannot be reversed. The second phase involves intracerebral bleeding and edema from the initial injury, which causes increased intracranial pressure (ICP). Management of head trauma is directed at the second phase and involves decreasing ICP. Early and late signs and symptoms are listed in Box 12.5 Signs and Symptoms of Increased Intracranial Pressure.

Box 12.5

Signs and Symptoms of Increased Intracranial Pressure

Early Signs and Symptoms of Increased ICP

- Headache
- Nausea and vomiting
- Amnesia
- Altered level of consciousness
- Changes in speech
- Drowsiness

Late Signs and Symptoms of Increased ICP

- Dilated nonreactive pupils
- Unresponsiveness
- Abnormal posturing
- Widening pulse pressure
- Decreased pulse rate
- Changes in respiratory pattern

FIGURE 12.4 Immobilization of a patient suspected of having a spinal cord injury using a backboard and cervical collar.

Spinal Trauma

Spinal cord injury most often results from motor vehicle crashes, sports injuries, falls, and assaults, with most cases occurring in men ages 16 to 30. The cervical spine is especially vulnerable to traumatic injury. Patients who have sustained severe multiple injuries should be suspected of having a spinal cord injury, especially when they have signs of head trauma. All trauma patients should be treated as though they have a spinal cord injury until proven otherwise. Moving a patient with a vertebral injury may cause displacement of the injured bones and may increase damage to the spinal cord. Patients should be moved only by qualified people. Stabilization of the neck and back with a cervical collar and backboard is essential until spinal cord injury is ruled out (Fig. 12.4).

SAFETY TIP

Do not move a patient with suspected vertebral or spinal cord injury until sufficient qualified help is available to prevent further injury to the spinal cord.

Chest Trauma

Chest trauma can damage the heart and lungs and cause life-threatening injuries, including pericardial tamponade, hemothorax, tension pneumothorax, and **flail chest**. Potentially life-threatening injuries include pulmonary and myocardial contusion, aortic and tracheobronchial disruption, and diaphragmatic rupture.

Chest trauma can result in laceration of lung tissue and cause a change in the negative intrapleural pressure. Air or blood leaking into the intrapleural space collapses the lung, resulting in a pneumothorax (air) or hemothorax (blood) and ineffective ventilation. In a tension pneumothorax, air is trapped in the pleural space during exhalation, resulting in increased pressure on the unaffected lung. The heart, great vessels, and trachea shift toward the unaffected side of the chest. As a result, blood flow to and from the heart is greatly reduced, causing a decrease in cardiac output. An uncorrected tension pneumothorax is fatal.

Chest trauma can also injure the heart and great vessels

and reduce the amount of circulating blood volume. The heart may be bruised (myocardial contusion) or may sustain direct trauma. **Cardiac tamponade** occurs when blood accumulates in the pericardial sac and increases pressure around the heart. The increased pericardial pressure prevents the heart chambers from filling and contracting effectively. A patient with cardiac tamponade exhibits hypotension, **tachycardia**, and neck vein distention and requires immediate intervention to reduce the pressure in the pericardial sac and restore normal filling and contraction of the heart chambers.

Abdominal Trauma

The organs of the abdomen are vulnerable to injury because there is limited bony protection. Injury to organs such as the spleen and liver, which have a rich blood supply, can result in rapid loss of blood volume and **hypovolemic shock**. Abdominal organs may be injured as a result of severe blunt or penetrating trauma. If hypotension is present, intra-abdominal hemorrhage may exist. If the urinary bladder ruptures, urine leaks into the abdomen and blood may be detected at the urinary meatus or perineum. Penetrating trauma can cause lacerations to abdominal organs, resulting in rapid blood loss and hypovolemic shock.

Orthopedic Trauma

Fractured bones can result in blood loss, compromised circulation, infection, and immobility. Unstable pelvic fractures can cause injury to the genitourinary system or disrupt the veins in the pelvis. Fractures of large bones such as the femur and tibia can cause significant blood loss. For example, a fractured femur can cause up to 1500 mL of blood loss and a fractured tibia or humerus can cause up to 750 mL of blood loss. Joint dislocations can cause neurovascular compromise by applying pressure to the nerves and blood ves-

LEARNING TIP

If an extremity is fractured, splint it as it lies to prevent further damage. If the distal circulation is severely compromised, the patient needs immediate medical intervention.

tachycardia: tachy—fast + cardia—heart condition

sels. Delayed fracture reduction (realignment or setting) can cause avascular necrosis, which leads to death of the affected tissue and bone.

Nursing Process for the Patient Experiencing Trauma

Assessment/Data Collection

The mechanism of injury is determined to identify the extent of injury. Loss of consciousness immediately after the injury indicates that a concussion has occurred. The Glasgow Coma Scale (GCS) is used to rate a patient’s level of consciousness (Fig. 12.5). The highest score is 15, indicating that the patient is alert and needs only observation. Scores lower than 13 may indicate the need for immediate treatment. Morbidity and mortality are highest for patients with GCS scores of 8 or lower. Pupil size and reaction are monitored and recorded. Dilated or nonreactive pupils indicate increased ICP and a need for immediate intervention.

Spinal nerves are located in the spinal cord and transmit motor and sensory impulses to the body. The higher a traumatic lesion is on the spinal column, the more extensive will be the loss of muscle and sensory function. The patient’s muscle functions correlate with the level of spinal injury (Table 12.3). A spinal cord injury at the level of C5 or above interferes with diaphragmatic function and affects respiratory effort, which must be carefully assessed. The patient’s level of muscle control and ability to feel each extremity is noted and recorded.

Patients with major chest injuries can have dramatic symptoms. They may exhibit classic signs of shock with

L2–L4 or above	Patient unable to extend and flex legs
C5–C7 or above	Patient unable to extend and flex arms

cyanosis, dyspnea, and restlessness. The patient’s breathing pattern and effectiveness of respirations are assessed. The rise and fall of the chest is observed, as well as symmetrical chest movement. Any bruising on the chest or upper abdomen is noted. Seat belts and restraint systems can cause significant bruising in high-impact crashes.

Vital signs are taken to detect tachycardia and hypotension from shock. The shape of the abdomen is observed to detect distention from intra-abdominal hemorrhage. Skin color, bruising, open wounds, and penetrating trauma are noted. The abdomen is auscultated for bowel sounds. The perineum is inspected for blood from the urethra.

Vital signs and pain level are assessed to detect orthopedic abnormalities. A respiratory assessment is done to detect a pulmonary embolism as a result of a long bone fracture. The injured extremity is inspected and skin color and capillary refill are noted. Skin integrity, protruding bone, or deformity is noted. Pulses distal to the injury are palpated to assess circulation to the area. Motor function and sensation are assessed to determine the extent of nerve injury.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to tissue trauma

EXPECTED OUTCOME: The patient will experience relief after measures are provided to relieve pain as evidenced by verbal and nonverbal expressions of pain relief.

- Apply ice, elevate, and immobilize the affected area to decrease swelling and relieve pain.
- Provide analgesics as ordered to relieve pain.

Impaired skin integrity related to trauma

EXPECTED OUTCOME: The patient will demonstrate healing of impaired tissue.

- Apply direct pressure to open wounds to control bleeding.
- Irrigate open wounds with sterile saline solution to thoroughly remove dirt and debris and clean exposed tissue to prevent infection.

Risk for infection related to tissue trauma

EXPECTED OUTCOME: The patient’s wounds will remain free of infection.

- With open wounds, give **tetanus** immunization as ordered if it has been more than 5 years since one was last given *to prevent infection*.
- Give antibiotics as ordered *to prevent infection*.

Ineffective tissue perfusion: cerebral, related to cerebral edema

EXPECTED OUTCOME: The patient maintains adequate cerebral homeostasis without cerebral edema as evidenced by a GCS of 14 or greater.

- Give oxygen as ordered *to maintain adequate oxygenation of brain tissues and prevent cellular damage from hypoxia at the cerebral level*.
- If the patient has an altered level of consciousness or deteriorating respiratory effort, anticipate and assist with endotracheal intubation as needed *to provide respiratory support to patient*.
- Elevate the head of the patient's bed 15 to 30 degrees, if possible, *to reduce ICP*.
- Maintain the patient's head position at midline *to ensure unobstructed venous drainage to help reduce ICP*.
- Maintain intravenous access for fluids to maintain hemodynamic stability and access for medications.
- Monitor mannitol IV, an osmotic diuretic, as ordered *to decrease cerebral edema*.
- If the patient is agitated, calm the patient as *agitation increases ICP*.

Ineffective breathing pattern related to neck injury or unstable chest wall segment or lung collapse

EXPECTED OUTCOME: The patient maintains effective respiratory rate and experiences improved gas exchange in the lungs.

- If the cervical spinal cord has been traumatized, the effectiveness of breathing may be altered. If signs of respiratory distress are present, use the jaw thrust or chin lift maneuver, along with suction and airway adjuncts as needed to maintain patency of the airway.
- Maintain cervical collar and backboard *to prevent further injury*.
- Give oxygen as ordered *to improve tissue oxygenation*. Advanced adjunct airway equipment, including an endotracheal tube, must be readily available.
- Administer supplemental oxygen as ordered *to promote tissue oxygenation*.
- Maintain chest tube drainage system if inserted *to help expand lung*.

Ineffective airway clearance related to neck injury

EXPECTED OUTCOME: The patient will maintain clear lung sounds.

- Suction the oropharynx and nasopharynx *to clear secretions and prevent aspiration of secretions into the airway*.
- If the patient vomits, log roll the patient onto side *to prevent aspiration of emesis*. Use suction as needed.

Impaired physical mobility related to neck injury

EXPECTED OUTCOME: Patient will maintain normal movement of extremities for patient.

- Maintain neck immobility during initial treatment of a patient with head or neck trauma *to prevent serious injury until trauma damage is identified*.

Decreased cardiac output related to compression of heart and great vessels

EXPECTED OUTCOME: The patient will maintain vital signs within baseline limits.

- Report unstable vital signs to physician as *patient may need immediate surgical intervention in the operating room*.
- Explain diagnostic testing to patients with stable vital signs if radiographic studies are ordered *to determine the extent of cardiac or pulmonary injury*.
- Monitor patient's vital signs and oxygen saturation continuously *to detect signs of shock*.

Deficient fluid volume related to hemorrhage or abdominal organ injury

EXPECTED OUTCOME: Patient will maintain vital signs within baseline limits.

- Monitor for signs of shock *to detect hypovolemic shock*.
- Maintain IV fluids as ordered per 18- or 16-gauge IV cannulas *to restore circulating volume*.
- Assist with peritoneal lavage if performed *to detect intra-abdominal hemorrhage*.
- Maintain nasogastric tube if ordered *to decompress the stomach*.
- Cover abdominal wounds with a sterile dressing *to prevent infection*.
- If abdominal organs are exposed, cover with sterile saline-soaked dressings *to prevent tissue necrosis*.
- Assist with blood and blood products administration as ordered per agency policy *to maintain circulating volume and improve tissue oxygenation*.

Impaired physical mobility related to bone injury

EXPECTED OUTCOME: Patient will maintain movement of extremities normal for patient.

- Remove all jewelry before applying a splint *as the extremity may swell after injury*.
- Maintain extremity in splint in the position found unless the distal circulation is severely compromised and keep immobilized if there is severe pain or deformity. *Splinting promotes comfort and prevents further damage to surrounding tissue by preventing movement of broken bone ends*.
- Immobilize the joints above and below the affected area using a folded towel or a pillow *until the patient is evaluated by a physician*.
- Monitor skin color, temperature, distal pulses, capillary refill, movement, and sensation of the extremity after splint application *to detect abnormalities*.

- Elevate and ice extremity *to reduce edema and relieve pain.*

Evaluation

If interventions have been effective the following results will be evident: the patient with trauma reports an acceptable pain level and the patient's wound heals without infection; the patient with spinal injury maintains a regular rate, rhythm, and pattern of breathing, clear lung sounds and maintains intactness of mobility and GCS of 14 to 15; the patient with chest trauma maintains a patent airway and effective breathing pattern; the patient with abdominal trauma has effective circulating volume as evidenced by vital signs within normal limits; patients with orthopedic trauma have strong and palpable pulses, normal blood pressure, normal skin color, skin that is warm and dry, and capillary refill that is less than 3 seconds, pain controlled to a satisfactory level, and normal motor function and sensation in the extremity.

BURNS

The skin protects the body by preventing bacterial or viral invasion, enhancing temperature regulation, and conserving body fluids and electrolytes. These functions are impaired with a burn injury and can lead to multisystem alterations. Burn injuries are acutely painful events that may be dramatic in appearance. Nursing care depends on the extent and depth of the burn injury and the presence of any associated factors such as smoke inhalation, blunt trauma, or fractures. The more extensive the burn injury, the greater the potential for complications and mortality. The patient's age may contribute to the risk of mortality as well. Infants under age 2 and elderly patients over age 60 have the highest mortality rates from major burns. (See Chapter 55 for more on burns.)

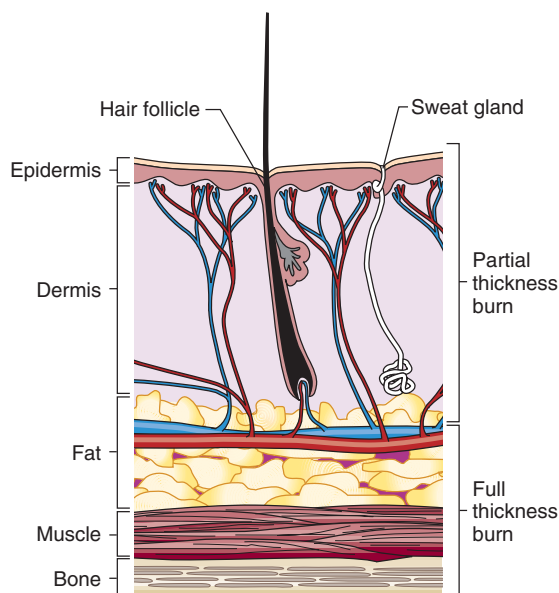

FIGURE 12.6 Partial- and full-thickness burns and structures affected.

FIGURE 12.7 A blistered partial-thickness thermal burn.

The assessment of the burn patient begins with the ABCDs of the primary survey. The history should include the mechanism and time of the injury and a description of the surrounding environment, including the presence of noxious chemicals and inhalation of smoke in an enclosed space. The greatest threat to life in a patient with a major burn injury is smoke or heat inhalation, which causes edema in the respiratory passages. Continuous assessment of respiratory status is essential when you observe burns or soot on the face, singed nasal hairs, a hoarse voice, coughing, or restlessness.

Burns of the face may swell rapidly and can compromise the airway. Facial burns are treated by elevating the head of the bed to 30 degrees to minimize edema. Oxygen is administered to the patient with potential pulmonary injury. Equipment for endotracheal intubation should be readily available. Because large fluid losses occur in burn injuries, an IV infusion with large-bore cannulas should be started. The patient's weight and the extent of the burn determine fluid resuscitation needs. The patient is kept warm because when skin is lost, a burn victim cannot maintain body heat. IV narcotics are administered for pain.

Burn depth is described as either partial thickness or full thickness (Fig. 12.6). **Partial-thickness burns** are either superficial (epidermis of the skin) or deep (entire epidermal layer and part of the dermis) (Fig. 12.7). **Full-thickness burns** involve all the layers of the skin and the subcutaneous tissue. Partial-thickness burns that involve a small area are cleaned with sterile saline solution, covered with a 1/8-inch layer of an anti-infective cream such as silver sulfadiazine (Silvadene, Flamazine), and covered with dry, bulky, fluffed dressings. Major full-thickness

LEARNING TIP

Over-the-counter ointments, lotions, butter, and antiseptics are never used on a major burn because they may promote infection, retain heat, and cause more pain.

CRITICAL THINKING

Mr. Smith

■ Mr. Smith is a 28-year-old man who was welding close to a natural gas line. The flame of the welder caused the gas line to explode, throwing Mr. Smith 50 feet. He landed on his back. He is brought to the emergency department by the rescue squad. Mr. Smith is awake, alert, and oriented. He has soot around his mouth and nose. He sustained deep partial-thickness burns to his neck, upper chest, and both forearms. He is complaining of pain from his burns and also thoracic back and hip pain. His pulse rate is 100. His blood pressure is 160/90. His respiratory rate is 20.

1. What is the first priority of care for Mr. Smith?
2. Is Mr. Smith at risk for respiratory burns? Why?
3. Are Mr. Smith's vital signs within normal limits?
4. Would wet or dry dressings be preferable for his large areas of deep partial-thickness burns? Why?
5. Mr. Smith is wearing a neck chain and a wedding ring. Should they be removed immediately, or should you wait until Mr. Smith's wife arrives to take them? Why?
6. Mr. Smith continues to complain of hip and back pain. In reviewing his mechanism of injury, what other injuries could Mr. Smith have?

Suggested answers at end of chapter.

wounds are covered with dry, sterile dressings or linen. Patients with major burns are transferred to a specialized burn unit.

HYPOTHERMIA

Normally the body maintains its temperature in a narrow range on either side of 98.6°F (37°C) to allow chemical reactions to work most efficiently. Body heat escapes to the environment through conduction, convection, radiation, and evaporation. Heat loss is inversely proportional to body size and body fat. Fat insulates because it has less blood flow and consequently has less ability to vasodilate and lose heat.

Hypothermia occurs when the core body temperature falls below 95°F (35°C). As the core temperature falls below 95°F, the body is less able to regulate its temperature and generate body heat, causing progressive loss of body heat to occur.

Nursing Process for the Patient with Hypothermia

Assessment/Data Collection

In cases of mild hypothermia (core temperature between 90°F [32°C] and 95°F [35°C]), the patient is usu-

TABLE 12.4 DEFINING CHARACTERISTICS AND OUTCOME CRITERIA FOR HYPOTHERMIA

Core Body Temperature	Defining Characteristics
Below 95°F (35°C)	<ul style="list-style-type: none"> • Skin cold to touch • Lack of coordination • Slurred speech
Below 91.4°F (33°C)	<ul style="list-style-type: none"> • Cardiac dysrhythmias • Cyanosis
Below 89.6°F (32°C)	<ul style="list-style-type: none"> • Shivering replaced by muscle rigidity • Hypotension • Dilated pupils
Below 82.4°F (28°C)	<ul style="list-style-type: none"> • Absent deep tendon reflexes • Hypoventilation (3–4 breaths per minute) • Ventricular fibrillation possible
Below 80.6°F (27°C)	<ul style="list-style-type: none"> • Coma • Flaccid muscles • Fixed, dilated pupils • Ventricular fibrillation to cardiac standstill • Apnea
Outcome Criteria	
<ul style="list-style-type: none"> • Core body temperature is greater than 95°F (35°C). • Patient is alert and oriented. • Cardiac dysrhythmias are absent. • Acid-base balance is normal. • Pupils react normally. 	

ally alert, shivering, and may appear clumsy, apathetic, or irritable (Table 12.4). Hypoglycemia can occur because glucose and glycogen stores are depleted by long-term shivering. Respiratory rate, heart rate, and cardiac output decrease.

More severe hypothermia occurs between 85 and 90°F (29.4 and 32.2°C). Shivering stops and muscle activity decreases. Initially, fine muscle coordination ceases. Then, as core body temperature continues to drop, all muscle activity stops and the muscles become rigid. The patient becomes lethargic and less interested in combating the cold environment. The patient's level of consciousness begins to markedly decrease at 89.6°F (32°C); the patient becomes lethargic and disoriented and begins to hallucinate. The pupils become dilated. As the core body temperature falls to 82°F (28°C), the patient becomes apneic, the pulse becomes slower and weaker, and cardiac dysrhythmias occur. The profoundly hypothermic patient has a core temperature of less than 80°F (27°C) and usually appears dead, with no obtainable vital signs. Determination of death should be made only after aggressive core rewarming to at least 90°F (32.2°C).

Nursing Diagnosis, Planning, and Implementation

See Box 12.6 Nursing Care Plan for the Patient with Hypothermia.

Initial treatment of the hypothermic patient consists of rewarming the patient, stabilizing vital functions, and preventing further heat loss. The patient is removed from the cold environment. All wet clothing is removed to prevent

Box 12.6 NURSING CARE PLAN for the Patient with Hypothermia

Nursing Diagnosis: Hypothermia related to exposure to cold environment

Expected Outcome Body temperature and vital signs are within normal limits

Evaluation of Outcome Is patient's body temperature greater than 95°F (35°C)? Is patient alert and oriented? Is cardiac rhythm normal?

Intervention

Monitor patient's core body temperature.

Monitor pulse and electrocardiogram (ECG) rhythm.

Monitor patient's level of consciousness.

Institute rewarming passively or actively as ordered.

Rationale

Abnormal body temperature can be detected and treated.

Cardiac dysrhythmias may occur at temperatures below 91.4°F (33°C).

Level of consciousness becomes markedly decreased at temperatures of 32°C (89.6° F).

Rewarming is necessary to return body temperature to desirable range.

Evaluation

Is body temperature greater than 95°F (35°C)?

Is pulse rate and ECG rhythm normal?

Is the patient alert?

Is body core temperature rising to normal range?

further heat loss. The patient's core body temperature guides treatment. If the body temperature is above 82.4°F (28°C), passive rewarming is preferred. The room temperature is set to 70 to 75°F (21.1 and 23.8°C). The patient is wrapped in warm, dry blankets. Heat loss from the head is reduced by covering the head with warm towels.

For a patient with a core body temperature below 82.4°F (28°C), active rewarming is needed. A heating blanket (carbon-fiber) and radiant heat lights are used. Warm, humidified oxygen is administered. Warm IV fluids are administered. Body temperature is constantly monitored using a rectal probe. Heated **gastric lavage**, heated peritoneal lavage, or cardiopulmonary bypass may be performed for profound hypothermia. Cardiac drugs are given sparingly because as the body warms, peripheral vasodilation occurs. Drugs that were trapped in the peripheral circulation are then suddenly released during rewarming, leading to a bolus effect that may cause fatal dysrhythmias.

Evaluation

Desired outcome criteria for the patient with hypothermia is a core body temperature higher than 95°F (35°C), no cardiac dysrhythmias, pulse and blood pressure within normal limits, and an alert and oriented status.

FROSTBITE

The extremities are vulnerable to cold injury. Frostnip occurs when exposed parts of the body become very cold but not frozen. This condition usually is not painful. The skin becomes pale and blanched. Contact with a warm object such as someone's hand may be all that is needed to rewarm the part. During rewarming, the affected part may tingle and become red.

Frostbite occurs when body parts become frozen. The extremities are at increased risk because blood shunts away from them to maintain core body temperature. The affected tissue feels hard and frozen. Most frostbitten parts are white, yellow-white, or blue-white. When rewarmed, the skin appears deep red, hot, and dry to touch. The severity of a cold injury is determined by the duration of the exposure, the temperature to which the body part was exposed, and the wind velocity during exposure.

Interventions for frostbite include protecting the affected area from further trauma. To prevent additional damage, the frostbitten part is handled gently and never rubbed. The injured part is loosely covered with a dry, sterile dressing. The patient is not allowed to stand or walk on a frostbitten foot. The affected extremity is elevated to heart level to minimize edema and promote blood flow.

HYPERTHERMIA

Usually the body's heat-regulating mechanisms work very well, allowing people to tolerate significant temperature changes. The body's most efficient mechanisms to decrease body heat are sweating and dilation of blood vessels in the skin. When blood vessels dilate, blood comes to the skin surface to increase the rate of radiation of heat from the body. However, when these mechanisms become overwhelmed, the consequences can be disastrous and irreversible. Those at greatest risk for heat illnesses include children, elderly people, and patients with cardiac disease.

Hyperthermia results when thermoregulation breaks down because of excess heat generation, an inability to dissipate heat, overwhelming environmental heat, or a combination of these factors. Unlike a fever, in which the thermal set point is elevated, in heat illness the thermal set point

SAFETY TIP

Older adults are vulnerable to hyperthermia. In times of extreme summer temperatures, older people who live alone should be checked to make sure they are not experiencing hyperthermia. If they do not have fans or air conditioning available, they should be taken to a cooler environment.

remains normal and hyperthermia occurs because of an inability to dissipate heat. Antipyretics are of no use in hyperthermia and may contribute to complications.

Nursing Process for the Patient with Hyperthermia

Assessment/Data Collection

Illness from heat exposure can take three forms: heat cramps, heat exhaustion, and **heatstroke** (Box 12.7 Defining Characteristics and Outcome Criteria for Environmental Hyperthermia). As heat illness progresses, circulating blood volume decreases, causing dehydration. Fluid intake is crucial in the prevention of heat illness.

HEAT CRAMPS. Heat cramps, the mildest form of heat illness, involve painful muscle spasms, usually in the legs or abdomen, that occur after strenuous exercise. Large amounts of salt and water can be lost as a result of excessive

sweating, causing stressed muscles to spasm. With adequate rest and fluid replacement, the body adjusts the distribution of electrolytes and the cramps disappear.

HEAT EXHAUSTION. Heat exhaustion occurs when the body loses so much water and electrolytes through heavy sweating that hypovolemia occurs. Heat exhaustion is largely a manifestation of the strain placed on the cardiovascular system attempting to maintain normothermia. Cerebral function is unimpaired, although the patient may show minor irritability and poor judgment. The ability to sweat remains. The skin is usually cold and clammy and the face gray. Sodium and water loss cause the patient to become dehydrated. The body temperature is usually normal or slightly elevated: from 100.4 to 102.2°F (38 to 39°C). The patient may complain of feeling dizzy, weak, or faint, with nausea or a headache. Vomiting and diarrhea may also be present.

HEATSTROKE. If symptoms of heat exhaustion are not treated, heatstroke can develop. Altered mental status and an inability to sweat are key symptoms in heatstroke. Some patients show confusion, irrational behavior, or psychosis; others develop seizures or go into a coma. Because the sweating mechanism has been overwhelmed, many heatstroke victims have hot, dry, flushed skin. The body temperature rises rapidly to 106°F (41°C) or more, and the patient's level of consciousness decreases. If heatstroke is not treated, death results.

Patients suffering from heatstroke are admitted to the intensive care unit because late complications can appear suddenly and require immediate management. Relatively common occurrences include seizures, cerebral ischemia, renal failure, late cardiac decompensation, and gastrointestinal bleeding. Long-term prognosis is variable, depending on the patient's previous state of health and length of time under heat stress.

Nursing Diagnosis, Planning, and Implementation

Hyperthermia related to exposure to hot environment

EXPECTED OUTCOME: The patient will maintain body temperature within normal limits.

- For heat cramps, remove the patient from the hot environment *to allow cooling to begin.*
- Have patient sit or lie down until muscle cramps subside *to prevent further injury.*
- Remove patient from the hot environment, undress patient to allow patient to cool. *Emergency treatment of heatstroke consists of reducing the body temperature and rapidly cooling the victim.*
- Use tepid water as a mist spray over the patient, with a strong continual breeze from electric fans *as evaporative cooling is the most efficient method of cooling.*

Deficient fluid volume related to hypovolemia

EXPECTED OUTCOME: The patient will maintain blood pressure within normal limits of baseline.

Box 12.7

Defining Characteristics and Outcome Criteria for Environmental Hyperthermia

Defining Characteristics

Early signs:

- Core body temperature 100.4 to 102.2°F (38 to 39°C)
- Diaphoresis
- Cool, clammy skin
- Dizziness
- Pulse rate >100

Late signs:

- Increasing body core temperature of 106°F (41°C) or more
- Hot, dry, flushed skin
- Altered mental status
- Coma or seizures possible
- Hypotension

Outcome Criteria

- Core body temperature less than 101°F (38.3°C)
- Patient alert and oriented
- Skin warm and dry to touch

- Give patient oral fluids or water or a diluted (half-strength) balanced electrolyte solution if patient is fully alert to *replace lost fluids*.
- Maintain IV fluids as ordered to *restore volume if patient is hypotensive*.

Evaluation

Interventions have been successful if the hyperthermic patient has a core body temperature below 101°F (38.3°C), warm and dry skin, a strong pulse, blood pressure within normal limits, and is alert and oriented.

POISONING AND DRUG OVERDOSE

Poisons are introduced into the body by ingestion, inhalation, injection, absorption, or venomous bites. Poisons act by changing cellular metabolism, causing damage to structures, or disturbing function. Many toxins and poisons alter the patient's mental status, making it difficult to obtain an accurate history.

Nursing Process for the Patient with Ingested Poisoning

Assessment/Data Collection

The primary nursing responsibility is to recognize that a poisoning has occurred and then attempt to determine the nature of the poison. The method of exposure is established so that removal or interruption of the toxin can begin. Most ingested poisons are drugs, but about one-third of poisonings are caused by cleaners, soaps, insecticides, acids, or alkalis. Many household plants are poisonous if they are accidentally ingested. Some plants cause local irritation of the skin, and others can affect the circulatory system, gastrointestinal tract, or central nervous system.

Empty medication bottles, scattered pills, or chemicals should be examined by emergency medical personnel at the scene to help establish the identity of the substance. The patient's physical appearance may also give a clue to the type of substance taken. Intravenous needle tracks, burns, erythema, and flushed skin may help identify the poison or toxic exposure. Poison control centers have access to information concerning virtually all poisonous substances, available antidotes, and appropriate emergency treatment.

Nursing Diagnosis, Planning, and Implementation

Risk for injury related to absorption of poisoning agent

EXPECTED OUTCOME: The patient will maintain normal vital signs and be free of injury.

- Administer syrup of ipecac (usual dose of syrup of ipecac is 15 mL for children ages 1 to 5 years and 30 mL for ages 6 years and up) as ordered if patient is fully alert and ingested substance is nonerosive and not petroleum based. Follow with several glasses of water. *Treatment for ingested poisons*

includes rapid removal of poison (vomiting usually occurs within 30 minutes) from gastrointestinal tract with dilution of any remaining poison.

- Repeat syrup of ipecac dose once as ordered if vomiting does not occur after 30 minutes.
- Assist with gastric lavage if indicated to flush ingested poisons from the stomach: large gastric tube inserted via nose or mouth into patient's stomach; water instilled via tube in 60-mL amounts and withdrawn to evacuate any remaining poison; repeated until 2 L of water has been lavaged or until the gastric return is clear of any pill fragments or substance. Activated charcoal with sorbitol is given to absorb toxins and facilitate rapid transit of the poison through the intestinal tract.

LEARNING TIP

Sorbitol and charcoal will cause the patient to have black diarrheal stools.

Evaluation

Interventions have been successful if the patient remains free from injury and has vital signs within normal limits.

Inhaled Poisons

Inhaled poisons include natural gas, pesticides, carbon monoxide, chlorine, and other gases. Carbon monoxide is odorless and can produce profound hypoxia by combining with hemoglobin molecules (and displacing oxygen) in red blood cells. The patient's carboxyhemoglobin levels are monitored to direct appropriate therapy. Inhalation of chlorine is very irritating to the respiratory system and can produce airway obstruction and pulmonary edema.

When an inhalation injury occurs, the patient must be moved into fresh air and away from the toxin. Supplemental oxygen is given as ordered. A patient exposed to prolonged inhalation of a poison may experience lung damage. Respiratory status must be closely monitored to detect complications.

Injected Poisons

Injected poisons pose compelling problems because they are difficult to remove or dilute. Usually they result from drug overdose, but they can also result from the bites and stings of insects or animals. Local swelling and tissue destruction may occur at the injection site. All jewelry is removed because swelling may occur. A cold pack is applied to decrease local pain and swelling around the injection site. The identity of the injected drug or toxin must be established so that adverse effects can be anticipated and managed.

Insects

Insect stings or bites cause anaphylaxis in a small percentage of people; however, symptoms are typically limited to

localized pain, swelling, heat, and redness. Potentially dangerous stings or bites may come from bees, wasps, yellow jackets, hornets, certain ants, scorpions, and some spiders. Treatment involves applying ice to the site and elevating the affected part. Cellulitis can occur hours later and may require medical treatment.

When a patient has sustained a bee or wasp sting, examine the area for the stinger and remove it by gently scraping it off the skin. Tweezers or forceps are not used to remove the stinger because squeezing the stinger can inject more venom into the patient. Placing ice over the injury site may help slow the rate of toxin absorption.

Two types of spiders—the black widow and the brown recluse—can inflict serious and sometimes life-threatening bites. Both species are found throughout the United States. Antivenin for treating the toxic effects of both is available. Black widow spiders are glossy black and have a distinctive, bright red-orange marking in the shape of an hourglass on the abdomen. They are found in dry, dim places around buildings, in woodpiles, and among debris. Their venom is neurotoxic and causes systemic symptoms, including cramping of large muscle groups, dyspnea, weakness, sweating, nausea, vomiting, and rash. Death is uncommon, and symptoms generally subside in 48 hours.

The brown recluse spider is dull brown and has a dark violin-shaped mark on its back. It tends to live in dark areas, under rocks, in woodpiles, and in old abandoned buildings. The venom of the brown recluse causes severe local tissue damage. The area becomes red, swollen, and tender and develops a pale, mottled, cyanotic center. A large ulcer can develop within 48 hours if not treated promptly. Systemic symptoms include fever, chills, nausea, vomiting, arthralgia, and weakness.

Snakebites

Only a small percentage of snakebites are caused by poisonous snakes. The most prevalent poisonous snakes are the coral snake and the pit vipers, which include rattlesnakes, copperheads, and cottonmouth moccasins. Envenomation occurs when the snake's hollow fangs puncture the skin and inject venom, which is stored in sacs located at the back of the snake's head. A poisonous snakebite has two small puncture wounds with surrounding discoloration, swelling, and pain. Envenomation by any of the pit viper snakes produces burning pain at the site of the injury. Swelling and discoloration occur within 5 to 10 minutes after the bite.

Interventions are focused on decreasing the circulation of venom throughout the patient's system by keeping the patient calm and immobilizing the affected part. Venous tourniquets placed above and below the fang marks help limit the spread of venom through the veins of the extremity. The tourniquets should not stop arterial flow. The patient's pulse should be palpable below the tourniquets after they are applied. The site of the bite is cleaned with soap and water. The patient is kept calm until antivenin can be given. Medical treatment of the patient with a poi-

sonous snake bite should be directed by an experienced toxicologist.

NEAR-DROWNING

Drowning is death from **asphyxia** after submersion in water. Near-drowning is submersion with at least temporary survival of the victim. Life-threatening complications of near-drowning are respiratory failure and ischemic neurological injury from hypoxia and acidosis. When submersion occurs, conscious victims hold their breath until reflex inspiratory efforts override breath holding. As water is aspirated, laryngospasm occurs, producing severe hypoxia. In wet drowning, the laryngospasm is less prolonged and fluid enters the lungs after the vocal cords relax. In dry drowning, cold water causes laryngospasm and vagal stimulation which leads to asphyxiation. Most successfully resuscitated victims experience dry drowning. Risk factors for drowning include inability to swim, diving accidents, use of alcohol and drugs prior to swimming, exhaustion, and hypothermia.

If a person survives submersion, acute respiratory failure may follow. The incidence of serious pulmonary complications is high in this group. Symptoms of impaired gas exchange (known as secondary near-drowning) may be delayed as long as 72 hours after the incident. Contaminants in the water can irritate the pulmonary system and cause inflammatory reactions and impaired surfactant functioning. Metabolic acidosis is usually present, leading to tissue anoxia and dysrhythmias.

Aggressive resuscitative efforts should be used on victims of cold water drowning when submersion time is 1 hour or less. Hypothermia can decrease the metabolic needs of the brain and contribute to neurological recovery after prolonged submersion.

Nursing Process for the Near-Drowning Patient

Assessment/Data Collection

Most near-drowning victims exhibit mild dyspnea, death-like appearance with blue or gray skin color, apnea or **tachypnea**, hypotension, slow heart rate (may be as low as less than 10 beats per minutes), cold skin temperature, dilated pupils, hypothermia, and vomiting. Vital signs are assessed to detect abnormal readings. Respiratory rate and pattern are observed. Any dyspnea or signs of airway obstruction are noted. Skin color or cyanosis is noted. The patient's level of consciousness may be altered due to anoxia.

Nursing Diagnosis, Planning, and Implementation

Ineffective tissue perfusion related to severe anoxia

EXPECTED OUTCOME: The patient will maintain level of

tachypnea: tachy—fast + pnea—breathing

consciousness and vital signs within normal range, with clear breath sounds that are equal bilaterally.

- Conduct ABCDs of the primary survey, *which always begin resuscitative efforts.*
- Give supplemental oxygen as ordered *to increase tissue oxygenation.*
- Ensure that adjunct airway equipment is available. *Endotracheal intubation and insertion of a nasogastric tube to decompress the stomach may be needed.*

Evaluation

Factors that influence the outcome of near-drowning include the temperature of the water, length of time submerged, cleanliness of the water, and age of the victim. The younger the patient, the better the chance of survival. Interventions have been successful if the patient has normal respiratory rate and pattern and vital signs, is alert and oriented, and skin that is warm and dry to touch with capillary refill of less than 3 seconds.

PSYCHIATRIC EMERGENCIES

A psychiatric emergency exists when people no longer possess the coping skills necessary to maintain their usual level of functioning. The patient's moods, thoughts, or actions may be so disordered that the patient has the potential to endanger or harm self or others if the situation is not quickly controlled. If acute psychiatric episodes are not managed, they can result in life-threatening, suicidal, violent, or psychologically damaging behavior. If an emotional trauma is not managed successfully, a condition known as posttraumatic stress disorder may result in which tension, anxiety, guilt, and fear concerning the traumatic event produce cognitive, affective, and behavioral responses to memories of the event long after the event has passed.

A crisis occurs when people enter a sudden state of emotional turmoil and are unable to resolve the situation with their own resources. Common emotional or behavioral manifestations of psychiatric crises include responses to stressful events, anxiety, depression, psychosis, and mania. Anxiety may range in severity from mild to panic. Panic evolves into complete disorganization and loss of control. The patient in panic is terrified and needs external controls to avoid harm. Depression is an affective disorder most commonly characterized by physical ailments and somatizations. Antidepressants are used to restore the balance of brain neurochemicals and diminish the symptoms of depression. Psychotic patients experience impaired thought processes and thought content characterized by hallucinations, delusions, ideas of reference, thought broadcasting, and thought insertion. Psychotic thinking and abnormal speech patterns interfere with the patient's attempt to communicate rationally. Manic behavior is most commonly the result of manic-depressive (bipolar) disorder. Manic persons typically exhibit bizarre, extreme, and hyperactive behaviors. Manic persons are also at high risk for injuring themselves or others.

Nursing Process for the Patient with a Psychiatric Emergency

Assessment/Data Collection

Causes of psychiatric emergency symptoms are varied and require thorough assessment of the patient's history and mental status. Information from the patient's medical history may produce possible organic causes contributing to the patient's presenting symptoms. Endocrine dysfunction, electrolyte abnormalities, and head trauma are examples of medical conditions that may cause changes in mental status. A medication history is obtained to determine compliance with medication regimens and any recent changes in medications. Information regarding recent use of alcohol or illicit drugs should be obtained because these substances can heighten psychiatric emergencies. A brief mental status examination is conducted. An assessment of the person's suicide risk is very important. The patient's appearance, behavior, cognitive function, thought content, and thought processes are noted. The nurse determines whether the patient is having problems concentrating, following instructions, or recalling his or her medical history.

Nursing Diagnosis, Planning, and Implementation

Anxiety related to situational stress

EXPECTED OUTCOME: The patient will state reduced anxiety.

- Establish an atmosphere of trust *so the patient feels free to discuss problems.*
- Use active listening *to acknowledge patient's physical and emotional concerns.*
- Speak directly and truthfully to the patient; do not promise unachievable things *to gain patient trust.*
- Trusted supportive members of the patient's family may be involved *to calm the person and encourage cooperation.*
- Do not allow bystanders or adversive family members to visit patient *who could create further upset for the patient.*
- Show respect for the patient *by not laughing or joking.*
- Correct misconceptions, but not in an argumentative manner.

Risk for injury related to impaired judgment

EXPECTED OUTCOME: The patient will remain free from injury.

- Do not threaten, challenge, or argue with a disturbed patient *to prevent injury.*
- Ensure environment is made safe, and external sources of stimulation are reduced *to prevent injury.*
- Be firm but unthreatening *to keep patient safe.*
- Administer antipsychotic medications as ordered and monitor their effect.
- Follow agency policy for use of physical restraint as necessary and ordered. *Restraints should only be used to ensure patient safety with physician order.*
- Document need for restraints and monitor patient and check pulses and capillary refill after restraints

applied. *Restraints must not cause patient harm or restrict circulation.*

- Administer haloperidol (Haldol) as ordered if patient requires rapid tranquilization.

Evaluation

Interventions are successful if the patient reports reduced anxiety and remains free from injury.

DISASTER RESPONSE

Disaster is defined as any event that overwhelms existing personnel, facilities, equipment, and capabilities of a responding agency, institution, or community. Potential sources of disaster include internal events such as fires and explosions; external events such as floods, storms, fires, earthquakes, and tornados; and created events such as motor vehicle accidents, plane crashes, and acts of terrorism.

External disasters involve a communitywide response of several different agencies, including emergency medical system (EMS) providers, fire agencies, law enforcement, and hospitals. These agencies work together to coordinate search, rescue, transportation, communication, and treatment of multiple victims. Hospitals serve as the major treatment area for victims of a disaster, referred to as casualties. When a disaster occurs, the hospital activates its disaster plan, which outlines specific duties for each nursing unit and the staff for each nonnursing department as well. Typically, each nursing unit prepares for the influx of casualties by calling all available off-duty staff to report to work and by discharging noncritical patients. In a hospital disaster plan, each nursing unit is usually designated to receive specific types of casualties, such as major trauma, burns, medical, pediatric, or psychiatric. The emergency department serves as the **triage** and stabilization area for the casualties. To facilitate the triage (sorting for the purpose of assigning priorities), stabilization, and transportation of numerous casualties, additional emergency department staff may be called in to work. In addition, the hospital disaster plan may require assigning one or more staff from each nursing unit and each nonnursing department to a specific area or task within the emergency department, such as triage, first aid, critical care, burn treatment area, family room, or transportation.

During a disaster, decision making and prioritization of patient care are guided by the resources and personnel available. Patients who are seriously injured and have the greatest chance of full recovery are treated first. Each hospital, as well as each agency involved in responding to a disaster, follows a disaster response plan that outlines the roles and responsibilities of the agency staff and the procedures to follow when interacting with the media, families, other agencies, and casualties. Disaster drills are conducted on a regular basis to evaluate and rework plans. You should be familiar with your agency's disaster plans and policies and know your role and responsibilities in a disaster.

BIOTERRORISM

Well before the 2001 anthrax outbreak, public health and government leaders in the United States recognized the need for increased preparedness to detect and respond to acts of biologic terrorism. The response to a **bioterrorism** attack is in many ways the same as the response to naturally occurring outbreaks of communicable disease. Both situations typically require early identification of ill or exposed persons, rapid implementation of preventive therapy, special infection control considerations, and collaboration or communication with the public health system.

During both bioterrorism attacks and naturally occurring outbreaks, nurses are faced with the challenge of identifying the disease in persons who are worried about potential exposure or who are ill with signs and symptoms similar to those of the outbreak disease. The nurse must have knowledge of the modes of transmission, incubation periods, and communicable periods of these diseases, as well as skill in both clinical evaluation and eliciting an appropriate and thorough history, including relevant occupational, social, and travel information.

Recognition of Potential Bioterrorism Agents

The Centers for Disease Control and Prevention (CDC) evaluates bacteria, viruses, and toxins thought to pose the greatest risk for use in a bioterrorist attack (see <http://www.bt.cdc.gov/>). Category A agents are thought to pose the highest immediate risk for use as biological weapons; and category B agents, the second highest risk. Category C agents are emerging threat risk agents that pose a potential, but not immediate, risk for use as biological weapons.

As in naturally occurring outbreaks, early recognition of a bioterrorist attack is critical for rapid implementation of preventive measures and treatment. Early recognition can be challenging, however, because patients presenting for medical care after exposure to a biological agent may initially exhibit nonspecific symptoms. One of the most important lessons learned from the 2001 anthrax attack was that clinical illness caused by agents prepared as biological weapons may differ from typical natural infections.

Smallpox/Variola Major

Smallpox is caused by the variola virus, an orthopoxvirus unique to humans. This virus is not known to be transmitted by animals or insects. Smallpox was declared eradicated in 1980, 3 years after the last naturally occurring case was reported. Smallpox is stable and highly infectious in the aerosol form. The risk for a smallpox attack currently is considered low but not zero.

Classification/Variola Major

Smallpox has an average fatality rate of 30%. The incubation period is 7 to 17 days. Symptoms of the initial phase include the acute onset of high fever, malaise, headache, backache, and prostration. Other prominent symptoms include vomiting and abdominal pain.

The characteristic rash occurs 2 to 3 days later, appearing first on the face and forearms. The rash progresses slowly, from macules to papules to vesicles and pustules and finally to scabs, with each stage lasting 1 to 2 days. The lesions are firm, discrete vesicles or pustules (4 to 6 mm in diameter) deeply embedded in the dermis. The patient remains febrile throughout the evolution of the rash, which may become painful as pustules enlarge. A second fever spike 5 to 8 days after onset of the rash may signify a secondary bacterial infection.

Pustules remain for 5 to 8 days, after which crusting occurs. They are more concentrated on the face and distal extremities than on the trunk, and may involve the palms and soles. Scarring occurs with scab separation from destruction of sebaceous glands.

Complications of smallpox include fluid and electrolyte disturbances, extensive skin loss that resembles burns, bronchitis and pneumonitis, blindness from infection of the eye, arthritis, and encephalitis.

Diagnosis

A suspected case of smallpox is a public health emergency. Local and state health authorities, the hospital epidemiologist, and other members of a hospital response team for biological emergencies should be notified immediately.

The differential diagnosis of smallpox includes other illnesses that can cause fever and a rash. Severe varicella (chickenpox) is the disease most likely to be confused with smallpox. However, familiarity with the clinical features of the two diseases, particularly the rash, should help differentiate them. Additional information that may be useful in differentiating smallpox from chickenpox includes a history of exposure to persons with chickenpox, a personal history of chickenpox, a history of vaccination against varicella or smallpox, and the clinical course of illness.

Infection Control and Postexposure Isolation

In the event of a limited outbreak, patients should be admitted to the hospital and confined to rooms that are under negative atmospheric pressure and equipped with high-efficiency particulate air (HEPA) filtration. Standard, contact, and airborne precautions, including use of gloves, gowns, and masks, should be strictly observed. Unvaccinated personnel caring for patients suspected of having smallpox should wear fit-tested N95 or higher quality respirators. Patients should wear a surgical mask and be wrapped in a gown or sheet to cover the rash when they are not in a negative-airflow room. All laundry and waste should be placed in biohazard bags and autoclaved before being laundered or incinerated. Surfaces that may be contaminated with smallpox virus can be decontaminated with disinfectants that are used for standard hospital infection control, such as hypochlorite and quaternary ammonia.

Anthrax

Anthrax is a disease caused by the spore-forming bacterium *Bacillus anthracis*. The organism is found worldwide in soil. Animals become infected through grazing in contaminated areas. Under natural conditions, humans contract the disease

after close contact with infected animals or contaminated animal products such as hides, wool, or meat. On exposure to tissues or blood of an animal or an infected human, the spores germinate.

Classification and Epidemiology

Anthrax occurs in three clinical forms in humans: inhalational, cutaneous, and gastrointestinal. In a biological attack, aerosol exposure to anthrax spores would be most likely. Before 2001, exposure to powdered anthrax spores in an envelope or package was not thought to be an efficient means of causing inhalational disease. However, exposure to anthrax spores sent through the U.S. mail in the 2001 anthrax attack resulted in cases of inhalational anthrax and cutaneous disease.

Cutaneous anthrax is the most likely way to develop anthrax. It results from inoculation of spores subcutaneously through a cut or abrasion. Gastrointestinal and oropharyngeal anthrax occur in rural parts of the world where anthrax is endemic. They result from ingestion of meat contaminated with spores.

Inhalational Anthrax

CLINICAL PRESENTATION AND DIAGNOSIS. Clinical symptoms develop rapidly after germination of anthrax spores. The incubation period for inhalational disease is most commonly reported as 1 to 6 days but may be prolonged by antibiotic administration.

Inhalational anthrax has been described as a two-stage disease. The initial stage is a nonspecific, flulike illness lasting from several hours to a few days. The early clinical presentation includes some combination of fever, myalgia, headache, cough, mild chest discomfort, weakness, abdominal pain, and chest pain. Profound malaise, fever, and drenching sweats are prominent symptoms, and nausea and vomiting are frequent. Classically, the initial stage is followed 1 to 3 days later, sometimes after brief improvement, by the rapidly progressive second stage, characterized by fever, dyspnea, diaphoresis, cyanosis, and shock.

There is no rapid screening test to diagnose inhalational anthrax in its early stages. In persons with a compatible clinical illness for whom there is a heightened suspicion of anthrax based on clinical and epidemiological data, the appropriate initial diagnostic tests are a chest x-ray or chest computed tomographic (CT) scan, or both, and culture and smear of peripheral blood. Pleural fluid and cerebrospinal fluid, as well as biopsy specimens taken from the pleura and lung, are also potentially useful for culture and other testing when disease is present in these sites, whereas sputum culture and Gram stain are unlikely to be useful.

THERAPEUTIC INTERVENTION. Early intravenous antibiotic treatment may improve survival in inhalational anthrax. Aggressive supportive care, including attention to fluid, electrolyte, and acid-base disturbances and drainage of pleural effusions, also play an important role in treatment. At present, intravenous ciprofloxacin or doxycycline plus one or two additional antimicrobials are recommended.

Cutaneous Anthrax

After an incubation period of approximately 7 days (range 1 to 12 days), the primary lesion of cutaneous anthrax appears as a nondescript, painless, pruritic papule, usually on an exposed area such as the face, head, neck, or upper extremity. The papule enlarges and develops a central vesicle or bulla with surrounding brawny, nonpitting edema. The central vesicle enlarges and ulcerates over 1 to 2 days, becoming hemorrhagic, depressed, and necrotic and leading to a central black eschar. Satellite vesicles may be present. The eschar dries and falls off over the next 1 to 2 weeks. Tender regional lymphadenopathy, fever, chills, and fatigue may occur. Systemic disease has been reported to have a mortality of 20% if untreated.

INFECTION CONTROL. Person-to-person transmission of anthrax is not known to occur. Patients may be hospitalized in a standard hospital room with standard barrier isolation precautions. No treatment is necessary for contacts of cases.

Plague

Plague is caused by the gram-negative coccobacillus *Yersinia pestis*. Under natural conditions, plague is transmitted to humans by the bite of an infectious flea and, less frequently, by direct contact with infectious body fluids or tissues of an infected animal or by inhaling infectious droplets. Plague has a long history of use and development as a biological weapon. After a biological attack, primary pneumonic plague would be most likely.

Clinical Presentation

Plague is a severe febrile illness. Pneumonic plague, the most fatal form of the infection, can develop from inhalation of plague bacilli (primary pneumonic plague).

The incubation period for pneumonic plague is typically 2 to 4 days (range 1 to 6 days). Presenting symptoms typically include the acute onset of malaise, high fever, chills, headache, chest discomfort, dyspnea, and cough concomitant with or followed rapidly by clinical sepsis. Hemoptysis is a classic sign that should suggest plague in the appropriate clinical context, but sputum may be watery or purulent. Gastrointestinal symptoms may be prominent with pneumonic plague; these include nausea, vomiting, diarrhea, and abdominal pain. A cervical bubo is infrequently present. The disease is rapidly progressive, with increasing dyspnea, stridor, and cyanosis. Rapidly progressive respiratory failure and sepsis within 2 to 4 days of onset of illness is typical of pneumonic plague.

Diagnosis

During a confirmed outbreak of pneumonic plague after a biological attack, a presumptive diagnosis can be made on the basis of symptoms, especially if there is a high index of suspicion. However, other causes of severe pneumonia or rapidly progressive respiratory infection with or without sepsis should be considered.

Laboratory findings are consistent with the systemic inflammatory response syndrome. The leukocyte count is elevated and the differential shows a neutrophil predominance, including immature forms. Platelets may be normal or low. Coagulation abnormalities include prolongation of the international normalized ratio (INR), prothrombin time (PT), and partial thromboplastin time (PTT). Elevated liver function tests and abnormal renal function tests are seen with systemic disease.

Therapeutic Intervention

When plague is suspected, antibiotic treatment should begin before laboratory confirmation of the diagnosis.

Botulism

Botulism is a paralytic illness caused by a potent neurotoxin produced by *Clostridium botulinum*, an anaerobic, spore-forming bacterium. Natural forms of the disease are foodborne botulism, wound botulism, and infant botulism. Foodborne botulism results from ingestion of improperly processed foodstuffs containing preformed toxin produced by *C. botulinum*. Wound botulism results from production of botulinum toxin by *C. botulinum* organisms that contaminate wounds. Infant botulism results from the colonization of the intestinal tract of infants after ingestion of spores. Botulinum toxin has been developed as a biological weapon. An aerosol attack is considered the most likely use of botulinum toxin for bioterrorism.

Botulinum toxin is the most potent lethal toxin known. The estimated toxic dose of type A botulinum toxin is 0.001 $\mu\text{g}/\text{kg}$ of body weight. Botulinum toxin acts to block neurotransmission by binding to the presynaptic nerve terminal at the neuromuscular junction and preventing the release of acetylcholine, resulting in skeletal muscle weakness. The toxin is colorless, odorless, and presumably tasteless.

Clinical Presentation

The incubation period for foodborne botulism is 2 hours to 8 days; the typical incubation period is 12 to 72 hours. The incubation period for inhalational botulism is not established. The neurological features of botulism are similar. Although initial symptoms in foodborne botulism may include nausea, vomiting, abdominal cramps, and diarrhea, these symptoms are thought to result from other bacterial metabolites in contaminated food and may not occur in inhalational botulism.

The so-called classic triad of botulism summarizes the clinical presentation: an afebrile patient, symmetrical descending flaccid paralysis with prominent bulbar palsies, and a clear mentation. Patients typically present with difficulty seeing, speaking, or swallowing. Clinical hallmarks include ptosis, blurred vision, and the so-called four Ds: diplopia, dysarthria, dysphonia, and dysphagia.

Anticholinergic symptoms are common, including dry mouth, ileus, constipation, nausea and vomiting, urinary retention, and mydriasis. Other symptoms include dizziness and sore throat. Sensory findings are not present, with the

exception of circumoral and peripheral paresthesias secondary to hyperventilation resulting from anxiety. Botulinum toxin does not cross the blood-brain barrier. Cranial nerve dysfunction and facial nerve weakness may make communication difficult; these symptoms may be mistaken for lethargy and signs of central nervous system involvement.

Diagnosis

Initiation of treatment with botulinum antitoxin should be based on the clinical diagnosis and should not await laboratory confirmation. For potential foodborne botulism, samples of stool, gastric aspirate, emesis, and suspect foods should also be submitted.

The possibility of a bioterrorist attack should be considered in any outbreak of botulism. A bioterrorist attack should especially be considered when a cluster of cases occurs, when an outbreak has a common geographical location but there is no common dietary exposure (suggestive of possible aerosol exposure), when there is an outbreak of an unusual botulinum toxin type, or when multiple simultaneous outbreaks occur. A careful dietary and travel history must be taken to help identify the source. Patients should be asked if they know of others with similar symptoms.

Therapeutic Intervention

The mainstay of treatment for botulism is supportive care, including intensive care, mechanical ventilation, and parenteral nutrition. Morbidity and mortality are usually from pulmonary aspiration secondary to loss of the gag reflex and

dysphagia leading to inability to control secretions, respiratory failure secondary to inadequate tidal volume from diaphragmatic and accessory respiratory muscle paralysis, and airway obstruction from pharyngeal and upper airway muscle paralysis. Careful and frequent monitoring of the gag and cough reflexes, swallowing, oxygen saturation, vital capacity, and inspiratory force are critical. Airway intubation is indicated for inability to control secretions and impending respiratory failure. Secondary infections are common and should be sought in patients who develop fever.

Trivalent (ABE) equine antitoxin is available from the CDC through state and local health departments and should be administered as soon as possible after clinical diagnosis. Antitoxin can prevent progression of disease caused by subsequent binding of toxin but does not reverse the effects of already bound toxin. For this reason, antitoxin is not useful if the patient is no longer showing progression of disease or is improving from maximum paralysis.

Transmissibility and Infection Control

Botulism is not transmitted from person to person. Botulinum toxin does not penetrate intact skin. Standard infection-control precautions are adequate. Clothes of persons exposed to an aerosol release of botulinum toxin should be removed and washed. Exposed persons should shower with soap and hot water. Exposed environmental surfaces can be decontaminated with 0.1% hypochlorite bleach solution.

REVIEW QUESTIONS

Multiple response item. Select all that apply.

- Which of the following assessments would the nurse include in a primary survey of a multisystem trauma victim?
 - Chronic disability
 - Breathing
 - Circulation
 - Airway
 - Vital signs
- The nurse is caring for a trauma patient who is hemorrhaging from a puncture wound. Which of the following interventions would the nurse use first to control the arterial bleeding?
 - Pressure at site
 - Application of a tourniquet
 - Pressure point massage
 - Pressure dressing
- Which of the following symptoms would alert the nurse to the potential for inhalation injury for a patient who was in a house fire?
 - Peripheral edema
 - Singed nasal hairs
 - Jugular vein distention
 - Increased capillary refill time
- Which of the following actions should be taken first for a patient who is found with hyperthermia?
 - Undress patient
 - Use tepid water as a mist spray
 - Remove patient from the hot environment.
 - Place patient in continual breeze from electric fans
- A patient who has ingested a poison is to be given activated charcoal with sorbitol by a nasogastric tube. Which of the following does the nurse understand is the purpose for the activated charcoal with sorbitol?
 - To absorb and expel toxins rapidly through the intestinal tract
 - To flush and withdraw the poisonous agent from the stomach
 - To induce vomiting
 - To coat the esophagus
- When interacting with a psychotic patient, which of the following interventions is helpful to gain the patient's trust?

- a. Play along
 - b. Make promises
 - c. Avoid eye contact
 - d. Show respect
7. Which of the following patients should be treated first in a disaster situation?
 - a. 10 year old with a closed fractured leg that is painful
 - b. 32 year old with slight bleeding hand laceration
 - c. 45 year old with open head injury, no pulse or respirations
 - d. 62 year old reporting chest pain and shortness of breath
 8. Which one of the following is an immediate threat to life during acute anaphylaxis?
 - a. Hypotension
 - b. Generalized itching
 - c. Airway obstruction
 - d. Tachycardia
 9. The nurse is assessing a patient who is hypovolemic. Which of the following signs and symptoms indicate that the patient is experiencing profound shock?
 - a. Sacral edema
 - b. Jugular vein distention
 - c. Decreasing blood pressure
 - d. Palpable, bounding pulse
 10. The nurse is to give penicillin G 500,000 units IM. The nurse has a 10-mL vial labeled penicillin 400,000 units/mL. How many milliliters should the nurse give?

_____ mL

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mr. Smith

1. The airway is the first priority because edema from inhalation burns can occlude the airway.
2. You know that Mr. Smith is at risk for respiratory burns because of the soot near his mouth and nose. He should be closely monitored. Assessment should include respiratory rate and pattern and the patient's ability to speak without a hoarse voice. Abnormal breathing sounds such as wheezing indicate partial upper airway occlusion.
3. The vital signs are within normal limits.
4. Deep partial-thickness burns should be covered with dry dressings. Because the skin can no longer protect the patient, wet dressings provide a medium for bacterial invasion. Wet dressings can also cause a decrease in body temperature because the skin can no longer maintain thermoregulation.
5. Jewelry should always be immediately removed before edema formation begins.
6. Mr. Smith was involved in an explosive incident and thrown 50 feet. He could have sustained fractures of the pelvis or back. He also may have internal organ injuries from blunt trauma.

spirituality (SPIHR-it-u-AL-it-tee)

QUESTIONS TO GUIDE YOUR READING

1. What are the eight developmental stages?
2. What are the effects of chronic illness?
3. What special needs do caregivers have?
4. What are health promotion methods?
5. What nursing interventions would you use in caring for a chronically ill patient?

HEALTH, WELLNESS, AND ILLNESS

Health is much more than just the absence of disease. Have you ever known someone with what appears to be a small health problem who considers himself unwell or disabled, or a person with major health problems who sees himself as well? Many things play a role in a person's perception of health. One is the ability to function or perform desired or necessary tasks such as activities of daily living (ADL). Another is the ability to fulfill one's social roles such as student, parent, worker, and so on. The quality of one's life is another component of health. A person's ability to adapt to changes in physical, psychological, social, and spiritual aspects of life needs to be considered when planning health care. *Wellness* is a term that is used to describe a progression toward a higher level of functioning. Even though a person has a disabling illness, he or she can still be seen as achieving a high level of wellness.

NURSING CARE TIP

To foster understanding of how an ill patient, especially an older patient, was once healthy and active, ask family members to bring in photos showing the patient at various ages or engaged in favorite activities. Displaying these photos in the patient's room or on a hallway bulletin board allows caregivers to see the patient in times not associated with illness.

The concept of illness is one of imbalance or disharmony with the environment, resulting from a problem that causes one to be sick. Physical causes of illness are more easily recognized, such as exercise that induces an asthma attack in an asthmatic person or a fall that causes a broken bone. Illness can also result from a psychological, sociological, cultural, or spiritual imbalance. After the loss of a spouse, one may experience loneliness and depression and a loss of balance in the social and psychological aspects of life. A hospitalization may increase disharmony if cultural beliefs and practices are not understood or upheld by health-care providers. A person faced with a terminal diagnosis may lose hope and direction in life, causing anxiety and despair. So rather than being exclusive concepts, **health** and **illness** are dynamic and ever-changing states of being. A health crisis such as a myocardial infarction (MI) overwhelms a patient's ability to maintain a normal level of wellness. Two months after the MI, however, this patient could be enjoying a higher level of wellness than before the MI if he or she has lost weight, is walking daily, and is eating a nutritious low-fat diet.

THE NURSE'S ROLE IN SUPPORTING AND PROMOTING WELLNESS

The goal of nursing care can best be defined as helping patients achieve their highest possible level of wellness. To do this, consider the patient's strengths, assets, and resources, as well as weaknesses, liabilities, and disabilities. Encourage the patient to take a personal inventory and recognize what is required to attain wellness. Working together, the patient, family, and members of the health-care team set wellness goals and develop a plan of action that will help meet those goals. The plan of care focuses on the following six main areas:

- Mobilizing resources
- Providing a safe and adaptable environment
- Assisting the patient to learn about his or her health problem and treatment
- Performing and teaching the patient to perform health-care procedures
- Anticipating problems and recognizing potential crises
- Evaluating the plan and progress toward the goals with the patient and family

The emphasis of care is changing from acute hospital care to preventive community-based care. Nurses assume a variety of roles in promoting the health of their patients such as advocate, consultant, caregiver, and educator.

DEVELOPMENTAL STAGES

Understanding the **developmental stage** of the patient can help the nurse accurately assess health and health practices. The developmental stages of life focus on the balance a person must achieve for high-level wellness within that stage. Across the life span at various ages and stages of life there are potential threats to health. Risk factors are related to growth and development, physical attributes, family, behavior, social interactions, environment, lifestyle choices, and ethnic background.

Erik Erikson described eight stages in the psychosocial development of the person. These stages illustrate the acquisition of a sense of trust in self and others and a sense of personal worth. Each stage must be completed before accomplishing the next. The first five stages describe the development of the child and adolescent.^{1,2} Developmental stages for the young adult, middle-aged adult, and older adult are discussed here.

The Young Adult

Developing intimacy versus isolation is the sixth psychological development task. The young adult's task is to develop

relationships with a spouse, family, or friends that are warm, affectionate, and developed through fondness, understanding, caring, or love. When this stage is not successfully resolved, the individual often experiences isolation from others. This stage encompasses ages 18 to 45. Physically, growth is usually completed by age 20. Socially, young adults begin to move away from their parents to develop their own families. The young adult begins to attempt to develop a place in society through school, work, and social activities. This is the stage in which intimacy or closeness develops with partners and friends. The decision to marry, have children, or have a pet is demonstration of the person's striving for intimacy. Challenges to intimacy are tasks that must be overcome in this stage. Within a marriage, communication, financial issues, and the needs of children must be successfully met to maintain the marriage. Melding one's traditions and customs with the traditions and customs of a spouse, family, or friends is a major responsibility, as is the passing on of culture to children. Values and beliefs, which arise from an individual's culture or conscience, serve as guidelines for behavior.

Common Health Concerns

The lifestyle choices of young adults may place their health at risk. Health promotion for this age group is mainly focused on preventing or limiting possible risk factors. Preventive measures that should be taught at this stage include monthly breast self-examination (BSE) for women and testicular self-examination (TSE) for men. Young adults need to understand the importance of diet and exercise in maintaining health. They are also in the position of teaching these lifelong habits to their children. Positive health practices in young adulthood help prevent long-term complications. Maintaining an aerobic exercise program and following a diet that is low in fat help keep weight down and avoid obesity, as well as promoting cardiovascular health. Blood cholesterol should be kept below 200 mg/dL. Avoiding sun exposure and using sunscreen are important to avoid sunburn and permanent sun damage to the skin. Years of sun exposure may cause skin cancer. Tobacco use started in the teen years is often carried on throughout young adulthood and is linked to chronic bronchitis, emphysema, and oral, throat, and lung cancer in later life.

In the early part of young adulthood, the individual is in the workforce or is preparing for the work world with a college or vocational education. Being a novice in the work world and accepting new independence, freedom, and responsibilities can introduce stressors into the young adult's life. Unfortunately, overeating, alcohol use, drug use, cigarette smoking, and family violence are all negative lifestyle choices and poor coping mechanisms for stress. Young adults need to be aware of their individual stressors and be encouraged to develop positive coping mechanisms for stress. Exercise, support groups, music, and meditation are just a few positive ways to cope with stress.

Although marriage commonly occurs within this age group, this group also has the highest rate of divorce. Trying

to make a marriage work is a hard task. The blending of two people into a couple requires a lot of creative communication and loving care. When stressors overwhelm the couple's coping mechanisms or coping strategy, the marriage relationship is in trouble. Sometimes because of the high rate of divorce many couples choose to live together without being married. However, the avoidance of making a commitment may set these relationships up for failure.

If young adults are sexually active with multiple partners, they are at risk for sexually transmitted diseases. Safer sex guidelines and information on birth control should be available for the young adult.

Pregnancy is a common health occurrence for women in this age group. Because research indicates that a mother's health practices directly affect the health of the developing fetus, nutrition, drug and alcohol use, physical health, and effective stress coping mechanisms are lifestyle issues that need to be discussed with every pregnant woman. Prenatal care should be encouraged and readily available to pregnant women.

CRITICAL THINKING

Mrs. Michaels

■ Mrs. Michaels, age 25, and her husband are trying to start a family. She visits her physician, who confirms that she is pregnant. Which information and health practices should Mrs. Michaels and her husband be instructed in during a prenatal health examination?

Suggested answers at end of chapter.

The Middle-Aged Adult

People ages 45 to 65 are considered to be in the middle adult years. The psychological developmental task of this age group is developing generativity versus self-absorption. Generativity includes a sense of productivity and creativity, and is demonstrated by a concern and support for others, along with a vision for future generations. Unresolved conflict could be seen as preoccupation with personal needs or self-absorption. Physically, middle-aged adults start to notice signs of decreased endurance and intolerance for physical exercise if they have not maintained healthy lifestyle choices. Socially, their children are adolescents or young adults who require extra attention and assistance with entering adulthood and launching their own careers and families. The term "empty nest" has been used to describe the middle-aged couple after the children have left the home. This period is often complicated by the challenging demands of caring for aging parents. Middle-aged adults also look over their lives and assess accomplishments versus unrealized goals. Midlife crisis may occur as this self-inspection leads to a desire to change work, social, or family situations to try to meet unrealized goals. Planning for retirement by developing meaningful pastimes and interests outside of work and preparing

for financial security is another important task during this period.

Common Health Concerns

Adverse health choices, such as smoking, use of alcohol, drug use, sedentary lifestyle, diet high in saturated fat, and overeating, often have serious consequences for middle adulthood. Hypertension and heart disease are major health concerns, as are chronic bronchitis, emphysema, and lung cancer. Cardiovascular disease and cancer cause most of the deaths in this age group. However, middle adulthood is not too late to begin lifestyle changes that positively affect health. Replacing high-risk habits with lifestyle choices such as regular exercise, healthful eating, weight reduction, and positive stress-coping mechanisms are positive changes. The need for immunizations continue into adulthood. Adults at high risk for hepatitis B (health-care workers, hemophiliacs, people on hemodialysis, intravenous drug users, and foreign travelers) should be vaccinated for hepatitis B if it was not done during childhood. Helping adults recognize the benefits of these lifestyle choices and empowering them to change is the major challenge for health-care professionals for this age group.

CRITICAL THINKING

Mr. Paul

■ Fifty-four-year-old Mr. Paul calls the doctor's office for the fourth time this month complaining of severe indigestion and requesting a medication that will work to fix it. He has refused to have an x-ray examination or other diagnostic tests because he "can't fit them into" his "busy schedule." Mr. Paul has his own insurance business. His wife quit her job to monitor the activities of their 13-year-old son, who was not going to school every day. The couple's twin daughters are both in college out of state.

1. What might be causing Mr. Paul to be experiencing health problems?
2. What is affecting the developmental tasks Mr. Paul needs to perform?

Suggested answers at end of chapter.

The Older Adult

Ageism is a term that describes stereotypical misconceptions about older adults in society. Although they are the most diverse age group, common misconceptions about old people include that they are senile, cranky, disabled, and in nursing homes. More positive attitudes about aging are developing, in part owing to the growing number of older adults. Advances in living conditions and health care have allowed more people to reach old age. People are living productive, fulfilling lives into their 80s, 90s, and even 100s. Many of these older adults are likely to be found working in their gardens, exercising, or socializing (Fig. 13.1).

FIGURE 13.1 Socialization helps older adults maintain integrity.

The developmental goal for people age 65 or older is integrity versus despair. In this stage, the older adult looks back and evaluates what has been done with his or her life. *Integrity* refers to accepting responsibility for one's life so far and reflecting on it in a positive way. Reaching this stage is a sign of maturity, while failing to reach this stage is an indication of unsuccessful completion of prior stages, resulting in feelings of despair that life has been lived in vain, and a fear of death. Reminiscence is one way for the nurse to assist the older adult to pass through this stage.

Aging is associated with role changes and transitions. Some roles, such as employee, son, or daughter, are lost because of death or illness, causing sadness or depression. Other roles may arise, such as widow, volunteer, or grandparent. With retirement, household management roles may need to change. If an older adult becomes ill and dependent and needs to be cared for by an adult child, there can be a reversal of the parent-child role.

Health state, environment, relationships, and lifestyle choices influence the diversity found in this group. Physical health is often a concern for older adults. Chronic health problems that require medication and treatment often also require lifestyle changes or adaptations.

Coping with loss is a major challenge for older adults. Life events such as retirement, illness, or death of a spouse

and changes such as decreased physical ability are losses facing older adults. The older adult's ability to cope with these stressors is essential for maintaining a sense of control. Coping with aging is also influenced by the individual's cultural beliefs. Cultural viewpoints on the social role and value of aged members affect the health of older adults. Sometimes the greatest loss for older adults is their lack of connection with the world and a lack of being part of a greater purpose. However, being alone is not the same as being lonely. For most older adults, being by oneself for a time allows for reflection to better understand one's situation. Older adults who feel unwanted or unloved are more likely to develop anxiety, depression, and failure to thrive.

Common Health Concerns

The focus of care for the older adult is on assisting them to meet their physical, psychological, cultural, sociological, and spiritual needs. Encouraging the use of community services for seniors and promoting self-care are important. Most older adults continue to live in their own homes or apartments, but impairment in mobility and the ability to carry out instrumental activities of daily living (IADL), such as shopping for groceries, preparing meals, and cleaning and maintaining a home, threaten their independence. Having to ask or pay others to perform tasks that they formerly were able to do themselves is seen as a significant loss by many older adults. Adding the loss of a spouse, the death of friends, or the lack of social contacts may further isolate an older person, leading to depression and **hopelessness**. The accumulation of losses can overwhelm an older adult's resources and coping mechanisms and is related to a high rate of suicide, especially for older men. Suicide is the ultimate expression of hopelessness.

Older adults need to be encouraged to remain active and to continue to pursue interests. Most communities have transportation services such as buses and vans that operate to meet the needs of older adults. Senior centers offer diverse programs and services to older adults. Some senior groups are focused on community service; others mainly plan trips or sponsor activities such as dances or bowling leagues. Older adults also have opportunities to continue to work in areas of interest as volunteers. Schools, hospitals, nursing facilities, parks, museums, zoos, community theaters, and youth groups all welcome older adult volunteers. Colleges and universities offer discounted tuition for senior citizens, and there are elder hostel programs across the country, which are programs especially designed for older adults. Elder hostels offer a variety of programs such as photography, Civil War history, nature survival, bird watching, and painting.

Chronic diseases can limit an older person's ability to be independent in self-care and activities of daily living. Hypertension is common, as are heart disease and strokes in this age group. Managing blood pressure, losing weight, eating a low-fat diet, smoking cessation, enhancing effective stress-coping strategies, and exercising regularly decrease the potential for cardiovascular disease.

One of the most difficult tasks for the nurse in dealing with the older adult is to distinguish normal age-related changes from pathological changes. Changes in mobility and chronic pain may limit an older person's activity and impede an active lifestyle. Falls are a serious concern for older adults, resulting in decreased independence and death. Osteoporosis is a bone disease, common among postmenopausal women and men over 80 years of age, causing bone weakness and fracture risk. Falls and accidents can be prevented by in-home safety assessments and altering the home environment to ensure the safety of the older adult. Bathrooms should be equipped with grab bars and nonskid mats. Bath chairs or benches make getting into a bath or shower safer. Removing clutter, throw rugs, small furniture, and electrical cords decreases the risk of falls.

Hearing and vision losses can affect the physical and psychological health of the older adult. Good sensory function is necessary to protect the individual from accidents, social isolation, and limitations in self-care. One of the most dramatic losses for many older adults is not being able to safely drive a car. This is usually associated with a loss of independence. Sensory impairments can further isolate the patient. Impaired vision can be caused by decreased peripheral vision, macular degeneration, cataracts, or glaucoma. Many older adults continue to drive during the day but not at night because of night vision problems. Decreased hearing is also common in older adults. Loss of high-pitch discrimination and reduced ability to filter background noises cause older adults to hear the background noise more clearly than a one-to-one conversation when in a crowded room. Social stigmas related to memory changes such as forgetfulness, dementia, and senility are a serious worry for many older adults. They often confuse depression with senility and attempt to hide their symptoms rather than seek treatment.

CHRONIC ILLNESS

A major challenge facing health-care providers is the management and prevention of chronic illness. **Chronic illness** is defined as an illness that is long-lasting or that recurs. Chronic illnesses usually interfere with the patient's ability to perform activities of daily living. Chronic illness is never completely cured or prevented. The human body wears out unevenly. The amount of disability depends not only on the kind of condition and its severity but also on the implications they hold for the person. The degree of disability and altered lifestyle relate as much to the person's perception of the disease as to the disease itself. For example, both John F. Kennedy and Franklin D. Roosevelt would have been eligible for 100% disability because of their chronic illnesses, but both managed to serve as presidents. Long-term effects of treatments like radiation therapy become chronic diseases in themselves. Radiation for a tumor can leave the person with persistent diarrhea that may cause the person to be malnourished and exhausted.

CRITICAL THINKING**Mrs. Riccardi**

■ Mrs. Riccardi, age 87, lives alone in her small apartment. Her daughter and son are both retired and live in the same community. Mrs. Riccardi had a dizzy spell, so her daughter brought her to the hospital emergency department (ED). Upon admission, Mrs. Riccardi's blood pressure was 208/128 and she had blurred vision in the left eye that resolved after 1 hour in the ED. She was diagnosed with hypertension, which had possibly contributed to a small stroke or transient ischemic attack (TIA). Mrs. Riccardi was started on metoprolol (Lopressor) 100 mg daily. She was discharged to her home with instructions to limit salt in her diet and to begin an exercise program. The plan of care addressed safety issues.

1. Why might Mrs. Riccardi be at increased risk of falling?
2. What nursing interventions would help promote Mrs. Riccardi's independence and safety?
3. The nurse is to give metoprolol 100 mg. Fifty-milligram tablets are available. How many tablets should the nurse give?

Suggested answers at end of chapter.

When caring for those with chronic illness, the goal of nursing care is to maintain and improve the patient's quality of life. A chronic illness also affects the patient's family's quality of life. Therefore, when planning patient care consider the family's needs for adapting to the patient's chronic illness.

Fostering hope is an important intervention that should be a primary foundation of care planning for the chronically ill. A chronic illness may appear to be a hopeless situation if no cure is possible. If recovery from an illness is not possible, it might be thought that nothing can be done for the patient. However, whenever there is life, there is potential for growth in areas such as developmental tasks, health promotion, knowledge, or spirit. Individuals have developmental tasks to perform even as they cope with illness or prepare for a peaceful death.

Incidence of Chronic Illness

The incidence of chronic illness is rising for several reasons. First, people are living longer, in part because of better hygiene, nutrition, vaccinations, antibiotic development, and exercise. Fewer people are dying from acute diseases. As a result, a larger elderly population is living long enough to develop many chronic illnesses. Second, medical advances have resulted in reduced mortality from some chronic illnesses, so that patients live longer with these illnesses. Third, today's technology and modern lifestyles affect the development of some chronic illnesses. Examples

include a sedentary lifestyle; exposure to air and water pollution, chemicals, and carcinogens; substance abuse; and stress.

Some of the most common chronic conditions include chronic sinusitis, arthritis, hypertension, orthopedic dysfunction, decreased hearing, heart disease, bronchitis, asthma, and diabetes. Preventive measures can be taught to reduce the incidence of these conditions.

Types of Chronic Illnesses

There are a variety of chronic illnesses resulting from several different causes (Box 13.1 Examples of Chronic Illnesses by Causes). These illnesses can have varying degrees of severity and can affect length of life. A chronic illness can lead to the development of other illnesses; for example, hypertension that then causes chronic renal failure. Chronic illnesses can have onsets at various ages, but with advancing age, the likelihood of developing a chronic illness increases, and older adults often have several chronic illnesses at one time (Box 13.2 Examples of Chronic Illnesses in the Older Adult).

Gerontological Influence

As people live longer, spouses or older family members are increasingly being called on to care for a chronically ill family member. Children of older adults who themselves are reaching their 60s are being expected to care for their parents. These older caregivers may also be experiencing a chronic illness themselves. The family unit is at great risk

for ineffective coping or further development of health problems. Assess all members of the elderly family to ensure that their health needs are being met.

Older adults are very concerned about becoming dependent on others. They may become depressed and give up hope if they feel that they are a burden to others. Establishing short-term goals or self-care activities that allow them to participate or have small successes are important nursing actions that can increase their self-esteem (Box 13.3 Cultural Considerations).

Barriers to caring for a chronically ill elderly patient include a lack of information about treatments, medications, or special diets and being unfamiliar with supportive services in the community such as meal programs or respite care. You should be aware of these and provide this information, as well as a resource number for questions.

Effects of Chronic Illness

For the patient to live as normally as possible with a chronic illness, many adjustments are usually necessary. Lifelong routines and habits may need to be changed. Daily living patterns are affected by routines that are established to cope with the illness. Treatment needs such as going to therapy sessions, performing peritoneal dialysis exchanges, or monitoring blood sugars can interrupt daily life.

**Box 13.3****Cultural Considerations: Traditional Appalachians**

Traditional Appalachians believe that disability is natural with aging and is inevitable. This belief discourages the use of rehabilitation as an option. Thus, to promote rehabilitation efforts among Appalachians, the nurse may need to stress self-help and a return to physical function.

Chronic Sorrow

Chronic sorrow is a normal response felt by those affected by a chronic illness. It is an intermittently occurring sadness in response to the loss caused by a chronic condition. It can be felt by the patient or the patient's significant others. It is a common feeling among those with chronic illness. The nursing diagnosis Chronic Sorrow may apply to those experiencing chronic illness. When this sadness occurs, nursing care should focus on being comforting and supportive. Providing information and assisting with coping strategies such as fostering support systems are great interventions to help those with chronic sorrow.

Spiritual Distress

Patients with chronic illness can experience spiritual distress when faced with the limitations of their illness. Maintaining patients' quality of life includes assisting patients with their spiritual needs. Religious and spiritual needs are important to most people whose lives have been disrupted with new challenges from chronic illness. Patients must be helped to find meaning in the illness and realistic hope. Interventions that address **spirituality** may need to be performed first to allow success of subsequent nursing care.

Develop a comfortable approach in assessing and meeting patients' spiritual needs. Several factors may make one uncomfortable in caring for the patient's spiritual needs. These factors include a lack of training, a lack of understanding of one's own spiritual needs and beliefs, and not recognizing or believing that this is your role. Examine your own spiritual needs to define a personal spiritual view. By doing this, you will develop insight into others' spiritual needs and resources, as well as gain a greater understanding of issues surrounding your patients' spiritual needs.

Many people use spirituality to cope with chronic illness. It helps give them a sense of wholeness, hope, and peace during a time filled with uncertainty and anxiety. Spirituality plays an important role in empowering patients to handle their condition. It is a source of inner strength that allows the patient to experience a sense of unity. Hospital interventions may include use of a meditation room for quiet reflection or prayer, chaplain visits, or worship services. To help meet the patient's spiritual needs, assist the patient with transportation to the meditation room or worship services.

**NURSING CARE TIP**

Spiritual needs should not be thought of in only a religious focus. Spirituality is feeling connected with a higher power. Everyone has spiritual needs that involve hope, peace, and wholeness. Spiritual care goes beyond simply asking the patient's religion. It is assessing patients' perceptions of spirituality and then devising ways to assist them to meet their spiritual needs.

Accreditation agencies require the spiritual needs of patients to be addressed and documented by nurses. Nursing diagnoses related to spiritual needs include Spiritual Distress, Risk for Spiritual Distress, and Readiness for Enhanced Spiritual Well-Being.

Powerlessness

Those with chronic illness may feel powerless because they are uncertain of their ability to control what may happen to them (Fig. 13.2). A chronic illness can take an unknown course in relation to its seriousness and controllability. This leaves the patient vulnerable to the many phases of a chronic illness (the diagnosis, the instability phase, an acute illness or crisis, remissions, and a terminal phase).

Treatments that the patient undergoes can be a new experience that is painful, frightening, and invasive. If patients do not understand what is happening, they can feel overwhelmed and alone. This contributes to a feeling of **powerlessness** because the patient cannot control the outcome. Patients with chronic illness are faced with a lack of control throughout their illness. It influences the reactions of the patient to the illness. The nursing diagnoses of Powerlessness or Risk for Powerlessness may apply to many chronically ill patients.

COPING. Patients can be helped to feel more in control of their illness if you remember to include them in their care;

FIGURE 13.2 Powerlessness-hopelessness cycle. (Modified from Miller, J: *Coping with Chronic Illness. Overcoming Powerlessness*, ed. 3. FA. Davis, Philadelphia, 2000, p 526.)

listen to their feelings, values, and goals; and explain all procedures first. Complex medical language should be avoided when talking with patients to increase their understanding and feeling of being included in their care instead of isolated. In addition, coping with a chronic illness can be aided if the patient develops a positive attitude toward the illness. This can be accomplished if the patient gains knowledge, uses a problem-solving approach to difficulties, and becomes motivated to continue adapting to the illness and not succumb to a defeatist attitude.

A variety of coping techniques can be useful. Ask the patient's perception of the illness and identify coping techniques that the patient has previously used successfully. New coping resources may need to be added to effectively deal with the patient-coping tasks that are associated with chronic illness. Support services in the community should be made available to the patient and family. To cope effectively, the patient should become comfortable with the newly defined person he or she is to become. The nursing diagnoses of Ineffective Coping, Compromised Family Coping, Disabled Family Coping, and Readiness for Enhanced Family Coping may apply to those dealing with chronic illness.

HOPE. Before coping resources can be used, hope must be established by the patient. False hope is not beneficial and should be replaced with realistic hope. Providing patients with accurate knowledge regarding their fears helps do this. Hope should not be directed toward a cure that may not be possible but rather at living a quality life with the functional capacity that the patient has. Over the course of the illness, hope needs to be maintained for both the patient and family. Periodically assess if the patient is maintaining hope. Many studies have shown that patients adapt better when hope is high.

Many nursing interventions may increase hope. The use of humor helps patients be lighthearted and hopeful. Patients should be encouraged to live each moment to the fullest and experience the joy of being alive. Awakening the senses to appreciate the environment can bring a feeling of hope and peace. Simple things, such as the smell of baking bread, the clean scent of the air after a rain, or the scent of pine trees, can make one appreciate the beauty of nature and inspire hope. Family members need to be encouraged to help foster hope for the patient. By doing this, family members may gain hope as well. During times of acute illness, the patient needs to maintain as much control as possible and be told that any loss of control related to treatments is usually temporary. This prevents a continual feeling of loss of power. The use of music or inspirational reading material can reduce stress and help the patient find meaning in life. This in turn fosters hope. Hopeful patients are empowered and no longer feel powerless. The nursing diagnosis of hopelessness may apply to the chronically ill.

Sexuality

Chronic illness can affect a patient's sexuality. Sexuality includes femininity or masculinity, as well as sexual activity. Body image changes affect the way patients view them-

CRITICAL THINKING

Mr. Soloman

■ Mr. Soloman, age 88, still lives in his own home with his wife of 60 years. He is in good health except for poor vision, which developed slowly over the last 8 years. He cares for his yard, which is his pride and joy, and grows prize-winning tomatoes each year. He plays golf three times a week and walks every day to the neighborhood grocery store or bank. The employees know him and cheerfully assist him with his vision limitations.

Mr. Soloman's wife had always been the homemaker, whereas he was the family provider. Now his wife is in the early stages of Alzheimer's disease, exhibiting confusion, fatigue, and paranoia. She is unable to perform activities of daily living, so he has willingly assumed the homemaker and caregiver roles. They complement each other's limitations because she can still see and is helpful to Mr. Soloman when she is not confused.

Over time, Mr. Soloman's wife's health declines and she must be institutionalized. Mr. Soloman remains in his home alone. His family is concerned about him being alone and eventually convinces him to move into a studio apartment in senior housing. He is very reluctant to leave his home and does not actively participate in moving and selling his home. Mr. Soloman rarely leaves his apartment, sleeps 14 hours a day, and eats one daily meal. He tries to visit his wife by taking the bus but finds it difficult because of his limited vision, so he rarely goes to see her. Within a year, Mr. Soloman develops pneumonia and after a brief illness dies in his sleep.

1. Why do you think Mr. Soloman behaved the way he did after he moved?
2. What interventions could have been used to empower Mr. Soloman?
3. Why might Mr. Soloman have developed pneumonia and died?

Suggested answers at end of chapter.

selves and are viewed by others. If patients have a negative body image perception, they may withdraw and become depressed. When interacting with patients, be aware of your facial expressions, nonverbal cues such as appearing hurried or keeping a distance, use of or lack of touch, and amount of time spent with the patient. When patients believe they have lost their femininity or masculinity, their self-worth decreases. Interventions to enhance sexuality should be used, such as obtaining a wig from the wig bank for patients undergoing chemotherapy.

There are many forms of sexual expression. Sexual intimacy can include touching, hugging, or sharing time together. Provide patients with the opportunity to discuss sexuality concerns or questions. Assume a professional and

confidential approach to this topic, which is usually considered a private matter by patients. Chronically ill patients can be referred to sex counselors for information on ways to cope with sexual issues in relation to their illness. Support groups can also be helpful.

Patients in extended-care facilities should be given private time with their significant other, if appropriate. Older patients need to have their sexuality needs met just as younger patients do. Because sexuality is a part of a person's lifelong identity, ensure that elderly patients' sexuality is addressed in their plans of care. Grooming methods can increase a patient's self-esteem and sexual identity. Women may get their hair and nails done; men can be shaved or get a haircut.

Roles

Chronically ill patients are usually faced with altering their accustomed roles in life. Common roles that may be affected for the adult patient include that of being a spouse, grandparent, parent, provider, homemaker, or friend. Not only is the patient faced with dealing with these role alterations, the family must also adapt to these changes. Family members may have to take on new roles themselves to compensate for roles the patient is no longer able to perform. The nursing diagnosis of ineffective role performance should be included in the plan of care for the patient and family.

The patient is faced with giving up aspects of old roles at the same time that new roles related to being chronically ill need to be assumed. Grieving accompanies the loss of old roles. If a patient is no longer able to participate in social events such as being a golf team member or a committee member, grief work needs to occur to help the patient accept the loss and maintain dignity. With other roles, only certain aspects of the role may change. For example, in the parenting role, patients may still be there as support systems for the child, although they are no longer able to be the disciplinarian. Whatever the role loss, the patient needs to be allowed to grieve the loss. The nursing diagnosis of Grieving may help in planning care for the patient.

The new roles the patient may have to assume related to chronic illness include dependency, ongoing health-care consumer, and self-care agent, and being chronically ill. Patients need to learn how to cope with these new roles. They need to gather knowledge and be given understanding as they become familiar with these roles. For patients used to being independent before the illness, being dependent on others to meet activities of daily living can cause a loss in self-esteem. Navigating the complex health-care and financial reimbursement systems can be overwhelming. Transportation needs and waiting times for medical appointments can be difficult for the patient who must deal with them on an ongoing basis. Becoming a self-care agent requires assuming responsibility for meeting one's own care needs. Handling chronic illness covers many areas, such as living with pain, having altered mobility, or complying with daily treatments. Deficient knowledge is a nursing diagnosis helpful for fostering learning for these new roles.

As patients live with chronic illness over time, they become experts on their own illness. However, today's health-care system tends to assume control over patients and does not respect the patient's own knowledge. Patients who are not given this respect take charge of caring for themselves by seeking knowledge and trying complementary healing methods. Be sensitive to the patient's knowledge and respect it because respect increases patients' self-esteem.

Family and Caregivers

Families are affected by the chronic illness of a family member in many ways. Chronic illness care is usually provided in the home so that families become involved in the management of the illness (Home Health Hints). Family members may have to take on new family roles or assume the role of caregiver. Decreased socialization, lost income, and increased medical expenses can increase family stress and tension. For more information, visit www.caregiver.org or contact Family Caregiver Alliance, 180 Montgomery St., Suite 1100, San Francisco, CA, 94104, (415) 434-3388 or (800) 445-8106.

Families must learn to cope with the stress of illness and its often unpredictable course. Most families develop ways to cope with the patient's illness the majority of the time and may become closer as a family unit. Children adapt better to a parent's illness when they receive parental support. Families often deal with the illness on a day-by-day basis and take a passive approach for most problems to let them work themselves out. During times of exacerbation or crisis, however, the family may need coping assistance.

Patients are often concerned about being a burden to their families. It is important to determine both the family's and the patient's feelings about the care required by the patient. The family's ability to provide this care adequately must also be considered in care planning. If the family lacks the desire, skills, or resources to adequately care for the patient, alternative care options must be explored such as home health care, adult foster care, or extended-care facilities.

Patients' caregivers often have certain ideas about the care that the patient should receive. This may come into conflict with the views of health-care providers. Caregiver input into the patient's plan of care should be sought so that everyone has a clear understanding of goals and expectations for the patient's care.

Caregivers commonly experience depression, role strain, guilt, powerlessness, and grieving related to caregiving. Be aware of this to detect indications that caregivers are in need of help in dealing with these feelings. Chronic-care coaches are resources available to caregivers who can provide insight, encouragement, and support for caring for the chronically ill. Nursing diagnoses for caregivers include risk for caregiver role strain or caregiver role strain.

RESPITE CARE. When caregivers are required to provide 24-hour care for a patient, they can experience burnout, fatigue, and stress, which, if extreme, in some cases can lead to patient abuse. Caregivers may not be able to leave

patients alone even briefly because of wandering behaviors, confusion, or safety issues. They may not ever be able to get a normal night's sleep and suffer from sleep deprivation because of the patient's wandering or around-the-clock treatment needs.

Caregivers must be given periodic relief from their responsibilities of caregiving to reduce the stress of always having to be responsible. Everyone requires private time for reflection or pursuing favorite hobbies. Caregivers may need to get away overnight or for a weekend simply to sleep soundly and be refreshed.

Respite care is designed to provide caregivers with a much-needed break from caregiving by providing someone else to assume the caregiver role. Know your community's respite care services to share with caregivers. Unfortunately, there are often not enough respite care services available to meet the needs of caregivers. Most respite care is provided by volunteers who receive training. As the number of chronically ill persons grows, more respite care programs must be developed to promote the health of the caregiver and in turn the patient.

CRITICAL THINKING

Mrs. Burden

■ Mrs. Burden, age 64, is caring for her husband, who has Alzheimer's disease. He exhibits wandering behaviors. He gets up at night and in freezing winter weather is found walking down the street in only his pajamas. He attempts to cook and burns the pans. He is unable to express his needs. He disrobes frequently and is incontinent. Mrs. Burden quit her job to care for him. She no longer goes to lunch weekly with her friends. Her children live out of town. She places a chair and tin cans in front of the home's doors as an alarm in case her husband tries to open the doors.

1. What indicates that Mrs. Burden is experiencing stress related to caregiving?
2. What nursing diagnoses should be included in a plan of care for Mrs. Burden?
3. What nursing interventions would be beneficial for Mrs. Burden?

Suggested answers at end of chapter.

Finances

Managing a chronic illness can be expensive. Income can be lost if the patient is unable to work or caregivers are forced to stay home. Family savings can quickly be wiped out. If the patient is covered by insurance, it may not cover all the patient's expenses or it may have caps on lifetime coverage amounts. Expenses may involve medications, medical equipment or supplies, therapy, acute care, and home care. Inadequate funds can place a strain on families. This can lead to the nursing diagnoses of Compromised Family

Coping, Disabled Family Coping, or Readiness for Enhanced Family Coping. Nurses may need to refer patients to a social worker or sources of financial aid to help them meet their financial needs.

Health Promotion

Health promotion is possible and necessary at all levels of age or disability. With the increase in the elderly population, it is essential to understand the role of health promotion for older adults who have chronic illness. Patients with chronic illness make daily lifestyle choices that affect their health. For example, the patient with chronic lung disease who smokes can make a choice to smoke or to quit smoking. Patients with degenerative joint disease can choose whether or not to keep their weight within ideal weight ranges to reduce wear and tear on their joints. Arthritic persons can reduce their fatigue levels by pacing their activities and scheduling daily rest periods.

Those with chronic illness consider health promotion important, so encourage health-promotion efforts. Patients need to be assisted to strive toward high-level wellness. This can be achieved by looking at the patient's strengths and weaknesses holistically to develop a plan of care. Determine the patient's risk factors to plan methods of promoting health. Providing patients with knowledge to make informed decisions empowers them to take control of their lives and reach for their greatest potential. The nursing diagnosis of Health-Seeking Behaviors can be used to assist patients in promoting their health.

Nursing Care

Nursing care is primarily devoted to caring for patients with chronic illness. Develop an understanding that the wishes of the patient must be respected even if you do not agree with them. Patients have the right to establish their own goals in partnership with the health-care team. Because of the nature of chronic illness, understand the unique needs of patients and families experiencing chronic illness. These needs differ from acute care as far as depth of knowledge needs and the compounding problems that are usually faced by the patient.

Most chronic illness care occurs in the home and community rather than the acute care setting. Therefore, family members and caregivers, even more so than in acute care, must be assessed and included in the plan of care. As the numbers of those with chronic illness grow, community support for the chronically ill and their caregivers needs to grow. Training programs for caregivers must be available and offered affordably.

A major focus of nursing care for the chronically ill is teaching. These patients and their families have tremendous educational needs if they are to successfully learn to cope

with a long-term illness. The following are primary tasks that the chronically ill need to perform:

- Be willing and able to carry out the medical regimen.
- Understand and control symptoms.
- Prevent and manage crises.
- Reorder time to meet demands caused by the illness, such as treatments, medication schedules, and pacing of activities.
- Adjust to changes in the disease over the course of time, whether positive or negative.
- Prevent social isolation from physical limitations or an altered body image.
- Compensate for symptoms and limitations in order to be treated as normally as possible by others.

Explain individualized interventions to deal with these tasks during teaching sessions. Provide dignity and show respect to these patients (Box 13.4 Patient Perspective). Unique approaches are needed to positively assist chronically ill patients and their families on their long-term journey.

Box 13.4

Patient Perspective

Mr. Lyman

To the nurse caring for me:

- Don't give me a huge glass of water—give me a small glass and don't fill it full. Otherwise when I drink it, it spills all down the front of me.
- Make sure my call light is where I can reach it.
- Make sure my overhead light is working and that I can reach it.
- Ask how I like my blankets, don't just do them the way you do for anyone else.
- Keep a waste basket where I can reach it.
- When you leave my meal tray, make sure I can reach it. Then when you take it away, don't leave a bunch of stuff on my table. There is not much room on those little tables.
- Try to talk quietly in the hallway, instead of being so loud.
- Ask if I need anything before you leave the room.
- Be polite!
- Don't call me sweetie or honey. My name is Mr. Lyman. If I want you to call me by my first name, I'll tell you.

Thank you for preserving my dignity and showing me respect. I appreciate it!

Home Health Hints

- Home care nurses can strengthen a patient's self-care capacity by (1) saying "Let me assist you" instead of "Let me do this for you"; (2) being a partner in caring instead of being a caregiver; (3) empowering the patient instead of doing it all for him or her.
- Using humor can be helpful during a visit, unless the patient is distraught, anxious, or angry. Comics or jokes from magazines can be read. Humor can relieve the patient's and caregiver's stress and humanize the care that must be performed. Keep in mind, however, that humor may be irritating if it is taken as downplaying the seriousness of a situation.
- When patients have the use of only one hand or arm, provide a sponge for personal grooming instead of washcloth; it is easier to use and hold.
- Encourage the family of bed-confined patients to purchase an inexpensive portable intercom (such as a nursery monitor) to give the caregiver freedom to move about the house and hear the patient if help is needed.
- The home health nurse has an opportunity to increase a patient's self-concept by emphasizing the patient's existing abilities, joys, and talents. This can be done by observing the home environment for clues: photographs, trophies, hobby paraphernalia, flowers, or homemade items. Each clue observed can be a springboard to discussing triumphs and losses. It can help the nurse understand how the patient copes to assist in planning care.
- Being attentive to any of the patient's efforts or accomplishments, such as number of steps taken, shaving without help, interest in a book or TV show, or decisions on fixing up the house or cleaning, provides opportunities to offer support and praise for accomplishments.
- The home health social worker should be informed of any patient concerns regarding cost of medicines or equipment. There are many programs to assist the chronically ill to obtain resources.
- Always carry a pocket mask for cardiopulmonary resuscitation (CPR).
- Encourage discussion regarding advance directives with the patient and family/caregiver early in the care process. Decisions regarding resuscitation and the use of technology to prolong life are more difficult when the patient is in crisis.
- Refer families to community CPR classes as desired. Families can be empowered and the patient may feel more secure when families are taught CPR.
- Patients and families should be taught that if an ambulance is called they should turn on an outside light, open the door, and move furniture to enable the emergency medical technicians to get to the patient more easily if possible.

REVIEW QUESTIONS

1. The nurse is collecting data regarding a 68-year-old patient's developmental stage and finds that the patient is retired and that the patient's spouse died 4 months ago. The nurse identifies the patient as being in which of the following developmental stages?
 - a. Generativity versus self-absorption
 - b. Identity versus role confusion
 - c. Intimacy versus isolation
 - d. Integrity versus despair
2. The nurse is planning care for a patient with diabetes. Which of the following effects does the nurse understand is most likely to occur with a chronic illness?
 - a. Powerfulness
 - b. Spiritual distress
 - c. Increased socialization
 - d. Hopefulness
3. A 70-year-old man is the primary caregiver for his wife who has moderately severe Alzheimer's disease. He becomes angry with her for spilling her dinner on the floor. He later feels guilty and begins to cry. The home health nurse is developing a plan of care. Which of the following would be an appropriate nursing diagnosis for the nurse to include?
 - a. Caregiver depression
 - b. Caregiver role strain
 - c. Ineffective caregiving
 - d. Risk for caregiving
4. A 64-year-old woman comes to clinic for a yearly physical. She has a history of hypertension and osteoarthritis. In contributing to the plan of care, which of the following is a priority intervention to promote wellness in this patient?
 - a. Teaching her about hypertension and osteoarthritis
 - b. Instructing her to take her own blood pressure
 - c. Encouraging socialization
 - d. Evaluating progress with the patient and family

Multiple Response Item. Select all that apply.

5. The nurse is providing care for a chronically ill patient. Which of the following are appropriate nursing interventions for a chronically ill patient?
 - a. Decreasing educational information
 - b. Encouraging visits by family members
 - c. Including family members in teaching sessions
 - d. Setting goals for the patient
 - e. Limiting visits from friends
 - f. Obtaining patient input on plan of care

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. Paul*

1. Mr. Paul's physical health is being affected by poor diet choices, excessive stomach acid secretion or other gastrointestinal problems, and stress.
2. It is easy to recognize the psychological stress related to parenting skills when a child is in trouble. Decreased family income with increased family expenses (two children in college) can cause financial strains and more economic pressure on Mr. Paul's business. With family problems or health problems, Mr. Paul may be questioning why things are happening to him and his family, causing him spiritual distress.

■ *Mrs. Michael*

Prenatal education information should be offered to Mrs. Michael and her husband. This education should include an overview of Mrs. Michael's health needs, what to expect during pregnancy, ways Mrs. Michael's husband can be supportive, and information on prenatal classes. Mrs. Michael's physical examination should include a vaginal examination, blood pressure, and blood work. It is important to be aware of any sexually transmitted diseases that may be transferred to the developing fetus or during birth. A rubella titer (a test for immunity to rubella or measles) is important because of potential birth defects if the mother has rubella while pregnant. Elevated blood glucose may be a sign of diabetes, and low red blood cell counts and low hemoglobin are related to anemia. To prepare a woman for pregnancy, prenatal vitamins or vitamins with iron and folic acid (necessary for effective neural tube development in the first 3 months of pregnancy) are recommended. Because of the increased workload of the heart during pregnancy, blood pressure needs to be closely monitored. A balanced diet, maintaining an exercise program, and continuing to develop effective and positive ways to deal with stress are very important

for pregnant women. In preparation for pregnancy, Mrs. Michael also needs information on the negative effects that cigarette smoking, alcohol use, and drug use can have on the developing fetus.

■ *Mrs. Riccardi*

1. Falls could be caused by environmental problems, such as throw rugs that may move or cause tripping, clutter, electrical cords in walking paths, lack of hand grips in the bathroom, or lack of nonskid mats in the shower or tub. Poor vision and altered depth perception can result in missing a stair step or obstacles. Weakness or orthostatic hypotension can cause an unsteady gait or fall.
2. It is important for the nurse to instruct the patient and family about home safety. Mrs. Riccardi may even benefit by using a cane or a walker if she is unsteady. Because Mrs. Riccardi lives alone, an emergency alert system, such as a small transmitter that is worn around the neck or wrist with a button that can be activated in emergencies, would be beneficial. When activated, the transmitter alerts an answering service to contact designated individuals to check on the patient. Safety with medications is also an important consideration. Patients who take medications that lower blood pressure must be aware of the potential for orthostatic hypotension. Orthostatic hypotension is a drop in blood pressure that happens when a person moves from a lying to sitting or sitting to standing position. It is often accompanied by dizziness or light-headedness. Some people may even faint, causing a fall.
3. 2 tablets of 50 mg each.

■ *Mr. Soloman*

1. Mr. Soloman had lost control of his world and felt powerless. His environment, both home and outdoors, was shrinking. He had to give up his daily routines and interactions with others. His purpose in life was gone when he was no longer caring for his

wife. He was separated from his loved one. His visual limitations made his new environment unfamiliar and frightening.

- Options to keep him safely in his home could have been explored with his input. After the move, he should have been thoroughly oriented to his environment. He should have been asked to explain what he wanted his life to be like as he adapted to this new developmental stage. Hobbies and interests should have been continued. Visual support services should have been contacted for ideas. Transportation should have been arranged to allow him to visit his wife. It should have been determined whether phone calls to his wife were possible.
- He was depressed and slept from a lack of any inter-

ests. His lungs were at risk for pneumonia because of his long periods of immobility. He lost hope and gave up on living, which decreased his ability to fight the pneumonia.

■ *Mrs. Burden*

- Mrs. Burden is at risk for sleep deprivation, fatigue, stress, and burnout.
- Nursing diagnoses include disturbed sleep pattern, fatigue, social isolation, risk for caregiver role strain, and deficient knowledge.
- Beneficial nursing interventions would include teaching about Alzheimer's, a chronic care coach, respite care referral, alarm devices for wandering, and stress management techniques.

QUESTIONS TO GUIDE YOUR READING

1. How would you define aging?
2. What are basic physiological changes associated with advancing age?
3. How would you describe psychological and cognitive changes associated with advancing age?
4. What are nursing implications for the physiological and psychological changes associated with advancing age?
5. What nursing practices promote safety for the older patient?

WHAT IS AGING?

Over time it is easy to visually notice changes that occur in the human body. Both physical structures and body functions undergo changes and declines with advancing age. Although there is not one commonly accepted definition or theory to explain these declines, there is an understanding that aging is a universal and normal process that starts at conception and continues until death.

Older adults are increasing in number. In 2000, 34.7 million adults were older than age 65 and by 2025 this number is expected to be 61.9 million.¹ The fastest growing segment within this group is of those older than 84 years of age. Although this group accounted for 4.9 million adults in 2000, this group is expected to grow to 7 million by 2025. For more population data, visit www.census.gov.

In this chapter, aging is defined as a maturational process that creates the need for individual adaptation because of physical and psychological declines that occur during a lifetime. Even though aging truly begins at conception, the focus in this chapter is on the maturational process that is experienced after age 65 (older adult). Those older than age 84 are usually the frailest. The changes discussed do not always occur in the sixth decade of life, so chronological age should not be the basis for determining health issues. For some people, aging effects go unnoticed in their daily functioning; for others these effects cause varying degrees of impairment. Functional age (health, independence, and functional abilities) should be used as the basis of individual care needs. It is important to understand that most older adults function independently in the home and community. Many are still working. With supportive, educative care as needed, these people are able to maintain their independent abilities. This chapter discusses aging changes and resulting disabilities that may require more intensive nursing care than independent, healthy older adults need.

NURSING CARE TIP

Placing older adults into age categories overlooks their unique aging experience. The concept of functional age recognizes that aging is individual and promotes individualized nursing assessment and development of plans of care for the older adult.

Although aging is universal, it remains a unique experience for each individual. Factors that contribute to this process can be grouped into two categories. **Intrinsic factors** focus on genetic theories of aging, such as biological clock theory or programmed aging theory, and some aspects of physiological theories of aging, such as wear-and-tear theory or stress adaptation theory. **Extrinsic factors** focus on environmental influences, such as pollutants, free radical

theory, and stress-adaptation theory. Regardless of which factors have the greatest influence on this process of aging, **perception** and attitude also play key roles in how the changes over time affect the individual. It is through the filter of perception and attitude that the individual identifies, defines, and adapts to the changes that occur in structure and function over time. These factors have implications not only for older patients but also for their families and the health-care providers working with them.

PHYSIOLOGICAL CHANGES

Over time, cells change and do not function as efficiently as in earlier years (Table 14.1). The physical changes that are seen when looking at the older patient are slight as compared with the cellular changes that occur. Cellular decline in structure and function increases in severity and extent over time. Although the body works hard to maintain **homeostasis**, it is often unable to fully adapt to many of the declines that result from aging. Cells that die cannot regenerate themselves. As a result, structures are altered, and the body tries to adapt to make the revised structure meet functional demands.

Common Physical Changes in Older Patients and Their Implications for Nursing

Key Changes in the Muscular System with Aging

Key aging-related changes in the muscular system include the following:

- Decrease in muscle mass, so muscles look smaller
- Decrease in muscle tone, so muscles look less toned
- Slower muscle responses, so response time is increased
- Decrease in elasticity of tendons and ligaments, restricting movements

NURSING IMPLICATIONS. Changes in the muscular system have implications for movement, strength, and endurance. Restricted movements are most commonly seen in the arms, legs, and neck of the older patient, who may demonstrate limited **range of motion (ROM)** in these areas. Because muscle response abilities are slowed, it will take longer for the older patient to move. This increased response time has implications on the older individual's confidence level regarding personal ability to perform routine tasks.

Key Changes in the Skeletal System with Aging

Key aging-related changes in the skeletal system include the following:

- Eroding cartilage
- Exaggerated bony prominence
- Joint stiffening and decreased flexibility

homeostasis: homios—similar + stasis—standing

TABLE 14.1 PHYSIOLOGICAL AGING CHANGES

Body System	Aging Change	Effect of Change
<i>Cardiovascular</i>	Increased conduction time Decreased cardiac output Decreased blood vessel elasticity Irregular heartbeats	Heart rate slows, unable to increase quickly Less oxygen delivered to tissues Increased blood pressure increases cardiac workload Poor heart oxygenation, decreased cardiac output, heart failure
<i>Endocrine and Metabolism</i>	Leg veins dilate, valves less efficient Basal metabolic rate slows Altered adrenal hormone production Decreased insulin release	Varicose veins, fluid accumulation in tissues Possible weight gain Decreased ability to respond to stress Hyperglycemia
<i>Gastrointestinal</i>	Reduced taste and smell Decreased saliva Decreased gag reflex, relaxation of lower esophageal sphincter Delayed gastric emptying Reduced liver enzymes Decreased peristalsis	Appetite may be reduced Dry mouth, altered taste Increased aspiration risk Reduced appetite Reduced drug metabolism and detoxification Reduced appetite, constipation
<i>Genitourinary</i>	Kidney size decreases Decreased bladder size, tone, changes from pear to funnel shaped Muscles weaken Decreased concentrating ability Less sodium saved Reduced renal blood flow	Able to live with 10% renal function Frequency of urination increased Incontinence Nocturia Risk for dehydration Decreased renal clearance of all medications
<i>Immunological</i>	Decreased function Increased autoimmune response	Infection and cancer risk greater Increased autoimmune diseases
<i>Integumentary</i>	Reduced cell replacement Water loss Increased pigmentation Thinning of skin layers Decreased subcutaneous fat Decreased sebaceous and sweat glands Hard, dry nails Thinning scalp hair Decreased melanin	Healing slower Dryness of the skin Aging spots Skin more fragile Less insulation and protective cushioning Dryness and decreased temperature regulation Brittle nails Baldness Gray hair
<i>Musculoskeletal</i>	Decreased skin elasticity Decreased muscle mass Decreased muscle tone Decreased elasticity of tendons and ligaments Muscle responses slowed Bone thinning, softening Joint stiffening Vertebral disk water loss	Wrinkle development Reduced strength Muscles look flabbier Movements are restricted Response time increased Decreasing bone density Decreased flexibility Decreased height
<i>Neurological</i>		
Central nervous system	Loss of brain cells Decreased brain blood flow Decreased regulation of body temperature Decreased endorphins	Able to maintain function with remaining cells Short-term memory loss Hypothermia, hyperthermia risk Increased depression
Peripheral nervous system	Decreased sensation Increased reaction times Decreased motor coordination	Risk for injury, burns Slow response, injury risk Unsteady, fall risk
<i>Respiratory</i>	Decreased lung capacity Decreased cough and gag reflexes Reduced lung tissue tone Reduced lung emptying on exhalation Decreased fluid and ciliary action	Dyspnea with activity Aspiration, infection risk Shallow, faster respirations CO ₂ retention Mucous obstruction, infection risk
<i>Sensory</i>		
Eye	Lens less elastic Lens opaque, yellows Cornea more translucent Smaller pupil Decreased violet, blue, green color vision Arcus senilis—blue or milky lipid ring on iris edge	Decreased near and peripheral vision Cataracts Blurry vision Decreased dark adaptation See red, orange, yellow colors better No effect on vision

Body System	Aging Change	Effect of Change
Ear	Degeneration of auditory nerve	Lose high-frequency tones, deafness
Nose	Excess bone impairs sound conduction Decreased smell	Deafness Decreased ability to smell substances such as smoke, gas causing safety risk; appetite reduced
Sexuality	Availability of partner or privacy decreases Slower sexual arousal time	Lack of sexual expression, suppression of desires Increased time needed for sexual stimulation
Men	Decreased erection, slower ejaculation	Psychologically causes concern
Women	Less vaginal lubrication Vaginal acidity reduced	Painful intercourse Increased vaginal infection risk

- **Osteoporosis**, a thinning and softening of the bone
- Shortening in height caused by water loss in the intervertebral disks of the spinal column, flexion of the spine, and stooped posture

NURSING IMPLICATIONS. Because muscles and bones work together for movement, aging skeletal changes are most obvious when the older patient is moving. **Contractures** of the fingers and hands can limit the individual's ability to perform self-care tasks called **activities of daily living** (ADL). It is important to assist the patient with ROM exercises if help is needed to prevent the long-term disabilities that contractures bring (Fig. 14.1). Performing ROM exercises in warm water helps the patient who experiences discomfort with these exercises. If the individual has arthritis, anti-inflammatory medications should be given so that their action peaks when the exercises begin. Older patients on anti-inflammatory medicines should be monitored closely for gastrointestinal upset or bleeding and taught the symptoms of bleeding to report.

Decreased bone density is influenced by diet and weight-bearing exercise, so balanced diets rich in calcium and vitamin D and safe and sensible exercise programs should be promoted. Patients should be encouraged to ambulate whenever possible, using supportive, sensible shoes with nonskid soles. In addition to making sure the environment is safe for walking, sturdy assistive devices such as handrails, canes, or walkers should be encouraged as needed. When the decreasing density of older bones is considered, it is easy to understand that broken bones do not always result from a fall but may indeed be the reason for the fall in many older patients.

SAFETY TIP

Implement a fall reduction program and evaluate the effectiveness of the program. Involve residents/ patients and their families to promote patient safety (2006 National Patient Safety Goals from www.jcaho.org)

Key Changes in the Integumentary System with Aging

Key aging-related changes in the integumentary system include the following:

- Increased dryness of the skin
- Increased pigmentation, causing liver or aging spots
- Thinning in the layers of the skin, which makes the skin more fragile
- Decreased elasticity of the skin, causing wrinkles to develop
- Decreased subcutaneous fat layer of skin, so older patients have less insulation and less protective cushioning
- Hardness and dryness of nails, making them more brittle
- Decrease in nail growth rate and strength
- Thinning of scalp hair (primarily men)
- Increased growth and coarseness of nose, ear, and facial hair

FIGURE 14.1 Nurse assists patient in range-of-motion exercises to prevent the development of contractures.

osteoporosis: osteon—bone + poros—a passage + osis—condition

- Decrease in melanin, which results in gray hair
- Decreased sebaceous and sweat glands, which has implications for dryness and decreased temperature regulation

NURSING IMPLICATIONS. The skin, which is the first line of defense against infection and injury, does not work as effectively in older patients (Fig. 14.2). In the older adult, skin injuries take longer to heal, and those longer healing times are usually complicated by the fact that many older patients have multiple chronic diseases, such as diabetes and circulatory ailments.

The older patient with limited mobility is especially prone to developing pressure ulcers (Fig. 14.3). These ulcers usually develop over a bony prominence of the body (e.g., ears, shoulders, elbows, tip of the spine, pelvic bone ridges, knees, heels, or ankles). Pressure ulcers are caused by ischemia that results from continuous pressure on an area of the body. Ischemia from unrelieved pressure can develop in 20 to 40 minutes. Early signs of **pressure ulcer** formation are warmth, redness, tenderness, and a burning sensation at the potential ulcer site. These potential ulcer sites are aggravated by lack of activity and the weight of the body. For this reason it is especially important to take the time to assess skin integrity daily, especially in high risk areas of the body.

SAFETY TIP

Monitor on ongoing basis each resident's/patient's risk for developing a pressure ulcer and implement plan of care for identified risks. (2006 National Patient Safety Goals from www.jcaho.org).

Skin care includes gently stimulating nonreddened intact skin sites with massage, moisturizing with creams regularly, avoiding the use of hot water and a complete daily bath, and limiting the use of soap. If able, patients should be

FIGURE 14.2 Thin, fragile skin of older person.

FIGURE 14.3 Pressure ulcer. (From Goldsmith, LA, Lazarus, GS, and Sharp, MD: *Adult and Pediatric Dermatology: A Color Guide to Diagnosis and Treatment*. FA. Davis, Philadelphia, 1997, p 445.)

taught to shift their weight every 15 minutes when sitting. For immobile patients, consistent repositioning is essential. Ideally, use of pressure-relieving devices or repositioning every 30 minutes as able is the most beneficial for high-risk patients to help prevent pressure ulcer development (see Chapter 54). Keeping bed linens clean, dry, and wrinkle free also aids in the prevention of pressure ulcer formation.

As with care of the skin, nail care is important for older individuals. Soaking in warm water helps soften nails to ease in their trimming while encouraging blood flow to the peripheral areas of the body. Filing the nails with an emery board is safer than cutting the nails. To prevent accidental injury to the feet, patients should be instructed not to walk barefooted. Potential pressure points of the feet should be identified and closely monitored, and the patient should be referred to a podiatrist for treatment should there be any concerns. Diabetics should assess their feet daily because they may have decreased sensation, causing lack of awareness of foot irritation or injury.

Key Changes in the Cardiovascular System with Aging

Key aging-related changes in the cardiovascular system include the following:

- Slowed heart rate
- Decreased cardiac output from less effective functioning of the heart and blood vessels, yielding less oxygen to body tissues
- Decreased elasticity of the blood vessels, so the circulatory system is less efficient
- Reduced ability of the heart to quickly increase its rate in response to an emergency because of thickening of the heart valves, left ventricle, and aorta (when rate finally does increase, the heart takes longer to return to resting rate)
- More irregular heartbeats, **arrhythmias**, which lead to poor oxygenation of the heart
- Commonly, a lack of classic symptoms of cardiac emergencies
- Increased peripheral vascular resistance in blood vessels, yielding increased blood pressure

- More visible superficial blood vessels of the legs
- Less efficient leg vein valves, creating the risk for an accumulation of excess fluids in the leg tissues.

NURSING IMPLICATIONS. Be a good observer when it comes to caring for older patients because many early symptoms related to circulatory problems are subtle. Cardiovascular disease, which is separate from the process of aging, accounts for half of all deaths in people older than 65 years. Older adults must be educated about prevention practices that promote healthy circulation and encouraged to take prescribed medications as ordered and maintain a balanced intake and output of fluids. Older patients receiving intravenous therapy should be monitored closely because fluid overload can occur quickly in older people.

Special care should be taken to maintain good skin integrity and provide appropriate stimulation. If **edema** is present in the legs, they should be elevated to assist the fluid return to the upper body and supportive, nonrestrictive stockings should be worn as ordered. Concerns regarding leg circulation should be identified and reported early to the physician before problems develop. It is important to identify whether the circulation problem is arterial or venous before treatment is ordered.

Because quick changes in body position can make the older patient feel weak and dizzy, it is important to stand next to older patients as they dangle their legs over the side of the bed before rising to stand. Changes in body positioning from lying to sitting to standing need to occur gradually to accommodate the less efficient circulatory systems of older patients. Older patients may find comfort in the security of an ambulatory belt or walker if they fear unsteadiness when in an upright position. Falls continue to rank as a leading cause of accidental death in older patients. Every effort should be made to decrease the risk of falling for the older patient. The fall history of patients should be assessed to identify whether they are at high risk of falling, so that preventive measures can be used.

Key Changes in the Respiratory System with Aging

Key aging-related changes in the respiratory system include the following:

- Decreased lung capacity
- Weaker cough or gag reflex, increasing risk for upper respiratory infections
- Reduced tone of lung tissue, so respirations increase to 16 to 25 per minute and are more shallow
- Reduced tone of the diaphragm muscle
- Less complete emptying of the lungs, with greater CO₂ retention
- Decreased blood flow to the lungs, contributing to cardiac arrhythmias

NURSING IMPLICATIONS. Because the respiratory system is less efficient with advancing age, the older patient

has a decreased tolerance for activity in general. Nurses should, therefore, pace activities for older patients instead of letting them confine themselves to bed. It is important to prevent overexertion, so rest periods should be scheduled. However, the rest periods should not outnumber the activity sessions planned throughout the course of the patient's day.

Cough, marked fatigue, and confusion may be early signs of an inadequate oxygen uptake. Respiratory rates greater than 25 per minute may be an early indication of a lower respiratory tract infection. Because overall muscle strength is reduced, the older patient performs the O₂-CO₂ exchange in the less efficient upper lobes of the lung instead of the larger lower lobes specifically designed for this purpose. Because lung recoil strength is decreased, mucus may be more difficult for the older patient to **expectorate**. This situation is compounded by the fact that older individuals also have less effective cough and gag reflexes, which creates greater potential for lung problems. Because of the normal changes in the respiratory system that occur with aging, it is important to include coughing, deep breathing, and position changes in the exercise program designed to stimulate all lobes of the older patient's lungs. At the prevention level, encourage the older individual to receive a pneumonia vaccine and an annual flu shot. This is important because influenza and pneumonia combine to be the fourth leading cause of death in people over age 65. Be aware that lifelong habits, such as smoking and respiratory pollutant exposure in employment settings, second-hand smoke, or paints and glues used in hobbies, are cumulative over time and can contribute to respiratory sensitivity for the older patient. Nurses can help prevent the spread of respiratory illnesses by getting flu shots themselves, hand washing between patients, not exposing patients to own illness, and using universal precautions.

SAFETY TIP

Reduce the risk of influenza and pneumococcal disease in older adults, (2006 National Patient Safety Goals from www.jcaho.org).

Key Changes in the Gastrointestinal System with Aging

Key aging-related changes in the gastrointestinal system include the following:

- Changes in taste and smell, which affect the enjoyment of eating
- Decreased saliva production
- Decreased gag reflex and relaxation of lower esophageal sphincter, increasing the risk of **aspiration**
- Delayed gastric emptying
- No functional changes in the small intestine

edema: oidema—swelling

expectorate: ex—out + pectus—breast

- Decreased tone in external sphincter
- Marked decline in liver enzymes, which affects drug metabolism and detoxification
- Decreased peristalsis from generalized weakness of muscle activity
- Alteration in bowel habits

NURSING IMPLICATIONS. Many factors can alter appetite, ingestion, digestion, and absorption of nutrients in food, regardless of an individual's age. However, the structural and functional changes that occur with advancing age put the older patient at greater risk for not obtaining the nutrients needed to sustain a healthy body (Box 14.1 Nutrition Notes).

There is little that can be done to change the physical alterations in the older body that make getting needed nutrients more difficult. Being knowledgeable and committed to providing the support necessary to meet nutritional goals is important. Patients should be assisted with toileting before helping them eat. An appropriate amount of time for the patient to accomplish the task of eating needs to be provided. If the patient needs assistance with eating, be sensitive to the patient's pace while allowing the patient to have as much control as possible.

Additional forms of support can focus on the need to recognize that for some cultures eating has a strong social component. Encourage the patient to eat out of bed and with others as much as possible, while respecting the patient's right of refusal to eat in a designated social setting. Some patients may not eat as well when seated next to agitated or confused residents in a common dining hall.

Offer continuing support by maintaining a calm and comfortable environment that aids digestion. Certain food combinations enhance nutrient absorption, such as vitamin C foods taken with plant foods high in iron; vitamin C increases the iron's absorption rate. Offer these selections together whenever possible. Family members can be asked to bring in familiar seasonings patients used at home. If acceptable, familiar seasonings in shakers that patients apply themselves can be used to stimulate a lagging appetite. Work closely with the dietitian or nutritionist, who may provide other ideas to promote healthful eating for older patients.

Although many older patients wear dentures or partial plates, it is important not to stereotypically assume that all older individuals wear dentures. Tooth loss is not a normal change of aging. With proper lifelong dental care, teeth should last a lifetime. If the older patient does have dentures, be aware that any significant change in body weight will affect their fit and comfort and the patient's nutritional intake. Because of this, it is important to conduct regular assessments of the mouth when assisting the older patient during oral care.

Medications may cause taste disturbances or problems with dry mouth that may also affect the older patient's ability to meet nutritional needs. Some medications create problems with bowel motility, resulting in **constipation**. Constipation can also result from a change in routine, stress,

Box 14.1

Nutrition Notes

Older Adult Nutritional Needs

Meeting the Nutritional Needs of the Older Adult

Energy needs decrease 5% for every decade after age 40, partly because a 70-year-old has 40% less skeletal muscle than in younger days. Adipose tissue requires fewer calories to sustain than skeletal muscle does, so special attention must be given to maximizing nutritional content in fewer calories if a healthy weight is to be maintained. A modified food guide pyramid for adults age 70 and older adds eight servings of water to the base of the pyramid, increases milk servings to three, and recommends calcium, vitamin D, and vitamin B₁₂ supplements. New recommended daily allowances for vitamin B₁₂ specify that fortified foods or supplements furnish most of this vitamin for people over age 50.

Decreased visual acuity and impaired dexterity may make shopping for food and preparing it difficult or even hazardous. Arthritis affects not only mobility, but also jaw movements, so chewing may be problematic. By age 65, about 40% of U.S. residents have lost all their teeth and have to develop skill in the use of dentures. It is recommended that an individual learn to drink with them first, then learn to manipulate soft foods, and lastly learn to bite and chew with the dentures. Older persons produce less saliva than younger people. The sense of taste declines in most but not all aging patients, who as a result may increase their intake of salt and sugar to the detriment of a prescribed diet plan.

Achlorhydria may occur as a result of aging or from chronic ingestion of antacids. In either case, protein digestion and absorption of iron and vitamins B₁₂ and C can be impaired by the lack of gastric acid. Although anemia can be caused by poor nutrition, older patients should be evaluated for hidden blood loss just as younger ones are. High-protein supplements should be offered to older individuals with caution, because normal aging reduces kidney function significantly and excretion of nitrogenous products of excessive protein intake could stress the urinary system. In addition, a high-protein intake increases calcium excretion. The vitamin necessary to metabolize calcium, vitamin D, may be deficient in older persons who neither drink milk nor spend time outdoors.

Many mature patients are at increased risk for food, nutrient, and drug interactions. Situations associated with these interactions are the use of many drugs, including alcohol; the need for long-term drug therapy in chronic illness; and poor or marginal nutritional status. Identification of any of these factors should prompt a thorough nutritional assessment or referral to a registered dietician.

and anxiety. To gain a greater understanding of the situation, talk with the patient about previous assistive procedures and establish an expectation baseline for bowel elimination. Educate the older patient about the important relationship between intake of fiber and water and exercise in the promotion of effective bowel evacuation. Enemas, suppositories, and medications should be considered for use only after dietary management is found to be ineffective.

Key Changes in the Endocrine-Metabolic System with Aging

Key aging-related changes in the endocrine-metabolic system include the following:

- Slowing in the basal metabolic rate, requiring a 5% reduction in calorie consumption to maintain weight
- Alteration in hormone production, including changes in estrogen, progesterone, and adrenal secretions
- Decreased pancreatic insulin release and peripheral sensitivity
- Decreased glucose tolerance with advancing age

NURSING IMPLICATIONS. Increased incidence of metabolic disease, such as diabetes, occurs with advancing years. Because of this, older patients should be encouraged to participate in screening programs for early detection of metabolic problems.

Because there is a notable decrease in the effectiveness and interaction of all hormones as one ages, it becomes especially difficult for the older body to respond appropriately to any stressful situations. Nurses should spend time addressing the psychological needs of patients by recognizing and addressing those actual and perceived stressors that affect their care. Preventive care to keep patients free from the stress of illness is also important.

Key Changes in the Genitourinary System with Aging

Key aging-related changes in the genitourinary system include the following:

- Decreased kidney size
- Decreased kidney function, urinary output, and adaptability
- Reduction of blood flow to the kidneys because of decreased cardiac output and increased peripheral resistance
- Diminished kidney filtration rate and tubular function, which cause a decrease in the renal clearance of all medications
- Decreased bladder size and tone
- Increased incidence of urinary tract infection with age, especially in women
- Longer correction times for fluid and electrolyte imbalances

NURSING IMPLICATIONS. Many older people have an urge to urinate at night, which is referred to as **nocturia**.

Changes in the kidneys, lack of gravity influence when in the recumbent position, fluid retention, and medication use contribute to nocturia. Approximately 30 minutes after lying down many older people need to urinate because fluid that was held in the legs by gravity is circulated through the kidneys and urine is produced, causing the urge to void. Emptying the bladder becomes more difficult to control from weakening of bladder and perineal muscles and also from a change in brain sensation regarding the need to void. As a result, the older patient may have difficulty controlling urination either knowingly or unknowingly, resulting in **urinary incontinence**.

NURSING CARE TIP

With age, the urge to void is not felt as early as it once was. This aging change combined with other changes in the urinary system, such as the bladder becoming funnel shaped, contributes to the older patient's voiding urgency. If the patient is not assisted to void promptly on request, incontinence can result.

First and foremost, the nurse must plan for safe access for all older patients who utilize the toilet alone or with assistance. Pathways to the toilet must be close and uncluttered. Toilets must be easy to access and clothing must be easy to remove. Incontinence is socially embarrassing and is one of the main reasons older people are placed in nursing care facilities by family members. Urinary incontinence in older men is most often attributed to benign prostate enlargement, while older women are more likely candidates because of short urethras and weakened perineal muscles. Because urinary tract infections are more frequent for older people (and often more dangerous), nurses must closely assess not only the quantity of intake and output for older patients, but also the quality of those measures.

Management of urinary incontinence needs to be tailored to the particular need of the patient. Bladder training programs have been effective when patients are reminded on a regular basis that it is time to urinate. If incontinence results from problems that affect the toileting task itself, such as clothing removal or distance to the bathroom, steps need to be taken to eliminate those obstacles that stand in the way of continence. Clothing with Velcro fasteners can replace buttons or zippers that are difficult for the patient to manipulate. Urinary briefs can help instill confidence in older patients who previously restricted activities because of fear of urine leakage. With use of the supportive incontinence brief, assess for early signs of perineal skin breakdown and proper application of the proper brief to meet individual needs.

Older patients who are aware of their incontinence may try to inappropriately decrease the chance for leakage by severely limiting fluid intake. This approach often results in

dehydration, which disturbs the acid-base and electrolyte balance in the body. Over time, dehydrated patients may have problems with vomiting, diarrhea, weakness, and confusion. Because fluid intake needs to be encouraged in older patients, focus educational efforts on topics such as liquid intake timing and beverage selection (e.g., teaching that caffeine and alcoholic beverages should be avoided because they normally increase urinary output).

In addition, review patient medications and personal medication practices, such as taking diuretics late in the day, which then causes nighttime urination. Teaching perineal muscle support exercises and techniques is successful for some. All patients with unexplained urinary incontinence should be referred to a specialist for further evaluation because it is not a normal condition of aging.

CRITICAL THINKING

Mr. Jones

■ Mr. Jones, age 72, lives at home. His home has wood floors with throw rugs. The bathroom is located in the hall outside his bedroom. Mr. Jones has nocturia and is occasionally incontinent from urgency to void. He takes bumetanide (Bumex) 1 milligram orally daily.

1. What additional assessment data should be obtained about Mr. Jones regarding his urinary status and home environment?
2. Are safety concerns present in the home environment?
3. What nursing diagnoses should be included in Mr. Jones's nursing care plan?
4. What should be included in a teaching plan for Mr. Jones?
5. The nurse is to give Bumex 1 milligram orally now. Bumex 0.5-milligram tablets are available. How many tablets will the nurse give?

Suggested answers at end of chapter.

Key Changes in the Immunological System with Aging

Key aging-related changes in the immune system include the following:

- Decreased immune response
- Decreased number and function of T cells, leading to impaired ability to produce antibodies to fight disease

NURSING IMPLICATIONS. Older patients tend to have more chronic diseases that may increasingly depress their immune responses over time. Although older patients have fewer colds, they are at higher risk for influenza and other complications once they get a cold. It takes longer to recover from infections, so patients and their family members need to be told that a prolonged recovery is to be expected. It is

also important to screen visitors for illness before they visit a recuperating older patient.

Efforts at prevention should focus on teaching the older patient about the importance of obtaining current immunizations, reducing stress, eating right, exercising, and maintaining a healthful lifestyle. Individuals on medications for conditions that put them at risk for immunosuppression, such as steroids, should be aware of the need to take additional safety precautions around others who are ill. Nurses can help patients help themselves by encouraging techniques such as proper hand washing that support universal precautions.

Key Changes in the Neurological System with Aging

Key aging-related changes in the neurological system include the following:

- Progressive loss of brain cells
- Decreased blood flow and oxygen utilization to the brain
- Decreased protein synthesis
- Decrease in sensitivity and the sensation pathways
- Increased reaction times
- Decreased motor coordination
- Decreased equilibrium
- Decreased ability of the hypothalamus to regulate body temperature
- Change in neurotransmitter secretion levels

NURSING IMPLICATIONS. Changes in the nervous system of the older patient can be seen in both the peripheral and central systems. These changes have significant meaning for the older individual, especially in the area of safety. With normal aging there is a slowed response to stimuli and a marked decrease in the speed of the psychomotor response to that stimuli. Because stronger stimuli are required to elicit any neurological response, the older patient is unable to perceive early signs of danger. To protect from accidental skin burns, the thermostat on water heaters should be lowered and electrical heating devices such as heating pads, electric blankets, and mattress pads should not be used.

Another safety issue of concern focuses on changes in balance. It is more difficult to maintain balance as one ages, especially when musculoskeletal changes are considered. Special caution should be taken to assist older patients with transferring and ambulation activities so optimum levels of safety can be maintained.

Fine tremors of the hand are a normal finding with advancing age and tend to increase when the older patient is cold, excited, hungry, or active. Assistive devices provided by an occupational therapist (such as handle grips or anchored equipment) can help eliminate the unsteadiness created when fine tremors make it more difficult to accomplish activities of daily living (Fig. 14.4). Accompanied by generalized muscle weakness, normal neurological changes that arise with advancing age usually occur on both sides of the body at the same time. One-sided weakness, sensory

FIGURE 14.4 Assistive devices for activities of daily living. (A) Sock and stocking aid. (B) Easy-pull hair brush. (C) Food guard. (Courtesy Sammons Preston, Inc., Bollingbrook, Ill.)

problems, and performance problems should always be referred for further evaluation. Coarse tremors of the finger, forearm, head, eyelids, or tongue that occur when the body part is at rest may be a sign of a neurological problem such as Parkinson's disease. These generally occur on one side of the body first and should always be referred for further evaluation.

Key Changes in the Sensory System with Aging

Key aging-related changes in the sensory system include the following:

- Decreased visual perception
- Decreased elasticity of the eardrum
- Decreased sense of smell
- Decreased taste perception
- Decreased touch sensation

NURSING IMPLICATIONS. Problems that occur with normal changes in the aging sensory system are not inevitable with advancing age. Early identification and prompt referral can minimize sensory loss, which has a strong impact on the older person's psychological health.

Normal aging changes in the eye affect the focus ability of the lens and the maneuverability of the eye muscles to meet the needs of near and far vision. It is especially difficult for older patients to read fine print, although it is usually manageable with reading glasses or a bifocal lens. When caring for patients who wear glasses, it is important to remind patients to consistently wear their glasses as needed and to help the patient keep them clean and in good repair.

When glasses are removed by the patient, keep them accessible and in a protective, labeled case.

The older patient has a more difficult time adjusting to changes between light and dark settings. Seeing in the dark can be enhanced with the use of a red night-light because red lighting is more easily detected by the cones and rods in the older patient's eye. Make every effort to reduce glare from bright sunlight because sensitivity to glare is enhanced with the normal changes that occur in the aging eye (Fig. 14.5). The glare from car headlights may impair vision in older patients and reduce their ability to drive at night.

Several eye disorders can affect the aging eye (see Chapter 52). **Cataracts**, one of the most common pathological problems affecting the aging eye, cloud the lens and impair vision. **Glaucoma** is a chronic disease characterized by increased intraocular pressure that can damage the optic nerve. Another common visual condition that occurs later in life is **macular degeneration**, which results in a loss of central vision. Regardless of the means, any visual loss in older patients puts them at risk for developing psychological problems with disorientation, withdrawal, or self-imposed isolation caused by **sensory deprivation**.

Hearing loss is a common condition found in older individuals. Although the severity of the hearing loss caused by aging is variable, the stigma it carries is the same. For older patients, the first difficult sounds to discriminate are the high-pitched tones. Therefore, it is often more effective to whisper when communicating with the hearing-impaired

FIGURE 14.5 (Left) Normal view. (Right) The effects of glare as seen by an older patient. (From Matteson, MA, and McConnell, ES: *Gerontological Nursing*. Saunders, Philadelphia, 1988, p 314.)

individual because whispering decreases the pitch of the sounds. Shouting is not helpful because both volume and pitch are increased. It is best to speak to a hearing-impaired person in a moderate volume and a lower tone. It is also helpful to stand in front of hearing-impaired patients so they can see the speaker's face during communication (Box 14.2 Communicating with Hearing-Impaired Patients).

Two types of hearing loss can occur separately or in combination in the hearing-impaired patient. Conduction loss is due to blockage or damage to the mechanisms that transmit sound to the middle ear, where it is carried by the acoustic nerve to the brain. Conduction hearing loss can be due to a variety of factors, some as simple as ear wax build-up, and in most cases can be successfully managed. The other type of hearing loss, sensorineural loss, is due to damage to the structures in the inner ear and is much more difficult to manage. This type of loss can result from illness, medication use, or long-term abusive noise pollution that damages the sensitive structures involved with sensation and interpretation of sound. It is important to use hearing protection throughout life because damage to the ear is usually not reversible.

New-technology hearing aids can help most people with either type of hearing loss. Patients should be referred to an audiologist for further evaluation if hearing loss is suspected. Hearing aids are not well accepted by all older persons or their family members because they are a visual sign of a loss. Because of this, maintain patient privacy if a referral for further evaluation is made. If the older patient already has a hearing aid, it should be kept accessible to the patient at all times. The hearing aid should be kept clean with soap and water. A cotton swab removes wax build-up in tiny areas of the hearing aid. When not in use, the hearing aid should be stored in a labeled protective container and the battery turned off to conserve it. Extra batteries should be readily available.

As discussed in the gastrointestinal section of this chapter, the senses of taste and smell work closely together. Like other sensory losses, a declining ability to taste is not a problem exclusive to the older individual. Both ill-fitting

dentures and poor oral care can contribute to an alteration in the sense of taste, as can certain medications, tobacco substances, and oral disease.

Although they are often treated together as one sensory loss, the incidence of loss of the sense of smell is more common than the disorder that focuses on the loss of taste. In some cases, the loss of smell may be due to sinus problems, nasal obstruction, or allergies. If olfactory receptors are the primary cause for losing the sense of smell, there is little that can be done to treat the loss. Assess patients' medication charts, as well as their oral cavity, if they report a recent loss of smell or taste sensation.

Nurses also need to be aware of the care environment they provide for the older patient. Overstimulation produced by **sensory overload**, commonly experienced in intensive care hospital settings, can create psychological and physical strains that can make it difficult for the older patient to cope. As a patient advocate, be sensitive to the patient's care environment and changes in the patient's health-care status, identifying and minimizing overload situations early in the recuperation period.

Box 14.2

Communicating with Hearing-Impaired Patients

- Ensure that hearing aids are on with working batteries, if applicable.
- Face patient so the speaker's face is visible to patient.
- Speak toward patient's best side of hearing.
- Speak in a clear, moderate-volume, low-pitched tone.
- Do not shout because this distorts sounds.
- Recognize that high-frequency tones and consonant sounds are lost first—s, z, sh, ch, d, g.
- Eliminate background noise because it can distort sounds.

Key Changes in the Sexuality System with Aging

Key age-related changes in sexuality include the following:

- Chronic illnesses, which may affect sexual functioning
- Functional sexual changes in older men, commonly alteration in ability to obtain or maintain an erection and to ejaculate
- Functional sexual changes in older women, such as decreased vaginal lubrication
- Sexual problems caused by psychological factors, which are more common than physical ones in older adult patients
- Longer sexual arousal time in the older patient
- Increase in sexual activities that focus on non-intercourse intimacy behaviors, including various forms of touch

NURSING IMPLICATIONS. The older patient's sexuality is an important aspect to consider when providing care. It is essential to accept that sexuality is one of the basic physiological needs identified in Maslow's hierarchy for all individuals regardless of age. Be aware of personal attitudes and values about sexuality, sex, and aging, being careful that personal stereotypes and beliefs do not interrupt the older person's attempt to maintain sexual identity. Because privacy remains a common problem for individuals in health-care settings, provide the patient some scheduled private time for sexual expression. As new sexual enhancement treatments become more available to patients, there may be a greater openness to discuss sexual expression in conversations with older patients. Still, there remain many older patients who may have difficulty overcoming barriers to sexual expression because of cultural or religious beliefs, lack of a suitable partner, fear of failure, fear of consequences, illness, side effects of medications, and certain chronic diseases that may alter libido or sexual functional abilities. Because sexual discussions with these patients may be more difficult, it is important to address the sexual history section as sensitively, professionally, and completely as other sections of the patient assessment form (Box 14.3 Nursing Assessment of Sexuality).

COGNITIVE AND PSYCHOLOGICAL CHANGES IN THE OLDER PATIENT

Cognition

In addition to those physiological changes that occur with advancing age, older patients also experience changes that have an effect on cognition. Cognition includes abilities related to intelligence, memory, orientation, judgment, calculation abilities, and learning. Cognition focuses on intake of information and storage, processing, and retrieval of stored information. For the most part, older patients store information without much conscious effort. If dealing with

Box 14.3

Nursing Assessment of Sexuality

As with any nursing skill, practice will increase your comfort in collecting sexuality data for the older patient so these needs are not ignored. Assessment of sexuality concerns may lead to the discovery of other health issues and is a valuable part of data collection. As you collect data, be aware of problems (e.g., pain, medication side effects, mobility, dexterity, elimination, angina, surgery) identified in the history that may impact sexual functioning. Also, establish rapport with the patient by collecting other data first and turning to sexuality data at the end of the history. Older patients often respond to sexuality questions but will not initiate the topic.

Naturally, you should use a professional approach and manner, and tell the patient that you will now ask questions about sexuality. Start with questions that are likely to be more comfortable for the patient, as follows:

- Address roles first. For example: What concerns (do you have or has your illness created) in carrying out your roles with your (spouse or sexual partner)?
- Address relationship issues next. For example: What effect on your relationship with your (spouse or sexual partner) has this (illness, symptom, chronic illness) had?
- Address body image. For example: What effect has your (illness, surgery [mastectomy, prostate, ostomy], chronic illness, aging-related changes) had on your self-concept of being a (man or woman)?
- Address sexually transmitted diseases. For example: Do you have any discharge or open sores (vaginal, penile)?

information becomes difficult, the older person may begin to worry. Unless this worry is addressed, the patient's concern may result in psychological problems and fears.

Many factors can affect cognition. Sensory changes and diseases associated with age can cause misinterpretation of information being collected. Pain from chronic diseases, such as arthritis, can limit cognition as pain takes over the body and mind. Sleep deprivation caused by worry or fear can make it more difficult to perform routine tasks. Medications that cause drowsiness as a side effect can also impair cognition.

Long-term memory retrieval is easier to accomplish in old age than short-term memory retrieval. Assist the patient having short-term memory problems by using written lists, visual cues, and other memory-enhancing systems to aid in strengthening short-term memory skills.

Intelligence does not decline as one ages if it is measured using an appropriate instrument that focuses on accuracy and not on speed of response. Although cognitive

abilities do tend to slow down with advancing age, they are not lost. Most of the subtle declines that do occur with information processing and retrieval do not need to interfere with the older patient's abilities in performing activities of daily living.

Nurses need to assist in the identification of individual problem situations and work with older patients and their families in developing strategies to better address their needs. It is common knowledge that health, good nutrition, and adequate sleep are important factors for brain functioning. These factors should be the cornerstones in planning care for the older patient.

Coping Abilities

How the individual chooses to adapt to a change in functional ability over time has a significant impact on how that individual will work through the entire maturational process called aging. In addition to normal aging changes, many older patients are coping with compounding changes that occur because of chronic disease. Nurses must not lose sight of the fact that in addition to changes caused by some decline in physical and cognitive functioning, older persons simultaneously work to deal with many societal and culturally perceived losses associated with advancing age. Changes in employment status and societal and family roles and shifts from independence to dependence may have a strong psychological impact on both older patients and significant others. With such a combination of "losses," an alteration in the confidence level of the older patient may be seen, requiring encouragement of self-care behaviors.

Personality, attitude, past life experiences, and the desire to adapt to change are all intrinsic influencing factors that assist the older patient in coping with changes brought on by advancing age. Extrinsic factors include things such as financial status, family support, and support provided by those who directly care for the patient. If older patients have the energy, desire, determination, and support of those who care for them, they are better able to optimize use of their cognitive functions toward health.

Depression

There are times when the psychological impact of change is too difficult to cope with, and loneliness, grief, or sadness does not easily allow the older person to cognitively focus on health. When this happens, **depression** can result, with the potential to disable the older individual's mind and body. Depression is the most common psychiatric problem among older adults. This psychological condition, which causes a disturbance in mood, increases the risk for suicide, physical health complaints, and sleep disturbances.

It is important to understand that the frequency and intensity of depression generally increase with advancing age. Depression can result from physical changes in the brain caused by medications or conditions that affect the neurotransmitters in the brain or from psychological

changes at an emotional level, such as maladaptive coping from a perceived loss. Regardless of the cause, depression is a condition that has the potential to be reversed with prompt identification and treatment. It is important, therefore, to be sensitive to what the older individual is and is not saying during communications. Patients should be referred for treatment if depression is suspected before maladaptive behaviors occur.

Dementia

Unlike depression, **dementia** involves a more permanent progressive deterioration of mental functioning. Dementia is often characterized by confusion, forgetfulness, impaired judgment, and personality changes. There are two main types of dementia: multi-infarct dementia and Alzheimer's disease.

The multi-infarct classification results from repeated strokes that affect the brain tissue. The onset for this condition can be sudden or gradual, but its course is marked by a cyclical worsening and lessening of signs and symptoms that vary with the intensity and location of the brain damage.

The cause of Alzheimer's disease is unknown, but symptoms gradually begin with impaired memory that progresses to language and motor function losses. The course of this disease is marked by stages that can occur up to 14 years before death. It is only on autopsy of the brain that a definitive diagnosis of Alzheimer's disease can be made. Until then, Alzheimer's is suspected after other types of dementia have been ruled out with testing.

With any dementia, help the older patient maintain an **optimum level of functioning** in an atmosphere that provides for physical and emotional safety. In efforts to help ground the confused patient, incorporate **reality orientation** or validation into all nursing interventions. Sensory overload should be decreased for confused patients. Speak calmly and slowly and provide nonthreatening therapeutic touch if accepted by the patient.

In addition, it is important to address the education and support needs of the patient's family as they learn to deal with changes in behavior demonstrated by the older patient. Refer any patient with confusion for a mental status examination to help in determining whether the person suffers from depression or dementia. It is essential that a sensory status examination be conducted on the older patient before a mental status examination is conducted to help ensure the accuracy of the test results.

Sleep and Rest Patterns

The need for sleep in older adult patients does not decrease with age, but the pattern usually varies from earlier times in their lives. As in any age group, the lack of sleep leads to fatigue, irritability, increased sensitivity to pain, and increased likelihood of accidental behaviors. This is why it is important to obtain a baseline sleep and rest history when the older patient is admitted to the health-care unit. Consider sleep patterns, bedtime rituals, rest and nap patterns, daily

exercise patterns, stress level, dietary intake patterns, and lifestyle issues such as caffeine, alcohol, and nicotine intake when completing the sleep and rest assessment of an older patient.

Circulatory problems may disrupt normal sleep patterns for the older person and may be the only clue of an impending health problem. The anxious patient who is unable to sleep may be calmed with back rubs, foot rubs, a warm bath, warm milk, or a glass of wine, if not contraindicated, when patterned bedtime rituals prove to be unsuccessful. Sleep medications should be used only as a last resort because they can affect the quality or depth of the sleep the older person receives and may produce unwanted side effects.

Medication Management

One of the most difficult tasks for older patients, their family members, and the health-care provider caring for them centers around the topic of medication management. Because older patients are more susceptible to drug-induced illness and adverse side effects for a variety of reasons already addressed in this chapter, nurses need to be especially aware of what the older patient is taking, how it is being taken, and what effect it is having.

Older patients use many medicines for various ailments. Most have more than one chronic illness for which they take medications. Sometimes these different medications interact and produce side effects that can be dangerous. Not only do health-care providers need to be concerned about prescribed medicines, they also need to look at the types of over-the-counter medicines older patients take, as well as the self-prescribed extracts, elixirs, herbal teas, cultural healing substances, and other home remedies commonly used by individuals of their age cohort.

Health-care providers not only need to be concerned about overuse and combinations of medications, but also misuse of them. If an older patient crushes a large enteric-coated pill so that it can be taken in food and easily swallowed, it destroys the enteric protection and can inadvertently cause damage to the stomach and intestinal system. Some patients intentionally skip prescribed doses in efforts to save money. When prescribed doses are not being taken as expected, problems do not clear up as quickly and new problems may result. The new Medicare Part D prescription coverage may help with this.

Work closely with older patients and their families on medication education. Patients need to know what each prescribed pill is for, when it should be taken, how it should be taken, and side effects to report. As a patient advocate, work with the pharmacist to remedy administration concerns so that the prescribed dose can be taken as directed. Write down early medication side effects, educating patients or designated care providers to be proactive in their care.

Medication use, abuse, and misuse need to be addressed regularly with older persons. Concerns need to be closely monitored and addressed before they evolve into

SAFETY TIP

- Use two patient identifiers that are not the resident's/patient's room number when giving medications.
- Obtain/document complete list of resident's/patient's current medications upon admission to the organization with involvement of resident/patient. Compare medications the organization provides to those on list.
- Communicate complete list of resident's/patient's medication list to the next provider of service with referral/transfer to another setting, service, practitioner or level of care within or outside the organization. (2006 National Patient Safety Goals from www.jcaho.org)

problem situations. Helping older patients consistently adhere to a prescribed medication routine with visual and verbal supports helps all those involved in the process of their medication management. This method also encourages self-care and supportive independence, as able, making for easier and safer medication use.

HEALTH PROMOTIONAL ROLE IN NURSING CARE OF THE OLDER PATIENT

Overall, the nurse who works with older patients must recognize the importance of developing strong skills in the areas of listening and observation. With competence in these skill areas, patterns of change can be readily identified and concerns can be addressed before they become problems for the older adult. Although this is important to consider for all patients who receive nursing care, it becomes especially important when working with older patients. This is because older persons often do not present with the typical symptom patterns associated with health problems seen in younger individuals, and early signs of health problems are often not evident in older patients.

By learning about normal changes expected with advancing age, older patients and their families can be helped to recognize commonly held societal myths associated with aging. In efforts to help older patients meet their optimum level of functioning, it is important to assess the older patient holistically, remembering that nursing assessment is an ongoing process. To assist in focusing on health promotion with older patients, look to health education activities, screening efforts for disease detection, immunization programs, and specific safety practices (Table 14.2).

TABLE 14.2 NURSING CARE FOCUS ON SAFETY ALPHABET FOR OLDER PATIENTS

A is for ABILITIES	<ul style="list-style-type: none"> • Know your abilities. • Know patient's abilities. • Base nursing actions on your abilities. • Seek out assistance when needed.
B is for BODY MECHANICS AND ALIGNMENT	<ul style="list-style-type: none"> • Use proper body mechanics. • Use appropriate assistive devices. • Ensure patient is in proper body alignment.
C is for COMFORT	<ul style="list-style-type: none"> • Ensure physical and emotional comfort during care. • Use pain scale during each assessment.
D is for DELIBERATE MOVEMENTS	<ul style="list-style-type: none"> • Plan ahead and communicate plans to patient. • Demonstrate confidence during care. • Alert patient to planned movements by saying, "Moving on three. One, two, three." • Ensure patient assists with moves as able.
E is for ENVIRONMENT	<ul style="list-style-type: none"> • Always place call light within reach. • Keep environment uncluttered and safe. • Ask patient's permission before moving items. • Put items back as patient prefers.
F is for FALLS	<ul style="list-style-type: none"> • Remember falls are a primary concern for older patients. • Use interventions to prevent falls: Assist patients with ambulation, use assistive devices, answer call lights promptly, provide accessible toileting facilities, use night-lights, avoid use of throw rugs.
G is for GIVING YOUR TIME	<ul style="list-style-type: none"> • Allow more time to perform actions. • Do not rush older patients. • Provide time for listening and observing, so concerns are addressed before becoming problems.
H is for HAND WASHING	<ul style="list-style-type: none"> • Use correct hand washing protocols to protect yourself and older patients. • Use standard precautions to protect yourself and older patients.

Home Health Hints

- Try to schedule therapy visits and nurse visits on the same day to decrease fatiguing the older patient.
- Because many older patients keep their homes warm, the home health nurse should wear layers of clothing, removing a layer as needed, rather than adjusting the heat in the older patient's home.
- Pagers should be placed on a silent mode if possible to avoid startling or confusing the older patient.
- Nurses should not assume that the older patient remembers them when they answer the door. Nurses should state their name and why they are there. A large-letter name tag should be in clear view.
- To enhance the effectiveness of a visit, the older patient should be asked to visit in a quiet room of the home with the primary caregiver invited in at the appropriate time. This may help the older patient stay more focused, offer privacy, and assist hearing.
- Making a sign for the door of the home giving visitors instructions, such as ringing the doorbell several times, knocking loudly, or using the other door, may be helpful to the older patient. Do not provide information that would inform a stranger that an older patient lives in the home.
- Suggesting that limiting visitors or not allowing persons with colds to visit can be helpful in preventing illness for the older patient.
- Stressors in a patient's life, such as annoying visitors, chastisement by caregivers, and harassment by bill collectors, are often experienced firsthand by the home health nurse. Document and share those with the home care team, so a coordinated approach can be taken.
- When auscultating lungs, ask the older patient to take deep breaths in and out through the mouth. This may stimulate coughing, which is an opportune time to teach deep breathing and coughing exercises.
- If the older patient seems fatigued early in the day, ask about sleeping patterns and things that disturb it, such as barking dogs, traffic noise, and visitors. Recommend ear plugs or changing rooms to obtain a good night's rest. Check medications for insomnia listed as a side effect and suggest dosing of these medications early in the day if appropriate. A 15- to 30-minute nap in the early afternoon can be helpful.
- One of the first signs of infection in the older patient is confusion.
- One of the first signs of dehydration is tachycardia. Instruct the patient regarding adequate hydration.
- Assist patients and/or caregivers with obtaining and setting up a weekly pill dispenser. These can be easily purchased at their local pharmacy. For those patients who are forgetful, a pill dispenser with a timer can be

purchased. An audible or visual alarm will go off when it is time for them to take medications. It is important for the home health nurse to assess the patient's ability to follow instructions. During visits check the medication dispenser to ensure that pills are being taken as prescribed. If there is a concern inform the physician.

- Assess the older patient's environment for safety hazards on each visit and promote safety. Patients can easily trip on a scatter rug or fall attempting to navigate around furniture. Encourage the patient and caregiver to dispose of scatter rugs and unnecessary furniture.
 - If the home is a two story, help the patient and caregiver consider how to relocate the bedroom to the first floor. Stairs are difficult to manage especially if patients have a visual disturbance or they use an assistive device.
 - Assist patients in obtaining a medical alert device that can be worn around their neck in case of falls. If they fall emergency medical services can be alerted when they push the button.
 - If the older patient has dentures, assess if they are worn for eating. If not, assess why they are not worn (e.g., sores, improper fit from weight loss) and discuss solutions.
 - Checking the refrigerator for outdated food is helpful. The older patient is often on a limited budget and has been taught not to waste food. These factors along with a decreased sense of smell and taste can lead to food poisoning in the older patient.
 - Encourage the uses of spices and herbs, such as parsley, oregano, lemon, garlic, and basil, instead of salt and sugar. Suggest keeping pared apples and slices of oranges in the refrigerator for snacks.
 - If a Meals on Wheels program is available, ask if the older patient would like to be placed on the service.
- Use a warming tray when feeding an older patient who takes a longer time to eat.
- When swallowing is difficult, freezing liquids helps, so they can be eaten with a spoon or like a popsicle. Milkshakes, high-protein drinks, instant breakfast mix, or eggnog are thicker liquids that are easier to swallow.
- If an older person wears perineal pads or adult briefs, ask how many are used in a 24-hour period to assess the degree of incontinency or amount of output. Have the patient keep a voiding diary to further assess the degree of incontinence.
- Suggest a bedside commode when a weakened older patient is on diuretics or has a history of falling or confusion. Placing it next to the bed at night helps reduce the risk of falls and eases the caregiver's burden.
- If the older patient reports constipation, review the diet and make suggestions regarding adequate fluid and fiber. A mixture of equal parts of applesauce, bran, and prune juice is often helpful to prevent or relieve constipation. Discourage the use of mineral oil because it can make vitamins less effective.
- When drawing blood from the hand of an older patient, use the smallest needle possible.
- Hold light pressure for at least 2 minutes after the needle is removed. Do not use a Band-Aid on the fragile skin of the older patient if the bleeding has stopped with pressure.
- When teaching, it is important to acknowledge the patient's knowledge and life experiences. When given a chance, patients tell how they have maintained their health over the years. Use open-ended scenarios for teaching, such as, "What would you do if you were alone and fell?" Teaching should occur with patients, not to them. The nurse is in the patient's home, which is a personal place. Patient dignity should always remain intact during home care visits and teaching sessions.

REVIEW QUESTIONS

1. Which of the following does the nurse understand is considered the definition of aging in planning care for the older adult?
 - a. A disease that results in the death of all of a person's body cells
 - b. A condition that starts for all people when they reach the age of 65
 - c. A maturational process that creates the need for individual adaptations due to physical and psychological changes in the body and mind over time
 - d. A state of accelerating and simultaneous decline in body functioning directly related to the death of body and brain cells and the diseases that result
2. The nurse is assessing a patient who says "I am shorter now." The nurse responds based on the understanding that which of the following commonly contributes to individuals becoming shorter with age?
 - a. Contractures
 - b. Bone degeneration in the legs
 - c. Hyperextension of the cervical spine
 - d. Water loss from spinal intervertebral disks
3. In teaching an older adult patient who is not cognitively impaired and was recently diagnosed with hypertension about prescribed antihypertensive medication, which of the following is the best approach for the nurse to use to encourage medication compliance?
 - a. The nurse looks the patient right in the eye and tells how medicines control the disease. The nurse then says "It is important that you take your BP pill every day." Do you understand this?

- b. The nurse talks to the patient about medication management for hypertension. The nurse then gives the patient a grid to record the time each day the BP pill is taken. The nurse then takes out a pencil and says “It’s 9:00 a.m. right after you took your BP pill with breakfast, show me how you will write it on this form that you will take to your next doctor’s appointment.” How do you see this working for you?
- c. After talking about the new BP medicine, the nurse asks the patient “Do you have a relative or friend who can call you everyday to remind you to take your BP pill? It is really important that you take it and as you get older it is harder to remember things.” Who do you think can help you with this?
- d. After the nurse talks about the new BP pill the patient will take home, the nurse says, “If you don’t take this pill you will probably have a heart attack or a stroke, so you better figure a way that you don’t forget to take it everyday.”
4. The nurse contributes to the plan of care for a patient on bed rest based on the understanding that pressure ulcers occur at sites of ischemia which can begin to develop in which of the following time frames?
- 5 to 10 minutes
 - 20 to 40 minutes
 - 60 minutes
 - 120 minutes
5. The nurse is planning care for a patient at risk of aspiration. Which of the following does the nurse understand increases the older patient’s risk for aspiration?
- Increased lung capacity
 - Decreased lung capacity
 - Decreased gag reflex
 - Increased gag reflex
- Multiple response item. Select all that apply.
6. Which of the following actions could the nurse institute to help prevent constipation in the older adult patient?
- Increasing dietary fiber intake
 - Decreasing water intake
 - Encouraging participation in ADLs
 - Reviewing medication effects
 - Increasing daily exercise

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mr. Jones

- Does he live alone? Does he have a fall history? If so, does he wear a device to signal for help? What type of night-light is used? How far is it to the bathroom? Does he take his bumetanide early in the day rather than at night? Does he void before going to bed? Does he anticipate needing to void 30 minutes after lying down?
 - Wood floors that are slippery when wet from incontinence are a safety hazard, as well as throw rugs that may slide or cause tripping. An appropriate night-light should be available.
 - Nursing diagnoses include functional incontinence related to distance to bathroom; deficient knowledge related to safety, medication administration, and nocturia; and risk for injury related to slippery floors from incontinence, use of throw rugs, lighting.
4. A teaching plan should include the following:
- Safety: Place urinal at bedside to prevent incontinence on way to bathroom. Use red night-light to improve vision and prevent falls. Use easily cleaned floor covering that is secure and absorbent to avoid falls. Consider the need for wearing a device that sends a signal for help.
 - Medication administration: Take diuretics early in the day to avoid having to get up frequently at night.
 - Nocturia: Void before lying down. Anticipate need to void after lying down by reclining in chair for 30 minutes before going to bed and then void on way to bed.

QUESTIONS TO GUIDE YOUR READING

1. How has the history of home health nursing shaped nursing care of today?
2. Who are the members of the home health team?
3. What needs to be included when documenting information about a home visit with a patient?
4. What are some of the differences between hospital-based nursing and home health nursing?
5. What are some steps the home health nurse can take to ensure infection control?
6. What is the difference between skilled care, hospice care, and private duty care?

INTRODUCTION TO HOME HEALTH NURSING

Home health nursing, as its name implies, is health care conducted in the home by qualified professionals. It is an important component of patient care. A majority of individuals who receive home care are elderly. Because of this, as the “Baby Boomer’s” population ages, there will be an increase in the need for nurses to work in home care. The Bureau of Labor Statistics has indicated that there will be increased job demand for licensed practical nurses (LPNs) and licensed vocational nurses (LVNs) in home care.¹

Also impacting home health care are advances being made in medicine. These advances will make it possible for patients to receive complex care outside the hospital setting. Home health care can offer a cost effective way for patients to receive these advanced medical services. It is important for the LPN/LVN to understand how care is received in the home setting since there are differences between the home and hospital setting that need to be considered. Recognizing these differences will assist LPN/LVNs in their role as part of the home care team.

HISTORY OF HOME HEALTH NURSING

Home care is not a new concept. Nurses have been giving care to patients in the home for hundreds of years. In 1893, Lillian Wald set out to improve the New York community in which she lived. Health care was available only to those who could afford it. Because of limited access to health care and lack of education, the home environment that poor families and immigrants were living in was not conducive to health and wellness. With the help of fellow nurse Mary Brewster, Wald established the Henry Street Settlement in New York City. These services initiated by Wald and Brewster laid the groundwork for establishing home care as a nursing specialty. Because of Lillian Wald and the nurses who worked with her, families were able to receive the necessary care and education in their homes to maintain or improve their health.² During the early 20th century nurses took the initiative to develop programs within the community to meet the needs of the patients in their care. Nurses in the 21st century can learn from this and be involved in improving the communities in which they live. Home health nurses can focus not only on the patient but also on the patient’s family and the community. In home health, nursing care and its differences from medical care can be truly understood.

HOME HEALTH ELIGIBILITY

Home health care requires skilled nursing care and must be delivered by a licensed professional nurse. Physical therapy and occupational therapy may also be needed, independent of nursing. A patient who is receiving home health nursing

is required to be home bound. If patients are able to drive, then it is felt they are able to transport themselves to health-care services. Patients are allowed to attend special events, go to church, or go to medical appointments and still be considered home bound. If the nurse suspects a patient is driving daily, the nurse needs to reinforce eligibility for home health and suggest alternative options for health care to permit the patient to maintain independence. These options can include activities such as going to a clinic to have a blood pressure reading done, attending an outpatient physical therapy or occupational program, or having skilled needs (such as dressing changes) completed in a day surgery facility. If you have concerns about this, discuss them with the registered nurse who can work to assist the patient in receiving the necessary care.

Home health services are usually ordered for care after discharge from the hospital when there is a need for skilled care in the home. Skilled care includes those skills that patients cannot complete by themselves and that require the interventions of a licensed health-care professional (Box 15.1 Skilled Activities for the Home Health Nurse).

It is not uncommon, though, for a physician’s office to request home health services after seeing a patient in the office. The physician might be concerned regarding how the patient is managing his or her care at home. For example, a patient who’s having difficulty controlling blood sugars could benefit from having a nurse come to the home to assess how the patient is using a glucometer, what types of food are being purchased, monitoring of blood sugar levels, and to teach the patient appropriate diabetic management. Another example would be patients who cannot easily get to the physician’s office to have their blood pressure checked weekly. If the physician has changed the patient’s medications, he or she might need to make sure the adjustment is improving the patient’s health as demonstrated by stable blood pressure readings. These types of visits are usu-

SAFETY TIP

Accurately and completely reconcile medications across the continuum of care.

Implement a process for obtaining and documenting a complete list of the patient’s current medications upon the patient’s entry to the organization and with the involvement of the patient. This process includes a comparison of the medications ordered for the patient while under the care of the organization to those on the list. A complete list of the patient’s medications is communicated to the next provider of service when a patient is referred or transferred to another setting, service, practitioner, or level of care within or outside the organization (2006 National Safety Goals from www.jcaho.org)

Box 15.1**Skilled Activities for the Home Health Nurse**

According to the Center for Medicare & Medicaid, the agency responsible for establishing home health rules and guidelines, a visit is considered skilled and necessary when the patient is unable perform that skill, there is not a family member available to perform the procedure, and the patient's medical issues deem it necessary to have a licensed professional nurse monitor and manage the situation.³ Examples of activities considered skilled include:

- Dressing changes
- Administration of IV medications.
- Management and assessment of newly inserted feeding tubes and tracheostomies.
- Management and assessment of a new colostomy or urostomy.
- Foley insertion and maintenance.
- Patient and family education.
- Monitoring a patient's status following a change in medications or condition.
- Blood draws only if the patient is receiving *other* home health services. This is not covered as an independent skilled visit.

If a family member is present and able to perform the skill part of the time, the nurse can teach that person how to perform that skill. The nurse is still allowed to complete skilled visits to monitor patient progress and attend to the patient's needs when family is not available. It is important to remember that there needs to be a skill involved, as discussed above. If the patient is able to manage the care either independently or with the help of a family member the services of a home health nurse may not be required.

ally short term with the goal of facilitating independent care by the patient and/or family.

THE HOME HEALTH CARE TEAM

LPNs and LVNs are an important part of the home care team. Demand for skilled health-care professionals to work in this area is increasing, and as a member of the home health team, licensed practical nurses will be included in this growth pattern. The home care team consists of: the physician, the registered nurse, the home health aide, physical therapy, occupational therapy, speech therapy, social services, assisted living facility staff, LPN/LVNs, and, of course, the patient. It is important to remember that the LPN/LVN is part of the health-care team and that care is **collaborative**. In others words, teamwork and communication play a large

part in ensuring that patients and the families receive the care they need.

The Physician

The physician is considered the team leader. In order for a patient to receive home care, a physician's order is required. The physician works closely with the registered nurse to determine what care the patient needs. Because the physician does not see the patient on a daily basis, he or she relies on the assessment findings of the nurse and communications with the home health agency staff.

The Registered Nurse

The registered nurse (RN) is considered the case manager while the patient is receiving home health. It is the RN who completes the initial assessment, establishes the plan of care, and makes changes as needed. The frequency of nursing and home health visits is established during the admission. After completing the initial assessment a schedule is established and forwarded to the physician for approval (Box 15.2 Scheduling Home Health Care Visits). If it becomes necessary, visits can be increased or decreased based on how the patient is progressing. The registered nurse also works with the physician to adjust treatments such as wound care and medications. These adjustments are based on the

Box 15.2**Scheduling Home Health Care Visits**

Home health care is ordered for a 60-day period. The start of care is considered the first day of the visit with the end occurring before day 60. Skilled visits are usually projected during the start of care. Orders are written as follows:

- Skilled nursing care: 3 × wk × 3 weeks, 2 × wk × 3 weeks, 1 × wk × 2 weeks for skilled observation of vital signs and patient response to medication changes and home health aide services; 3 × wk × 8 weeks for assistance with personal care.
- Skilled nursing care: 7 × wk × 4 weeks, 4 × wk × 2 wk, 2 × wk × 2 weeks for wound observation and dressing changes, family education of wound care technique.

Included in the start of care orders are the supplies necessary to complete the ordered skills, such as dressing supplies, urinary catheter supplies, or medical equipment. These need to be authorized and ordered by the physician. Including them with the start of care paperwork ensures all services are ordered by the physician. This function is completed by the Registered Nurse in conjunction with the physician.

Adapted from Centers for Medicare & Medicaid Services: Home Health Agency Manual, 2004.

nurse's assessment of the problem. Remember, the physician is relying on the home health team to be his or her eyes and ears in the home. The nurse's ability to expertly assess a situation is critical to the progress of the patient receiving home health services. The LPN/LVN works closely with the RN collaboratively, or together, in order to help the patient reach the best possible health. The plan of care or treatment plan is certified, or ordered, for 60 days. The treatment plan includes number of skilled visits required, supplies and equipment necessary to complete the care, other services that are required such as a home health aide, and a nursing care plan that establishes goals for discharge. At the end of this period, the patient is either discharged or services are extended or recertified for another 60 days. The registered nurse works closely with all members of the home care team so that the plan of care remains relevant to the patient's situation.

The Home Health Aide

The home health aide assists patients with performing activities of daily living (ADLs). This includes bathing, dressing, grooming, and toileting. The home health aide's frequency of visits is established based on the patient's acuity level and available help within the home. Each case is different. One example would be an alert and oriented patient discharged home following spinal surgery who is widowed and has no assistance in the home. This patient might require frequent visits to ensure ADLs are met. Conversely, there is the patient who is discharged home following open heart surgery who has extensive family available to assist with personal care. Although this patient's acuity is higher, he or she has help available, thus requiring less frequent visits. During visits, the LPN/LVN can assist with identifying if frequencies for care need to be adjusted. Findings can be discussed with the RN who can contact the doctor to adjust the plan of care.

The Physical Therapist

Physical therapists (PTs) are part of the home care team who work autonomously. The physical therapist is responsible for developing a plan of care and visit frequency. Physical therapists work to help the patient regain strength and mobility. They teach the patient and family how to use assistive devices such as walkers and canes and develop exercise regimens that the patient can perform independently. The PT also works with medical supply companies to obtain equipment that is needed. If nurses feel patients might benefit from physical therapy services, such as a patient having difficulty regaining stamina following surgery, they can recommend this service to the physician. The nurse can also reinforce the physical therapy instructions during visits and check to ensure that the activities are being completed as prescribed.

The Occupational Therapist

Occupational therapists (OTs) also function autonomously. Similar to PTs, they establish their own treatment plan and visit frequencies. Occupational therapists' goals are to assist the patient to regain independence with ADLs and improve

strength. They teach the patient how to use equipment that improves the patient's independence with daily activities. Nurses can also identify a patient who might benefit from these services. A patient who seems to be having a difficult time performing activities such as bathing, cooking, or cleaning would benefit from the services of an OT. As with the PT, the nurse can review instructions from OT with the patient to ensure they are understood.

The Speech Therapist

Speech therapy (ST) is ordered for patients who require assistance because of swallowing difficulties or speaking difficulties. After assessing the patient, the speech therapist identifies a plan of care and visit frequencies. If the nurse assesses a change in how the patient is swallowing or speaking, he or she can recommend a speech therapy evaluation. Once any new medical concerns have been ruled out, speech therapy can be initiated. As with other therapies, the nurse works closely with the ST and the patient to monitor understanding of instructions.

The Social Worker

Social services visits are usually completed in a shorter period of time. The social worker works closely with many community resources and can assist the patient with obtaining community assistance. Resources the social worker can assist with include things such as obtaining a prescription card, setting up Meals on Wheels, assisting the family with long-term care placement if necessary, identifying private agencies that offer **respite** care and homemaker services, helping the patient create a living will, and helping the patient with financial assistive services. Nurses who work in the patient's home are in a unique position to identify if the patient would benefit from social services. The case manager (RN) can relay the concerns of the home care team to the physician and obtain an order for a social service visit.

CRITICAL THINKING

Mr. Jones

■ Mr. Jones, 75 years old, was just discharged from the hospital following an acute exacerbation of heart failure (HF). You notice that he has little food in his house. It appears that the home has not been cleaned in several weeks, and that the clothes he is wearing are torn and soiled. Talking with him you learn that he lost his wife 6 months ago to cancer and has had a difficult time adjusting.

1. What are some community services that might be available to Mr. Jones?
2. What information would be important to discuss with Mr. Jones's physician?
3. Are there any other services that the home health agency can offer to assist Mr. Jones?

Suggested answers at the end of the chapter.

Assisted Living Facilities

Assisted living facilities (ALFs) become part of the home care team if the nurse has a patient residing in an ALF. Because these homes are not considered skilled nursing facilities, the staff is not able to perform nursing skills. Home health nurses need to understand the facility's policies when visiting a patient in assisted living. Many times the nurse visits several patients in the same location. If appropriate, communicate with staff regarding health-care instructions (e.g., keep the dressing clean and dry). Home health for patients residing in assisted living can be ordered for wound care, blood sugar monitoring, blood pressure monitoring, urinary catheter insertion and maintenance, and patient education.

TRANSITION FROM HOSPITAL-BASED NURSING TO HOME HEALTH CARE

When working in the hospital, the nurse has many resources available. There are secretaries, nurses, respiratory therapists, and physicians to name a few. Patients who enter the hospital are leaving behind the comfort of their own homes. They are scared and isolated, not only trying to adjust to an illness, but also to a new environment. The opposite is true in home health nursing. In the patient's home, the nurse is the visitor. There are no support staff to answer questions and the surroundings are not familiar. This can be a difficult adjustment. As your confidence in being a home health nurse grows so too will your comfort level with entering someone else's home. It is important to remember that you have entered *their* home. Cultural issues also need to be recognized and considered (Box 15.3 Cultural Considerations). Do not make quick judgments because the dishes are not done or the bed is not made. People have different values that may not always agree with yours. (See Chapter 3 for further information regarding cultural considerations.) If the home is in such a state that it poses a health or safety risk, then it might be necessary to intervene by talking with the RN.

Box 15.3

Cultural Considerations

Within the Hispanic culture, the number of members in a family is typically large while the living space may be small. When the nurse first enters the home, there might be a feeling that the lack of space is unhealthy. It is important, however, to realize that this is part of the Hispanic culture. The nurse must evaluate the overall home environment, not just its appearance. Chapter 3, Cultural Influences on Nursing Care, offers further discussion on understanding transcultural nursing care.

Resources are not always quickly available when working in a patient's home. As such, it is important to have a good understanding of nursing skills. Home health nursing requires an ability to adapt and remain flexible since the home environment, unlike the hospital environment, can be unknown. Because of this, it is necessary to assess both the patient and her or his home setting. Consider the patient who has been referred to home health services following a fall at home and subsequent fracture of an arm. The referral was for initiating physical therapy services, not skilled nursing. During the initial assessment the nurse notes that the patient is lethargic and experiencing extremely low blood pressure readings upon standing. Further data gathering of the home environment leads the nurse to find that the patient's wife has not been administering the patient's heart medications appropriately—actually administering too much. The home health nurse can contact the supervising registered nurse to contact the doctor to obtain the necessary orders to assess the patient's blood levels of this medication. This example demonstrates how nurses in the home need to evaluate the patient's case not just based on the referral diagnosis, but also what can be occurring within the home that could have contributed to that diagnosis, remaining flexible, and adapting to the patient's needs.

Families play a large part in your care of patient's in the home. Do not be surprised to walk into a home and find several anxious family members with a list of questions they would like answered. They too will be very involved during your visits. This can be very intimidating at first. When preparing for a visit, take the time to review and learn about an unfamiliar diagnosis or medication. This will help you feel more comfortable and assist with developing a trusting relationship with your patient and their families.

SAFETY TIP

Encourage the active involvement of patients and their families in the patient's care as a patient safety strategy. Define and communicate the means for patients and their families to report concerns about safety and encourage them to do so (2006 National Patient Safety Goals from www.jcaho.org)

Because of the **autonomous**, or independent, nature of home health, most agencies require at least 1 year of medical surgical nursing experience. This will ensure that you have gained the necessary knowledge to work in home care. Home health agencies also hire nurses in specialty areas; for example, cardiac nursing or wound care. Nurses with a specific specialty will usually work with patients with diagnoses with which they are familiar. See Box 15.4 (Liability Issues to Consider When Working in Home Health) for liability issues.

(Continued on following page)

Always be prepared for the unexpected. Carry extras of common supplies; for example, various sizes of catheters, sterile dressing gauze, different types of tape, and plenty of alcohol wipes.

THE ROLE OF THE LPN/LVN IN HOME HEALTH

The nurse's role in home health is varied and complex. The nurse works closely with all members of the health-care team. Tasks may be similar to those performed in the hospital setting such as wound care or administration of IV medications (Fig. 15.1). The difference is the setting of where these skills are completed. Many factors need to be considered when assisting patients in the home (e.g., having the necessary supplies, infection control, patient education material, documenting, and personal and patient safety).

Box 15.4

Liability Issues to Consider When Working in Home Health Care

When starting in home health care, review your state's Nurse Practice Act and your scope of practice. The National Council of State Boards of Nursing, <http://www.NCSBN.org> lists all the State Boards of Nursing websites. This is a very useful tool for any nurse. Understanding your scope of practice will ensure that you complete care that follows your state's guidelines. When in patients' homes they might ask you to perform a skill or request something that is outside your scope of practice. It is important that you explain to them that it is outside your scope of practice but still address their concern by contacting your agency immediately to find out how to handle their request. It is important to address their request as it could indicate a change in their status. For example, if a patient asks you if it is "okay" to increase a medication, you should understand that as a nurse you cannot prescribe medications. So if you were to say it was okay, you would be altering the prescribed dose, and thus practicing outside your scope of practice since only a physician or nurse practitioner can prescribe medications.

Always discuss your concerns with your supervisor and review your agency's guidelines, policies, and procedures. Know what you can and cannot do before you start and never be afraid to question something that you feel or know violates your nurse practice act. Remember it is your license so follow your nurse practice act!

FIGURE 15.1 Patient receiving home IV therapy.

STEPS IN THE HOME HEALTH VISIT

Preparing for the Visit

A typical day for the home nurse consists of six to seven visits. Visits generally last 30 to 45 minutes. Most agencies attempt to arrange visits in the same geographical location for convenience. If your visits are focused on a specialty, such as wound care, you might travel long distances to visit your patients, although your patient assignment would be less than seven visits. Agencies allow for mileage reimbursement, so be sure to keep close track of mileage from house-to-house. The night before your visit, you need to develop a plan of action for how your visits will be structured. Sometimes you will need to be at a certain place at a particular time, so factor this into your planning. Each patient needs to be contacted. Give the patient a 1- to 2-hour window for your arrival time. Remember, you cannot always anticipate what is going to happen during a visit. It is better to let your patients know a time frame range as opposed to an exact time. If you are unsure of how to locate your patient's home, ask while you are arranging the visit time. The agency will usually provide you with an information sheet reviewing the patient's diagnosis, pertinent medical information, and reason for home health. Keep these handy; writing directions to the patient's home on these forms is an easy way to have the information close by. It is important to be organized with this process. If you have

too many papers with information on it, it is difficult to manage both your time and the patient's needs, leading to frustration.

LEARNING TIP

The World Wide Web is a great place to find travel information. Mapquest is one such site. The user can type in the beginning and ending address and receive detailed directions on how to get to destinations. The web address is <http://www.mapquest.com>.

Other things to carry with you are a map and cell phone. Even the best of directions can be confusing once on the road. If for any reason you are going to be late, contact the patient to let him or her know. Remember, these patients are home bound and anxious; arriving late can interfere with developing an effective therapeutic relationship.

Safety Considerations

Home health nurses' travels can take them to dangerous areas. It is important to be vigilant about personal safety. See Box 15.5 (Safety Guidelines for Home Health Nurses) for tips on how to protect yourself before, during, and after a home health visit.

Patient safety is of particular importance in the home. Unlike the hospital, once you leave, there might not be anyone else to visit until you are scheduled to work again. The nurse needs to be alert to things in the home that can pose a hazard to the patient. Box 15.6 (Gerontological Issues) offers some ideas for patient safety consideration in the home.

Remember to consider requesting a referral for physical or occupational therapy. These services can work with the patient to build strength, teach the patient how to use assistive devices, as well as assisting with obtaining those devices. Educating the patient on how to prevent injuries in the home is the best intervention.

Infection Control

Maintaining asepsis in the patient's home may be a challenge. In the hospital, everything is available to ensure infection control. In the home, the nurse is responsible for bringing supplies to ensure safe care. The home health agency will provide information during in-service orientation of their policy and procedures regarding infection control. It is always important to have extras of basic equipment, including:

- Personal safety equipment—disposable gowns, masks, and shoe covers
- Gloves—some latex free
- Red bags of various supplies
- Several biohazard containers

Box 15.5

Safety Guidelines for Home Health Nurses

In general, home health is very safe. Most communities recognize the importance of the role of home health nurses and are receptive to their visits. It is still important to understand how you can protect yourself in case an unsafe situation arises.

Tips for maintaining safety when completing a home health visit:

- Always carry a map, whistle, and cell phone.
- Keep gas tank filled.
- Complete recommended maintenance on your car and have the tires checked regularly.
- If possible, park in the street or road in front of the house. This prevents someone from blocking you in the driveway.
- When entering a home be aware of where the exit doors are and any windows that will allow for safe evacuation from the home.
- Be aware of your outside surroundings. When leaving the home have your supplies packed up and keys out, ready to open the car door.
- If lost in an unknown area, leave and go to a familiar place and contact the patient for directions. Call your agency if concerned about home safety.
- If you need to complete a visit at night, request an escort. Many communities will have a police officer accompany you to and from the home. Discuss this option with your supervisor.
- Never complete a visit if you feel concerned for your safety.

Box 15.6

Gerontological Issues

The elderly make up a significant proportion of home health patients. Because of changes in their health, many items in the home can become potential safety hazards. The home health nurse should always assess the patient's safety in the home. Things to look for are:

- Overcrowded spaces
- Scatter/throw rugs
- Bathroom safety
- Adequate lighting
- Access to needed supplies
- Steps to enter the home
- Pets
- Electrical cords

CRITICAL THINKING

Mrs. Smith

■ Mrs. Smith was referred to your home health agency following an appointment with her physician. During that visit it was found that Mrs. Smith was anemic resulting in dizziness, fatigue, and alterations in her blood pressure. The physician requested home health nurses visit for Mrs. Smith to assess her safety and recommend appropriate safety devices.

1. What are some safety devices that can assist Mrs. Smith?
2. What are some hazards in the home the nurse should look for?

Suggested answers at end of chapter.

- Disposable underpads—can be used to provide a clean field for supplies; also good to place one on the floor to put your home health bag on.
- Antibacterial soap
- Sanitizing liquid
- Disinfecting spray to clean your equipment and bag after each visit
- Alcohol wipes for disinfecting thermometers and stethoscopes
- A small chemical spill kit

All these supplies are provided by the home health agency. Periodically go through your supply of this equipment to make sure you have enough. One other important tip to remember is washing your hands. It is important to clean your hands with soap and water prior to beginning and after completing your patient care. If water is not available, use your sanitizing liquid. Do not wash your hands in the patient's kitchen sink, always ask to use the bathroom for your hand washing.

Documentation

Documentation in home health can be challenging. Because of reimbursement guidelines, the nurse needs to document specific things during the visit. Home health agencies receive their income based on a prospective pay system, not per visit payments. On admission, the registered nurse fills out information that is entered into a computer system. This information is called the **Outcome and Assessment Information Set**, or OASIS. This tool is used to generate information about the home health agency and patient outcomes. It is also used to help develop a plan of care that best meets the patient's problems. The LPN/LVN needs to be familiar with the general function of this form and its relevance to creating a plan of care, although as already stated it generally is the RN who collects this data from the patient.

In order for home health agencies to be reimbursed, they need to demonstrate that a skill was completed. Documenting information is based on the patient's plan of care

and the corresponding skill that was completed at the visit. For example, the physician has ordered skilled nursing observation and medication management for a patient. The nurse completing this visit needs to identify when documenting that this skill was completed. Documentation would include:

- Patient's response to a medication—vital signs, level of consciousness, or other potential side effects.
- Patient's current understanding of medication regimen and the action the nurse took to improve that understanding.
- Patient's response to that education and any areas the patient might continue to need assistance.

Home health agencies, like hospitals, have different ways of documenting. The following things are generally included in all home health documentation:

- Arrival and departure times of the nurse
- Assessment findings
- Vital signs
- An area for a narrative note
- Patient's signature verifying the nurse was present in the home

This flow sheet is returned to your facility within an identified time frame (usually within 24 hours of a visit). Nurses who wish to drop off paperwork during times when the office is closed need to find out if their agency has a secure after hours drop box to leave paperwork. If dropping off paperwork after hours, it is necessary to be sure that your forms are neatly organized and papers clipped together.

Information is also kept at the patient's residence. It usually consists of a folder that contains relevant patient information and a communication form that all staff members need to complete at each visit. Similar to hospital charting, this documentation is important to ensure continuity of care, even more so in the home setting because staff members might not cross paths for a verbal report.

LEARNING TIP

An easy way to ensure you always have the handouts that you need is to organize them into a three-ringed binder. Always have plenty of these handouts when making a visit. Many times families who do not reside with the patient request copies so that they can have them at home. You can organize the information in several different manners; for example, based on the diagnosis or alphabetically.

Patient Education

A primary responsibility of nurses in home health is educating the patient regarding her or his illness and how to effectively manage that illness at home, hopefully decreas-

ing the chance of needing hospitalization. There are many handouts available to offer the patient to help reinforce the verbal instructions you are providing. It is best to utilize forms that are available from your home health agency.

NURSING PROCESS: THE HOME HEALTH PATIENT

Assessment/Data Collection

Monitor and document patient and family's adjustment to change and illness. Perform a complete patient assessment during each visit. Assess the home environment for potential safety hazards and need for devices to assist with care.

Nursing Diagnosis, Planning, and Implementation

Therapeutic regimen management: ineffective related to deficient knowledge, complexity of medical needs, and limited access to social support

EXPECTED OUTCOME: The patient will demonstrate changes in lifestyle necessary to maintain health.

- Work with the patient in developing both short- and long-term goals.
- Recognize small accomplishments positively to reinforce the progress the patient has made.
- Educate the patient on management of the health-care regimen.
- Provide educational material in both written and verbal format to allow for understanding of complex issues with care.
- Review the plan of care with the patient to facilitate involvement and eventual independence with care.
- Identify and work with social support systems.
- Assist the patient with obtaining necessary supplies to promote wellness.
- Assess the home environment for hazards and assist the patient with making necessary changes to promote safety.
- Assess the patient for changes in health status that can affect progress.

Caregiver role strain related to the management of a chronic illness and lack of understanding of resources available

EXPECTED OUTCOME: The caregiver will identify effective ways for dealing with the complexity of a chronic illness.

- Include the caregiver in the plan of care to help develop an understanding of the management of the illness.
- Assist the caregiver with identifying community resources available such as respite care, Meals on Wheels, and support groups.
- Enlist the help of a social worker to facilitate contact with community resources.
- Assess the caregiver's expectations of the patient's health. Misconceptions regarding progress can fos-

ter anger and frustration toward the patient.

Discuss ways to help the caregiver deal effectively with these feelings.

- Acknowledge the change in roles: for example, child taking care of a parent, and the challenges associated with this change in family roles.

Evaluation

The patient and caregiver will acknowledge acceptance and understanding of the change in health status. This is evidenced by involvement in the plan of care and participation with goal setting, utilization of community resources, maintaining of a safe home environment, and demonstration of ability to manage medical regimen.

OTHER TYPES OF HOME HEALTH NURSING

So far this chapter has focused on Medicare home health that is covered under the Medicare and Medicaid systems. The purpose of this version of home health is to assist the patient with managing health needs on an intermittent basis. There are also other types of home agency service work available for nurses, including private duty nursing and hospice nursing.

Private Duty Nursing

Private duty nursing consists of scheduled care to assist the patient with personnel and homemaking needs. These services have been called home companion services, homemaker services, and private duty care. Many of the services that are offered focus more on companionship and respite care. Families who are taking care of a patient with complex needs, such as an Alzheimer patient, may need time away from the home to complete personal tasks. These agencies provide both licensed and unlicensed assistive personnel (UAP) to help the patient while the family is away. Unlike Medicare home health, these services are considered an out-of-pocket expense, and are not covered by Medicare and Medicaid.

Families can contract with an agency to have a staff member spend 2 to 3 hours a day in the home. The staff can complete homemaking tasks and companion tasks, such as arts and crafts or playing cards. Nurses can work in these agencies in the role of supervisor to unlicensed assistive personnel (UAP). Another role that the nurse can be involved in is assisting the patient with filling weekly medication dispensers. Many nurses enjoy this type of work because of the relationships that are formed with patients and families. They can be involved with the same family for months to years, as opposed to a few months, as is typically seen with Medicare home health patients.

Hospice Nursing

Hospice home agencies work with patients who have a terminal illness with less than 6 months to live. The focus of

hospice is not curing the disease but to offer comfort and palliative care for patients who are dying. Hospice nurses are available around the clock, allowing the patient's family to contact them at anytime with questions or when the patient dies. Hospice care also offers bereavement services to the family for up to a year after the patient has died. This service is covered by Medicare. As one can see, hospice can offer many advantages not available through a regular home health agency. A referral to hospice is usually initiated in the hospital. There might, though, come a time when you are working with a patient whose condition declines rapidly. It is important to discuss available options with the home care team before approaching the option of hospice with the patient. Patients need to be ready to accept the fact that they have an incurable illness. Even with that acceptance, sometimes the patient prefers to stay with the agency that they have been working with because of a relationship that has been developed with the staff. Involving social services can help inform the patient of the variations in care they can

receive. See Chapter 16, Nursing Care of Patients at the End of Life, Home Health Hint boxes for assistance in understanding how to assist the patient who is dying at home.

HOME HEALTH NURSING

Home health nursing is a rewarding career path to choose. Nurses who work in the home have the unique opportunity to assist the patient during a time of crisis and be able to experience the results of their interventions. Home health nursing will continue to grow in the 21st century, and the need for qualified professionals will offer many opportunities for the LPN/LVN. Thinking back on the impact that nurses like Lillian Wald had and her ability to change the lives of so many because of her willingness to meet those patients in their homes demonstrates the importance home health nurses have in the successful progression for patients from illness to health and wellness.

REVIEW QUESTIONS

1. What impact did Lillian Wald have on the nursing profession?
 - a. Allowed nurses to function as medical care providers
 - b. Demonstrated the impact nursing can have on patients' health and wellness
 - c. Made it possible for nurses to obtain prescription drugs for patients in the home
 - d. Developed the Henry Street Settlement in 1890

Multiple response item. Select all that apply.

2. Which of these are members of the home health team?
 - a. LPN/LVN
 - b. Physician
 - c. Social worker
 - d. Home health aide
 - e. Lawyer
3. A patient is being seen by home health nurses for monitoring of his weight and vital signs and education about medication changes following an acute exacerbation of heart failure. Documentation for this visit needs to include which of the following?
 - a. What the patient ate for breakfast
 - b. How far the patient was able to ambulate while working with physical therapy
 - c. Education about the role of the home health aide in assisting the patient with personal care
 - d. Education about how to keep a log of daily weights and when to contact the physician regarding a potential problem.
4. An LPN/LVN has started working for a local home health agency and is concerned about the transition to home health nursing after working in the hospital for 10 years. What are some recommendations that would ease this transition for the LPN/LVN?
 - a. Explain that home health nursing is just like hospital nursing
 - b. Instruct him or her to always be prepared, to keep paperwork organized, and spend some time the night before a visit to review patient health information to help her or him gain confidence in the home.
 - c. Allow an opportunity for exploring feelings and acknowledging that this is a hard transition.
 - d. Let the nurse know it is not possible to completely adjust to home health nursing because of variability in the home.
5. What steps can the home health nurse take to ensure that the patient is not exposed to infectious materials in the home?
 - a. Disinfect the home health bag after each patient visit with a germicidal spray supplied by the home health agency.
 - b. Wash hands in the kitchen sink rather than the bathroom sink.
 - c. Use the same red bag from patient-to-patient for disposing of soiled dressings.
 - d. If a chemical spill occurs contact agency to send personnel to clean it up.
6. In reinforcing teaching to a patient about the primary difference between hospice care and home health care, which of the following would the LPN/LVN include in the explanation?
 - a. Visits occur weekly in hospice versus daily in home care.
 - b. Volunteers provide hospice care but nurses provide home care.
 - c. Patients must enter hospice if they are dying.
 - d. Palliative care versus managing a return to a functional level of wellness.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mr. Jones*

1. The loss of Mr. Jones' wife and his subsequent health problems have impacted his ability to properly care for himself. A proper diet is important for healing and maintenance of health. A referral to Meals on Wheels would be appropriate. This agency will deliver at least one healthy meal each week day (usually lunch). The meal can be adapted to meet the patient's dietary guidelines. Many communities offer elder services to patients at a reduced cost to assist with housekeeping services. Helping the patient set up homemaker services will help him through this difficult time. Offering the patient information about grief counseling services in the community can be beneficial during this time. Once discharged from home health the patient can begin attending counseling services. Other community resources to consider are: neighborhood socials, church services if appropriate, and online communities that match the patient's values.
2. The physician needs to be contacted about the patient's withdrawn demeanor and lack of interest in self care. Mr. Jones may be experiencing a situational depression because of the recent loss of his wife and his own health problems. During this time the physician might decide to prescribe an antidepressant to help.
3. The nurse recognizes that Mr. Jones needs extra help at this time. Consider a referral for social services to

assist with community resources and grief counseling. Because heart failure is a chronic disease that can contribute to fatigue, an occupational therapist can work with the patient in developing energy conserving techniques for completing activities of daily living. Also the services of a home health aide can help with personal care and provide additional emotional support.

■ *Mrs. Smith*

1. Since anemia can cause extreme fatigue it is important for Mrs. Smith to have safety devices in the home to prevent falls. These devices can be obtained from a medical supply store and are usually covered by Medicare. Equipment to consider includes a bath stool for the shower so the patient can sit while bathing, a detachable shower head, hand rails in the shower and hallways, a bedside commode, an over-the-toilet seat, a reacher to assist with obtaining objects at a distance, a medical alert device that can be worn at all times, and if fatigue is severe enough a motorized wheelchair.
2. The home has many hazards. Important things to assess for include: scatter/throw rugs, overcrowded spaces, sharp edges along furniture, inadequate lighting, and stairs. Instruct the patient to keep frequently used kitchen appliances and foods on shelves that are easy to reach. The same is true for the bathroom and bedroom. Assist the patient with setting up a "command center" in the living room so that favorite items are kept in close proximity and the patient does not have to get up so frequently.

Living Will (LIV-ing WIL)

Durable Medical Power of Attorney (DUR-uh-buhl POW-ur uv uh-TUR-nee)

hospice (HOS-pis)

postmortem care (pohst-MOR-tum KARE)

QUESTIONS TO GUIDE YOUR READING

1. Who is the patient who is approaching the end of life?
2. What are the necessary legal documents for patients with life-limiting illness?
3. What choices are available to patients at the end of life?
4. How do you communicate with dying patients and their families?
5. What are the expected physical changes in the dying process?
6. What are nursing interventions you can provide at the end of life?
7. What is post mortem care?
8. What are nursing interventions you can implement for the grieving patient and family?
9. What is the role of the LPN/LVN in hospice care?

CASE STUDY

Mr. Moran, 89 years old, resides in a nursing home, and has been losing weight and growing weaker for the last 6 months. Despite treatment for depression, he continues to grow weaker and more dependent on his caregivers. As you read this chapter, consider what decisions this family will face and what resources are available to them in their quest to provide appropriate care for him.

A GOOD DEATH

Despite our best efforts, there will become a time that all our patients will die. Death is the expected end to a life well lived. In America, only 10% of us will die suddenly. The remaining 90% will experience a gradual decline over a period of months or years.

In the 21st century, most Americans will die from chronic and acute illnesses from diseases such as cancer, heart disease, stroke, and dementia. We have the technology to prolong life, but sometimes this longer life can carry with it profound disability and reduced quality of life. Our patients sometimes tell us that this is not what they intended for the last phase of their life. The challenge for nurses then is twofold: 1) to help identify patients with life limiting illnesses early, so they and their families have the opportunity to define their goals of care, and 2) to help our patients communicate their wishes to healthcare providers, both orally and in writing, to assure that their wishes are understood.

Perhaps the most important role for nurses is to give our patients support and validation as they move through the series of losses leading to a *good death*. Dying is, after all, the final phase of our growth and development. The developmental tasks associated with this phase involve reflecting on our lives, saying goodbye, saying “I am sorry” and saying “I love you.” The goal of having a “good death” is a valid goal.

In a 1999 study, a focus group of terminally ill patients defined what would constitute a *good death* for them. The results fit into 5 categories:

- Adequate pain and symptom management
- Ability to make their own decisions
- Dying that is not prolonged
- Minimal emotional and financial burden on their families
- Ability to use remaining time to strengthen their relationships with their loved ones.

This definition of a good death helps nurses listen to what patients want and to focus on how best to help them achieve their goals. Nurses who choose to provide care for the dying experience personal growth in their own lives. Facing the inevitability of our own mortality can force us to look more deeply at our beliefs, values, and priorities in life. This can result in a richer, more focused life.

IDENTIFYING IMPENDING DEATH

Although most Americans voice that they want to die at home, almost 80% today die in facilities. 20% die in nursing homes, but by the year 2020, it is estimated that 50% will die in nursing homes. Some researchers have found that 1/3 to 1/2 of the patients who enter nursing homes die within a year. Nurses who are working in long-term care and assisted-living facilities will find themselves in a position to both identify patients who are likely to die soon and also to support these patients’ families in planning for a good death.

Death can be caused by disease, but some patients simply show weight loss and progressive weakness as indicators that they are in the final months of life. Research has shown that measuring progressive weight loss and increasing dependency can help identify patients who are dying. One research study showed that elderly patients in nursing homes who lose 10% of their body weight in 6 months, have an 85% chance of dying in the next 6 months. Weight loss caused by depression or acute illness can sometimes be reversed with aggressive treatment. But if neither depression nor acute illness is the cause of the patient’s decline, he or she may be entering the final months of life.

Experience tells us that elderly patients with gradually increasing weakness and increasing dependence for activities of daily living (ADLs) are declining. Elderly patients who are having trouble swallowing and require treatment for aspiration pneumonia are likely to die within a year. Their decreased respiratory muscle strength, lack of lung elasticity, and poor immune response make recovery unlikely. Elderly patients with poor renal and cardiac functions are at high risk for dying. The final truth is that for some patients with chronic illness, many treatments offer little benefit. This chapter explores some of the choices people have to make at the end of life.

ADVANCE DIRECTIVES, LIVING WILLS, AND DURABLE MEDICAL POWER OF ATTORNEY

The *Patient Self Determination Act* ensures that every patient has the right to accept or refuse any medical treatment that is offered. The Act also requires health-care professionals to ask patients entering a hospital if they have prepared an **Advance Medical Directive**. In preparing an Advance Medical Directive, patients are exercising their rights to make their wishes known regarding specific medical treatments should they become incapacitated. The Directive requires the signatures of two witnesses, neither of whom can be a family member or health-care provider. There are really two parts to an Advance Medical Directive: a **Living Will** and a **Durable Medical Power of Attorney for Health Care**.

Living Wills are documents instructing physicians about patients’ preferences (such as to withhold or withdraw

life-sustaining procedures) in patients who are unable to communicate, found to be permanently unconscious, and/or have been declared “terminal.” A Durable Power of Attorney document specifies who will speak for the patient when he or she cannot speak for himself or herself. Many states have standard forms to use, and may require both a Durable Power of Attorney and Living Will to be legal. An attorney, although not necessary, may be helpful for some families.

Encourage patients to not only fill out the necessary forms, but also to discuss their wishes with all family members. It is estimated that only about 15% of Americans have an Advance Medical Directive. Some patients are reluctant to complete an Advance Directive. They are concerned that they may change their mind about treatments in the future. It can be helpful to talk about advance care planning as a *process*. Treatments we choose to have today may not be wanted tomorrow.

Remind patients that they can revoke an Advance Directive at any time and in any place and institute a new one. What matters most is that they get started and document their wishes today.

END OF LIFE CHOICES

Cardiopulmonary Resuscitation

During the 1960s, cardiopulmonary resuscitation (CPR) was developed as a method of rescuing healthy people who suffered a cardiac or respiratory arrest. Some of the early guidelines specified that CPR was not to be used in patients with terminal illnesses. It was intended for healthy patients with reversible conditions. Today, CPR has become standard in both hospitals and nursing homes. All patients will receive CPR unless they have a **Do Not Resuscitate (DNR)** order. There is also a perception that CPR can save most lives. The *real* statistics about CPR are as presented in Table 16.1.

One reason for such low survival rates is that CPR must begin within 3 to 5 minutes of collapse. The most successful cases are ones in which CPR plus AED (automatic external defibrillator) are used within 3 to 5 minutes. Medical researchers reviewed 113 studies on the use of CPR in hospitals over a 33-year period and found some additional reasons for the low survival rate. They found that patients with the lowest chance of survival (less than 2% chance) were those who (1) had more than one or two medical problems, (2) were unable to live independently, and (3) had a terminal illness. All patients living in nursing homes and assisted-

living facilities are unable to live independently. Patients with terminal illness would include cancer, dementia, or any progressive illness.

Some patients choose to have CPR because they fear that without CPR they will be deprived of treatments that will benefit them or alleviate their distress. Most patients do not realize that their chance of survival is statistically low and also that after CPR, if they survive, their quality of life may be diminished. A small number of patients actually believe that CPR is a procedure that may improve their overall medical condition. A helpful way of presenting the DNR option is to talk about three issues: (1) the statistics outlined above, (2) that the choice is really whether the patient will receive aggressive comfort care as they are dying or CPR, which may cause distress and will likely prove futile, and (3) even if elderly patients receive successful CPR, their quality of life is usually greatly reduced, not improved.

Do Not Resuscitate Orders

A “No Code” or **Do Not Resuscitate (DNR)** order is written in a hospital or nursing home setting after collaboration with the patient, family, and health-care provider, usually after it has been determined that the patient will not benefit from receiving cardiopulmonary resuscitation (CPR). DNR simply means that CPR will not be done. Patients still must decide whether they want aggressive treatment of their underlying condition, up to but not including CPR, or whether they want only comfort measures without therapeutic treatment. Some hospitals offer several options:

- Do Not Resuscitate, Comfort Care Only
- Do Not Resuscitate, Full Therapeutic Support
- Full Code

Outside of the hospital, at home, or in most nursing facilities, patients will have fewer options for aggressive treatment. Patients can, however, choose to have a DNR order that will be recognized by emergency personnel. Many states have a “Durable DNR” document that, once signed, can be displayed in the patient’s home to advise rescue personnel that the patient does not want to receive CPR. These may also be called “out of hospital” or “prehospital” DNR orders.

Many people assume that their documented desire *not* to receive resuscitation in a living will is all that is necessary. In states that have an out of hospital DNR policy, the patient will receive CPR regardless of their stated wishes in their Advance Medical Directive unless they have completed the Durable DNR document.

Some patients fear that in choosing DNR status they will suffer and be alone at the time of their death. It is important to tell patients that DNR does not mean “do not treat.” Even patients who have a DNR/Comfort Care order can receive oxygen, medications, and other comfort measures to aggressively manage their symptoms and assure a comfortable death. All DNR orders and discussions with families

TABLE 16.1 SUCCESS OF CPR IN SAVING LIVES

<i>In Hospital: All Patients</i>	10%–15% survival rate
<i>In Hospital : Elderly Patients</i>	Less than 5% survival rate
<i>Out of hospital: All patients</i>	Less than 5% survival rate
<i>Nursing Home Patients</i>	1%–2% survival rate

Box 16.1

Patient Perspective

Anna

My mom, Anna, was diagnosed with cardiomyopathy and congestive heart failure when she was 60 years old. At that time she was still working, and had just remarried. She thought she had many years left in life. She did not have an Advance Directive—Why would she?

Two years later, as her disease progressed, she decided she did not want to “live on machines.” So with the help of her doctor and our family, she wrote her Living Will and made her new husband her Durable Power of Attorney, with me as his backup person. Since she was still functioning really well with lots of medications and occasional hospitalization, she chose a DNR status, but with full therapeutic, aggressive interventions. She even took a tour of Europe during this time in her life, knowing she would not be able to do it later.

By the age of 67, she had a lot less energy to do things, and her heart failure really cramped her lifestyle. But she still enjoyed life, and her goal was to see her oldest grandson, my son, graduate from high school. She considered a heart transplant, but her doctor told her she was too old to qualify. She did have a new kind of valve surgery that was supposed to make her feel better, but it didn't help much.

Three months after my son's graduation, she was hospitalized several times with progressively worse outcomes. She weighed barely 100 pounds, and could not eat much. She was only 70 years old, and still looked and acted so young! Finally, she was in a semicoma in the hospital, and our family had to make the difficult decision to withdraw all therapeutic support. She was now a DNR, with Comfort Measures only. We were confident this would be what she wanted because we had talked about it with her.

She was discharged home with hospice care, and died within a week. I moved in for her final days to help out, and between me, her husband, and her hospice nurse (who was a godsend), and frequent visits from family and her minister, she had a really good death. We kept her comfortable with lots of attention and morphine. She was alert and able to converse much of the time. She ate what and when she wanted, which amounted to one-quarter of a cheese and tomato sandwich one day, but she enjoyed it! She could finally enjoy a glass of grapefruit juice, which she had been unable to have for years because it interacted with one of her heart medications.

At the end, she died with me holding her right hand and her husband holding her left. We were telling her we loved her. It was a good death.

CRITICAL THINKING

Mrs. Hart

■ Mrs. Hart has written a living will specifying her wishes should she become incapacitated. Because she has advanced disease, she tells you she would not want to be resuscitated if she has a cardiac arrest. She is currently hospitalized but will be discharged to her home in a few days. What documents does she need to have in place to ensure she will not receive resuscitation?

Suggested answers at end of chapter.

should be documented on the patient's chart (Box 16.1 Patient Perspective).

Artificial Feeding and Hydration

When patients can no longer eat or drink, it may happen as a result of three conditions. It may be due to an acute illness, or after a long illness with multiple medical problems, or simply due to the aging process. Otherwise healthy patients who are unable to eat while recovering from an acute illness will probably benefit from tube feeding. Patients who are declining either due to multiple medical problems or the aging process probably will not.

In recent years, there has been important research to help guide the decision to insert a feeding tube. In 1999, a 30-year retrospective review of dementia patients who received feeding tubes revealed the following. These patients did not live longer (than patients who were hand fed), the feeding tube *increased* rather than *decreased* the risk of aspiration pneumonia, the feeding tube did not prevent or reverse weight loss, and it did not heal or prevent decubitus ulcers. As a result of this research, The National Alzheimer's Association recommends that instead of a feeding tube, these patients receive an effective program of hand feeding. It has long been known that although a feeding tube or TPN (total parenteral nutrition) is helpful for cancer patients who are losing weight due to therapeutic treatments such as chemotherapy, it is not helpful for patients who are actively dying from cancer.

There are even some benefits in withholding **artificial feeding** and **artificial hydration** in the final weeks of life in actively dying patients. These benefits are:

- Fewer pharyngeal and lung secretions, which can reduce dyspnea
- Reduced swelling around tumors, which can reduce associated pain
- Less urination, resulting in dryer skin with less breakdown.

It has been theorized that as dehydration occurs, the body produces a form of endorphin, which enhances comfort. As ketone levels rise (from breakdown of body fat), patients experience an anesthetic effect that creates a sense

of well-being. Hospices have done comparative research studying patients who received IV hydration and those who did not to understand the effect of hydration on comfort. They surveyed both groups of patients in the days before death, asking about discomfort. They discovered that both groups were comfortable and both voiced only one complaint, having a “dry mouth.” Neither group reported complaints of hunger or increased pain. Because both groups experienced dry mouths, it was speculated that the cause of dry mouth was due to the medications used at end of life. When frequent mouth care was added to the care plan, the complaint of dry mouth dissipated.

The issue of feeding is a very emotionally difficult one for families. Often their loved one has been ill a long time. Bringing favorite foods may have been one of the ways they showed love and communicated caring. Families will need support in making decisions about feeding in three important ways: (1) identifying goals of care and evaluating whether artificial feeding will help meet those goals, (2) weighing the benefits and burdens of feeding, and (3) finding new ways (besides feeding) to communicate their love such as skin care, mouth care, or reading to their loved one.

For a different perspective on artificial feeding, see Box 16.2 Ethical Considerations.

Hospitalization

A hospital is where patients go to receive aggressive medical treatment. The goal of care in a hospital is to improve the patient medically and transfer him or her to an appropriate level of care that will better meet individualized needs. There are burdens associated with hospitalization for elderly patients approaching the end of life. These patients may actually decline more rapidly in a hospital setting. Research has shown that *all* elderly patients lose weight in a hospital. Research on dementia patients has shown that patients with dementia lose weight and suffer irreversible cognitive decline with each hospitalization. They enter a foreign environment and are cared for by health-care workers who do not know them. Often the patients are restrained as they become agitated and become fearful away from where they call *home*. Patients who are frail and have poor immunity are also at risk. They often enter the hospital with one infection and are discharged with infections resistant to antibiotics or ones caused by antibiotics, such as *Clostridium difficile* infections.

Patients living in nursing facilities with end-stage dementia who have severe cognitive impairment will benefit from having a “Do Not Hospitalize” order. This will main-

Box 16.2

Ethical Considerations

Euthanasia

Karen has worked in a long-term care facility for the past 9 years. She works very hard in her job as an LPN to ensure that all of her patients receive the best care possible during their stay. Karen values life and has a special interest in palliative care and end of life issues.

Karen has been caring for Adam since he came to the hospice 5 years ago. Adam is a 28-year-old man who has been in a “waking coma” since a car accident. He has made no progress over the time he has been in care. Adam is married and both his wife and parents are actively involved in his care.

Adam occasionally makes indistinguishable sounds, his eyes are open but do not fix upon any object, and he can move his head from side to side. He can’t swallow, so he has a gastric feeding tube. Adam is unable to move, and has extensive limb contractures and chronic decubitus ulcers. He is incontinent, so he wears an adult brief and has a urinary catheter. He suffers from frequent bouts of stomatitis, skin and urinary tract infections, and occasionally pneumonia.

Adam’s wife believes that Adam will never fully recover or regain any meaningful control over his body. She believes his tube feeding should be discontinued. Should this happen, it seems certain that Adam will die from dehydration soon after. Adam’s parents, however, remain hopeful that Adam will eventually recover and regain some normal func-

tion. They are also firm believers in the value of human life, in any condition, and believe it would be wrong to allow him to die. As a result, Adam’s wife has petitioned the courts to have his feeding tube stopped. There is tension between the two parties, and they try to avoid each other as much as possible.

Eventually, Adam’s wife wins her fight to have the feeding stopped. On the day that this is to happen, Karen is the LPN on duty and it falls to her to discontinue the feeding and clamp the tubing. The tube is left intact in case it is needed to administer medications needed for comfort. Karen is aware that once the feeding is stopped, Adam will not be able to eat or drink by himself and will most likely die in the near future.

What are the important issues here? First, there are two opposing sides. Adam’s wife insists that Adam has no viable future and would not have wanted to endure such a state for such a long time. She points out that there has been extensive neurological damage that cannot be reversed, leading to her conclusion that Adam, as he was known, no longer exists. His parents maintain that life, in whatever form and at whatever cost, should be supported and protected. Who is right?

What principles should guide Adam’s care?

What is Karen’s primary obligation?

Who is protecting Adam’s rights?

Should Karen stop the feeding?

tain the patient in an environment that feels “safe” and preserves his or her chosen quality of life.

Hospice Care

Many people think of **hospice** as a “place.” It is actually a service. The service is provided in private homes or independent and assisted-living facilities. It can also be provided in hospitals and nursing homes when there is a signed contract between the hospice organization and the facility. In order to qualify for hospice, a patient must have a prognosis of living for 6 months or less.

Some indicators of a 6-month or less prognosis (regardless of diagnosis) are 10% loss of weight in 6 months, functional decline, frequent hospital admissions, and recurrent infections. The goal of hospice care is holistic: to manage symptoms such as pain and nausea, to provide emotional and spiritual counseling for the patient and family, and to support the patient in achieving his or her goals of care. Each patient is assigned a multidisciplinary hospice team (Table 16.2).

Most health insurance companies now provide a hospice benefit. Many are modeled after the Medicare Hospice benefit. The Medicare benefit pays for both routine hospice care at home and inpatient hospice care provided in a hospital or a skilled nursing facility via contract or in a freestanding hospice unit. Medications, medical supplies, oxygen, and durable medical equipment are also covered if they are related to the “terminal” diagnosis.

Hospice care can assist a family to take care of a patient at home, but hospice nurses do not routinely provide 24-hour in home care. Nurses and other team members make regular visits to support the patient and family. (A nurse is “on call” for in home visits 24 hours a day.) If the patient does not have family support for 24-hour care at times of

medical crisis, then short-term inpatient hospice services or 24-hour in home continuous nursing care may be provided under some hospice benefits.

COMMUNICATING WITH PATIENTS AND THEIR LOVED ONES

Terminal illness is a family experience. *Family* is defined by the patient and may include blood relatives, friends, significant others, or partners. The primary role of the nurse is to facilitate a comfortable death that honors the choices of the patient and family. The nurse, therefore, becomes the **advocate**, assuring that the patient and family wishes are communicated to other members of the health-care team. In addition, the nurse is often the *professional caregiver* and *educator* of the nonprofessional caregivers and family.

In order to successfully work with dying patients and families, you must demonstrate empathy, unconditional positive regard, trustworthiness, and critical thinking. You are part of an interdisciplinary team. The team consists of the physician; nurse; social worker; chaplain, physical, occupational and speech therapists; and others. Each discipline has expertise and can lend support to the others in providing care. As illustrated in the section on end of life choices, patients and their loved ones need support and evidence-based medical information to make good decisions. All members of the team can assist with this support.

Good communication requires that you take time to listen, answer questions honestly, help to identify choices, and allow verbalization of fears. Eighty percent of communication is nonverbal, such as eye contact, body language, and tone of voice. Take time to identify your own communication barriers that will affect your ability to talk with families. Do you have fears about your own mortality, lack personal experience with death, fear being blamed for decisions, or disagree with decisions that were made? These barriers will affect your ability to sit with patients and families in crisis, sustain eye contact, and support them in their process. Practice attentive listening with patients and families. Encourage them to talk; be silent, don’t change the subject, and know that you do not have to have all the answers. Your role can be to help them reflect on what they are trying to communicate and to clarify their goals of care so you may better advocate for them.

Set the stage for communication by sitting down to show you are not in a hurry (Figure 16.1). Maintain eye contact, encourage them to speak, repeat what they said to gain clarification, and reflect on its meaning. Some things to say to facilitate good communication include:

- “Do you feel like talking?”
- “Tell me more about your fears of”
- Use repetition: “You mentioned you were upset by”
- Reflect: “So are you saying that?”
- “What does this mean to you?”
- “How can I help you?”

TABLE 16.2 THE HOSPICE TEAM

Physician	Works with the patient’s primary physician, offering suggestions to improve care. Directs the activities of the team and often will make visits to the patient’s home.
Nurse	Makes routine home visits, assessing patient’s needs and implementing plan of care. Nurses are available to visit 24 hours per day as needed.
Social worker	Provides emotional counseling and long term planning, assisting patients with insurance issues and helping to identify community resources.
Chaplain or minister	Provides spiritual counseling or coordinates care of spiritual issues with the patient’s chosen spiritual counselor. May participate in funeral or memorial service.
Home health aide	Provides personal care, linen changes, light housekeeping.
Volunteers	Give caregivers support by staying with the patient while they get out of the house. May also read to patient, run errands, etc.
Bereavement counselor	Provides counseling for family and significant others for 13 months after the date of the patient’s death.

FIGURE 16.1 Nurses can be a comfort to patients and family members.

From the patient's perspective, there are many factors that influence the content and quality of communication with you. Some patients are so afraid they cannot hear what they have been told about their illness. It can be helpful to ask what the doctor has said in order to get baseline information about where they are in understanding their disease.

Patients may use denial as a mechanism to protect themselves from becoming overwhelmed by emotion. The denial is necessary to enable them to survive on a day-by-day basis. It is not necessary for you to remove their denial. Some patients remain in denial throughout the course of their illness. When patients in denial ask you a direct question about their condition, it can be an indicator that they are ready to hear the truth. It is essential that you always answer questions honestly and to the best of your knowledge. Dishonestly destroys trust and credibility.

Patients and their families may also feel angry. Allowing them to express their anger will validate it and enable them to progress emotionally. Comments like, "It is okay to be angry with God and anybody else," will encourage them to continue to talk. Patients who fully understand their prognosis will express sadness and regret. Sitting with patients as they express sadness will allow them to share their feeling and give you an opportunity to offer emotional support.

THE DYING PROCESS

This section discusses the expected changes in the days and hours before death. Assessing the patient for these changes, planning and implementing treatments, and evaluating patient's response to interventions are all important. See Box 16.3 Nursing Care Plan for the Patient at the End of Life for nursing interventions.

Educating caregivers about what to expect is essential. Caregivers who anticipate the expected changes and understand the rationale behind the interventions are more successful in their care giving and have fewer regrets or concerns after the death. See Box 16.3 Nursing Care Plan for the Patient at the End of Life for specific communications that may help caregivers understand what is happening and how they can help.

Eating and Drinking

As bodies move toward death, there is less desire for food and fluids. Patients are conserving energy and often do not feel hunger. The swallowing reflex can be impaired with increased risk of choking. Patients fear choking and may hold their mouth tightly closed when food or fluids are offered. This is normal and the resultant dehydration will enhance comfort due to endorphin production and rising ketone levels.

Changes in Breathing

It is estimated that 50% to 70% of patients have dyspnea at end of life. Dyspnea may be reported by alert patients. Those who are not alert may exhibit tachypnea (respiratory rate >24), facial grimacing, and use of accessory muscles to breathe. Untreated dyspnea will lead to fear and agitation, leading to more dyspnea. Some patients will also have episodes of apnea in the days or hours before they die.

There are many causes of dyspnea. Pneumonia, anemia, congestive heart failure, and pleural effusion can be successfully treated early in the course of illness. Dyspnea that occurs in the final hours of life is not treated by correcting the underlying condition, but can be effectively managed and controlled (see Box 16.3. Nursing Care Plan for the Patient at the End of Life).

Oral Secretions

Saliva that the patient is now unable to swallow may collect in the back of the throat causing a sound sometimes called a "death rattle." This can be disconcerting for the family. See Box 16.3 Nursing Care Plan for the Patient at the End of Life for interventions.

Temperature Changes

As the body loses its ability to control temperature, the patient may become diaphoretic or feel cold all the time. Some patients have experienced fevers as high as 105°F (40.5°C). As death approaches, the feet and legs may become cyanotic and mottled. This is often an indicator that death will occur within hours.

Bowel and Bladder Changes

Most patients will become incontinent of bowel and bladder during the course of the illness. Urine output will decrease as dehydration occurs. Urine will often darken in color and have a strong odor.

(Text continued on page 281)

Box 16.3 NURSING CARE PLAN for the Patient at the End of Life

Nursing Diagnosis: Impaired gas exchange related to dying heart and lungs as evidenced by dyspnea, change in respiratory rate, $\text{Sao}_2 < 90\%$

Expected Outcomes Patient will state breathing is comfortable; respiratory rate is between 12 and 20 per minute, $\text{Sao}_2 \geq 90\%$.

Evaluation of Outcomes Is patient's breathing relaxed and rate between 12 and 20? Is $\text{Sao}_2 \geq 90\%$?

Interventions	Rationale	Evaluation
Monitor respiratory rate and effort.	Increased rate and effort indicate distress.	Is patient in distress? Are further interventions needed?
Administer diuretics or antibiotics as ordered.	Diuretics or antibiotics may be given to treat the dyspnea and promote comfort, not to prolong life.	Do diuretics or antibiotics reduce dyspnea?
Explain to the family the rationale for medical interventions.	Blood transfusions may be given to improve oxygenation and reduce dyspnea; a thoracentesis may promote lung expansion. These are not intended to prolong life, but to promote comfort.	Are additional interventions needed and effective? Does family understand rationale for their use?
Plan activities to conserve energy.	Spacing rest with activity will help reduce oxygen consumption.	Is patient able to tolerate spaced activities?
Place patient upright in a recliner with pillows to 45 degrees.	An upright position allows lung expansion.	Does positioning reduce dyspnea?
Offer alternative comfort measures such as massage and muscle relaxation.	Relaxation reduces anxiety and resulting dyspnea.	Are alternative measures effective?
Administer oxygen as ordered.	Oxygenation raises Sao_2 and reduces dyspnea.	Does oxygen raise Sao_2 and relieve dyspnea?
Place a fan in room if patient desires.	The feeling of breeze may reduce subjective feelings of dyspnea.	Does patient state or appear more comfortable with fan on?
Administer low dose morphine as ordered.	Morphine causes peripheral vasodilation, which can reduce pulmonary edema. It can also reduce anxiety.	Are respirations less labored after morphine?
Explain to patient and family: <i>This very small dose of morphine will help to slow his breathing down so that he feels more comfortable. It also works on the part of the brain that makes him feel short of breath, to take away the sense of panic.</i>	The informed patient and family will be able to cooperate and assist with keeping the patient comfortable.	Do patient and family understand reasons for care and feel secure that patient is receiving best possible care?

Nursing Diagnosis: Ineffective airway clearance related to excessive secretions and inability to swallow as evidenced by gurgling sound, "death rattle"

Expected Outcomes The patient's airway will be free of secretions.

Evaluation of Outcomes Is patient's breathing quiet and unlabored?

Interventions	Rationale	Evaluation
Adjust the patient's head to allow secretions to move down the throat.	This will help the patient swallow the secretions and decrease frightening noise.	Is breathing quieter?
Place a humidifier in the room.	Humidified air can liquefy secretions and help the patient to cough.	Is patient able to cough up secretions?

(Continued on following page)

Box 16.3 NURSING CARE PLAN for the Patient at the End of Life (Cont'd)

Interventions

If secretions are copious, administer hyoscyamine or scopolamine as ordered.

Administer low dose morphine as ordered.

Suction patient prn.

Teach patient and family *“Because he can no longer swallow saliva, it collects in the back of his throat. This medication will help to reduce the secretions and reduce his feeling of shortness of breath.”*

Rationale

These are anticholinergic medications that can dry secretions.

Morphine also has anticholinergic action that can help dry secretions.

If secretions are not controlled by non-invasive measures, suctioning may be necessary.

The informed patient and family will be able to cooperate and assist with keeping the patient comfortable.

Evaluation

Do medications help dry secretions?

Does morphine help quiet breathing and help patient stay calm?

Is suctioning necessary? Is it effective?

Do patient and family understand reasons for care and feel secure that patient is receiving best possible care?

Nursing Diagnosis: Imbalanced nutrition: less than body requirements related to inability to swallow and lack of appetite as evidenced by refusing food, weight loss

Expected Outcomes The patient will state satisfaction with amount and types of food offered. The patient will not aspirate food or fluid.

Evaluation of Outcomes Does patient appear content with foods and fluids offered? Does he or she swallow without aspirating?

Interventions

Allow the patient to choose when and what to eat. Do not force the patient to eat if he does not wish.

Sit the patient upright to eat or drink.

Explain to family as needed: *“He is afraid to swallow now because his swallowing is impaired and it causes him to choke. As he becomes dehydrated, comfort will be enhanced as the body produces endorphins and naturally occurring anesthesia.”*

Rationale

The goal is no longer providing adequate nutrition, but keeping the patient comfortable.

This can help the patient swallow and prevent aspiration.

The informed patient and family will be able to cooperate and assist with keeping the patient comfortable.

Evaluation

Is the patient receiving the foods and fluids he wants?

Does patient swallow effectively?

Do patient and family understand reasons for care and feel secure that patient is receiving best possible care?

Nursing Diagnosis: Impaired oral mucous membrane related to dehydration, not eating

Expected Outcomes The patient’s mucous membranes will be clean and moist.

Evaluation of Outcomes Are mucous membranes clean and moist? Does patient indicate that his mouth is moist?

Interventions

If alert, offer the patient ice chips or sips of water.

Provide frequent mouth care with sponge tipped toothettes.

Apply lanolin to lips.

Rationale

To keep mucous membranes moist.

This can keep mucous membranes moist when patient is not able to drink adequate fluids.

To keep the mouth and lips from becoming dry and crusty.

Evaluation

Does patient indicate mouth feels comfortable?

Is mouth clean and moist?

Are lips smooth and moist?

Nursing Diagnosis: Impaired comfort (pain, terminal restlessness) related to disease process, dying process, medications

Expected Outcomes The patient will state he or she feels comfortable. If unable to speak, he or she will appear calm and peaceful, not restless or agitated.

Evaluation of Outcomes Is patient comfortable, calm, and peaceful?

Interventions

Assess for reversible causes of agitation.

- Assess the patient for pain or other discomfort.
- Assess for urinary retention or fecal impaction.
- Assess for medications that are no longer beneficial.
- Assess SaO₂.

Reposition in bed at least every two hours and prn.

If SaO₂ is low, administer oxygen as ordered.

Discuss with the physician discontinuing all uncomfortable procedures, such as blood draws and finger sticks for blood glucose.

If the cause of the agitation cannot be determined, try medication for pain, dyspnea, or anxiety as ordered.

Keep the patient safe with one on one monitoring and side rails up.

Keep perineal area clean and dry, frequently checking adult briefs.

Teach patient and family
“Restlessness can have many causes. It can be a sign of pain, bowel or bladder problems or due to medication. I will work with the healthcare provider to improve the situation.”

Rationale

Often agitation is a sign of discomfort. Identifying and removing the cause of the discomfort can help calm the patient.

Ask the healthcare provider to simplify the medication regimen.

Repositioning frequently can promote comfort and relieve pressure on bony prominences. When other medical interventions are discontinued, the patient still needs to be repositioned regularly to prevent uncomfortable complications.

Low SaO₂ causes dyspnea, which is not comfortable.

Many procedures provide information to the staff but are not beneficial to the patient at the end of life. They should be discontinued.

Medication may need to be administered based on objective observations if the patient is unable to communicate.

A fall would increase the patient’s discomfort.

A wet brief is not comfortable. Unchanged briefs can also lead to skin breakdown, another source of discomfort.

The informed patient and family will be able to cooperate and assist with keeping the patient comfortable.

Evaluation

Can causes be identified? Are they removed?

Does repositioning promote comfort?

Is SaO₂ raised to 90%? Is patient’s breathing unlabored?

Are any uncomfortable procedures still being carried out that are not absolutely necessary?

Does medication promote comfort?

Is patient safety maintained?

Is patient clean and dry with intact skin?

Do patient and family understand reasons for care and feel secure that patient is receiving best possible care?

(Continued on following page)

Box 16.3 Nursing CARE PLAN for the Patient at the End of Life (Cont'd)

Nursing Diagnosis: Hypothermia or hyperthermia related to dying central nervous system and inability to regulate body temperature

Expected Outcomes The patient's temperature will be maintained as close to normal as possible, and discomfort from temperature extremes will be managed.

Evaluation of Outcomes Is temperature within normal limits (WNL)? If unable to control temperature, does patient appear comfortable?

Interventions

Administer acetaminophen suppository as ordered.

Keep the patient clean and dry.
Change gown and bed lines as necessary.

If the patient is cold, add blankets as necessary. Do not use an electric blanket or heating pad.

Rationale

Acetaminophen is an antipyretic. It is given by suppository if the patient cannot swallow.

A fever can cause diaphoresis, and lying in damp sheets can be uncomfortable and cause skin breakdown.

Blankets will warm the patient without risking burns from electric heating devices.

Evaluation

Does acetaminophen reduce fever?

Is patient kept dry and comfortable?

Are blankets helpful?

Nursing Diagnosis: Disturbed thought processes related to neurological changes

Expected Outcomes The family will voice understanding that confusion is not uncommon, and will demonstrate appropriate responses if it occurs.

Evaluation of Outcomes Does the family respond appropriately to patient during times of confusion?

Interventions

Assure families that some confusion is common phenomenon.

Do not correct the patient but instead encourage the patient to talk about what is happening.

Keep a dim light on in the room and remind the person gently of who is present.

Explain to family: *"Many patients make statements that don't make sense at times. It is as if they are in 2 worlds at the same time. He will become less distressed if you allow him to talk about what he is experiencing."*

Rationale

If they are prepared, it will be less disturbing.

Sometimes patients talk about their fears in metaphor. Allowing them to express this fear will promote relaxation and decrease loneliness.

Being able to see clearly helps keep the patient oriented if he awakens during the night.

The family will be less distressed if they understand what is happening.

Evaluation

Is family informed? Do they verbalize understanding of what to expect?

Is the patient less distressed after speaking?

Is light on? Is patient able to orient himself when he awakens?

Does the family respond appropriately to the patient's confused statements?

Nursing Diagnosis: Disturbed sensory perception related to changes in neurological function

Expected Outcomes The patient will be treated as still present and respected, and not as though he is already gone.

Evaluation of Outcomes Is communication respectful toward the patient?

Interventions

When providing care, always speak to the patient as if he can hear you. When conversing with family members in the room, remember that the patient also can hear what you are saying.

When giving care, explain softly to the patient what you are doing and why.

Explain to family: *Hearing is the last sense to go. This can be a good time to say the things you have not been able to say. He may still hear you.*

Rationale

Knowing what is happening can reduce anxiety and increase cooperation.

Continued communication can be comforting to both the patient and the family.

Evaluation

Are caregivers and family members sensitive to the patient's presence when communicating?

Does patient appear calm? Does he respond to your explanations?

Is communication appropriate?

Nursing Diagnosis: Anticipatory grieving related to impending death

Expected Outcomes The patient and family will be able to openly communicate their feelings to each other, and say goodbye.

Evaluation of Outcomes Are patient and family able to communicate effectively and say goodbye to each other?

Interventions

Be present with the patient. Just sit quietly and hold his hand for a period of time.

Show appropriate concern.

Provide a quiet environment where each loved one can say goodbye in a way that will reflect their cultures and values.

Consult a minister or religious counselor of family's choice.

Ask about the family's cultural and religious beliefs and allow time for prayers and ceremonies.

Rationale

This can help the patient to feel less alone, especially if there are no family members present. Many patients fear dying alone. This will promote trust and empower the family to ask for what they need.

These interactions will serve as valuable memories after the death and provide a feeling that each participant did what they needed to do for their loved one.

A minister often has special skills and training in communicating with people during difficult times. Talking about an afterlife may also be comforting to the patient and family.

Providing a culturally familiar environment will reduce the patient and family's anxieties and give them more control over the process.

Evaluation

Is someone present with the patient as much as possible?

Is the family communicating openly with the providers?

Do family members appear satisfied with their participation in the process?

Does the family appear to benefit from the presence of a minister or religious counselor?

Do family members feel free to carry out cultural and religious beliefs?

Sleeping

In the final weeks of life, patients may be sleeping for most of the day. This is due to a change in metabolism. They also begin to emotionally detach from families as part of their preparation to leave.

Mental Status Changes

As patients progress, they often have confused episodes due to electrolyte imbalance. Some patients will say things like, "I have to catch a train" or "I need my passport." This metaphorical communication is well documented in the hos-

piece literature. It is almost like patients are living in two worlds.

Terminal Restlessness

Terminal restlessness is a syndrome observed in a significant number of patients with various diagnoses during the final days of life. The patient may be unable to concentrate or relax, and may exhibit nonpurposeful motor activities such as picking at the sheets. The patient may hallucinate or try to climb out of bed. Terminal restlessness can have many causes, including hypoxemia, metabolic abnormalities, or hepatic failure. Some physical causes may be reversible so it is important to assess if pain or urinary or fecal impaction is the cause.

Restlessness may also be caused by medications. As kidney and liver functions are reduced, medication levels rise in the body and cause toxicity. Consult with the physician and pharmacist to determine if all the medications the patient is receiving are beneficial or necessary. See Table 16.3 for medications that might be helpful at the end of life.

Unconsciousness

The majority of patients are unconscious for hours or days before they die. Before they lose consciousness, their ability to see may be diminished. Hearing is the final sense to be lost. It is important for you to remember as you are caring for the patient and conversing with the family that your patient likely hears everything you are saying. Encourage the family to continue to talk to the patient.

CRITICAL THINKING

Mr. Johnson

■ Mr. Johnson is in the final hours of his life and has become increasingly short of breath throughout the day. With each inspiration, his respirations are moist and noisy. Currently, his respiratory rate is 30 per minute, and you notice he is using his accessory muscles to breathe.

What is the cause of his noisy breathing?

What can be done to lower his respiratory rate and decrease his dyspnea?

Suggested answers at end of chapter

CARE AT THE TIME OF DEATH AND AFTERWARD

Death has occurred when you observe the absence of heart-beat and respirations. The body color becomes pale and waxy, the eyes may remain open, and pupils are fixed. Telling the family that the patient has died should be done with sensitivity, providing small amounts of information according to the family's level of understanding. Be sure to check and adhere to the policies in your setting and state regarding death pronouncement and organ donation. Document the general appearance of the body, including absent pulse and lung sounds. Your goal now is to provide a personal closure experience for the family.

TABLE 16.3 MEDICATIONS TO INCREASE COMFORT AT THE END OF LIFE

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Opioids Bind to opioid receptors to reduce pain and dyspnea	Morphine (MS, MS-IR, MS Contin) Hydromorphone (Dilaudid) Fentanyl (Sublimaze, Actiq)	IV, SQ, PO, SL Rectal suppository IV, SQ, PO, SL Patch, IV, SL	Constipation, dry mouth, respiratory depression	Must be given routinely to be effective. Give routinely. Give short-acting analgesia for 24 hours until Fentanyl takes effect.
Anxiolytics Depress central nervous system to reduce anxiety	Lorazepam (Ativan) Diazepam (Valium)	IV, PO, SC	Dry mouth, unsteadiness. Assess for oversedation if used with opioids.	Not first line drugs for treating dyspnea
Neuroleptics Reduce severe agitation, terminal restlessness	Haloperidol (Haldol)	PO, IM	Tardive dyskinesia, Pseudoparkinsonism	Useful in treating anxiety when lorazepam ineffective.
Anticholinergics For treating excessive pharyngeal secretions	Hyoscyamine (Cystospaz) Scopolamine (Transderm-Scop) Glycopyrrolate (Robinul)	SL Patch SQ	Urinary retention, dry mouth	Works faster than scopolamine patch. For early treatment of secretions. Consider if hyoscyamine ineffective.

After death, you provide **postmortem care**. First, remove the tubes, medical supplies, and equipment. Bathing and dressing the patient and making him look presentable for the family shows respect. Some cultures dictate the care of the body after death and who should provide that care. The nurse can assess and advocate for cultural practices requested by the family. Work toward providing a clean, peaceful impression of the deceased. Position the body in proper alignment; replace dentures, place dressings on leaking wounds, and use briefs as necessary. Allow the family time with the body. Embalming is necessary within 12 hours. Do not remove the body until the family is ready. Covering or uncovering the face at removal should be done according to the family's preference. Additional activities, such as contacting the physician or funeral home, should be carried out according to institution policy.

GRIEF

Grief is the emotional response to a loss. Loss is a daily experience in everyone's life. Loss can occur due to divorce, children leaving home, loss of job, loss of possessions, or other losses. People express grief in their own way according to their coping skills, life experiences, and cultural norms. In end of life care, grief is a process that begins before the death of the patient and continues through a series of tasks that the survivors move through to resolve grief. The feelings associated with grief include anger, frustration, regret, guilt, sadness, and many others. This process can be divided into stages (Table 16.4).

Interventions for the grieving patient are addressed in Box 16.4 Nursing Care Plan for the Patient at the End of Life. Nursing process for the grieving family is addressed below.

Nursing Process for the Grieving Family

Assessment/Data Collection

Some things to consider when assessing grief include:

- Where is the family in the grief process?

- Are family members experiencing physical problems such as shortness of breath, sweating, skin color changes?
- Is the stress of grieving exacerbating medical conditions?
- What support systems are available to the family?
- What interventions can I use to facilitate their grief process?

Nursing Diagnosis, Planning, and Implementation

Although many nursing diagnoses may be appropriate, the priority diagnosis is simply Grieving.

Grieving related to impending death or loss of loved one

EXPECTED OUTCOME: The family will be able to express feelings of anger, guilt, or sadness. They will be able to think about the future and perform ADLs as needed.

- Simply be present. *Sitting with the bereaved, without having to have all the answers is very powerful. If you don't know what to say, just be silent.*
- Actively listen, allowing the bereaved to talk about the loved one and their feelings about the loss. Ask open-ended questions to encourage them to continue talking. *One of the greatest needs of the bereaved is to trust someone enough to share their pain.*
- Help family members identify their support systems (church, friends, family) and encourage them to use them. *Support systems can help in practical ways (meals, transportation) as well as lend emotional support.*
- Consider acknowledging the event by attending the memorial service or sending a card. *This simple act of caring is very important to families.*

Evaluation

Healing takes time. If interventions have been effective, however, the family will have the support to function effectively while they grieve.

TABLE 16.4 STAGES OF GRIEF

Stage	Tasks	Characteristics
Stage 1 Shock and disbelief	Acknowledge the reality of the loss. Recognize the loss.	Has difficulty with feelings of numbness, emotional outbursts, poor daily functioning, and avoidance.
Stage 2 Experience the loss	Work through the pain by expressing and experiencing the feelings.	Anger, bargaining, depression. May feel guilt over not preventing the death or not providing enough care. May feel angry at loved one who has "left them behind." May experience insomnia, loss of appetite, apathy, lack of interest in daily life.
Stage 3 Reintegration	Adjust to an environment without the deceased.	Finds hope in the future, participates in social events, feels more energetic.

THE NURSE AND LOSS

Working with dying patients triggers awareness of your own losses and fears about death and mortality. Adapting to the care of the dying requires that you explore and experience your personal feelings toward death. Unresolved losses from your past can resurface and affect your ability to care for dying patients. You may find that you continue to think about patients who have died long after the event. Emotionally continuing to care about deceased patients takes energy away from the daily care you are providing to current patients and your own family. Unresolved grief can lead to symptoms that resemble burnout, such as insomnia, headaches, and fatigue.

If you find yourself distancing and withdrawing from your dying patients, it is an indicator that you need to attend to the care of yourself. Some nurses may find counseling helpful in order to effectively process losses from the past and learn healthy ways to process future losses.

Both formal and informal support systems should be in place to support staff through multiple losses. Informal support can be one-on-one sharing of experiences with coworkers, peers, pastoral counselors, and physicians. Understanding and acknowledging your limitations, asking for help, regular exercise, and relaxation are important components. Some nurses find journal writing a helpful process, where writing down feelings allows you to release them. Formal support systems can be established in many different ways:

- Preplanned gatherings where nurses can express feelings in a safe environment
- Postclinical debriefings after difficult deaths to alleviate anxiety and promote learning
- Ceremonies such as memorial services in facilities

Home Health Hints

- Allow time during your visit to sit quietly with the patient and caregiver. Sitting quietly lets the patient and caregiver know you are there to meet both medical and emotional needs.
- Encourage family involvement with care. Families need reassurance that they are not going to hurt the patient; take the time to teach them how to assist the patient with basic care.
- Prepare the family for what to expect as death approaches.
- When the patient is no longer conscious, encourage the family to spend time at the bedside sharing personal thoughts and memories with the patient. For example, a spouse might talk about when they first met, or family members can play a favorite song.

to allow both staff and residents to recognize and honor the loss of patients

REFLECTIONS ON CASE STUDY

Remember Mr. Moran from the beginning of the chapter? Clearly he is approaching the end of life. Assess what he and his family want to happen in the final months of his life and where he wants to be. What are the goals of care? If comfort is the goal, how can this best be achieved? If keeping him in his familiar and safe environment is the goal, then help his family weigh the benefits and burdens of CPR, hospitalization, artificial feeding, and artificial hydration.

REVIEW QUESTIONS

1. A 94-year-old gentleman is admitted from home to the hospital with pneumonia. What factors lead the nurse to believe he is nearing the end of his life?
 - a. His abdomen is distended and his skin tone is yellow.
 - b. He has a fever of 101.6°F and a respiratory rate of 28.
 - c. He has been having difficulty swallowing and is losing weight.
 - d. He has crackles in his lung bases bilaterally.
2. What is a Durable Power of Attorney?
 - a. A document that outlines a patient's wishes at the end of life.
 - b. A document that gives a patient a "Do Not Resuscitate" status.
 - c. A person who will make decisions for a patient once the document is signed.
 - d. A person who will make decisions for a patient when the patient is no longer able to speak for himself.
3. A patient's family member says, "I heard someone say my mother could have a 'good death.' What on earth is a good death?" Which response by the nurse is best?
 - a. "Some things that can contribute to a good death are allowing patients to make their own decisions at the end of life, and assuring that they die comfortably."
 - b. "In reality, no death is a good death, but we do our best to make sure patients are comfortable right up until they die."
 - c. "Research has shown that patients can die good deaths if they are kept sedated so they don't really know what is happening during the last days until they die."

- d. "A good death occurs when the patient is kept alive as long as possible, so she can take care of all her 'unfinished business' first."
4. A husband whose wife has just died cries, "What am I going to do? She is all I had." What is the best response you can provide?
- "You are going to go on with your life. You still have your work and your children."
 - "I am sorry you lost your wife, but I know she would not want you to be sad. You have to be strong for her."
 - "I know how you feel. I lost my grandmother recently, and it was really hard."
 - There is no need to say anything. Just be present and listen.
5. A dying patient has excessive secretions that are causing dyspnea. Which medication will best help dry the secretions and increase comfort? Select all that apply.
- Haloperidol
 - Scopolamine
 - Acetaminophen
 - Diazepam
6. What are nursing interventions the nurse can provide at the end of life? Select all that apply.
- Position the patient to increase comfort and prevent complications.
 - Provide comfort measures such as massage.
 - Research experimental treatments that may help the patient find a cure.
 - Administer medications to increase comfort.
 - Teach the family CPR for use if the patient dies when the nurse is not present.
 - Sit quietly with the patient and family.
7. A patient has just died, and his family is waiting to see him. What postmortem care is essential first?
- Document the time and circumstances of the death.
 - Place identification on the body according to hospital policy.
 - Clean the patient up and make him look peaceful.
 - Cover the patient's body and face with a sheet.
8. The wife of a hospitalized patient who died an hour ago is crying and unwilling to leave his hospital room. The rest of the family is in the waiting room. The admitting department just called and wants to have the room cleaned for a new patient. Which action should the nurse take?
- Allow the wife to stay in the room as long as she likes.
 - Call a taxicab for the wife and gently guide her out of the room.
 - Sit with the wife for a few minutes, then take her to the waiting room.
 - Tell the wife that you are sorry for her loss, but that another patient needs the room.
9. A patient who has been receiving hospice care for 3 months tells the LPN he has decided he wants to return to active treatment of his disease. What should the LPN do?
- Encourage the patient to discuss his desire with his physician.
 - Tell the patient that he cannot change his goals once hospice care has been initiated.
 - Check his medication supply for any leftover medications he was taking during treatment.
 - Explain to the patient that since he is terminal, treatment will not help the course of his disease.

ETHICAL CONSIDERATIONS

Allowing someone to die, like abortion, generates huge controversy and debate. Each side of the argument can justify its stance using moral and ethical principles. Again, like abortion, religious and secular views may conflict. Both sides put forward strong arguments. For example, those supporting a peaceful death for Adam could state that respect for autonomy would mean that if Adam gave clear indication that he would not want to live in such a progressively worsening condition, his wishes for being allowed to die peacefully should be upheld, regardless of personal or public opinion. Conversely, the opposing side could argue that Adam's autonomy should be protected while he is in this state. He is incapable of making such choices and until the time comes when he can, his right to choose must be protected.

Karen chose to work in a facility where people often die, so she would be familiar with the process. As to whether she could actually participate in an act that

would contribute to the death of a patient is the central question. Essentially, Karen must examine her own personal moral values in order to direct her actions. In this case, the ethical principles dictating the interaction between patient and nurse must be weighed carefully against what Karen holds dear. Karen may also want to distinguish between causing someone to die versus allowing someone to die of natural causes after stopping artificial feeding. Beneficence, nonmaleficence, and autonomy have their place in this scenario regardless of opposing sides. It is important to consider Adam's wishes if they are known. Sometimes the person who is the subject of the debate can be forgotten while groups argue about which approach is right.

In the end, the courts decided Adam's outcome. If Karen can't in good conscience discontinue his feeding, she may be able to ask for reassignment during this shift.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Hart

Mrs. Hart will need both a Do Not Resuscitate order in the hospital setting and when she goes home, she will need an out of hospital, prehospital, or durable DNR, whatever is called for in her state of residence. In addition, her family members should be aware of her wishes.

■ Mr. Johnson

Mr. Johnson's dyspnea is commonly seen in the final hours on life. He may benefit from oxygen. Low-dose morphine will decrease his respiratory rate and improve his oxygenation. Morphine also has a "drying effect" on secretions. If morphine is unsuccessful, the addition of hyoscyamine may be helpful.

neutrophil (NEW-troh-fil)
passive immunity (PASS-iv im-YOO-ni-tee)
white blood cells (Wight Bluhd Cells)

QUESTIONS TO GUIDE YOUR READING

1. What type of immunity is obtained with a vaccine?
2. How does aging affect the immune system?
3. What subjective data are collected when caring for a patient with a disorder of the immune system?
4. What objective data are collected when caring for a patient with a disorder of the immune system?
5. What nursing care is provided for patients undergoing diagnostic tests for the immune system?
6. What are common therapeutic interventions used for a patient with disorders of the immune system?

NORMAL IMMUNE ANATOMY AND PHYSIOLOGY

Immunity is defined as the ability to destroy pathogens or other foreign material and to prevent further cases of certain infectious diseases. Immunity is most often thought of in terms of the body's response to microorganisms such as bacteria, viruses, and fungi, all of which are foreign to the body. However, immunity also involves processes directed toward other cells or substances that are identified by the body, correctly or incorrectly, as foreign. Malignant cells are foreign in that they have mutated from normal form and are usually destroyed by the immune system before they become malignant. Transplanted organs unfortunately are also perceived as foreign; rejection of a transplanted organ is an immune response. Occasionally, the immune system mistakenly reacts to part of the body itself (autoimmune

disease) or to a substance that should be tolerated (allergic reaction).

The immune system consists of lymphoid organs, **lymphocytes** and **other white blood cells**, and the many chemicals produced that are involved in activation of our own cells for the destruction of foreign **antigens** (Fig. 17.1). The lymphatic system consists of lymphatic vessels that help return tissue fluid to the circulatory system; lymph nodes and nodules, which are masses of lymphatic tissue that differ in size and location; the spleen, where macrophages phagocytize pathogens and B and T cells carry out immune functions; and the thymus, which functions primarily in childhood and atrophies with age. Lymph nodes are grouped along lymph vessels to destroy foreign material. Three major

lymphocyte: lympho—lymph + kytos—cell

antigen: anti—against + gennan—to produce

FIGURE 17.1 Immune system organs, lymph vessels, and major lymph nodes.

groups are the cervical, axillary, and inguinal nodes. Lymph nodules lack encapsulation and are smaller than nodes; lymph nodules are found under the surface of mucous membranes (e.g., tonsils).

Antigens

Antigens are chemical markers that identify cells or molecules. Examples of molecular antigens include bacterial toxins, plant pollens or proteins that trigger allergies, and the protein products of viral activity within cells. Human cells (except red blood cells [RBCs]) have their own self-antigens—thousands of markers that identify the cell as belonging in the body. These are the major histocompatibility complex (MHC) antigens, also called human leukocyte antigens (HLAs), which are genetically determined. The MHC antigens of identical twins are identical. These MHC antigens serve as a comparison for cells of the immune system; the antigens of foreign cells do not “match” MHC antigens and may therefore be recognized as foreign and destroyed in one of several ways.

Lymphocytes

There are three types of lymphocytes: natural killer (NK) cells, thymus-derived lymphocytes (T cells), and bone marrow-derived lymphocytes (B cells), each with very different functions.

Natural Killer Cells

Natural killer cells are found in the blood, red bone marrow, lymph nodes, and spleen and are able to destroy many kinds of infected body cells and tumor cells. NK cells attack any self-cell that displays abnormal plasma membrane proteins. After binding with an abnormal cell, NK cells release toxins in granules, either perforins or granzymes. Perforins create a hole in the plasma membrane of the attacked cell; the result is cytolysis. Granzymes induce apoptosis (self-destruction) of the target cell. Any released microbes are phagocytized by WBCs. The action of NK cells is considered a nonspecific resistance mechanism because it is effective against a variety of foreign antigens.

T Cells and B Cells

The lymphocytes called T cells and B cells are involved in specific immune responses; that is, each cell is genetically programmed to respond to one kind of foreign antigen. It is estimated that the human immune system can respond to hundreds of millions of different foreign antigens.

Both T cells and B cells arise in the red bone marrow. T cells then migrate to the thymus, where the thymic hormones bring about their maturation. Most T cells arise before puberty, but the process continues at a slower pace throughout life. From the thymus, T cells migrate to the lymph nodes and nodules and to the spleen. B cells mature in the bone marrow and migrate directly to lymphatic tissue. When activated during an immune response, some B cells become plasma cells that produce antibodies; meanwhile others become memory cells.

Antibodies

Antibodies are also called immunoglobulins (Ig) or gamma globulins and are proteins produced by plasma cells in response to foreign antigens. Antibodies do not themselves destroy foreign antigens, but rather become attached to such antigens to “label” them for destruction. Each **antibody** is specific for only one antigen, and the B cells (those that become plasma cells) of an individual are capable of producing millions of different antibodies. There are five classes of human antibodies, designated by letter names: IgG, IgM, IgA, IgE, and IgD. Their functions are summarized in Table 17.1.

Mechanisms of Immunity

The two mechanisms of immunity are **cell-mediated immunity**, which involves T cells, and **humoral immunity**, which involves primarily B cells but is assisted by T cells. Although the mechanisms are different, invasion by a pathogen often triggers both.

The first step in the destruction of a foreign antigen is the recognition of it as being foreign. B cells in lymphatic tissue are able to recognize and bind with the foreign antigens to become activated B cells. Their activation is greatly enhanced if the foreign antigen is presented to them by antigen-presenting cells called dendritic cells. T cells have foreign antigen recognition only if subjected to an antigen-presenting cell, such as a dendritic cell, macrophage, or B cell that has previously processed the antigen.

TABLE 17.1 CLASSES OF ANTIBODIES

Immunoglobulin (Ig)	Location	Function
G	Blood, extracellular fluid, lymph	Crosses the placenta to provide passive immunity in newborns Provides long-term immunity following a vaccination or illness recovery
A	External secretions (e.g., tears, saliva)	Provides passive immunity for breastfed infants Found in secretions of all mucous membranes
M	Blood, lymph	Produced first during an infection (IgG production follows)
D	B cells	Are antigen-specific receptors on B lymphocytes
E	Mast cells or basophils	Important in allergic reactions Mast cells release histamine

Source: Scanlon, V, and Sanders, T: Understanding Human Structure and Function. FA Davis, Philadelphia, 2003, p 313.

Cell-Mediated Immunity

This mechanism of immunity does not involve the production of antibodies, but it is effective against intracellular pathogens (such as viruses or fungi), malignant cells, and grafts of foreign tissue. The first step is the recognition of the foreign antigen by helper T cells, assisted by macrophages. The newly activated T cells divide many times and become specialized in one of several ways. Cytotoxic, or killer, T cells (CD8) are able to lyse cells such as cancer cells or those infected by viruses or other intracellular parasites, malignant cells, or transplanted tissues. They also release chemicals that activate phagocytes such as macrophages and **neutrophils**.

Memory T cells remember the specific foreign antigen and quickly activate an immune response should the antigen reappear. Suppressor T cells are believed to inhibit the proliferation of both T cells and B cells, which limits the immune response to just what is needed and no more.

Humoral Immunity

Humoral immunity is also called antibody-mediated immunity and involves antibody production. Again, the first step is the recognition of the antigen as being foreign; this time by B cells. The helper T cells (CD4) that recognize the antigen further stimulate the activated B cells to proliferate and differentiate. Some B cells become plasma cells that produce antibodies specific for this particular antigen. Other B cells become memory B cells that will remember this antigen and initiate a rapid response should it return. Humoral immunity is effective against extracellular pathogens,

which are usually bacteria but can also be viral or fungal infections.

Although B cells are stationary, the antibodies produced by plasma cells circulate throughout the body. The antibodies bond to the antigen, forming an antigen-antibody complex. This immobilizes the bacteria; also the antigen is now “labeled” for phagocytosis by macrophages or neutrophils. The antigen-antibody complex also stimulates the process of complement fixation.

Complement is a group of over 30 plasma proteins that circulate in the blood until activated by an antigen-antibody complex in the classic pathway. (There are two alternative pathways that initiate the complement cascade.) The activation of complement may result in the formation of a protein complex that lyses the cell and brings about its death. Other complement proteins bind to foreign antigens and serve as further labels to attract macrophages.

ANTIBODY RESPONSES

The first exposure to a foreign antigen stimulates antibody production, but the antibodies are produced too slowly to prevent the disease. However, with time, the individual has accumulated antibodies and memory cells that are specific for that pathogen. On a second exposure to the antigen, the memory cells initiate rapid production of large amounts of antibody, often enough to prevent a second occurrence of the illness (Fig. 17.2). This is the basis for the protection given by vaccines. A vaccine contains an antigen that is not pathogenic (e.g., bacterial capsules in the case of the pneumococcal vaccine). The vaccine stimulates the formation of antibodies and memory cells.

neutrophil: neutro—neuter + philein—to love

FIGURE 17.2 Antibody responses to a first and then subsequent exposure to a pathogen. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. FA Davis, Philadelphia, 2003, p 317.)

FIGURE 17.3 Antibodies. (A) Structure of the five classes of antibodies. (B) Antibody activity (Adapted from Scanlon, V and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 4. FA Davis, Philadelphia, 2003, p 312.)

Antibodies may also neutralize viruses; that is, they attach to a virus and render it unable to enter a cell (Fig. 17.3). Viruses cannot reproduce outside of living cells, and those coated with antibodies are phagocytized by macrophages. Another aspect of our defenses against viruses is interferon, a chemical produced by cells infected with viruses. Although it does not help the infected cell, interferon protects surrounding cells by enabling them to resist viral replication.

Antibodies are also involved in allergic responses, in which the immune system responds to foreign but harmless antigens (an allergen), such as plant pollen. IgE antibodies bond to mast cells, which break down and release histamine and other chemicals that contribute to inflammation. **Anaphylactic** shock is an allergic reaction, but it is massive in nature. It is characterized by loss of plasma from capillaries (an effect of histamine) and a sudden drop in the intravascular blood volume and blood pressure.

TYPES OF IMMUNITY

Two categories of immunity are **passive immunity** and **active immunity**. In passive immunity, antibodies are not produced by the individual but are obtained from another source. One form of naturally acquired passive immunity includes placental transmission of antibodies from mother to fetus and transmission of antibodies in breast milk. Artificially acquired passive immunity involves injection of preformed antibodies; this may help prevent disease after exposure to a pathogen such as the hepatitis B virus. Passive immunity is always temporary, in that antibodies from another source eventually break down.

Active immunity means that the individual produces his or her own antibodies. An example of naturally acquired active immunity occurs when a person recovers from a disease and then has antibodies and memory cells specific for that pathogen. Artificially acquired active immunity occurs as the result of a vaccine that stimulates production of anti-

bodies and memory cells. The duration of active immunity depends on the particular disease or vaccine; some confer lifelong immunity, but others do not.

AGING AND THE IMMUNE SYSTEM

The efficiency of the immune system decreases with age (Fig. 17.4). As such, older adults are more susceptible to infections and autoimmune disorders (Box 17.1 Gerontological Issues). The incidence of cancer is also higher; malignant cells that might once have been quickly destroyed by the immune system live and proliferate.

IMMUNE SYSTEM ASSESSMENT

Nursing Assessment

Disorders of the immune system can affect every system in the body so it is important to collect head-to-toe data as well as a patient history (Table 17.2).

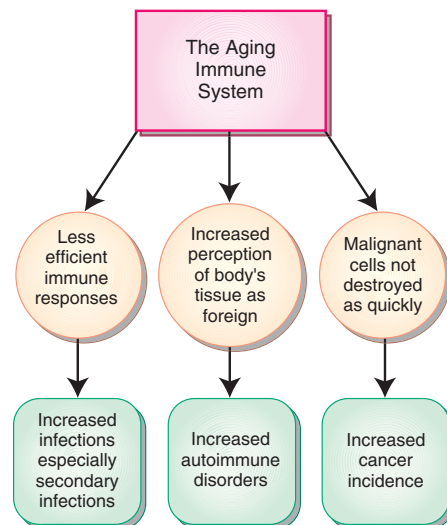

FIGURE 17.4 This concept map shows the effects the aging process has on the immune system.

**Box 17.1****Gerontological Issues**

Significant changes occur in the immune system of the older adult. These changes are known as immune senescence, which refers to a decline in immune system function. Some specific changes include the following:

- Thymus gland decreases in size, increases production of immature T cells, and has a subsequent decline in response to antigens.
- Antibody response to foreign organisms decreases.

Immunizations to support the immune responses of older adults include the following:

- Diphtheria tetanus booster every 10 years
- Pneumovax once in a lifetime (reimmunization or boosters usually not necessary)
- Influenza vaccine yearly (before influenza season), mid October to mid November
- Hepatitis B vaccine if medium to high risk for exposure to hepatitis B.

Subjective Data

DEMOGRAPHIC DATA. The patient's gender and ethnicity are important to note because some disease processes tend to be associated with a particular gender or ethnicity. For instance, systemic lupus erythematosus (SLE), an autoimmune disorder, tends to affect women eight times more than men.

HISTORY. Inquiring about the patient's history of past and present medical conditions should also include a family history. Many atopic (allergic) disorders such as allergic rhinitis and asthma or autoimmune disorders such as SLE and ankylosing spondylitis are thought to be either familial or have a genetic predisposition in certain ethnic or cultural groups (Box 17.2 Cultural Considerations).

Patients' previous surgeries may give clues about their current condition or prior health. For example, with thymus gland removal (thymectomy), T-cell production may be altered, which affects the cell-mediated immune response. Or if the spleen was removed (splenectomy), lymphocyte and plasma cell production may be altered, which affects the humoral immune response.

Asking about current medications should specifically include prescription, over-the-counter drugs, and herbal preparations. Corticosteroids and immunosuppressants decrease the immune response, whereas some anti-infectives or antineoplastics depress the bone marrow. This results in decreased production of the cells made in the bone marrow. Bone marrow depression of WBCs can alter cell-mediated and humoral immune responses. The herbal preparation licorice, which is sometimes used for its anti-inflammatory and expectorant effects, when taken concurrently with corticosteroids, produces additive effects of corticosteroids.

**Box 17.2****Cultural Considerations**

The Navajo people have a high incidence of severe combined immunodeficiency syndrome (SCIDS) and immunodeficiency syndrome unrelated to acquired immunodeficiency syndrome (AIDS). SCIDS result is a failure of the antibody response and cell-mediated immunity. Infants who survive initially are sent to tertiary care facilities. They must receive gamma globulin on a regular basis until a bone marrow transplant can be performed. Thus far, studies indicate that SCIDS is unique to this Navajo population.

A patient's lifestyle may influence immune system function and should be assessed. Anaphylactic reactions can be caused by exposure to latex, which may be found in gloves and other medical products that healthcare workers and their patients touch. Be aware of this potentially life-threatening reaction and know the agency's latex allergy protocol. Patients who are allergic to latex should wear a medical alert bracelet and carry an anaphylactic epinephrine kit. Knowing a patient's dietary habits and supplemental vitamins gives insight into the potential reserve of the patient's immune system for fighting infection.

The patient's life stressors, coping behaviors, and support systems should be explored. Stress (environmental, physical, and psychological) can depress the immune system's function. Coping behaviors are essential in keeping stress within manageable limits to maintain an optimum-functioning immune system. Support systems play an important role in coping with stress and should be encouraged and nurtured by nurses.

Current Problem

Use the WHAT'S UP? format to collect data about the current immune system problem. For immune disorders, the patient is asked the following questions:

- **Where is it?** What part of the body is affected?
- **How does it feel?** Painful? Itching?
- **Aggravating and alleviating factors?**
- **Timing.** Was there exposure to a pathogen? Did you have a previous infection? Does it occur only in certain settings? Did you have chemotherapy or radiation therapy? How long have symptoms persisted?
- **Severity.** Does it affect activities of daily living (ADLs)? Work? Roles?
- **Useful data for associated symptoms.** Immunosuppression? Family history? Allergies?
- **Perception of the patient of the problem.** What do you think is wrong?

The following are examples of common signs and symptoms that may be found with immune disorders: fever, fatigue, joint pain, swollen glands, weight loss, and skin rash.

TABLE 17.2 SUBJECTIVE ASSESSMENT OF THE IMMUNE SYSTEM

Category	Questions to Ask During History Assessment	Rationale/Significance
Demographic Data	What is your age?	The immune system decreases in functional effectiveness as one ages and a number of immune disorders tend to afflict individuals of particular age ranges.
	Where were you born? What is your ethnic or cultural background?	This information can aid in determining ethnic and cultural background influences. Some immune disorders tend to afflict individuals of particular cultural/ethnic groups more than others.
	Where have you lived?	This information can aid in determining ethnic and cultural background as well as possible environmental influences.
History	Where do you currently reside?	This information may lead to a direct cause of current symptoms and provides information regarding the status of the patient's immune system.
	Do you have allergies to any medications? Latex? Foods? Insects? Environmental allergens? If yes, have you had a recent exposure to any of these?	
	Is there anyone in your family is allergic to medications? Latex? Foods? Insects? Environmental allergens?	If family members (especially immediate) have severe reactions to substances, the patient may be predisposed to immune reactions to the same antigen or in general.
	What medications are you currently taking?	Some medications can mask symptoms or immune responses, others can suppress immune responses. May provide clues to patient's current condition or symptoms.
	What illnesses or conditions are you currently being treated for? Have you been treated for?	
	What surgeries have you had?	Have any immune organs been removed, therefore reducing immune function? May also provide indications to overall health.
	Have you ever had a blood transfusion? If so, why?	Antibodies to various antigen markers on the blood cells may have been formed. Additionally may provide indications to overall health.
	What is your occupation? Have you been exposed to hazardous chemicals, fumes, or radiation?	Many chemicals can produce local reactions, usually skin reactions or systemic immune reactions, and some can lead to bone marrow suppression in which all cell production is reduced.
	Do you engage in any form of risky behavior?	Risky behavior, such as intravenous drug usage and unprotected sex with multiple partners, increases a patient's chances of contracting the human immunodeficiency virus (HIV), which leads to a reduction in the immune system function.
	Describe your overall stress level and life stressors.	Stress is known to suppress the immune system and over prolonged periods can lead to a variety of illnesses.
	What do you do to cope with stress?	Not all coping behaviors and mechanisms are healthy, therefore it's important to assess what the patient's coping behaviors are to see if the patient needs education.
	What sort of support systems do you have?	Support systems can buffer the day-to-day stress as well as during crisis.

Objective Data

PHYSICAL ASSESSMENT. Physical data collection begins by observing the patient's general appearance, color, posture, gait, facial expression, skin, and nailbeds (Table 17.3). Any cyanosis or erythema (redness) is noted. Rashes should be examined for size, shape, location, texture, drainage, and pruritus (itching). Visual and hearing changes can be associated with an immunological disorder. Eye movements are assessed by testing the six cardinal positions of gaze for muscle weakness. (See Chapter 51.)

Adventitious lung sounds, such as wheezing, may indicate asthma or an allergic response. Crackles are often associated with an upper respiratory infection. Crackles heard with a dry cough and labored tachypnea are a sign of *Pneumocystis carinii* pneumonia, a common opportunistic lung infection in patients with HIV. Lymph nodes should be inspected and then gently palpated (often done by the advanced practitioner). (See Fig. 17.1.) Normally, lymph nodes are not palpable in the adult (normally they can be palpated in young children). If on palpation a lymph node is

LEARNING TIP

A normally functioning immune system is required to trigger an inflammatory response that produces the signs of inflammation or infection: fever, redness, pain, swelling, and warmth. If the immune system is suppressed or functioning abnormally, this normal inflammatory response may not occur. Thus the patient may exhibit only a low-grade fever with none of the other signs of inflammation or infection (redness, pain, swelling, and warmth).

Recognize patients with suppressed immune systems so that low-grade fevers are reported to the physician for prompt treatment. This may be the only sign of a life-threatening infection that develops because of the suppressed immune system.

CRITICAL THINKING

Laura Sims

■ Laura is scheduled for a lymph node biopsy and is seen in preadmission testing before surgery. As the licensed practical nurse/licensed vocational nurse (LPN/LVN) prepares to draw blood specimens, he learns that Laura is allergic to latex.

1. Why is this patient allergy information important?
2. What should the LPN/LVN do next?
3. What precautions should the LPN/LVN use for drawing the blood specimen?

Suggested answers at end of chapter.

enlarged, the following characteristics need to be noted: location, size, shape, tenderness, temperature, consistency, mobility, symmetry, pulsation, and if red streaks, redness, or edema are present.

If enlarged, the spleen may be palpable (by the advanced practitioner) in the left upper quadrant of the abdomen with disorders in which there is an overproduction or excessive destruction of red blood cells.

The renal system may also show impairment because of an immunological disorder manifested by a change in urinary output, flank pain, edema, weight gain, or elevated renal function studies.

A general neurological assessment of muscle strength and coordination, changes, or abnormalities is noted. Changes may be an indication of an immunologically

TABLE 17.3 OBJECTIVE ASSESSMENT OF THE IMMUNE SYSTEM

Category	Physical Assessment Findings	Possible Abnormal Findings/Causes
Neurological	Alertness and orientation	Frequently confusion or lethargy seen in later stages of systemic lupus erythematosus (SLE) and acquired immunodeficiency syndrome (AIDS)
Skin	Warm, dry, smooth, supple, even coloring, nonpruritic	Rashes, urticaria, pruritus, pustules seen with many forms of allergic reactions “Butterfly rash” (red rash over bridge of nose and cheek bones) seen in 55%–85% of SLE patients Painless purple lesions are seen with Kaposi’s sarcoma, which is frequently associated with HIV and AIDS.
	Pink mucous membranes	Pale edematous mucous membranes along with rhinorrhea and “allergic shiners” (dark circles under the eyes) are seen with allergic rhinitis Pale conjunctiva is associated with anemia Periorbital edema may also be indicative of hypothyroidism
	Nail attached to nailbed	Onycholysis (nail detaches from nailbed) is seen in patient’s with Hashimoto’s thyroiditis
Heart Sounds	Clear S1 and S2	A pericardial friction rub may be heard with rheumatoid arthritis or in SLE patients owing to inflammation of the connective tissue surrounding the heart (pericardium)
Lung Sounds	Clear throughout	Pleural effusion as evidenced by tachypnea with diminished sounds in bases may be seen in SLE or rheumatoid arthritis patients or a pleural friction rub may occur in these patients. Crackles with a dry cough may be indicative of <i>Pneumocystis carinii</i> pneumonia (PCP)
Lymph Nodes	Nonpalpable and nontender	Enlarged lymph nodes that are painless, firm, and fixed are associated with cancerous lesions, whereas painful enlarged lymph nodes are associated with inflammation and infection
Gastrointestinal	Appropriate appetite without nausea or vomiting	Anorexia, nausea, and vomiting may be associated with immune disorders.
	Regular pattern of brown, soft, formed stools	Diarrhea frequently occurs in patients with irritable bowel syndrome (IBS)
Renal	An average of 30 mL per hour of clear, yellow/amber urine without presence of protein or pain	Urine output of less than 30 mL per hour, the presence of protein in the urine, and edema are seen in patients with SLE or serum sickness Transfusion reactions may cause hematuria, flank pain, or oliguria Glomerulonephritis may cause hematuria, flank pain, or oliguria
Musculoskeletal	Painless and nonswollen joints with full range of motion	Swollen, painful joints are seen in rheumatoid arthritis along with limited joint range of motion
	Overall strength, endurance and coordination appropriate for age and physical fitness	Decreased strength and coordination occur with patients with multiple sclerosis Patients with myasthenia gravis lose strength and endurance with repetitive movements

based disorder such as multiple sclerosis or myasthenia gravis.

Diagnostic Tests

Presenting signs and symptoms and the patient's history determine which tests and procedures may be ordered. Table 17.4 describes the most common blood tests for patients with allergic, autoimmune, or immune disorders. Table 17.5 presents common noninvasive and invasive procedures for immune disorders.

Gene Testing

Mapping of the human genome has made current and future gene testing and manipulation possible. Scientists are now

able to test for numerous diseases, predisposition to diseases, and enzyme deficiencies that can alter immune response.

THERAPEUTIC INTERVENTIONS

Allergies

A medical alert bracelet or some sort of readily available identification of an allergy should be worn by the patient. It is important always to be aware of patient allergies. Allergies should be noted before giving any medications or foods. All allergies, including those to food, must be taken seriously.

Food allergies create serious management problems and have caused numerous deaths from anaphylactic shock

TABLE 17.4 DIAGNOSTIC LABORATORY TESTS FOR IMMUNE SYSTEM

Test	Definition/Normal Value	Significance of Abnormal Findings																		
Red Blood Cells	Number of red blood cells per 1 mm of blood: Adult male: $4.7\text{--}6.1 \times 10^{12}/\text{L}$ Adult female: $4.2\text{--}5.4 \times 10^{12}/\text{L}$	Decreased in all forms of anemia, such as pernicious anemia that develops from the autoimmune form of gastritis or idiopathic autoimmune hemolytic anemia.																		
Differential	Each of these tests (MCV, MCH, MCHC, RDW) provides information about the RBC size, shape, color, and intracellular structure. MCV: $80\text{--}95 \text{ mm}^3$ MCH: $27\text{--}31 \text{ pg}$ MCHC: $32\text{--}36 \text{ g/dL}$ RDW: $11.0\%\text{--}14.5 \%$	Can help determine the cause of anemia. Pernicious anemia can develop because of the autoimmune form of gastritis.																		
White Blood Cells	Number of white blood cells per 1 mm of blood. Adult: $5\text{--}10 \times 10^9/\text{L}$	Increased with immunosuppression and an increase with infection.																		
Differential	Percentage of type of white blood cells in 1 mm of blood. Or the actual numbers of specific types of WBCs if an absolute count is performed.	Eosinophils elevate with type I hypersensitivity reactions such as allergic rhinitis or anaphylaxis.																		
	<table border="1"> <thead> <tr> <th></th> <th>%</th> <th>Absolute/mm^3</th> </tr> </thead> <tbody> <tr> <td>• Neutrophils</td> <td>55–70</td> <td>2500–8000</td> </tr> <tr> <td>• Lymphocytes</td> <td>20–40</td> <td>1000–4000</td> </tr> <tr> <td>• Monocytes</td> <td>2–8</td> <td>100–700</td> </tr> <tr> <td>• Eosinophils</td> <td>1–4</td> <td>50–500</td> </tr> <tr> <td>• Basophils</td> <td>0.5–1.0</td> <td>25–100</td> </tr> </tbody> </table>		%	Absolute/ mm^3	• Neutrophils	55–70	2500–8000	• Lymphocytes	20–40	1000–4000	• Monocytes	2–8	100–700	• Eosinophils	1–4	50–500	• Basophils	0.5–1.0	25–100	
	%	Absolute/ mm^3																		
• Neutrophils	55–70	2500–8000																		
• Lymphocytes	20–40	1000–4000																		
• Monocytes	2–8	100–700																		
• Eosinophils	1–4	50–500																		
• Basophils	0.5–1.0	25–100																		
Erythrocyte Sedimentation Rate (ESR)	A nonspecific test for generalized inflammation. Measures the red blood cell descent (in millimeters) in test tube after being in normal saline for 1 hr (Westergren method). Male: up to 15 mm/hr Female: up to 20 mm/hr	There may be a false negative if steroids or nonsteroidal anti-inflammatory drugs (NSAIDs) are being used when test is performed.																		
Rheumatoid Factor (RF or RA)	An abnormal protein found in serum when IgM reacts with an abnormal IgG; found in 80% of clients with rheumatoid arthritis and other autoimmune disorders. Normal value: negative.	Increased in rheumatoid arthritis, SLE, leukemia, tuberculosis, older age, scleroderma, infectious mononucleosis.																		

Test	Definition/Normal Value	Significance of Abnormal Findings
Antinuclear Antibody (ANA)	Measures autoantibodies that attack the cell's nucleus. Normal value: negative.	Most commonly present in SLE (with >95% sensitivity), leukemia, scleroderma, rheumatoid arthritis, and myasthenia gravis; many medications influence levels.
Complement	Specific serum proteins that help mediate inflammation. Measures the amount of each of the components in the complement system. Total: 75–160 U/mL C3: 0.55–1.20 g/L C4: 0.2–0.5 g/L	Deficiencies of specific complement proteins are seen with SLE clients.
C-Reactive Protein (CRP)	An abnormal protein found in plasma during acute inflammatory processes; more sensitive than sedimentation rate. <10 mg/L	Increased in rheumatoid arthritis, cancer, SLE. Suppressed by aspirin and steroids.
Radioallergosorbent test (RAST)	Patient serum is mixed with a specific allergen, incubated with radiolabeled anti-IgE antibodies, and then the total amount of the specific IgE antibodies is measured.	A viable alternative to skin testing if the patient does not have multiple allergies.
ELISA	Antibodies in patient's blood are tested for on HIV antigen test plates.	Positive results may indicate HIV infection, but results <i>MUST</i> be confirmed by another test, usually the Western blot.
Western Blot	A blood test to detect the presence of any of the four major HIV antigens. Is considered positive when at least two of the four are detected. Used as a confirmation test.	If being used as the confirmation test, positive results indicate HIV infection. False positives do occur in patients who have autoimmune disease, leukemia, lymphoma, or syphilis, and in alcoholics.
Immunoglobulin Assay or Electrophoresis	Antibodies are made up of immunoglobulins, of which there are five different classes. <i>Normal in milligrams/deciliter (mg/dL):</i>	IgG. Increase: in all types of infections, liver disease, rheumatoid arthritis, dermatologic disorders. Decrease: agammaglobulinemia, lymphoid aplasia, Bence Jones proteinuria.
IgG	500–1500	Increase: malaria, infectious mononucleosis, SLE, rheumatoid arthritis.
IgM	50–300	Decrease: lymphoid aplasia, chronic lymphoblastic leukemia.
IgA	100–490	IgA
IgE	<100 IU/mL	Increase: during exercise, obstructive jaundice.
IgD	<3 U/mL	Decrease: immunosuppressive therapy, benzene exposure, congenital IgE. Increase: allergic reactions, allergic infections.
CD4+ Count	The CD4+ T lymphocytes are counted. Percentage: 60–75 No./ μ L: 600–1500	Decrease: agammaglobulinemia. Increased in allergy-proven patients. Decreased in cancer, HIV and AIDS, and immunosuppression.
CD8+ Count	The CD8+ T lymphocytes are counted. Percentage: 25–30 No./ μ L: 300–1000	Increased in viral infections. Decreased in SLE.
CD4+/CD8+ Ratio	The ratio of the CD4+ and CD8+ absolute counts are determined. >1	As HIV and AIDS progresses the CD4+/CD8+ ratio will become smaller as the CD4+ count decreases and the CD8+ count remains relatively unchanged.

MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; RDW = red blood cell distribution width.

TABLE 17.5 DIAGNOSTIC PROCEDURES FOR IMMUNE SYSTEM

Procedure	Definition/Normal Finding (if applicable)	Significance of Abnormal Findings	Nursing Management (if applicable)
<i>Noninvasive</i>			
<i>Chest X-ray</i>	Radiographic picture to determine size, shape, density of structures within the chest.	Pericarditis, pleuritis, pleural or pericardial effusions or may occur with systemic lupus erythematosus (SLE) or rheumatoid arthritis. Arthritic changes may also be noted on x-ray.	None.
<i>Gene Testing</i>	A sample of DNA which can be taken as an oral or nasal swab is examined and mapped for a variety of genetic disorders.	Abnormal findings may confirm a certain diagnosis or indicate that the patient may develop symptoms or pass a disorder on to offspring.	Assess support systems and for possible counseling referral.
<i>Magnetic Resonance Imagery (MRI)</i>	May be invasive or non-invasive depending upon if an injected contrast dye is used. No radiation is used; rather, magnetic fields are employed. Various body planes can be examined with the MRI. Provides better visualization of the central nervous (CNS) than with the computerized tomography scan.	Destructive bone and joint lesions. Brain lesions, tumors, abscesses, aneurysms, hematomas, and demyelination of nerves can be visualized.	If dye is used, check for iodine allergy and have the patient's height and weight on record. Patients weighing over 300 lb, are pregnant, requiring continuous monitoring or intravenous equipment, have implanted metal objects (bone pins, screws, pacemakers), are agitated, or are claustrophobic may not be eligible for an MRI.
<i>Invasive</i>			
<i>Biopsy (of Specific Organ in Question)</i>	Used to confirm a diagnosis, determine a prognosis, or evaluate treatment. May be performed as an inpatient, outpatient, or in a physician's office. The specimen may be obtained through a needle aspiration, incision, excision, or gavage and with or without endoscopy, fluoroscopy, stereotaxic, or needle localization.	The biopsy tissue is examined microscopically for diagnosis. Cancers, lymphomas, leukemias, transplant rejections are diagnosed in this manner.	Informed consent must be obtained prior to the procedure. Other preoperative/postoperative care determined by specific organ biopsied. Most organs are quite vascular and there is a high risk for bleeding complications after the biopsy. So vital signs and site monitoring are important.
<i>Computerized Tomography (CT Scan)</i>	This may be invasive or non-invasive depending upon if an injected contrast dye is used.	See MRI above.	If dye is to be used, check for iodine allergy and have patient's height and weight on record.
<i>Skin Testing</i>	Done if immune system is intact. Testing done for <i>Candida</i> , tetanus, or tuberculosis (purified protein derivative [PPD] test) or specific allergens such as medications, food, or environmental factors.	If erythema (redness) or induration (firmness) occurs at the site within a prescribed time frame, test is positive. Indicates patient has either been exposed to an organism, has an active infection, or has developed antibodies that stimulate an immune response.	Ask if patients have any allergies and the type of reaction or symptoms that occur.

(Box 17.3 Nutrition Notes). The offending allergen may be present in extremely small amounts. Sometimes a food product is contaminated by a previous batch of food made with the same equipment. Occasionally, the allergen may enter the body not by ingestion but by inhalation or contact with skin or mucous membranes.

Epinephrine is the drug of choice for life-threatening

anaphylactic reactions. If possible, treatment should begin immediately with administration of epinephrine until other medical care can be provided.

An EpiPen is often prescribed for patients with allergies to food or insect stings. It is a prepackaged, single-use device that allows the patient to self-inject a physician-ordered dose of epinephrine right through clothing. The patient must carry

Box 17.3

Nutrition Notes

Respecting Food Allergies

Allergy to food can be fatal. An analysis of 13 anaphylactic reactions to food identifies points along the critical path that had the potential to alter the outcome. Of 13 cases identified, 6 were fatal.

- In all cases, the patient was known to have asthma and to be allergic to some food.
- None of the patients was aware that the allergen was present in the foods consumed (candy, cookies, and pastry).
- Symptoms began soon after ingestion but in some cases abated before becoming severe.
- Of particular significance is the fact that *fewer than half the children had self-injectable epinephrine prescribed and only one of the six children used a dose*. The average delay between ingestion of the allergenic food and receipt of a dose of epinephrine was two and one-half times as long in the fatal cases as in the nonfatal cases.
- More of the fatal cases occurred in public places rather than private homes.

Several recommendations came from this study:

- Epinephrine should be prescribed, kept available, and used for patients with IgE-mediated food allergies.
- Children and adolescents who have an allergic reaction to food should be observed for 3 to 4 hours after the reaction at a center capable of dealing with anaphylaxis.
- Parents of such children should be taught to ensure an appropriate, rapid response by schools and other institutions.

Source: Summarized from Sampson AA, Mendelson I, Rosen JP: Fatal and near-fatal anaphylactic reactions to food in children and adolescents. *N Engl J Med* 327:380, 1992.

the EpiPen at all times when insect stings are possible. The expiration date of the EpiPen must be checked routinely and replaced as necessary. The patient needs to be instructed that the EpiPen does not replace the need for immediate and continued medical attention because the duration of the single dose of epinephrine varies from 1 to 4 hours.

Immunotherapy

To help desensitize a patient with anaphylactic reactions to allergens or with chronic allergic symptoms, immunotherapy involves injecting small amounts of an extract of the

allergen. Over time the strength of the allergen injected is increased until the desired hyposensitivity is reached. The subcutaneous injections are given once or twice a week initially, then every few weeks indefinitely for years. It is important that the patient not miss a dose. If this happens, the allergen strength may need to be reduced. This therapy is helpful for insect sting allergies.

When administering the allergen injection, it is important to understand that an anaphylactic reaction can occur. A physician and emergency equipment should be readily available. The patient should be observed following the injection for about 20 to 30 minutes to detect a reaction. The patient and family should be taught that a reaction could occur up to 24 hours after the injection and how to respond if it does occur.

Medications

Medications are one of the primary treatment options for immune disorders. General categories of these medications include epinephrine, corticosteroids, antihistamines, histamine (H₂) blockers, decongestants, mast cell-stabilizing drugs, antivirals, antibiotics, immunosuppressants, interferon, leukotriene antagonists, and hormone therapy. (See Chapter 18.)

Surgical Management

In some cases, splenectomy is necessary to control symptoms of an immunologic disorder.

New Therapies

Monoclonal antibodies can be produced against a variety of antigens. A monoclonal antibody is made by cloning one specific antibody and then growing unlimited amounts of it in tissue cultures. Many uses are being found for these antibodies, such as in dealing with transplant rejections.

Recombinant DNA technology combines genes from one organism with genes from another. This therapy is used for replacing an abnormal or missing gene to produce a normal gene. The normal gene can then be injected into the patient in an attempt to cure the disorder as the patient's body reproduces the normal genes. T-lymphocyte-directed gene transfer for severe combined immune deficiency has been performed successfully. Along these same lines is the research regarding injection of the precursors to all cells, the stem cell, into abnormal areas to produce normal cells. Studies continue in this area for possible uses of gene therapy, and since the completion of the mapping portion of the Human Genome Project, new discoveries in this area occur daily. For additional up-to-date information on these topics, visit the National Institutes of Health at www.nhgri.nih.gov or www.ncbi.nlm.nih.gov.

REVIEW QUESTIONS

- The nurse who is teaching a patient about vaccines would be correct in teaching that a vaccine provides which of the following types of immunity?
 - Naturally acquired passive immunity
 - Artificially acquired passive immunity
 - Naturally acquired active immunity
 - Artificially acquired active immunity
 - Which of the following vaccines are recommended annually for the older patient?
 - Influenza
 - Pneumovax
 - Diphtheria tetanus
 - Polio
 - The nurse is assisting with data collection. Which of the following past surgeries found in the history may influence immune system dysfunction?
 - Splenectomy
 - Thyroidectomy
 - Pneumonectomy
 - Parathyroidectomy
 - During data collection the patient reports tenderness in the cervical lymph nodes. The nurse recognizes that lymph nodes that are enlarged and tender usually indicate which of the following problems?
 - Cancer
 - Degeneration
 - Inflammation
 - Arthritis
 - The nurse is caring for a patient with suspected HIV. The nurse anticipates that which of the following is a confirmation test that will be ordered to test for HIV antibodies?
 - Murex SUDS
 - Western blot
 - Enzyme-linked immunosorbent assay
 - p24 antigen testing
- Fill in the blank:
- Biaxin 200 mg oral suspension is ordered for a patient. The nurse has 125 mg/5 mL available. How many milliliters should the nurse give?
Answer: _____ mL

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Laura Sims*

- The patient can have an anaphylactic reaction if exposed to latex, which may result in death for some patients.
- The LPN/LVN should follow the agency's latex allergy protocol, enter this information into the patient's medical record, notify surgery scheduling so latex precaution protocols can be planned for surgery, and have the patient's physician informed.
- Following the agency's protocol, the nurse should wear nonlatex gloves and use nonlatex equipment to draw the specimens.

Nursing Care of Patients with Immune Disorders

SHARON M. NOWAK

KEY TERMS

anaphylaxis (an-uh-fi-LAK-sis)

angioedema (AN-gee-o-eh-DEE-ma)

ankylosing spondylitis (ANG-ki-LOH-sing SPON-da-LIGHT-is)

histamine (HISS-ta-mean)

urticaria (UR-ti-KAIR-ee-ah)

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the immunological mechanism for the four types of hypersensitivities?
2. How would you explain the pathophysiology of disorders of the immune system?
3. What are the etiologies, signs, and symptoms of immune system disorders?
4. What care would you provide for patients undergoing tests for immune system disorders?
5. What is the current medical treatment for immune system disorders?
6. What data are collected when caring for patients with disorders of the immune system?
7. What factors alter or influence the self-recognition portion of the immune system?
8. What nursing care will you provide for patients with disorders of the immune system?
9. How will you know if your nursing interventions have been effective?

Disorders of the immune system can be divided into three categories. The first category is hypersensitivity reactions, which include conditions such as **anaphylaxis**, hemolytic transfusion reactions, measles, and transplant rejections. Autoimmune disorders (e.g., rheumatoid arthritis, ulcerative colitis, and multiple sclerosis) are the second category. The third category includes the immune deficiencies, such as hypogammaglobulinemia and acquired immunodeficiency syndrome (AIDS). (See Chapter 19.)

HYPERSENSITIVITY REACTIONS

The immune system is an adaptive, protective system of the body. However, there are times when this system causes injury to the body because of its exaggerated response. One of these occasions is when a hypersensitivity reaction occurs.

In the past, these reactions were classified as either immediate or delayed hypersensitivity. Gell and Coombs have developed a more precise classification system, which is used today. This four-division system (types I, II, III, and IV) classifies hypersensitivity reactions according to the way the tissue is injured.

anaphylaxis: ana—up + phylaxis—protection

Type I

A type I reaction, an anaphylactic reaction, is an immediately occurring reaction when exposure to a specific antigen occurs (Fig. 18.1). The reaction can be mild to severe and life threatening. The patient must have had previous exposure (sensitization) to the antigen. During this exposure, immunoglobulin E (IgE) antibodies are made and attach to mast cells throughout the body. When a subsequent exposure occurs, the antigen causes IgE to trigger mast cells to release their contents. One of the substances released is **histamine**, which causes vasodilation, changes in vascular permeability, an increase in mucus production, and contraction of various smooth muscles.

If the second antigen exposure is localized, the reaction is small and remains local. However, if the exposure is systemic, the reaction is massive and widespread. Respiratory allergies, such as allergic rhinitis and allergic asthma, with associated disorders of atopic dermatitis, tend to be reactions of a larger scale. Anaphylaxis, **urticaria**, and **angioedema** are the severest forms of type I reactions.

A type I reaction occurs when the patient has a positive reaction to a scratch test. A scratch test is done to identify specific allergens to which a patient is reactive. Tiny amounts of a variety of common allergens are scratched

angioedema: angeion—vessel + oidema—swelling

FIGURE 18.1 Type I hypersensitivity

onto the skin, which is then observed for indications of a reaction: redness, edema, and pruritus. If these indicators occur, it is considered to be a local reaction.

Allergic Rhinitis

Allergic rhinitis is the most common form of allergy. When symptoms occur throughout the year, it is called perennial allergic rhinitis. If the symptoms occur seasonally, it is called hay fever. The causative antigens are environmental and airborne.

PATHOPHYSIOLOGY. Allergic rhinitis is the result of an antigen-antibody reaction. Ciliary action decreases and mucous secretions increase. Vasodilation and local tissue edema occur.

SIGNS AND SYMPTOMS. Signs and symptoms vary in intensity and include sneezing, nasal itching, profuse watery rhinorrhea (runny nose), and itchy red eyes. The nasal mucosa is pale, cyanotic, and edematous. Frequently there are dark circles under the eyes, called allergic shiners, caused by venous congestion in the maxillary sinuses.

DIAGNOSTIC TESTS. Sometimes, skin testing is performed to identify the specific offending allergens to allow avoidance of the allergen. However, skin testing is expensive, does not always identify the allergen, and has limited usefulness for allergens that cannot be easily avoided once identified.

THERAPEUTIC INTERVENTIONS. Initial treatment involves eliminating the offending environmental stimuli. Antihistamines and nasal decongestants may be prescribed for symptomatic relief. If the symptoms are severe, corticosteroids via inhalation or nasal spray may also be given.

Rhinophototherapy is a newer treatment that uses light waves to reduce the body's hyperimmune response seen in this disorder. The treatment is usually done three times a week for 3 weeks and relieves symptoms such as sneezing, itching, and runny nose.

Immunotherapy, referred to as allergy shots, is reserved for patients with severe or debilitating symptoms. Immunotherapy involves receiving weekly subcutaneous injections in the allergist's office of tiny amounts of the offending antigen. Once a tolerance to a particular dose is reached, the amount of antigen is slightly increased. This therapy continues until the patient no longer exhibits symptoms when exposed to the environmental antigen. Being alert to signs of anaphylaxis during these procedures is essential for the nurse.

Atopic Dermatitis

Atopic dermatitis, often called eczema, is an inflammatory skin response.

PATHOPHYSIOLOGY. These skin lesions are not typical for a type I hypersensitivity reaction, and there usually is not a specific antigen identified as the cause. However, it is believed that the pathophysiology of atopic dermatitis is a type I hypersensitivity reaction, mediated by IgE antibodies, because it is commonly found in patients with allergic rhinitis or allergic asthma.

SIGNS AND SYMPTOMS. Initially there is pruritus, edema, and extremely dry skin, which is followed by eruptions of tiny vesicles (blisters); these eventually break open, crust over, and scale off. There is decreased sweating in these areas with the skin eventually thickening in the areas of dermatitis.

DIAGNOSTIC TESTS. There are no tests to confirm this diagnosis. A detailed history and physical examination are used to diagnose it. Of course, if there is an infection, culture and sensitivity tests may be ordered to determine the infecting organism and appropriate treatment.

THERAPEUTIC INTERVENTIONS. Treatment focuses on symptoms. Oil-in-water lubricants such as Alpha-Keri oil tend to be the most effective for dryness. Topical corticosteroids may be ordered for their anti-inflammatory properties. Topical calcineurin inhibitors also reduce the inflammatory response and relieve itching and rash when steroids are not effective. If skin lesions become infected, topical or systemic antibiotics are prescribed.

Anaphylaxis

Anaphylaxis is a severe systemic type I hypersensitivity reaction. There are numerous causes of anaphylaxis (Table 18.1).

TABLE 18.1 SUBSTANCES THAT COMMONLY TRIGGER ANAPHYLACTIC REACTIONS

Antibiotics	Foods
Penicillins	Beans
Sulfonamides	Chocolate
Tetracyclines	Eggs
Cephalosporins	Fruits (e.g., strawberries)
Amphotericin B	Grains (e.g., wheat)
Aminoglycosides	Nuts
	Shellfish
Medical Products	
Latex rubber	
Diagnostic Agents	Pollens
Contrast dyes	Grass
	Ragweed
Anesthetics/Antiarrhythmics	Proteins
Lidocaine	Horse serum
Procaine	Rabbit serum
Other Medications	Venoms
Barbiturates	Bees, wasps, hornets
Phenytoin (Dilantin)	Fire ants
Protamine	Snakes
Salicylates	
Diazepam (Valium)	
Food Additives	Hormones
Bisulfites	Insulin
Monosodium glutamate (MSG)	Vasopressin
	Estradiol
	Adrenocorticotrophic hormone

PATHOPHYSIOLOGY. IgE antibodies produced from previous antigen sensitization are attached to mast cells throughout the body. In this reaction, the antigen is introduced at a systemic level, which causes widespread release of histamine and other chemical mediators contained within the mast cells

The most profound complications of an anaphylactic reaction are respiratory and cardiac arrest. Immediate treatment is necessary to prevent death.

SIGNS AND SYMPTOMS. Anaphylaxis produces sudden and life-threatening signs and symptoms (Table 18.2). Generalized smooth muscle spasms occur, causing bronchial narrowing and creating stridor, wheezing, dyspnea, and laryngeal edema, which can lead to respiratory arrest. Cramping, diarrhea, nausea, and vomiting also result from these spasms. Capillary permeability increases, allowing

fluid to shift from the vessels to the interstitium. This causes hypotension, tachycardia, and an increase in respiratory symptoms. The blood volume within the vessels decreases while the blood vessels dilate, resulting in a further decrease in circulating blood volume. The dilation also causes diffuse erythema (redness) and warmth of the skin. Neurological changes include apprehension, drowsiness, profound restlessness, headache, and possible seizures.

DIAGNOSTIC TESTS. There is no time for tests to be performed during an anaphylactic reaction other than those needed to guide symptom treatment, such as arterial blood gases or electrocardiogram (ECG) monitoring. Anaphylaxis is diagnosed based on physical assessment and history from the patient or significant other. After the patient's recovery, allergen testing may be considered for future prevention.

THERAPEUTIC INTERVENTIONS. Intravenous access is a priority for administration of intravenous epinephrine and vasopressor drugs (dopamine) to increase blood pressure. Oxygen therapy is started. If respiratory symptoms are severe, a tracheostomy or endotracheal intubation may be necessary, with mechanical ventilation. Antihistamines and corticosteroids may also be given orally, by injection, or intravenously.

CRITICAL THINKING

Mrs. Barnes

■ Mrs. Barnes, a 32 year old, was brought into the emergency room after having been stung multiple times by bees while gardening. She has numerous red welts over her body which she states are itchy and is very anxious. Her temperature is 99.2°F (37.22°C), blood pressure is 102/58 mm Hg, pulse is 102 bpm, and respiratory rate is 26 per minute.

1. What might be causing Mrs. Barnes's symptoms?
2. What additional information is needed?
3. What should you do to help Mrs. Barnes?

Suggested answers at end of chapter.

Urticaria

PATHOPHYSIOLOGY. Urticaria (hives) is a type I hypersensitivity reaction. The antigen-stimulated reaction of IgE antibodies causing the release of mast cell contents, especially histamine, triggers urticaria.

ETIOLOGY. There are numerous causes of urticaria. In addition to medications and foods, cold, local heat, pressure, and stress can also cause urticaria. Many patients with underlying chronic conditions, such as systemic lupus erythematosus, lymphoma, hyperthyroidism, or cancer, are susceptible to urticaria.

SIGNS AND SYMPTOMS. The lesions of urticaria are raised, pruritic, nontender, and erythematous wheals on the

skin. They tend to be concentrated on the trunk and proximal extremities.

DIAGNOSTIC TESTS. Diagnosis is made on the basis of physical examination and history.

THERAPEUTIC INTERVENTIONS. Treatment depends on the degree of symptoms. In the most severe cases, epinephrine may be given to quickly resolve the urticaria. Corticosteroids (orally, topically, or intravenously) may be given. Antihistamines and histamine (H₂) blockers may aid in resolution by blocking the release of histamine.

Angioedema

PATHOPHYSIOLOGY AND ETIOLOGY. Angioedema is a form of urticaria. The pathophysiology and etiology of angioedema are the same as for urticaria. However, angioedema affects submucosal and subcutaneous tissues rather than the skin.

SIGNS AND SYMPTOMS. Angioedema is painless and minimally pruritic, with dermal erythematous and subcutaneous eruptions. There is also skin and mucous membrane edema. The eruptions may last longer than with urticaria.

DIAGNOSTIC TESTS. A comprehensive history and physical examination confirm the diagnosis. Skin testing may be performed to determine the specific antigen.

THERAPEUTIC INTERVENTIONS. The most basic treatment involves avoidance of the antigen. Symptomatic relief may be obtained through the use of antihistamines and corticosteroids. For long-term treatment, immunotherapy for allergen desensitization may be indicated.

NURSING PROCESS: HYPERSENSITIVITY DISORDERS

TYPE I. Assessment/Data Collection. Gather information about the patient's signs and symptoms. Immediately report any sudden dyspnea, shortness of breath, anxiety, restlessness, or chest or back pain. Identify any allergies the patient may have as well as the signs and symptoms that occur with exposure to the allergen. Perform a thorough skin assessment and carefully document any lesions or rashes. Note any changes in rashes or lesions or **signs of infection: redness, warmth, drainage.** Assess the patient's knowledge of disease process, **causes, treatment plan, and self-care.** **Note responses to treatments.**

Nursing Diagnosis, Planning, and Implementation.
Impaired gas exchange related to laryngeal edema

EXPECTED OUTCOME: The patient will maintain clear lung fields and remain free of signs of respiratory distress.

- Monitor respiratory rate, depth, and effort such as use of accessory muscles, nasal flaring, or abdominal breathing *to identify problems early.*
- Monitor the patient for restlessness, changes in mentation, level of consciousness, changes in voice, or dysphagia *in order to identify problems and intervene early.*

- Position the patient in a high-Fowler's or semi-Fowler's position *in order to improve ventilation and decrease upper airway edema.*

Anxiety related to dyspnea or pruritus

EXPECTED OUTCOME: The patient will state anxiety is controlled.

- Stay with the patient and speak calmly *to reduce fear or frustration.*
- Teach patient to visualize the absence of anxiety, itching or dyspnea *to decrease anxiety.*
- Provide family with the information needed to distinguish between anxiety or panic versus a serious physiological problem *in order to make informed decisions regarding obtaining emergency medical care.*

Risk for impaired skin integrity related to effects of allergic reaction

EXPECTED OUTCOME: The patient's skin will remain intact.

- Assess and document skin and lesions *to provide a basis for interventions and evaluation.*
- Teach patient to keep fingernails short and clean *to minimize the damage or risk for infection if scratching does occur.*
- Teach patient to apply clean, white cotton clothing over affected area (socks, gloves/mittens, undershirt), especially at bedtime *to minimize scratching while allowing for air movement with minimal irritation from dyes.*
- Teach patient to use gentle rubbing or pressure instead of scratching *to minimize the amount of skin trauma.*

Ineffective health maintenance related to lack of knowledge of methods to decrease inflammation and pruritus and reduce episodes of inflammation

EXPECTED OUTCOME: The patient or caregiver will state understanding and follow the mutually agreed upon plan of care.

- Assess patient's knowledge of disease and its causes *to provide a basis for teaching and evaluation.*
- Assess patient's values and beliefs regarding plan of care *in order to have patient's values and beliefs correspond with the plan of care, thereby improving compliance.*
- Assess barriers to patient's ability to carry out plan of care and plan interventions to decrease barriers *in order to improve the likelihood of the patient implementing the plan of care.*
- Teach patient to wear medical alert identification for allergies *in order for prompt medical attention to be given if the patient is unable to give information.*
- Discuss methods of avoiding allergen with patient such as wearing mask when mowing the lawn or working outdoors, having heating ducts cleaned, covering heat registers with filters, and frequent

home vacuuming and dusting to promote an understanding of preventative methods and prevent allergen exposure and anaphylaxis.

- If antigen is environmental (e.g., insect sting or foods) explain need to obtain prescription for epinephrine pen and teach how to use it. (See Chapter 17.)
- For atopic dermatitis, teaching plan includes signs and symptoms of infection, use of humidification during the winter months to prevent dryness, wearing cotton clothing to minimize irritation, and cool soaks to decrease pruritus.
- For urticaria, some patients may benefit from instruction on stress management and relaxation techniques to relieve urticaria. Teach patient to follow therapeutic regimen including prescribed medications and their correct usage to reduce symptoms.
- Document teaching and patient understanding.

Evaluation. If interventions have been effective, there will be no signs of respiratory distress and the lung fields will be clear. The patient's posture, facial expressions, gestures, and concentration will reflect no anxiety. The skin will remain intact. If there are lesions, they will be reduced and healing. The patient will express knowledge of disorder and treatment plan. The patient will verbalize no barriers to attaining treatment goals.

Type II

A type II hypersensitivity reaction involves the destruction of a cell or substance that has an antigen attached to its cell membrane, which is sensed by either immunoglobulin G (IgG) or immunoglobulin M (IgM) as being a foreign antigen (Fig. 18.2). When an antigen marker is sensed as foreign, an antibody attaches to the antigen on the cell membrane, causing lysis of the cell or accelerated phagocytosis (engulfing and ingestion). When a cell is foreign, such as a bacterium, this process is beneficial. However, sometimes antigens on the surface of a red blood cell (RBC) can be sensed as foreign for the different ABO blood types, which results in the RBC being destroyed.

Hemolytic Transfusion Reaction

PATHOPHYSIOLOGY. A hemolytic transfusion reaction is a type II hypersensitivity reaction in which incompatible surface antigens on RBCs are transfused. These antigens may be ABO or Rh incompatible. The recipient's antibodies attach to the foreign antigens on the transfused RBCs causing rapid lysis of the RBC. The rapid RBC lysis results in a massive amount of cellular debris that occludes the blood vessels throughout the body. This leads to ischemia and necrosis of tissue and organs and can be life threatening.

ETIOLOGY. Occasionally, antibodies form after a bacterial or viral infection. However, prior sensitization is usually from a previous blood transfusion or past pregnancy. ABO and Rh blood type must be matched for transfusions. The ABO blood types are A, B, AB, and O. People with blood

FIGURE 18.2 Type II hypersensitivity

type O are universal donors as they do not have A or B antigens. However, those with type O blood can receive only type O blood. Individuals with type AB blood are universal recipients, as they do not make A or B antibodies. Those with blood types other than AB can not receive AB blood as they have A or B antibodies.

Rh antigens are present in persons who are Rh⁺. Rh antibodies are present in those who are Rh⁻. Those who are Rh⁺ can receive Rh⁻ blood but those who are Rh⁻ have antibodies to Rh⁺ blood. If maternal and fetal blood Rh factors (RBC surface antigens) are different, the mother becomes sensitized by the fetal Rh type, which can affect future fetuses. For example, a Rh₀(D)-negative pregnant woman becomes sensitized by a Rh₀(D)-positive fetus. As a result, the blood cells of future Rh₀(D)-positive fetuses can be destroyed by maternal antibodies crossing the placenta.

CRITICAL THINKING

Blood Types

1. Who is the universal ABO Rh recipient?
2. Who is the universal ABO Rh donor?
3. Can someone with an A Rh⁻ blood type safely receive O Rh⁺ blood?

Suggested answers at end of chapter.

SIGNS AND SYMPTOMS. With a hemolytic transfusion reaction, there is usually a rather sudden onset of low back (flank) or chest pain, hypotension, fever rising more than 1.8°F (1°C), chills, tachycardia, tachypnea, wheezing, dyspnea, urticaria, and anxiety (Table 18.3). The patient may also complain of a headache and nausea.

DIAGNOSTIC TESTS. The direct Coombs' test confirms this diagnosis. In the laboratory, a small amount of the patient's RBCs are washed to remove any unattached antibodies. Antihuman globulin is added to see if agglutination (clumping) of the RBCs results. If agglutination occurs, an immune reaction such as a hemolytic transfusion reaction is taking place.

THERAPEUTIC INTERVENTIONS. To prevent production of anti-Rh₀(D) antibodies, a Rh₀(D) immune globulin (RhoGAM) injection is given to Rho(D)-negative patients accidentally given Rh₀(D)-positive blood or exposed to Rho(D)-positive fetal blood by delivery, miscarriage, abortion, amniocentesis, or intra-abdominal trauma. When antibodies do not form, then a hemolytic reaction can be prevented.

If a reaction occurs, examples of medications used to treat the reaction are listed in Table 18. 4.

NURSING PROCESS: HEMOLYTIC TRANSFUSION REACTION. Assessment/Data Collection. Prevention of hemolytic reactions is crucial. Following strict institutional

guidelines for blood transfusion administration helps ensure the patient's safety. After blood is released from the hospital blood bank, two nurses, designated per institutional policy, double-check specified data. At the bedside, transfusion guidelines include double-checking the patient's name and identification number on the chart, unit of blood, and patient's identification bracelet, as well as checking the patient's blood type in the chart, on the unit of blood, and paperwork with the unit of blood.

Agency policy is followed for taking vital signs during a blood transfusion. Minimally, vital signs are taken before the beginning of the blood transfusion, at 15 minutes into the transfusion and when the transfusion is completed. It takes only a small amount of blood to trigger a hemolytic transfusion reaction, so it is critical to stay with the patient at the bedside during the first 15 minutes of any blood transfusion. This enables detection of a blood transfusion reaction early for quick action to minimize cell destruction and complications, including death.

If symptoms of a reaction are noted, the blood is immediately stopped and agency policy for a suspected transfusion reaction is followed. A normal saline infusion with new tubing is started to keep the vein patent. The physician and blood bank are immediately notified. A nurse remains with the patient for reassurance and monitoring of symptoms and vital signs. If a blood incompatibility is suspected, the unused blood and blood tubing is returned to the blood bank for testing. A series of blood and urine specimens are collected and sent to the laboratory for analysis. The physician's orders are followed to treat the patient's symptoms.

TABLE 18.3 HEMOLYTIC TRANSFUSION REACTION SUMMARY

Signs and Symptoms	Low back or chest pain Hypotension Fever rising more than 1.8°F (1°C) Chills Tachycardia Tachypnea, wheezing, dyspnea Urticaria Anxiety Headache Nausea
Diagnostic Tests	Direct Coombs' test - small amount of patient's RBCs are washed - antihuman globulin is added - if agglutination (clumping) occurs, an immune reaction is occurring
Therapeutic Interventions	Depends on severity of reaction and organs affected Antihistamines Corticosteroids Epinephrine Diuretics, to assist kidneys
Complications	If severe: shock, acute renal failure
Possible Nursing Diagnoses	Fear Ineffective tissue perfusion Risk for injury

SAFETY TIP

Every unit of blood, even of the same blood type, is unique and can trigger a blood transfusion reaction. Careful monitoring with every transfusion is necessary.

Nursing Diagnosis, Planning, and Implementation. Fear related to serious threat to health status

EXPECTED OUTCOME: The patient will state reduced fear.

- Allow patients to express their concerns *to allow inaccurate information to be corrected.*
- Inform patients about procedures and treatments *to reduce fear.*
- Remain with patient and allow significant others *to offer support.*

Ineffective tissue perfusion: cardiopulmonary, peripheral related to arterial/venous blood flow exchange problems

EXPECTED OUTCOME: The patient demonstrates adequate tissue perfusion AEB palpable peripheral pulses,

TABLE 18.4 MEDICATIONS USED IN HEMOLYTIC TRANSFUSION REACTIONS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antihistamines				
Block histamine at histamine ₁ -receptors therefore preventing or reversing the effects of histamine (capillary permeability, itching, and bronchospasms)	Diphenhydramine (Benadryl)	PO	Significant drowsiness	Take with or without food; avoid ETOH & CNS depressants & OTC antihistamines; avoid prolonged exposure to sunlight; caution with activities requiring mental alertness
	Cetirizine (Zyrtec)	PO	Once a day dosing; nonsedating; highly protein bound	
	Azelastine (Astellin)	Intranasal	Nasal mucosa irritation General side effects: dry mouth; fatigue, pharyngitis, dizziness	
Corticosteroids				
Hormones with marked anti-inflammatory effects due to inhibition of prostaglandin synthesis and accumulation of macrophages and leukocytes at site.	Dexamethasone (Decadron)	IM IV	Burning, dryness, stinging, headache, edema, muscle wasting, thrombophlebitis, masking of infections, elevation of blood glucose, gastric irritation	Take PO with food. NEVER stop taking suddenly. Monitor weight. Assess for edema, shortness of breath, jugular vein distention, and signs/symptoms of congestive heart failure. Monitor blood glucoses. Monitor for signs/symptoms of GI bleeding.
	Hydrocortisone (Solu-Cortef)	PO Topical		
	Methylprednisolone (Solu-Medrol)	Ophthalmic Intra-articular		
	Prednisolone (Delta-Cortef)			
	Prednisone (Deltasone)			
	Beclomethasone (Beconase)			
Sympathomimetics				
Marked stimulation of alpha and beta _{1&2} receptors causing vasoconstriction, bronchodilation, and cardiac stimulation	Epinephrine (Adrenalin) (EpiPen)	IM IV SQ Inhalation Topical	Disorientation, panic, anxiety; ventricular fibrillation; cerebral hemorrhage, decreased urine output, urinary retention, angina	Only use 1:1000 solution for IV; 1:100 IV will cause death. Do not expose drug to heat, light, or air. Ophthalmic and nasal preparations may sting. May elevate blood sugar.

urinary output of 30 mL per hour, and no respiratory distress.

- Maintain airway and provide oxygen to promote oxygenation.
- Monitor vital signs, intake and output to detect changes for prompt treatment.
- Position patient with head elevated if short of breath to aid breathing.
- Assess for pain and provide pain relief measures.

Risk for injury related to prolonged shock resulting in multiple organ failure, death

EXPECTED OUTCOME: The patient will remain free of injury.

- Use two methods to identify client before giving blood products to prevent incorrect identification and administration of blood product.
- Remain with patient during first 15 minutes of transfusion and then obtain vital signs to detect signs of reaction.
- Give medications as ordered to support affected tissues and organs such as epinephrine or steroids.

- Give diuretics as ordered to assist kidney excretion of cellular debris from reaction.

Deficient knowledge related to lack of exposure to blood transfusions

EXPECTED OUTCOME: The patient will state understanding of blood transfusion options.

- Encourage patient to discuss autologous (self) blood donation option with physician. This may be an option for patients having elective surgery to avoid a transfusion reaction.
- After a hemolytic transfusion reaction, tell patients importance of informing future health care providers of reaction, so that specific blood tests are performed for less common antibodies if the patient is ever typed for a blood transfusion again.

Evaluation. If interventions have been effective, the patient states reduced fear, shows normal organ and tissue function, and reports understanding of blood transfusion options to prevent transfusion reactions.

FIGURE 18.3 Type III hypersensitivity

Type III

A type III hypersensitivity reaction involves immune complexes formed by antigens and antibodies, usually of the IgG type (Fig. 18.3). The patient is sensitized with an initial exposure to the antigen, and on a subsequent exposure the reaction occurs. The reaction is localized and evolves over several hours, with symptoms ranging from a red, edematous skin lesion to hemorrhage and necrosis. The process involves the formation of antigen-antibody complexes within the blood vessels as the antigen is absorbed through the vessel wall. Neutrophils are attracted to the area and release enzymes that ultimately lead to blood vessel damage.

Serum Sickness

PATHOPHYSIOLOGY. Serum sickness is a type III hypersensitivity immune reaction in which antigen-antibody complexes are formed and cause symptoms of inflammation.

ETIOLOGY. In the past, serum sickness occurred after inoculation of equine (horse) antiserum for diseases such as tetanus and diphtheria. With the refinement of these vaccines, serum sickness does not usually occur from them. Today, serum sickness is seen occasionally after administration of penicillin and sulfonamide.

SIGNS AND SYMPTOMS. The signs and symptoms usually occur 7 to 10 days after the exposure. The most predominant manifestation is severe urticaria and angioedema. The patient may experience a fever, malaise, muscle sore-

ness, arthralgia, splenomegaly, and occasionally nausea, vomiting, and diarrhea. Lymphadenopathy may occur, especially of the lymph nodes closest to the antigen entry site.

DIAGNOSTIC TESTS. With serum sickness there is often a slight elevation in the white blood cell count and the sedimentation rate, and complement assay decreases.

THERAPEUTIC INTERVENTIONS. Antipyretics may be given for the fever and analgesics for the arthralgia. Antihistamines and epinephrine may be prescribed for the urticaria and angioedema. If the symptoms continue to persist, corticosteroids may be ordered.

NURSING PROCESS: SERUM SICKNESS. Assessment/Data Collection. Symptoms are noted. Responses to prescribed medications is documented. Identification of the causative agent may be done through the history-taking process and is important for the patient to know to prevent a recurrence of the condition.

Nursing Diagnosis, Planning, and Implementation. Pain related to muscle and joint soreness

EXPECTED OUTCOME: The patient will state pain is reduced to acceptable level.

- Monitor pain using pain rating scale of 0 to 10.
- Provide analgesics as ordered to relieve symptoms.

Risk for deficient fluid volume related to fever and gastrointestinal fluid loss

EXPECTED OUTCOME: The patient will maintain blood pressure, pulse, and urine output within normal limits.

- Observe for signs of hypovolemia: restlessness, weakness, muscle cramps, headaches, inability to concentrate, irritability and postural hypotension.
- Monitor intake and output *to detect imbalances*.
- Provide antiemetics as ordered *to relieve nausea*.
- Encourage oral replacement therapy with hypotonic glucose-electrolyte solutions such as sports replacement drinks, or ginger ale *as they increase fluid absorption and correct deficient fluid volume*.
- If ordered, maintain IV fluids at ordered rate *to replace lost fluids but avoid fluid overload*.

Evaluation. Goals are met if the patient reports less pain, and if vital signs and urine output are within normal limits.

Type IV

A type IV hypersensitivity reaction, also called a delayed reaction, occurs when a sensitized T lymphocyte comes in contact with the particular antigen to which it is sensitized (Fig. 18.4). The resulting necrosis is caused by the actions of the macrophages and the various T lymphocytes involved in the cell-mediated immune response.

Contact Dermatitis

PATHOPHYSIOLOGY. When a substance or chemical comes in contact with the skin, it is absorbed into the skin and binds with special skin proteins called haptens. With the

FIGURE 18.4 Type IV hypersensitivity

first contact, there is no reaction or symptoms, but within 7 to 10 days, T memory cells are formed. Therefore, on subsequent exposures, the T memory cells quickly become activated T cells, which secrete the chemicals that may cause symptoms.

ETIOLOGY. Poison ivy and poison oak are the most common irritants causing this reaction. Latex rubber has also been found to be a cause for contact dermatitis and can trigger type I anaphylactic reactions.

Latex Allergy. Latex allergy is a serious problem for health-care workers. Anaphylactic reactions to latex can be fatal. Exposure to latex for health-care workers has increased dramatically since the implementation of universal precautions and the use of latex gloves began in 1987. Many times latex gloves are worn unnecessarily, which increases exposure to the latex protein. Latex-free gloves are available for health-care workers. For patients who are allergic to latex, special protocols are followed using latex-free equipment. For information about latex allergy, visit the American Academy of Allergy, Asthma, and Immunology at www.aaaai.org. Also visit the U.S. Food and Drug Administration at www.fda.gov.

SIGNS AND SYMPTOMS. Within a number of hours from the exposure, the area of contact becomes reddened and pruritic, with fragile vesicles. Secondary infections may develop. (See earlier discussion of atopic dermatitis.)

DIAGNOSTIC TESTS. Diagnosis is made by assessment of the skin and lesions and a detailed patient history.

THERAPEUTIC INTERVENTIONS. Treatment consists of controlling symptoms. Oral or topical antihistamines and topical drying agents may be used. Topical corticosteroids may be used, and if the symptoms are severe, systemic corticosteroids may be prescribed.

NURSING PROCESS: CONTACT DERMATITIS.

Assessment/Data Collection. Symptoms are assessed for planning of interventions. Identification of the causative agent is noted in the patient's history. Patient recognition of the cause is important to prevent a recurrence of the condition. Special protocols are used for patients allergic to latex. Some institutions may prepare special latex free kits containing common supplies nurses use to care for patients. Ensure that latex allergy protocols are followed if a patient has a latex allergy to prevent life threatening anaphylaxis that could develop.

Nursing Diagnosis, Planning, and Implementation. See Box 18.1 Nursing Care Plan for the Patient with Contact Dermatitis.

Transplant Rejection

ETIOLOGY AND PATHOPHYSIOLOGY. Any form of transplanted living tissue is sensed as foreign material by the immune system. This is why lifelong immunosuppression is necessary to help prevent transplant rejection, which can occur at any time. Lymphocytes become sensitized during an induction phase immediately after the tissue is trans-

Box 18.1 NURSING CARE PLAN for the Patient with Contact Dermatitis

Nursing Diagnosis: Risk for impaired skin integrity related to effects of allergic reaction and pruritus

Patient Outcomes Patient's skin will remain intact.

Evaluation of Outcome Is patient's skin intact? If not intact, is skin healing? Does patient express a plan for preventing impaired skin integrity?

Interventions

Assess and document skin and lesions.

Teach patient to keep fingernails short and clean.

Teach patient to apply clean, white cotton clothing over affected area (soaks, gloves/mittens, undershirt), especially at bedtime.

Teach patient to use gentle rubbing or pressure instead of scratching.

Explain tepid baking soda baths, colloidal oatmeal baths (e.g., Aveeno), and cool washcloths or cool baths reduce itching.

Rationale

Assessment provides a basis for intervention planning and evaluation of healing.

Short, clean nails cause less damage or infection if scratching occurs.

Cotton allows air movement. White cloth is less irritating than those with dyes. Scratching is decreased during sleep with the use of gloves/mittens or covering affected area.

Use of gentle rubbing or pressure instead of scratching causes less skin trauma.

These items help dry the vesicle and minimize the pruritus.

Evaluation

Are lesions present? Are lesions healing?

Does skin remain intact in spite of scratching?

Are symptoms of skin irritation reduced?

Does skin remain intact in spite of itchy sensation?

Is itching reduced?

Nursing Diagnosis: Ineffective health maintenance related to lack of knowledge of methods to decrease inflammation and reduce episodes of inflammation

Patient Outcomes Patient or caregiver will follow the mutually agreed upon plan of care.

Evaluation of Outcome Can patient express knowledge of etiology, signs and symptoms, and treatment plan? Does patient discuss any emotional, social, financial, or material blocks to attaining treatment goals?

Interventions

Assess patient's knowledge of disease and causes.

Assess patient's values and beliefs regarding plan of care.

Assess barriers to patient's ability to carry out plan of care and plan interventions to decrease barriers.

Teach patient to wear medical alert identification for allergen.

Discuss methods of avoiding allergen with patient.

Teach patient to wash with a brown soap (e.g., Fels-Naptha) or, if unavailable, any soap when contact with the offending agent is suspected.

Teach patient not to scratch skin.

Rationale

Assessment provides a basis for the teaching plan.

Patients are more compliant if their belief system fits into plan of care.

Barriers can prevent patient from carrying out plan of care.

With allergen identification, prompt medical care can be given in case patient is unable to give information.

Understanding prevention methods can help prevent allergen exposure.

This removes offending agent.

Scratching can spread the dermatitis, as well as cause infection.

Evaluation

Does patient state baseline knowledge?

Does patient's belief system work with plan of care?

Are barriers identified? Are solutions to barriers planned?

Does patient agree to use allergen identification?

Can patient state methods to help prevent allergen exposure?

Does patient state understanding of need to wash off agent with exposure?

Does patient avoid scratching?

planted. If immunosuppression is not effective, the sensitized lymphocytes invade the transplanted tissue and destroy it via the release of chemicals and macrophage activity resulting in varying degrees of transplant rejection.

SIGNS AND SYMPTOMS. Various signs and symptoms occur depending on the transplanted tissue or organ that is involved and the severity of the rejection (Table 18.5). Signs and symptoms reflect failure of the organ or tissue, such as renal failure for a rejected kidney.

COMPLICATIONS. A total failure and loss of the transplanted tissue or organ can occur, or the tissue or organ can be damaged from immunological reactions and not function at full capacity. The greatest cause of death following a transplant is from infection. Immunosuppression therapy, which is necessary to prevent tissue rejection following the transplant, is a major contributory factor for severe infection development. Because the immune system is suppressed, it is unable to effectively fight infections.

DIAGNOSTIC TESTS. Biopsy, scans, blood tests, arteriography, and ultrasonography are some tests that may be performed to aid in diagnosing a transplant rejection.

THERAPEUTIC INTERVENTIONS. Depending on the type of transplant, the body's immunological system is prepared before surgery with medications, transfusions, or radiation to minimize the risk of rejection. After the transplant, lifelong immunosuppression is needed. If rejection occurs, medications may be used to attempt to reverse the rejection. Supportive care is provided based on the failing organ such as hemodialysis if a kidney rejection occurs.

TABLE 18.5 TRANSPLANT REJECTION SUMMARY

Signs and Symptoms	Depending on: - the involved transplanted tissue or organ - severity of reaction Reflect failure of the organ or tissue
Diagnostic Tests	Biopsy Scans Blood tests Arteriography Ultrasonography
Therapeutic Interventions	Depends upon the type of transplant Preventative preoperative preparation with medications, transfusions, or radiation to minimize the risk of rejection
Complications	Total failure and loss of transplanted organ or tissue Cause of death is most commonly due to infection with immunosuppression therapy a contributory factor
Possible Nursing Diagnoses	Grieving (actual or anticipatory) Fear Deficient knowledge Others depend upon which organ is failing

NURSING MANAGEMENT. Nursing care depends greatly on the type of transplant performed. Initially the patient is in an intensive care unit under close observation and support. Observing for signs of rejection is a priority throughout the patient's hospitalization. Another consideration for nursing care is the psychological support of the patient and family. Many patients wait on a transplant list a long time before a donor match is found. Once a matching donor is found, there is usually great elation. Yet if a donor's death made the transplant possible, the patient and family may be simultaneously feeling a profound sadness for the donor's family. Patients need time to verbalize feelings and understand that these feelings are normal and diminish with time. Also, the fear of transplant rejection is always present and must be discussed.

Education. Rejection can take place weeks, months, or years following a transplant (with decreasing risk). The patient and family need to be educated about specific signs and symptoms of rejection. Also, because infection is a major complication resulting from long-term immunosuppressive medications, the patient and family need to know signs and symptoms of infection and when to notify the physician of problems. Steroid use may mask the symptoms of infection, so small indicators such as a low-grade fever should be promptly reported. Education regarding prescribed medications is a must because long-term success of a transplant is dependent on compliance with immunosuppressive medication therapy. Avoidance of people with colds or infections is also important to reduce the patient's infection risk due to immunosuppression.

AUTOIMMUNE DISORDERS

In autoimmune disorders, the immune system no longer recognizes the body's normal cells as self and not foreign. Instead the antigens on these normal body cells are recognized as foreign material, and an immune response to destroy them is launched.

A number of factors either cause or influence this breakdown of self-recognition, including viral infections, drugs, and cross-reactive antibodies. Some microbes stimulate the production of antibodies but are so closely related to normal cell antigens that the antibodies also attack some normal cells. Hormones have also been found to influence this breakdown of self-recognition.

Table 18.6 lists additional autoimmune disorders and the chapters in which they are discussed.

Pernicious Anemia

PATHOPHYSIOLOGY. Antibodies that destroy gastric parietal cells lead to decreased production of intrinsic factor. Intrinsic factor plays a role in vitamin B₁₂ absorption in the small bowel, so a vitamin B₁₂ deficiency may result causing decreased production of RBCs. Intrinsic factor is involved in most vitamin B₁₂ absorption, but there is now evidence that

TABLE 18.6 AUTOIMMUNE DISORDERS

Disorder	Refer to
<i>Idiopathic thrombocytopenic purpura</i>	Chapter 28
<i>Multiple sclerosis</i>	Chapter 50
<i>Myasthenia gravis</i>	Chapter 50
<i>Rheumatoid arthritis</i>	Chapter 46
<i>Ulcerative colitis</i>	Chapter 34

there is a route independent of intrinsic factor for some absorption of vitamin B₁₂. This has important treatment implications.

ETIOLOGY. There tends to be a familial tendency toward pernicious anemia in relation to immune causes. Non-immune-related causes of pernicious anemia include any type of gastric or small bowel resections coupled with no or inadequate vitamin B₁₂ or intrinsic factor replacement.

SIGNS AND SYMPTOMS. The patient experiences increasing weakness, loss of appetite, glossitis, and pallor. Irritability, confusion, and numbness or tingling in the extremities (peripheral neuropathy) occur because the nervous system is affected.

DIAGNOSTIC TESTS. On microscopic examination of the patient's RBCs, macrocytic (enlarged cells) anemia is diagnosed. Macrocytic anemia and low vitamin B₁₂ levels are indicators of pernicious anemia and folic acid deficiency. To determine if the diagnosis is pernicious anemia, intrinsic factor antibodies and parietal cell antibodies can be tested. A Schilling test may be done but is used less today as it is complicated. For the Schilling test, radioactive vitamin B₁₂ is administered to the patient. The patient's urine is then collected for 24 hours (48 hours for patients with renal disease), and the amount of radioactive vitamin B₁₂ excreted in the urine is measured. If intrinsic factor is decreased, gastric absorption of vitamin B₁₂ is also decreased, so that more vitamin B₁₂ is excreted in the urine. Gastric secretion analysis is done to measure levels of hydrochloric acid (HCl) because low or absent HCl may be indicative of pernicious anemia.

THERAPEUTIC INTERVENTIONS. Corticosteroids may correct the problem if it is immunologically caused. Otherwise vitamin B₁₂ therapy is needed usually for life. It has been found that oral vitamin B₁₂ can be effective so that injections may not be needed as was thought in the past.^{1,2}

NURSING MANAGEMENT. Vitamin B₁₂ is administered as ordered. Care related to fatigue and safety are important. Ambulation, frequent rest periods, and providing assistance with activities of daily living (ADLs) as indicated by the patient's activity tolerance are helpful for the patient with anemia.

Education. The patient and family need education regarding oral or parenteral medication therapy. If vitamin B₁₂ injections are prescribed, they must understand that this is a lifelong need to prevent the return of symptoms. Patients

should not miss injections, periodic B₁₂ level testing, or follow-up appointments.

Idiopathic Autoimmune Hemolytic Anemia

PATHOPHYSIOLOGY. Autoantibodies, for no known reason, are produced that attach to RBCs and cause them to either lyse or agglutinate (clump). When lysis occurs, fragments of the destroyed RBCs circulate in the blood. If agglutination occurs, occlusions in the small blood vessels followed by tissue ischemia occurs.

SIGNS AND SYMPTOMS. Clinical manifestations vary from mild fatigue and pallor to severe hypotension, dyspnea, palpitations, and jaundice.

DIAGNOSTIC TESTS. The RBC count, hemoglobin (Hgb), and hematocrit (Hct) are low, and microscopic examination reveals fragmented RBCs. Lactate dehydrogenase (LDH) is elevated because of RBC destruction and tissue ischemia.

THERAPEUTIC INTERVENTIONS. Supportive measures such as supplemental oxygen may be initiated. Folic acid may be prescribed to increase production of RBCs. The use of immunosuppressive medications and corticosteroids may be useful in obtaining remission. In more severe cases, blood transfusions and erythrocytapheresis (a process whereby abnormal RBCs are removed and replaced with normal RBCs) may be instituted. A splenectomy may be performed in an attempt to stop the destruction of RBCs for severe cases.

NURSING MANAGEMENT. The patient's signs and symptoms should be monitored and reported as necessary. Frequent rest periods should be planned into the patient's daily routine to prevent fatigue. Blood products are administered as ordered to replace RBCs.

Education. The patient and family are instructed on the medical regimen, and their understanding is verified.

Hashimoto's Thyroiditis

PATHOPHYSIOLOGY. Autoantibodies for thyroid-stimulating hormone (TSH) form in Hashimoto's thyroiditis. However, instead of inactivating TSH, the autoantibodies bind with the hormone receptors on the thyroid gland and stimulate the thyroid gland to secrete thyroid hormones. The thyroid gland enlarges as a result of this overstimulation (hyperthyroidism). It becomes infiltrated with lymphocytes and phagocytes, causing inflammation and further enlargement. Then different autoantibodies appear that destroy thyroid cells, which slows secretion activity, causing hypothyroidism.

ETIOLOGY. The exact cause is unknown, although it occurs in females eight times more often than in males. It is also more common in people 30 to 50 years old and patients with Down's syndrome and Turner's syndrome.

SIGNS AND SYMPTOMS. Initially the manifestations are those of hyperthyroidism, such as restlessness, tremors, chest pain, increased appetite, diarrhea, moist skin, heat intolerance, and weight loss.

These manifestations may go unrecognized and progress quickly into hypothyroidism. At this point, an enlarged thyroid gland (goiter) may be seen. Clinical manifestations may include fatigue, bradycardia, hypotension, dyspnea, anorexia, constipation, dry skin, weight gain, sensitivity to cold, facial puffiness, and a slowing of mental processes.

DIAGNOSTIC TESTS. Immunofluorescent assay, a test that detects antigens on cells using an antibody with a fluorescent tag, detects antithyroid antibodies. Serum thyroid-stimulating hormone levels are elevated, while triiodothyronine (T_3) and thyroxine (T_4) levels are low. A thyroid scan is also done.

THERAPEUTIC INTERVENTIONS. Thyroid hormone replacement therapy of thyroxine is the primary means of treatment. Lifelong thyroid hormone therapy is needed.

NURSING MANAGEMENT. If the patient has a goiter, a soft diet may be necessary for comfort. Frequent rest periods may be necessary, as well as slowly increasing patient activity. Antiembolic stockings may help prevent venous stasis during the low-energy, decreased-activity phase. Daily weights and monitoring intake and output when cardiac status is compromised are important to detect abnormalities such as fluid retention. Because weight gain and facial puffiness alter patients' self-image, they need an opportunity to verbalize their feelings to help them adjust to this disease process.

Education. Patients taking thyroid hormone replacement therapy should avoid foods high in iodine. The diet should also consist of large amounts of fiber to combat constipation. During the hyperthyroidism phase, a diet high in protein and carbohydrates encourages weight gain. Education regarding prescribed medications is also needed.

Lupus Erythematosus

PATHOPHYSIOLOGY. There are three types of lupus: discoid (DLE), drug-induced systemic lupus erythematosus, and systemic lupus erythematosus (SLE) (Table 18.7). The discoid type consists of skin lesions only. Drug-induced SLE develops after use of certain medications (see Table 18.8). SLE is a chronic, inflammatory, multisystem disorder. The body develops antibodies against its own tissue. It is very unpredictable. See Table 18.9 for a list of flare triggers.

Etiology

Systemic lupus erythematosus tends to develop in young women of child-bearing years and occurs in the African American and Hispanic populations more frequently. First-degree relatives of lupus patients also have a greater tendency than the general population to develop SLE.

SIGNS AND SYMPTOMS. Clinical manifestations vary from mild to severe. See Table 18.7 and Figure 18.5.

FIGURE 18.5 Lupus erythematosus: red papules and plaques in butterfly pattern on face. (From Goldsmith, LA, Tharp, M, Lazarus, G, et al: *Adult and Pediatric Dermatology*. FA Davis, Philadelphia, 1997, p. 230.)

Therapeutic Interventions

Medications used to treat lupus erythematosus are listed in Table 18.10.

NURSING MANAGEMENT. It is vitally important for the patient and family to be aware of and avoid flare triggers. Fatigue during activities of daily living can be minimized through the use of a daily personal schedule. Additionally, a minimum of 8 hours of sleep per night with naps as necessary are important to combat fatigue. Since the majority of patients with SLE develop transitory arthralgia, maintaining fitness and joint range of motion through a regular fitness program while decreasing activity during flares is vital. Warm baths may help with morning stiffness while application of heat and cold compresses, splints, assistive devices, and physical therapy may help soreness. Eating a well-balanced diet will also influence their level of fatigue and weight gain from the corticosteroids which in turn can affect the joint soreness too.

Education. Explain the signs of bleeding and of cardiac and vascular problems, such as myocardial infarction and thrombophlebitis. Encourage the use of a medical alert bracelet. Provide smoking cessation information to those patients who smoke. Since renal disease is a major complication of SLE, patients must learn the signs of impending problems that need to be relayed to the physician immediately. These are such findings as facial puffiness and “foamy” urine or “coke-colored” urine indicative of proteinuria and hematuria, respectively. Explain that regular ophthalmic examinations are necessary for early detection and treatment of the complications that the antimalarials and corticosteroids can produce, such as retinal bleeding, glaucoma, and cataracts.

Finally, but most importantly, the patient's psychological state and support systems need to be addressed. From the onset of symptoms to the diagnosing of lupus is usually costly in time, money, and emotions. Patients may exhibit anger, frustration, and confusion prior to the diagnosis. For many, at diagnosis, there is a sense of relief that may quickly be replaced with feelings of anger, fear, depression, or grief. It is here when empathy, support, hope, and, most importantly, education for the patient, family, and significant others is vital for successful long-term coping skills to be acquired. In addition, local support groups and educational and self-management programs available through the Lupus Foundation of America can provide avenues for attaining more specific knowledge and skills for coping and taking control of their lives.

CRITICAL THINKING

Mr. Ellis

■ Mr. Ellis is suffering from a flare of SLE. The physician has ordered Solu-Cortef 80 mg IM to be given every 8 hours. Solu-Cortef 125 mg per 2 mL is available. How many mLs will the nurse administer per dose?

Suggested answers at end of chapter.

Ankylosing Spondylitis

PATHOPHYSIOLOGY. Ankylosing spondylitis, also called rheumatoid spondylitis, is a chronic progressive inflammatory disease of the sacroiliac, costovertebral, and large peripheral joints. The inflammatory process begins in the lower region of the back and progresses upward. A

ankylosing spondylitis anayle—stiff joint + osing—condition + spondyl—vertebrae + itis—inflammation

TABLE 18.9 COMMON LUPUS ERYTHEMATOSUS FLARE TRIGGERS

Sunlight (can be reflected off water and snow, emitted from fluorescent and halogen lights; glass does not fully protect)
Stress
Emotional crisis
Overworked
Lack of rest
Infection
Surgery or injuries
Hormones
Pregnancy and postpartum
Stopping medications suddenly
Environmental sensitivities or allergies
Immunizations
Certain prescription drugs
Some over-the-counter drugs such as cough syrups

specific histocompatibility antigen (antigen that identifies self), human leukocyte antigen (HLA) B27, is formed that stimulates an immune response.

ETIOLOGY. There is strong evidence of a familial tendency, but no other specific causes are known. Ankylosing spondylitis tends to afflict men more than women.

SIGNS AND SYMPTOMS. There is an insidious onset of lower back stiffness and pain, which is worse in the morning. As the disease progresses, the pain worsens and there are spasms of the back muscles. The normal curvature of the lower back (lordosis) flattens, and the curvature of the upper back increases (kyphosis). Patients may also experience fatigue, anorexia, and weight loss.

DIAGNOSTIC TESTS. Findings such as a positive family history, radiographs of the joints, a positive HLA-B27 blood test, and negative Rh confirm a diagnosis of ankylosing spondylitis. There are no specific immunological tests to diagnose ankylosing spondylitis.

THERAPEUTIC INTERVENTIONS. Because there is no cure for ankylosing spondylitis, treatment consists of measures to minimize the symptoms. Analgesics for pain relief, anti-inflammatory agents to decrease joint inflammation, and physical therapy to maintain muscle strength and joint range of motion are used. Surgery can be done to replace fused joints. For kyphosis, cervical or lumbar osteotomy can be performed.

NURSING MANAGEMENT. Nursing care focuses on patient education and administration and evaluation of prescribed medications. Pain management, rest periods, and assistance with ADLs are provided.

Education. The patient and family need information about the disease process. Proper posture and range-of-motion exercises are taught and reinforced by nursing staff. The patient should also be instructed not to stay in any one position for any length of time. The patient should sleep on

TABLE 18.10 MEDICATIONS USED FOR LUPUS ERYTHEMATOSUS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Nonsteroidal Anti-inflammatory Drugs (NSAIDs)	Ibuprofen (Motrin)	PO	Gastric distress Headache Tinnitus Dizziness Rash Pruritus Fluid retention	Take with food Avoid taking with ethyl alcohol Protect from ultraviolet rays. Assess for abnormal bleeding.
	Indomethacin (Indocin) Naproxen (Naprosen)			
Antimalarials Action is not clearly understood but can significantly help reduce inflammation, decreases platelet aggregation while lowering plasma lipid levels	Chloroquine (Aralen)	PO	Gastric distress Anorexia, vomiting Diarrhea Headache Muscle weakness Alopecia Blurred vision Irritability Dry, itchy skin rash	Administer before or after meals at the same time of day. Obtain a thorough assessment for a baseline, including an ophthalmic exam. May take weeks or months for effects to be noticed.
	Hydroxychloroquine sulfate (Plaquenil)	PO		
Corticosteroids Reduces inflammation and suppresses immune response	Dexamethasone (Decadron)	PO IV IM topical inhaled	Increased facial hair, acne Round "moon" face Mood changes Irritability Depression Increased appetite Increased weight Poor wound healing Headache Peptic ulcers Osteoporosis Steroid-induced diabetes	NEVER stop taking suddenly. Don't miss doses. Measures to avoid infection. Take with food or milk. Assess for weight gain >5 pounds, decreased urine output, pulse irregularities, increased blood pressure, edema and temperature. May elevate blood sugar.
	Hydrocortisone (Solu-Cortef)	PO IV IM topical		
	Methylprednisolone (Solu-Medrol)	PO IM IV		
	Prednisone (Deltasone)	PO		
Immunosuppressants Target and damage autoantibody producing cells	Azathioprine (Imuran)	PO IV	Gastric distress Nausea, vomiting Abdominal pain Oral ulcers Dark urine Pale stools Jaundice	Assess joints for range-of-motion, edema, temperature, and erythema. Protect patients from those who may carry infections. Monitor CBC, renal and liver function tests. Give with food if gastrointestinal upset. Monitor for abnormal bleeding.
	Cyclosporine (Sandimmune)	PO IV		
	Methotrexate (Rheumatrex)	PO IM IV		

CRITICAL THINKING

Mr. Beck

■ Mr. Beck, a truck driver who was recently diagnosed with ankylosing spondylitis, verbalizes concern about how this diagnosis will affect his ability to work.

1. How would you answer his questions?
 - a. “What is happening to me?”
 - b. “Will I have to quit my job driving an interstate truck?”
 - c. “Am I eventually going to be in really bad pain?”
 - d. “Am I eventually going to be dependent on someone?”
2. Mr. Beck plans to continue driving his truck and therefore has a need upon discharge for specific interventions that will help him maintain his independence. Why is each of the following instructions given to Mr. Beck upon discharge?
 - a. Perform range-of-motion exercises daily.
 - b. Do not stay in one position too long. You may need to stop and walk around often.
 - c. Sleep on a firm mattress without a pillow.
 - d. Maintain good posture, even when driving the truck.

Suggested answers at end of chapter.

a mattress that is firm without a pillow to help reduce pain and stiffness.

IMMUNE DEFICIENCIES

Immune deficiencies occur when one or more components of the immune system are either completely absent or deficient in quantities sufficient to elicit or sustain an adequate immune response to combat an infectious agent.

Hypogammaglobulinemia

PATHOPHYSIOLOGY AND ETIOLOGY. This condition is either a hereditary congenital disorder or acquired after childhood from unknown causes. It is characterized by the absence or deficiency of one or more of the five classes of immunoglobulins (IgG, IgM, IgA, IgD, and IgE) from defective B-cell function. The lack of normal function of these antibodies makes the patient prone to infections. The congenital form of this disorder affects males. Patients usually have a normal life span.

SIGNS AND SYMPTOMS. The infant is usually asymptomatic until 6 months of age, when the maternal immunoglobulins are gone. At this time, the infant begins having many recurrent infections, especially from *Staphylococcus* and *Streptococcus* organisms.

DIAGNOSIS. Until the infant is 9 months old, diagnosis is extremely difficult. At 9 months of age, immunoelectrophoresis, which measures the level of each immunoglobulin, can be performed.

THERAPEUTIC INTERVENTIONS. Treatment is aimed at minimizing infections while increasing the immune system through injections of immunoglobulin. These injections mainly contain IgG, so fresh frozen plasma is given to replace IgM. IgA cannot be replaced, increasing the risk for frequent pulmonary infections.

NURSING MANAGEMENT. The infant is monitored for infections. Any break in the skin must be cleansed immediately and monitored for infection development. Genetic counseling may be recommended for parents.

Education. The family is educated about signs and symptoms of a variety of infections and the importance in seeking medical help immediately. They are taught that the infant should not be in crowds and that good nutrition, hydration, and hygiene are important in preventing infections.

Home Health Hints

Atopic Dermatitis

- Instruct patients with atopic dermatitis to use a skin moisturizer daily to help prevent dryness, which can lead to the complications of eczema. Avoid baby lotions or any lotion that contains perfumes since these can be irritating to the skin.
- Use of regular soaps can be drying to the skin. Discuss with your patient and family to only use soaps labeled for sensitive skins.
- Oatmeal baths can be helpful in relieving the skin dryness. Many oatmeal bath products are available over-the-counter. Assist the patient with choosing the correct one.

- Patients and families can be taught to use an ice pack applied to the irritated area to help relieve the itching associated with atopic dermatitis.
- If patients experience a rash anywhere, especially around the torso and abdomen, consider the clothing detergent they are using. Encourage them to switch to a detergent that is mild such as one of those used to wash baby clothes (e.g., Dreft).

Latex Allergy

- Always have on hand latex-free gloves.
- Indwelling catheters are also made from latex. You can obtain a latex-free silicone catheter to use to prevent latex exposure and potential complica-

tions for individuals who have experienced latex sensitivities.

Transplants

- Patients who have had a transplant are required to take medications that turn off their immune system. Because of this, it is important to instruct them to avoid public places such as malls and food stores. If they do go out,

let them know that they should wear a surgical mask to help prevent exposure to illness.

- The importance of taking medications as prescribed needs to be reinforced, especially for immunosuppressive medications for cardiac transplant patients.
- Patients with cardiac transplants should not be exposed to people with illnesses such as colds or the flu. This should be explained to family members and visitors.

REVIEW QUESTIONS

Multiple response item. Select all that apply.

1. The nurse is contributing to the plan of care for a patient with allergic rhinitis. Which of the following interventions should the nurse anticipate will be included in the treatment plan?
 - a. Antihistamines
 - b. Epinephrine
 - c. Gold salts
 - d. Steroids
 - e. Anticholinergics
 - f. Decongestants
 - g. Immunotherapy
 - h. Avoiding environmental stimuli
2. Which of the following components of a complete blood count with differential would the nurse see elevated in the patient with allergic rhinitis?
 - a. Hemoglobin
 - b. Eosinophils
 - c. RBC Distribution Width (RDW)
 - d. Bands

Multiple response item. Select all that apply.

3. A patient who has an allergy to penicillin is receiving preoperative medications, which include ranitidine (Zantac), metoclopramide (Reglan), and cefazolin (Ancef) intravenously. Fifteen minutes after the cefazolin is started, the patient reports an uneasy feeling, as well as feeling very warm. The nurse would appropriately recognize that the patient is experiencing anaphylaxis and perform which of the following?
 - a. Offer the patient ice water
 - b. Discontinue the IV
 - c. Stay with the patient
 - d. Turn off the IVPB
 - e. Call for assistance
 - f. Place the patient in Trendelenberg position
 - g. Monitor vital signs
4. The nurse is contributing to the plan of care for a patient with ankylosing spondylitis. Which of the fol-

lowing interventions would be appropriate for the nurse to suggest?

- a. Avoid massage.
 - b. Use interferon injections.
 - c. Avoid one position for prolonged periods.
 - d. Use topical steroids.
5. The nurse is contributing to the plan of care for a patient with an immune system deficiency. Which of the following complications should the nurse consider is most likely to occur when recommending prevention interventions?
 - a. Overwhelming infection
 - b. Fatal allergic reaction
 - c. Asphyxiation
 - d. Delayed anaphylactic reaction
 6. A patient is admitted with an autoimmune disease and asks the nurse what autoimmune means. Which of the following would be the appropriate response by the nurse?
 - a. "Immune cells produce too many antibodies."
 - b. "Immune cells grow and multiply too rapidly."
 - c. "Immune cells are not produced in sufficient amounts."
 - d. "Immune cells are unable to distinguish between 'self' and 'not self.'"

Multiple response item. Select all that apply.

7. The nurse is contributing to the plan of care for a patient with systemic lupus erythematosus. Which of the following would be appropriate for the nurse to suggest?
 - a. Take warm showers or baths to relieve the joint stiffness.
 - b. Take corticosteroids without food.
 - c. Work the pain out of painful or inflamed joints.
 - d. If they have stomach upset when taking the corticosteroids they should stop taking it for a few days until the GI symptoms diminish.
 - e. Encourage the patient and family members to participate in the planning of care and safety measures for at home.
 - f. The patient may eat whatever desired.

8. As a patient is being discharged after being diagnosed with SLE the patient verbalizes that soon they are leaving on a three week tour of the Grand Canyon and white water rafting. Which of the following patient statements conveys to the nurse understanding of the patient's plan of care?
- "As long as I wear sunscreen, I'll be fine in the sun."
 - "I'll need to wear a long-sleeved shirt and pants, hat, and use sunscreen on all exposed skin."
 - "If I develop a rash, I should avoid the sun."
 - "I should avoid the sun in the morning."
9. A patient is admitted to the hospital with no allergies to any food, medications or environmental stimuli. The physician orders amoxicillin PO four times a day for the patient. After receiving the second dose of amoxicillin the patient reports itching on the chest, neck and arms, and difficulty swallowing. The nurse notes urticaria on the face, neck, chest and arms of the patient, and the

neck and tongue appear to be slightly swollen. The physician is notified and gives orders for Benadryl IM and a change in the antibiotic. The patient asks the nurse how an allergy can develop to a medication that has been taken before without problems. Which of the following is the most appropriate for the nurse to respond?

- "It probably is due to your age, because as you age your body becomes more sensitive to environmental stimuli which leads to hypersensitivities."
- "What have you eaten in the last 24 hours? Most medications are altered by food thereby producing different effects in the body."
- "Viral illnesses, exposure to various chemicals and environmental substances can alter the immune system and its response to previously benign stimuli."
- "Patients that have autoimmune disorders such as lupus or arthritis tend to develop sensitivities to common medications."

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Barnes

Further assessment might include: Identification of any previous allergies to food, medications and environmental stimuli and what reactions occur with any allergies. Thorough respiratory assessment, noting any adventitious sounds, in particular, wheezing. Note any dysphagia or changes in her voice,

Mrs. Barnes is most likely having an anaphylactic reaction to the bee stings with urticaria or even angioedema.

Therapeutic measures to implement: monitoring vital signs, staying with the patient, semi-Fowler's to high-Fowler's position; oxygen at 2 to 3 liters per minute; ensuring a patent intravenous access. Notify the RN and/or physician right away. Anticipate the administration of antihistamines, epinephrine, and fluids.

■ Blood Types

- AB Rh⁺
- O Rh⁻
- No, they can safely receive only A Rh⁻ or O Rh⁻ blood.

■ Mr. Ellis

1.28 mL per dose

■ Mr. Beck

- "Human leukocyte antigen B27 is formed, stimulating a chronic immune (inflammatory) response specifically in the sacroiliac, costovertebral, and large peripheral joints. This leads to thickening of the joints, joint pain, and stiffness."
 - "No, you shouldn't have to quit your job, but you may need to alter the way you go about driving your truck."
 - "No, you may not eventually be in severe pain, with use of medications and exercise."
 - "No, this disease may not affect your independence, with proper treatment and rehabilitation."
- "Range-of-motion exercises will help maintain joint mobility and a full range of motion and prevent contractures from forming."
 - "Again, this frequent movement prevents stiffness and joint pain and contractures of joints."
 - "Sleeping on a firm mattress without a pillow keeps the spine in correct alignment, which in turn helps prevent progressive changes in spine alignment (kyphosis, scoliosis), which affect various major body systems (respiratory, etc)."
 - "Again, good posture will aid in preventing bone deformities."

QUESTIONS TO GUIDE YOUR READING

1. What is human immunodeficiency virus (HIV) and how is it transmitted?
2. How is HIV diagnosed?
3. What is the prognosis for HIV and acquired immunodeficiency syndrome (AIDS)?
4. What would you include in a teaching plan to prevent HIV infection?
5. What are prevention measures to decrease infection and opportunistic diseases for patients with HIV?
6. What would you include in a teaching plan for a patient with HIV receiving highly active antiretroviral therapy?
7. What nursing care will you provide for patients with HIV/AIDS related to medications, coinfection prevention and maintaining nutritional status?

Acquired immunodeficiency syndrome (AIDS) is the final phase of a chronic, progressive immune function disorder. AIDS is caused by the **human immunodeficiency virus (HIV)**. Not all HIV-infected people have AIDS. The Centers for Disease Control and Prevention (CDC) defines the diagnosis of AIDS (Box 19.1). There is no cure for AIDS, which may develop after a long period of HIV infection and may eventually be fatal.

LEARNING TIP

HIV disease is no longer characterized as a life-ending illness. With highly active antiretroviral therapy (HAART), HIV disease is a chronic, usually progressive immune disorder.

AIDS, more than any other chronic disease in recent history, is a multidimensional disease that challenges nurses to call into play their physical, emotional, social, and spiritual care skills. As you care for patients who are HIV positive or have AIDS, it is important for you to understand current information. Being informed helps you to provide caring, competent, nonjudgmental care without fear. Knowledge and treatment related to HIV and AIDS rapidly changes with new discoveries. Current information and guidelines can be found at AIDS info, www.hivatis.org or 1-800-HIV-0440 (1-800-448-0440). For other resources, see Table 19.1.

INCIDENCE

The HIV and AIDS epidemic was first reported by the CDC in June 1981 (Table 19.2). A rapid increase in HIV/AIDS was seen through the 1980s, followed by a decrease in the later 1990s. As we move into the third decade of the epidemic, an estimated 40,000 new cases of HIV infection continue to be reported each year in the United States. Increases in HIV infection are occurring fastest in women and men who have sex with men; 65 percent of these infections are in racial and ethnic minority groups. In the United States from 1981 through 2003, 929,985 persons developed AIDS; of these, 524,060 died. The number of persons living today with HIV/AIDS is at its highest level because of treatment with highly active antiretroviral therapy (HAART), which was introduced in 1996. Although any age group can be affected by HIV and AIDS, 85 percent of those diagnosed with HIV/AIDS have been 25 to 44 years old. Given the long latency period between infection with HIV and an AIDS-defining illness, most people diagnosed with HIV disease younger than the age of 30 years were probably infected as adolescents. The number of infections in persons over age 50 has doubled in the past 5 years. Older adults are increasingly contracting HIV and must be educated about prevention. In recent years in the United States, of those with HIV, male-to-male sex has caused the greatest exposure, followed by heterosexual contact, and then by

Box 19.1

CDC Conditions in the AIDS Surveillance Case Definition

CD4+ T-lymphocyte count below 200/ μ L, or a CD4+ T-lymphocyte percentage under 14 of total lymphocytes, or the presence of one of the following specified clinical conditions:

- Candidiasis of bronchi, trachea, or lung
- Candidiasis, esophageal
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcus, extrapulmonary
- Cryptosporidiosis, chronic intestinal (greater than 1-month duration)
- Cytomegalovirus (CMV) disease (not including liver, spleen, or nodes)
- CMV retinitis with loss of vision
- Encephalopathy, HIV related
- Herpes simplex, chronic ulcers; or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (greater than 1-month duration)
- Kaposi's sarcoma
- Lymphoma, immunoblastic
- Lymphoma, Burkitt's
- Lymphoma of the brain, primary
- *Mycobacterium avium intracellulare* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome

Modified from Centers for Disease Control and Prevention: Revised classification system of HIV infection and expanded surveillance case definition for AIDS among adolescents and adults, MMWR 41 (RR17):2, 1992.

injected drugs. Current statistics can be found at www.cdc.gov.

Although HIV/AIDS can occur in a person of any age, this chapter focuses on adults with HIV/AIDS.

PATHOPHYSIOLOGY

Infection with the HIV virus causes destruction of immune cells. There are two identified subtypes of the HIV virus:

Source: Data from Centers for Disease Control and Prevention: HIV and AIDS—United States, 1981–2003 2003, <http://www.cdc.gov/hiv/stats.htm>.

HIV-1 and HIV-2. Both of these subtypes can cause AIDS. HIV-1 is found in Asia, Europe, and the Western Hemisphere. HIV-2 is found in West Africa. Without a normally functioning immune system, infections and cancers may take over. AIDS is the result of this immunodeficiency.

HIV is a retrovirus (which only has ribonucleic acid [RNA] for genetic material). HIV is attracted to immune cells with a surface-attaching site referred to as a CD4 receptor. Cells with CD4 receptors include lymphocytes (called CD4+ T lymphocytes, T4 lymphocytes, or helper T lymphocytes) and macrophages (in which HIV hides). HIV begins its infection by binding to the CD4 receptor of the host cell. The CD4+ T lymphocytes are the primary targets for HIV infection. Because CD4+ T lymphocytes orchestrate all immune functions, HIV's attack on these cells results in progressive impairment of the body's immune response. The CD4+ T lymphocytes do not function normally and are too busy replicating more HIV to perform their own immune function. Recent understanding of how HIV fuses with the cell has been the focus of new developments of treatment for preventing infection by blocking fusion of HIV with its host cell. After fusion with the host cell, the HIV viral particle is taken into a human cell and its covering is destroyed to expose its viral RNA. The retrovirus then uses an enzyme called reverse transcriptase to force the human cell to produce a new piece of deoxyribonucleic acid (DNA) from the viral RNA. The new DNA is integrated into the person's cellular DNA. As a result, the human cell creates more viral particles, which spread through the lymphoid system (Fig. 19.1). Inhibitors of reverse transcriptase were the first anti-HIV medications developed and are still an essential part of current treatment.

Once the genetic material of HIV has been changed to DNA, the enzyme integrase integrates it into the genetic

FIGURE 19.1 (A) Normal immune system. (B) HIV contains several proteins: gp 120 protein around it and viral RNA and p24 protein inside. The gp 120 proteins attach to CD4+ receptors of T lymphocytes; HIV enters the cell and makes viral DNA; the enslaved host cell produces new viruses that bud, which destroys the host cell's membrane, causing cellular death and allowing the virus to leave to attack other CD4+ T-lymphocyte cells.

material of the host cell. The cell is then translated into viral proteins. Among these proteins is HIV protease, which is required to process other HIV proteins into their functional forms. Protease inhibitors, potent types of antiviral medications, act by blocking this critical step. Following development of the cell surface, the virus then buds from the cell and is released to infect another cell. The virus spreads throughout the body unless interrupted by treatment. HIV may persist in a latent state for many years. This makes it very difficult to eradicate or cure HIV. Because of this, currently, patients must remain on antiviral treatment for life. The ultimate challenge is to use knowledge of the HIV life cycle to develop treatments that will eradicate HIV from those who are infected and to create a vaccine that will prevent new infections in the future.

After a person has been infected with HIV, other immune system components form antibodies to fight the HIV. Detection of these antibodies via laboratory testing is the most common way HIV is diagnosed. HIV antibodies typically become present within 3 weeks to 3 months after infection. The time between infection and developing antibodies is called the “window period.” Laboratory tests are available that detect the virus directly, rather than antibodies, but these are more costly for routine HIV testing.

LEARNING TIP

Being HIV positive means that the person has been infected with the HIV virus. It does not mean that the person has AIDS.

Progression

The initial infection is followed by a relatively symptom-free period called the clinical latency stage. The virus remains in the lymph nodes, liver, and spleen and reproduces. If the infection is untreated, a gradual decrease in CD4+ T lymphocytes continues. B lymphocytes also become dysfunctional and dysregulated by the events of HIV progression. B and T cells work together for a normal healthy immune system, so this may further impair the immune system. This period, from infection to the beginning of the symptomatic stage, varies for each person and averages 8 to 12 years. During this stage, the person is considered to be HIV infected. (Many are not aware of their HIV infection until they become symptomatic, and unknowingly pass the virus on to others and do not have the benefit of antiviral treatments to maintain health.) During the early symptomatic

stage of HIV disease, symptoms of the weakening immune system are seen. When the immune system is severely weakened, opportunistic infections and cancers may occur. When this occurs, the person is diagnosed with AIDS (Box 19.1 CDC Conditions in the AIDS Surveillance Definition).

LEARNING TIP

Opportunistic diseases are referred to as opportunistic because a normal immune system would prevent them from occurring. With an impaired immune system, invading organisms have the “opportunity” to survive.

PREVENTION

Prevention and education are the best ways to manage the HIV/AIDS epidemic. Education regarding the disease and its transmission should begin with the older school-age child and include the general population, as well as older adults (Box 19.2 Gerontological Issues).

Mode of Transmission

HIV is a fragile virus that is transmitted from human to human only through infected blood, semen, vaginal secretions, or breast milk. HIV is not spread casually. Kissing, hugging, shaking hands, or sharing eating utensils, towels, or bathroom fixtures with an HIV-positive person does not transmit HIV. There is also no evidence that HIV can be transmitted through insect bites or tears, nasal secretions, saliva, sweat, sputum, emesis, urine, or feces unless blood is present. Even then the transmission risk is considered very low. Blood transfusions before 1985 may have been a source for HIV transmission. However, since 1985, donated blood has been tested for HIV.

HIV needs a portal of entry into the body, such as a tear in a mucous membrane or nonintact skin, or access to the bloodstream or lymphatic tissue. Routes of transmission for HIV are as follows:

- Sexual—anal, vaginal, or oral sexual contact of mucous membranes to infected body fluids
- Parenteral—injection by needles contaminated with infected blood, sharing needles, transfusions of contaminated blood products
- Perinatal—infected mother to fetus/infant during pregnancy, childbirth, or breastfeeding

LEARNING TIP

An HIV-infected person can transmit HIV to others within a few days after initial infection and then throughout all stages of the disease. This is thought to be true even when HAART treatment has driven the viral load below detectable levels.

Box 19.2

Gerontological Issues

Nearly 10 percent of diagnosed AIDS cases occur in people age 50 and older. Numbers will continue to rise as the older population increases, yet little attention has been given to this age group. This may be due to an ageist view of the older adult and sexual activity.

It is important to understand that HIV infection can occur at any age. Older adults should be asked about their sexual and drug use history and be given preventive education and information about products that reduce transmission of HIV and sexually transmitted diseases. At-risk people older than age 50 are less likely than younger at-risk adults to use condoms during sex or to be tested for HIV. In this age group, condoms are often thought of as a birth control measure.

HIV/AIDS is thought of as being a disease of young, sexually active people. Older people remain sexually active, and may have multiple partners. Older people are also contracting the virus through homosexual contact.

A decline in the older adult's immune system increases the risk for infection with HIV. Increased vaginal dryness and friability further increases an older woman's susceptibility to HIV infection. Because older adults are not usually taught HIV prevention, the rise in HIV infection among older adults is expected to continue. With AIDS death rates dropping as a result of more effective treatments, the number of older adults living with HIV will increase.

Symptoms of HIV in older adults may be confused with commonly perceived problems of aging, such as fatigue, decreased endurance, and altered cognitive status. The effect of HIV on the brain can be mistaken for Alzheimer's disease, delaying proper treatment.

Counseling

Early knowledge of HIV status aids in reducing the spread of HIV infection. The CDC has recommended guidelines for counseling and testing people at risk for HIV. Counseling should be done by trained workers to help the patient make an informed decision about testing. Education should also be provided that is culturally sensitive and fits the patient's personal risk situation. Posttest counseling is provided to help the patient understand the test results, assist with informing sexual partners and drug needle sharers, risk factor reduction, and care options if needed.

Sexual Transmission

HIV is transmitted more easily to women than men. This is because the vagina has a greater amount of mucous membrane than the penis, as well as the increased amount of virus found in semen as compared with vaginal secretions. Sexual acts that are the riskiest for transmission of HIV are those that promote contact between infected body fluids and

mucous membranes or nonintact skin. These risky acts include oral sex or anal sex. Anal sex is the riskiest type of sexual act, for either gender, because it often results in tearing of the mucous membrane that is then exposed to infected semen.

Safer Sex Practices

Abstaining from sexual intercourse is the only sure way to prevent sexual exposure to HIV. A mutually monogamous sexual relationship is considered safe if both partners are not and will not become infected with HIV. Alternative methods of sexual activities can be used that prevent exposure to blood and secretions, such as massage or masturbation. The benefits of limiting sexual partners should be explained. For vaginal or anal intercourse, the use of male or female condoms and safer sex techniques should be discussed (Box 19.3 Patient Education: Condom Use to Prevent HIV Transmission). Latex gloves protect hands during genital or anal contact. Dental dams (latex sheets) should be used as a barrier between the mouth and genitals or anus.

Parenteral Transmission

The best way to prevent parenteral transmission of HIV is to avoid injection drug use. Drug injection equipment should not be shared. If a person who uses injected drugs is unable or unwilling to stop sharing needles, he or she should be carefully taught how to clean the needle and syringe: To optimize the effectiveness of cleaning, soon after use the needle and syringe should be flushed with water until visibly clear of blood. Next, the syringe is filled with full-strength household bleach and shaken for 1 minute. The bleach is flushed through the needle and syringe and they are

then rinsed with water. Additionally, sexual activity should be strongly discouraged when judgment is impaired from drug use because protective measures may not be used.

Autologous (one's own) blood transfusion, when possible, is the safest type of transfusion to prevent HIV infection. Screening of blood for HIV antibodies is done on all donated blood in the United States. There is a very small chance of HIV transmission from blood that is infected but has not yet had time to develop antibodies.

Perinatal Transmission

The U.S. Public Health Service guidelines for HIV screening of pregnant women recommend that voluntary HIV pretest counseling and testing be offered during prenatal care for all pregnant women.¹ Pregnant women who know they are HIV positive can reduce the risk of perinatal HIV transmission to less than 4 percent by taking antiretroviral therapy during pregnancy, labor, and delivery. Every effort should be taken during labor and delivery to avoid any procedure such as a scalp monitor or episiotomy that increases the risk of exposure of the infant to the mother's blood. At the time of delivery, pregnant women who have not been tested for HIV or received prophylactic treatment should be offered testing for HIV. After delivery, the infant is given zidovudine (AZT, Retrovir) for 6 weeks.

Health-Care Workers and HIV Prevention

It is essential to understand and use proper infection control practices to protect yourself from exposure and transmission of HIV. Following hand washing protocols, using **personal protective equipment** (gloves, surgical masks, goggles, gowns, and booties) and preventing needle sticks are very important. Personal protective equipment (PPE) to be used is selected and based on the task to be performed and the exposure risk the task presents along with the type of isolation precautions in use. If you are unsure of the appropriate PPE or isolation precautions to use, ask your instructor or the patient's nurse before providing care to the patient.

Needle Sticks

Needle-stick injury is a source of HIV transmission to health-care workers. The Needlestick Safety and Prevention Act is designed to aid health care workers in preventing needle-stick injuries. Careful use of needles—including not recapping needles, use of needless systems, and needle safety devices—can reduce needle-stick injury. Consider an occupational exposure an urgent medical concern and seek medical care immediately. To prevent HIV after a needle stick or other forms of exposure to patient body fluids, the CDC has developed postexposure prophylaxis guidelines (Table 19.3).

Standard Precautions

All those at risk of contacting blood and body fluids and substances must follow CDC standard precautions to reduce their risk of HIV exposure as well as other bloodborne pathogens. (See Chapter 7.) Health-care workers should

Box 19.3

Patient Education: Condom Use to Prevent HIV Transmission

Condoms should be:

- New for each intercourse act.
- Latex (or polyurethane if allergic to latex) because other materials have large pores that allow HIV to pass.
- Nondamaged, current (not past expiration date).
- Applied before partner is touched. (Tip of condom is held while unrolled over erect penis, allowing room at tip for semen collection.)
- Used with adequate amounts of only water-soluble lubricants. (Petroleum or oil-based lubricants such as petroleum jelly, cooking oil, shortening, or lotions can damage latex condoms.)
- Replaced if broken. (If ejaculation occurs before replacement, immediate use of a spermicide may give some protection.)
- Withdrawn from partner by holding condom against base of erect penis to avoid semen leakage.

TABLE 19.3 OCCUPATIONAL HIV EXPOSURE: POSTEXPOSURE PROPHYLAXIS

Consider occupational exposure an urgent medical condition.	
<i>Immediate care</i>	Wash exposure site with soap and water. For mucous membrane exposure, flush with water.
<i>Consider exposure risk</i>	What is the type of fluid person was exposed to? What is the type of exposure?
<i>Test exposure source</i>	Assess risk of infection and test known sources for HIV antibody.
<i>Postexposure prophylaxis</i>	Start treatment within hours of exposure for 4 weeks. Consider pregnancy test if of childbearing age. Basic prophylaxis regimen or alternate basic prophylaxis regimen available: zidovudine (Retrovir, ZDV, AZT) 300 bid and lamivudine (EpiVir, 3TC) 150 mg bid; or as combination tablet of both drugs: Combivir one tablet bid. Expanded prophylaxis regimen (basic prophylaxis regimen and one of the following): indinavir (Crixivan, IDV) 800 mg q8h; nelfinavir (Viracept, NFV) 750 mg tid or 1250 mg bid; efavirenz (Sustiva, EFV) 600 mg qh; or abacavir (Ziagen, ABC) 300 mg bid. Trizivir, a combination of ZDV, 3TC, and ABC, may be used.
<i>Follow-up testing and counseling</i>	HIV-antibody testing at baseline, 6 weeks, 3 months, and 6 months after exposure or if a retroviral syndrome-type illness occurs. During postexposure care, exposed person should use precautions to prevent secondary transmission of HIV, including abstaining from sex or using condoms; no donation of blood, plasma, organs, or semen; if breastfeeding, consider stopping.

Source: CDC: Basic and Expanded HIV Postexposure Prophylaxis Regimens. MMWR 50(RR11):47, 2001.

always use these precautions for all patients to protect themselves and other patients. Additionally, to protect patients, HIV-infected health-care workers with open lesions or weeping dermatitis should avoid direct patient care.

SIGNS AND SYMPTOMS

Initially after HIV infection, the patient may have no symptoms or may develop mononucleosis-like symptoms (called an acute retroviral syndrome), such as extreme fatigue, headache, fever, lymphadenopathy (enlarged lymph nodes

in two different sites other than inguinal nodes), diarrhea, or a sore throat (Fig. 19.2 and Box 19.4 HIV/AIDS Summary). Symptoms generally develop 6 to 12 weeks after HIV transmission and may last a few days to weeks. These symptoms are usually mild and not attributed to an HIV infection.

Each patient's response to HIV is unique. After an extended asymptomatic phase, untreated HIV infection usually progresses to a symptomatic stage when the virus has greatly impaired the immune system. The patient may exhibit shortness of breath, fever, weight loss, fatigue, night sweats, persistent diarrhea, oral or vaginal candidiasis ulcers, dry skin, skin lesions, peripheral neuropathy,

FIGURE 19.2 Typical phases of HIV infection, AIDS development, and CD4+ T-lymphocyte counts without treatment. Length of latency period varies but is usually many years. As CD4+ T-lymphocyte counts drop, symptoms, AIDS, and then death result.

shingles (varicella zoster virus reactivation), seizures, or dementia. In the final stage of HIV infection, AIDS is diagnosed when the CD4+ T-lymphocyte count is below 200 or opportunistic infections and diseases, with their specific signs and symptoms, occur. (See Box 19.1 CDC Conditions in the Aids Surveillance Definition.)

COMPLICATIONS

Many complications are seen with HIV/AIDS that vary from patient to patient. Some of the common complications are discussed next.

Box 19.4

HIV/AIDS Summary

Signs and symptoms

Initially vary: None or acute retroviral syndrome
Asymptomatic phase
Immune system impairment: dyspnea, fever, weight loss, fatigue, night sweats, persistent diarrhea, oral or vaginal candidiasis ulcers, dry skin, skin lesions, peripheral neuropathy, shingles, seizures, or dementia
AIDS diagnosed when CD4+ T-lymphocyte count below 200 or opportunistic infections and diseases occur.

Diagnostic tests

HIV antibody tests
Complete blood cell count/lymphocyte count
CD4+/CD8+ T-lymphocyte count
Viral load testing
Viral culture
Genotyping

Therapeutic Interventions

Nonnucleoside reverse transcriptase inhibitors
Nucleoside/nucleotide reverse transcriptase inhibitors
Inhibitors
Nucleoside/nucleotide reverse transcriptase inhibitors
Protease inhibitors
Fusion inhibitors

Complications

AIDS wasting syndrome
Opportunistic infection and cancer
AIDS dementia complex

Possible Nursing Diagnoses

Risk for infection
Acute or chronic pain
Fatigue
Imbalanced nutrition
Ineffective individual coping

AIDS Wasting Syndrome

AIDS wasting syndrome occurs in most patients with AIDS. The syndrome is defined by the occurrence of the following:

- Involuntary baseline body weight loss of more than 10 percent
- Chronic weakness or fever for more than 30 days or chronic diarrhea of two loose stools daily for more than 30 days

Several factors contribute to this syndrome: decreased appetite, oral lesions, altered metabolism, malabsorption, gastrointestinal (GI) infections, diarrhea, medication side effects, and cognitive impairment. The progressive weight loss impairs function of all body systems from malnourishment. Careful intervention, planning, and education of the patient when HIV is first diagnosed can help maintain body weight.

NURSING CARE TIP

AIDS wasting syndrome is challenging. Do not give up! Be creative in developing interventions to help increase the patient's appetite and caloric intake.

Opportunistic Infection and Cancer

Opportunistic infections (OI) are a primary complication of HIV/AIDS because the person with HIV/AIDS has a very impaired immune system. Other types of infections that occur even with a healthy immune system are seen as well, such as tuberculosis. OI are not spread to those with healthy immune systems, but other types of infections can be. Certain kinds of cancer incidence also rise when the immune system is impaired. Opportunistic infections can be viral, bacterial or mycobacterial, fungal, protozoal, or parasitic. They can affect many different areas of the body. Some OI can now be prevented by prophylactic treatments. Some common OI are discussed here.

Candida Albicans

Candida albicans is a fungus normally found in the GI tract that does not infect a person with a healthy immune system. In AIDS, overgrowth of this fungus occurs from the impaired immune system. Candidiasis of the mouth or esophagus occurs often with AIDS. Signs and symptoms of candidiasis include oral or esophageal pain, dysphagia, and yellow-white plaques that look like cottage cheese in the mouth and throat. Nutrition can be affected by oral or esophageal candidiasis. Recurrent vaginal candidiasis is more common in women with AIDS. Severe itching and a white discharge occur.

Cytomegalovirus

Cytomegalovirus (CMV) is a common viral infection that can affect many areas of the body. The eye is a common site (cytomegalovirus retinitis). Vision impairment ranges from

little impairment to total blindness. Prompt diagnosis and treatment can minimize the loss of vision. A variety of symptoms are seen when other areas are involved, such as fever, fatigue, diarrhea, GI upset, and hepatitis, to name a few.

Pneumocystis Carinii Pneumonia

Pneumocystis carinii pneumonia (PCP) is caused by a fungus (formerly thought to be a protozoa) that produces shortness of breath, fever, nonproductive cough, and fatigue. PCP is the most common opportunistic infection in HIV/AIDS. To prevent PCP, oral trimethoprim-sulfamethoxazole (Septra) is given prophylactically. Other treatments for those who cannot tolerate Septra are available, including dapsone, Mepron, and pentamidine isethionate (Pentam) inhalation therapy to prevent PCP when CD4+ T-lymphocyte counts fall below 200/ μ L. PCP may be treated with oxygen, oral or intravenous trimethoprim-sulfamethoxazole, or parenteral pentamidine isethionate. Steroids may also be given to reduce lung inflammation.

Tuberculosis

Tuberculosis is a bacterial infection and may occur in up to 10 percent of those with AIDS. Symptoms include dyspnea, cough, chest pain, fever, night sweats, and weight loss. A purified protein derivative (PPD) skin test should be performed at least annually in patients with HIV infection. Induration of 5 mm or more is defined as a positive result in patients with HIV infection. (See Chapter 31.)

NURSING CARE TIP

When assessing the results of a PPD test, only the raised area (if present) is measured and recorded in millimeters. (If there is no induration, it is recorded as 0 mm.)

Viral Infections

Herpes simplex virus infections may be found in the oral, genital, or rectal area of those with AIDS. Symptoms include blister-like lesions that rupture and leave ulcerations, fever, pain, or bleeding. Varicella zoster virus infection is usually the result of the virus being present from a prior episode of the chickenpox. The virus remains present in the nerve ganglia. With depressed immune function, the virus can cause shingles.

Neoplasms

Kaposi's sarcoma (KS) is the most common cancer associated with AIDS. Painless, small purple-blue lesions on the skin occur. The lesions may scale, ulcerate, and bleed. KS may occur anywhere on the body in patients with HIV. HAART has affected the incidence of KS, decreasing it by approximately 60 percent since 1996. Cervical neoplasia is more common in women with HIV. Non-Hodgkin's lymphoma is more likely to occur in persons with substantial immunosuppression.

AIDS Dementia Complex

HIV infection of the brain or other parts of the central nervous system results in AIDS dementia complex (ADC). Symptoms range from mild to severe and may include memory impairment, personality changes, hallucinations, leg weakness, loss of balance, and slower responses. ADC is a common complication of HIV/AIDS. With ADC, safety is an important consideration for the patient and caregiver. The only treatment for AIDS dementia is optimal viral suppression from antiviral treatment.

DIAGNOSIS

Finger-stick blood, oral fluid, and urine and serum specimens are used for HIV testing. Rapid HIV testing provides results the same day. Home sample collection devices can be purchased; the sample is sent in for HIV testing, with the person calling for results, counseling, and referral if needed.

HIV Antibody Tests

After HIV infection, antibodies may not be formed for 3 weeks to 3 months or longer in some cases. The typical HIV antibody testing pattern is as follows:

- Enzyme-linked immunosorbent assay (ELISA) test is done to detect antibodies in the patient's blood to HIV antigen on test plates.
- If positive, the ELISA test is repeated because false positives may occur (0.1 percent).
- If the ELISA test is again positive, the Western blot test is done to detect the presence of antibodies to four major HIV antigens. The test is positive if two antibodies are present.
- If all test results are positive, the patient is HIV-antibody positive.
- (If the test is negative, the patient is said to be in the window period or HIV negative.)
- Other tests can be used, especially if initial test results are not conclusive such as viral cultures to confirm HIV status.

Complete Blood Cell Count/Lymphocyte Count

Because patients with HIV are susceptible to leukopenia, lymphopenia, anemia, and thrombocytopenia related to HIV infection and as a complication of antiretroviral therapy, a complete blood cell count (CBC) including a lymphocyte count should be obtained. The CBC should be repeated at 3- to 4-month intervals or more often if there is a change in therapy or the patient's clinical course is unstable.

CD4+/CD8+ T-Lymphocyte Count

The count of CD4+ and CD8+ (cytotoxic cells) T lymphocytes is essential for evaluating the status of the immune system. In healthy adults, CD4+ levels average 500 to 1600 cells per mm^3 . In HIV/AIDS, CD4+ cell levels drop but

CD8+ cell levels do not. A low ratio of CD4+ cells to CD8+ cells is seen as HIV/AIDS progresses. It is recommended that CD4+/CD8+ T-lymphocyte counts be performed at 3-month intervals for most patients.

Viral Load Testing

Viral load testing measures the amount of HIV RNA in plasma and is extremely important for determining prognosis and monitoring the response to antiretroviral therapy. Combination antiretroviral regimens usually produce a 50 percent decrease in total-body HIV levels within just a few days. Viral loads should be performed 1 month after initiation of new treatments and at 3-month intervals thereafter.

Genotyping

Genotyping measures resistance to current antiviral treatments. This information guides medical providers in choosing treatment regimens that will most likely be effective against that individual's virus.

General Tests

Standard serological testing for syphilis is recommended annually in patients who are sexually active. Hepatitis A, B, and C serologies and liver chemistry panels are indicated in the early evaluation of most patients because of the high incidence of concurrent hepatitis for HIV-positive patients.

THERAPEUTIC INTERVENTIONS

Because there is no cure for HIV/AIDS, the goal of therapy is to prevent or delay development of opportunistic diseases. There is some inconsistency in the recommendations of when to start an antiretroviral regimen. The 2005 Guidelines for Use of Antiretroviral Agents in HIV-1 Infected Adults and Adolescents are clear that they should be started before the CD4 cell count falls below 200 cells/mm³, but there are inconsistent data on the value of starting when the CD4+ T-lymphocyte cell count falls below 350 cells per cubic milliliter (Table 19.4). To increase life expectancy and treatment cost effectiveness, it may be recommended that patients be prophylactically treated for opportunistic infections, especially hepatitis A and hepatitis B viruses, herpes simplex virus, *Mycobacterium avium* complex, and *Pneumocystis carinii* pneumonia (Table 19.5). Other opportunistic infections are treated with appropriate medications if they occur.

Antiretroviral drugs that inhibit reproduction of the virus (but do not kill it) are used to treat HIV infection. These antiretroviral agents have been developed to act predominantly on processes specific to the viral particle to keep the integrity of the host cell. Several potential strategies specifically aimed at interruption of the viral life cycle have been defined, including the following:

(Text continued on page 333)

TABLE 19.4 MEDICATIONS FOR HIV INFECTION

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Nonnucleoside reverse transcriptase inhibitors (NNRTIs) Block active site of HIV reverse transcriptase	delavirdine (Rescriptor)	PO: 200 mg, 2 tid. Take with/without food.	Rash, headache	Monitor WBC count, liver tests, especially with history of hepatitis B or C. Do not give within 1 hour of antacids or didanosine (ddI, Videx).
	efavirenz (Sustiva)	PO: 600 mg daily. Take on an empty stomach, preferable at bedtime.	Rash, vivid dreams, CNS symptoms False-positive cannabinoid test	Monitor for rash (especially during first month); may be severe and life threatening. Teach patient to report rash.
	nevirapine (Viramune)	PO: 200 mg daily for 7 days, then 200 mg bid. Take with/without food.	Rash	Monitor for rash (especially first month); may be life threatening and require stopping drug immediately. Teach patient to report rash immediately. Stevens-Johnson syndrome may occur. Monitor liver tests. For contraception advise a nonhormonal contraceptive during therapy.

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs) Inhibit production of reverse transcriptase and viral replication.	combivir (lamivudine, [3TC] and zidovudine [AZT])	150 mg of lamivudine and 300 mg of zidovudine PO: bid. With/without food	Peripheral neuropathy	Monitor for peripheral neuropathy and report
	emtriva (Emtricitabine or FTC)	PO: 200 mg daily. Take with/without food.	Minimal side effects Lactic acidosis rare	Monitor for symptoms of lactic acidosis.
	epivir (Lamivudine, 3TC)	PO: 150 mg bid or 300 mg daily. Take with/without food	Peripheral neuropathy	Monitor for peripheral neuropathy and report.
	epizicom (abacavir sulfate and lamivudine)	PO: abacavir 600 mg + lamivudine 300 mg daily. With/without food	See sections for the two meds in this drug.	See sections for the two meds in this drug.
	hivid (Zalcitabine, ddC)	PO: 0.75 mg q8h. With/ without food	Peripheral neuropathy	Monitor for peripheral neuropathy and report.
	zidovudine (Retrovir, AZT, ZDV)	PO: 300 mg bid. With/ without food	Nausea, vomiting, dizziness. Decrease in bone marrow function and liver and kidney toxicity.	Monitor CBC for anemia. Use strategies to decrease nausea and vomiting. Monitor labs for kidney and liver function.
	trizivir (Abacavir + lamivudine + zidovudine)	PO: Abacavir 600 mg, lamivudine 150 mg, zidovudine 300 mg bid With/without food	See sections for the each of the three meds.	See sections for each of the three meds.
	truvada (emtricitabine + tenofovir)	PO: Emtricitabine 200 mg + Tenofovir 300 mg daily With/without food	See sections for the two meds in this drug,	See sections for the two meds in this drug.
	videx (Didanosine, ddI)	PO: 200 mg bid on an empty stomach. Chew or dissolve in water. (Take at least 30 minutes before or 2 hours after a meal.)	Peripheral neuropathy, pancreatitis, nausea, diarrhea	Monitor for peripheral neuropathy. Monitor CBC for bone marrow suppression.
	videx EC (Didanosine, ddI)	PO: 400 mg if >60 kg. Also comes in 250 mg.	Peripheral neuropathy, pancreatitis, nausea, diarrhea	Monitor for peripheral neuropathy. Monitor CBC for bone marrow suppression.
viread (tenofovir)	PO: 300 mg daily With/without food	Nausea, vomiting, diarrhea, headaches, flatulence	Monitor for hepatomegaly with steatosis for lactic acidosis, which can be fatal, especially in women. Take 2 hours before or 1 hour after didanosine.	
zerit (Stavudine, d4T)	PO: 40 mg bid. With/without food.	Peripheral neuropathy, lactic acidosis (which can be fatal)	Monitor for peripheral neuropathy and report. Monitor liver function and report.	
ziagen (Abacavir sulfate)	PO: 300 mg bid or 300 mg daily With/without food	Fever, rash, nausea, vomiting, malaise or fatigue, loss of appetite, respiratory symptoms such as sore throat, cough, shortness of breath (Hypersensitivity reaction, which can be fatal)	Flulike symptoms indicate need to discontinue drug or life-threatening condition may develop. Report immediately.	

(Continued on following page)

TABLE 19.4 MEDICATIONS FOR HIV INFECTION (Continued)

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Protease Inhibitors (PIs) Bind to active site of HIV protease enzyme, which cuts reproduced HIV strands. Interrupt formation of mature viral particles and reduce viral replication. Rapid resistance development if not taken as directed	agenerase (Amprenavir)	PO: 8- to 150-mg caps bid or 8- to 150-mg caps + 100 mg Norvir daily With/without food	Nausea, vomiting, diarrhea Rash, oral paresthesias hyperglycemia, transaminase elevation, lipodystrophy and lipid abnormalities	Care for GI intolerance. Report rash. Monitor labs. Watch for increased bleeding in patient with hemophilia.
	crivivan (Indinavir)	PO: 800 mg q8h on an empty stomach	Nephrolithiasis, GI intolerance, headaches, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, hemolytic anemia, hyperglycemia, lipodystrophy, elevated lipids	Teach about importance of hydration. Manage GI symptoms. Monitor labs.
	fortovase (Saquinavir)	PO: 6- to 200-mg caps tid with food	Nausea, diarrhea, abdominal pain, headache, dyspepsia, hyperglycemia, lipodystrophy, elevated lipids, elevated transaminases	Manage GI intolerance. Monitor labs. Watch for increased bleeding if patient has hemophilia.
	invirase (Saquinavir)	PO: 5- to 200- mg caps + 100 mg Ritonavir bid with food	GI intolerance, headache, hyperglycemia, lipodystrophy, elevated lipids, elevated transaminases	Same as fortovase
	kaletra (Lopinavir/ritonavir)	PO: 3 caps bid with food	GI intolerance, asthenia, hyperglycemia, lipodystrophy, elevated lipids, elevated transaminases	Refrigerate caps. Manage GI symptoms. Monitor labs. Watch for increased bleeding in patients with hemophilia.
	lexiva (Fosamprenavir)	PO: 2- to 700-mg tabs bid OR 2- to 700-mg tabs + 200 mg Ritonavir daily OR 700 mg + 100 Norvir bid with/without food	Skin rash, GI intolerance, headache, hyperglycemia, transaminase elevation, lipodystrophy, elevated lipids, elevated transaminases	Manage GI symptoms. Report rash. Watch for increased bleeding in patients with hemophilia.
	novir (Ritonavir)	PO: 6- to 100-mg caps bid. With food. Dose is titrated up slowly. (Mainly used in small doses to boost other PIs.)	GI intolerance, paresthesias, hepatitis, pancreatitis, asthenia, taste perversion, elevated lipids, hyperglycemia, lipodystrophy	Manage GI symptoms. Monitor labs. Monitor side effects. Watch for bleeding episodes in patients with hemophilia.
	reyataz (Atazanavir)	PO: 2- to 200-mg caps daily or 300 mg with 100 mg Norvir daily with food.	Indirect hyperbilirubinemia, hyperglycemia, lipodystrophy	Watch for jaundice and report. Monitor labs. Watch for bleeding episodes in patients with hemophilia.
	viracept (Nelfinavir)	PO: 5- to 250-mg caps bid or two 625-mg tabs bid with food	Diarrhea, asthenia, hyperglycemia, lipodystrophy, elevated lipids, elevated transaminase	Manage diarrhea. Monitor labs. Watch for increased bleeding in hemophilia patients.
Fusion Inhibitors Blocks HIV-1 fusion with the CD4+ cell membrane to prevent cell entry.	enfuvirtide (Fuzeon) www.fuzeon.com	SC: 90 mg (1 mL) bid. Mix with 1.1 mL sterile water for injections. Rotate sites: upper arm, abdomen, upper thigh.	Local injection site reactions. Hypersensitivity reaction (rash, fever, nausea, vomiting, chills, rigor, hypotension), diarrhea, nausea, fatigue, bacterial pneumonia	Teach: Does not cure HIV. Must continue other HIV meds. Drug resistance can develop if used alone. Use aseptic technique for administering injections. If dizzy, do not drive.

CBC = complete blood count; CNS = central nervous system; GI = gastrointestinal.

TABLE 19.5 TREATMENT FOR AIDS-RELATED CONDITIONS

Opportunistic Infection/Complication	Treatment
Candidiasis	Nystatin, ketoconazole (Nizoral), fluconazole (Diflucan), amphotericin B (Fungizone)
Cytomegalovirus retinitis	Ganciclovir (Cytovene)
Hepatitis B virus	Hepatitis B virus vaccine when HIV infection diagnosed, unless already infected with hepatitis B
Hepatitis C virus	Interferon, lamivudine, tenofovir for infection; pegylated interferon and ribavirin
Herpes simplex, herpes zoster, varicella zoster	Acyclovir (Zovirax) therapy, valacyclovir, famciclovir, foscarnet
Influenza	Annual influenza vaccine
<i>Mycobacterium avium</i> complex	Azithromycin, clarithromycin, ethambutol
Pneumococcal pneumonia	Pneumococcal vaccine when HIV infection diagnosed
<i>Pneumocystis carinii</i> pneumonia	Trimethoprim-sulfamethoxazole (Bactrim, Septra), dapsone, atovaquone, pentamidine isethionate
Tuberculosis	PPd testing; drug therapy per CDC guidelines: pyrazinamide, isoniazid (Laniazid, Isotamine), ethambutol (Myambutol)
HIV wasting	<p>Patient education:</p> <p>Eat three high-calorie and high-protein meals with snacks daily.</p> <p>Drink liquids before meals.</p> <p>Eat low-residue diet for diarrhea control.</p> <p>Control odors.</p> <p>Develop easy meal plan: favorite foods, meal programs, frozen dinners, cold food to control nausea.</p> <p>Use antiemetics, appetite stimulants, and/or testosterone.</p> <p>Rest, listen to music.</p> <p>Numb painful oral sores with ice, popsicles, or topical analgesic; avoid spicy foods.</p> <p>Use artificial saliva for dry mouth.</p> <p>Use nutritional supplements.</p> <p>Use food stamps, community food pantries, or free meal programs as needed.</p> <p>Exercise to increase muscle mass.</p> <p>Take medications prescribed to treat HIV wasting.</p>

- Preventing the virus from attaching to the CD4+ receptor of the T-4 lymphocyte
- Interfering with “uncoating” of the virus within the cell, the first essential step in allowing the virus to integrate into the cell’s DNA
- Inhibiting reverse transcriptase (RT), a viral enzyme specific to retroviruses, which enables the virus to make a DNA copy from single-stranded viral RNA prior to integration into cellular DNA
- Blocking viral regulatory and transactivating proteins, which are involved in the transcription and translation of viral RNA proteins from proviral DNA as the virus goes from the quiet, integrated state to active replication
- Inhibiting protease, a viral enzyme responsible for the adherence of viral proteins both before proviral integration and as the viral particles recombine into functional proteins needed for viral maturation
- Preventing viral assembly and budding out of the cell

For more information, visit the Medscape quick reference guide to antiretrovirals at www.medscape.com.

Highly Active Antiretroviral Therapy (HAART)

Aggressive treatment with multiple-drug therapy, aimed at reducing the viral load to an undetectable amount, is the

most effective line of treatment for HIV. (See Table 19.4.) “Cocktails” of multiple antiretroviral drugs (i.e., HAART) have reduced viral loads in the bloodstream and increased CD4+ T-lymphocyte counts, resulting in prolonged survival. HAART, in use since 1996, has made monotherapy (using one drug) an outdated concept except for some cases involving pregnant women. Many combination drug regimens can be used. The use of HAART is important to help reduce drug resistance, which is a common cause of treatment failure. The major cause of drug resistance occurs when HAART is not taken as directed. “Adherence” is the word used to describe taking medications exactly as directed.

Many anti-HIV drugs have side effects. If they occur, the drug regimen may be changed or interventions may be used to help control side effects. The patient should be taught always to report side effects immediately, especially rashes (such as with trimethoprim-sulfamethoxazole) and abdominal pain (such as with zidovudine [AZT, Retrovir]); they could be serious and potentially life threatening.

Fusion Inhibitors

Fusion inhibitors (also referred to as entry inhibitors) are the newest class of antiretroviral agents. (See Table 19.4.) This is the first treatment to work outside the CD4+ cell by blocking HIV fusion with the CD4+ cell membrane and preventing cell entry. This prevents infection of healthy CD4 cells if HIV is not able to gain entry into the cell. This type of medication is used in combination therapy with

other anti-HIV medications. Fusion inhibitors reduce the viral load (amount of HIV present in the blood) and increase CD4 cell levels. This type of drug can be helpful to those who have become resistant to other medications since it works in a different way than other medications. One drug, enfuvirtide (Fuzeon), has been approved by the Food and Drug Administration (FDA) for use while several others are in development. These drugs are given either by injection or intravenously.

Integrase Inhibitors

Integrase inhibitors, which block the third HIV enzyme integrase (protease and reverse transcriptase are the other two HIV enzymes), are a new class of drugs in development for the treatment of HIV.

Blocking integrase prevents the integration of the virus's DNA into the cell's chromosome. If this occurs, then the cell cannot be infected with HIV. Look for more information on the development of these drugs as it becomes available.

NURSING MANAGEMENT

Nursing Process: The Adult Patient with HIV/AIDS

Assessment/Data Collection

Ongoing assessment is important for the patient with HIV/AIDS to detect problems early. Health history information is obtained (Box 19.5 Assessment: Health History Information for HIV/AIDS). Determining patient understanding of HIV/AIDS information is necessary for planning and teaching. A physical assessment provides data on the effects of HIV/AIDS and antiviral treatments. Assessing the patient's pain level is ongoing. It is helpful to have patients use standardized pain rating scales such as the Wong Baker faces scale. (See Chapter 9.) As the disease

LEARNING TIP

Key points to remember:

- HIV and AIDS are disease labels, not people labels.
- Each person reacts to an HIV or AIDS diagnosis differently.
- It is not HIV that ultimately causes death; it is compromised immunity and the invasion of an opportunistic infection or disease that the patient's body is unable to successfully fight off even with medical intervention.
- With today's current successful anti-retroviral treatments, HIV has changed from being a life-ending infection to more of a chronic disease requiring constant management.

progresses, patients may have more pain but reduced cognitive ability to express the pain level. Several types of standardized pain rating scales allow assessment of pain with reduced cognitive ability. Signs and symptoms of opportunistic diseases are noted.

Nursing Diagnosis

Nursing care is individualized to the patient's presenting symptoms. Primary nursing diagnoses for HIV/AIDS include:

- Risk for infection related to decreased immune function
- Impaired gas exchange related to respiratory infection
- Acute or chronic pain related to neuropathy, cancer, infection, or dyspnea
- Fatigue related to HIV infection and/or side effects of treatments
- Imbalanced nutrition: less than body requirements related to anorexia, nausea and vomiting, increased caloric need, diarrhea, dysphagia, oral lesions
- Impaired oral mucous membranes related to decreased immune function
- Diarrhea related to infection, medications

Box 19.5

Assessment: Health History Information for HIV/AIDS

Demographic data: Gender, age, marital status, occupation, residence

Date of diagnosis of HIV/AIDS

Past medical history and surgeries

Current health status and concerns

Allergies

Medications history of antivirals used with reason for discontinuing

Current medications, dose and frequency (including over-the-counter medication and supplements)

Immunizations

Family history

Height/weight: weight loss

Infections/cancers (see Box 19.1, CDC Conditions in the AIS Surveillance Case Definition)

Sexually transmitted diseases and treatments

Social history, sexual practices, risk behaviors, safe sex practices

Needle and blood exposure, injection drug use, blood transfusions/treatment for hemophilia

Tobacco use

Drug and alcohol use

Exercise and sleep

Pets

Occupational history

Nutrition history

Women's health, last Pap, ob/gyn

- Impaired skin integrity related to infection, cancer, immobility, incontinence
- Social isolation related to fear of disclosure of status, infection control, transmission of virus
- Risk for situational low self-esteem related to body image changes
- Deficient knowledge related to lack of prior experience with HIV/AIDS and treatment

Additional diagnoses may include:

- Anticipatory grieving related to loss of function or death
- Disturbed thought processes related to AIDS dementia
- Disabled family coping related to chronic, progressive disease

- Ineffective coping related to chronic progressive disease
- Ineffective sexuality pattern related to disease transmission
- Risk for injury related to weakness, fatigue, sedation, neurological impairment

See Box 19.6 Nursing Care Plan for the Patient with AIDS.

Implementation

HIV/AIDS affects every system of the body and every aspect of a person's life. Nurses have the opportunity to positively influence the patient's experience with HIV/AIDS with a nonjudgmental approach, empathy, and psychological support.

Box 19.6 NURSING CARE PLAN for the Patient with AIDS

Nursing Diagnosis: Risk for infection, nosocomial related to weakened immune system, skin breakdown, intravenous therapy, and possible invasive procedures

Expected Outcomes Patient will remain free of nosocomial infections. Patient will describe measures to maintain skin integrity and avoid infections.

Evaluation of Outcomes Is patient free of nosocomial infections? Can patient explain and demonstrate skin maintenance techniques?

Interventions

Assess patient's risk factors, such as skin condition, laboratory results, portals of entry for infections, and presence of any infections.

Caregivers should use standard precautions and strict aseptic technique for *all* patients and procedures.

Instruct visitors about techniques to avoid transmission of infection, such as hand washing and not visiting when they have an infection. The nurse with an infection, especially respiratory infection, should not care for patient with AIDS. (If must care for patient, wear a mask and explain why you are wearing mask.)

Promote skin integrity by frequent turning, optimum mobilization, protective mattress and chair pads, application of emollient to dry areas, and prompt treatment of any injuries.

Teach strategies for skin care and avoidance of infection to patient.

Rationale

Status of these assessment factors determines plan for care.

Transmission of microorganisms can occur in both directions. Many patients with HIV are not aware of their HIV status

The immune system is damaged by HIV. Ability to combat infections may be severely compromised. A minor infection for most people may kill a person who has AIDS.

Skin is the body's first line of defense.

Self-care offers a measure of control in frequently uncontrollable situation.

Evaluation

Does patient have intact skin or nonreddened, nonpurulent sites of interrupted integrity?

Do all caregivers use standard precautions?

Do those with infections avoid contact with patient until their infection is resolved? Do laboratory tests indicate that patient is so immunocompromised that reverse isolation may be necessary?

Does patient's skin remain intact and infection free?

Does patient satisfactorily explain or demonstrate good skin care and knowledge of how to avoid infection?

(Continued on following page)

Box 19.6 NURSING CARE PLAN for the Patient with AIDS (Continued)

Nursing Diagnosis: Risk for injury related to impaired mobility, weakness, fatigue, possible electrolyte imbalances, neurological impairment, and sedative effects of pain medications

Expected Outcomes Care and mobility needs will be met without injury.

Evaluation of Outcomes Does patient remain free from injury?

Interventions

Assess patient's abilities and disabilities.
 Look for potential hazards in environment (hospital or home) and eliminate as many hazards as possible.
 Instruct patient about how to avoid hazards (if cognitively and physically able to comply).
 Encourage self-care as much as is feasible without tiring patient.
 Assist with care activities as needed.

Institute safety measures as required, such as close observation, frequent reorientation, two staff members for ambulation, use of side rails, bed motion alarm, or room near nurse's station.

Rationale

Particular disabilities may increase danger to patient.
 Awareness of hazards is necessary to decrease occurrence of accidents and injuries.
 Patients can help avoidance of injury if they understand hazards.
 Self-care promotes feelings of self-efficacy and can combat depression.
 Varying levels of assistance with care are necessary due to the potentially debilitating nature of disease.
 Protection of patient against inadvertent removal of tubes or equipment, falls, and other injuries may require extraordinary measures due to neurological damage.

Evaluation

Does patient have deficits?
 Are there any hazards in the environment presently?
 Is patient effectively avoiding hazards, or is patient a danger to self?
 Does patient evidence satisfaction with self-care efforts?
 Are patient's care and mobility needs being met satisfactorily without injury?
 Are safety measures effective for patient? Does patient respond negatively to the protective measures? Can these be modified to be less offensive?

Nursing Diagnosis: Ineffective individual coping related to terminal disease and progressive debility

Expected Outcome Patient will show use of effective coping skills.

Evaluation of Outcome Does patient show use of effective coping skills?

Interventions

Establish and maintain open and trusting therapeutic relationship.
 Allow grieving to take place (keeping a journal has been effective for some patients who have AIDS).
 Encourage patient to express feelings and concerns. Contact counselor, chaplain, or AIDS support worker if patient so desires.
 Provide patient with desired information or refer to others who can supply information.
 Ask if patient would like information about support group and arrange such.

Rationale

Effective communication is based on trust—assurance of confidentiality is essential.
 AIDS brings about losses of health, strength, employment, and in many cases friends and threatens one's sense of security and reasonableness of life. Healthy grieving is a natural coping response.
 Talking about feelings and concerns helps defuse anger, clarify needs, and relieve tension.
 Knowledge dispels unreasonable fears and helps patient prepare adequately to cope with stressors.
 Social support can help patient cope.

Evaluation

Does patient talk about concerns with nurse?
 Is grief being expressed? Is patient finishing things that matter to him or her?
 How are family members, friends, and support persons interacting with patient? How is patient responding to family members, friends, and support persons?
 Does patient evidence enough understanding of disease to be able to cope effectively?
 Does patient show satisfaction with coping resources?

RISK FOR INFECTION. To reduce infection risk, the patient should be taught to wash hands frequently, especially before eating and after toileting; bathe regularly; avoid sharing personal grooming items (e.g., toothbrush, toothpaste, razor); cleanse toothbrush; and wash all dishes between uses (Table 19.6). In addition, the patient is taught signs of

infection to report to health-care provider immediately (Box 19.7 Patient Teaching: Signs and Symptoms of Opportunistic Infections to Report). Treatment of opportunistic infections is most effective when begun early.

IMPAIRED GAS EXCHANGE. If a patient develops a con-

TABLE 19.6 PATIENT TEACHING: PREVENTING OPPORTUNISTIC INFECTIONS

Precaution Category	Reducing Exposure Risk	To Protect From
<i>Environmental/ Occupational</i>	<p>Consider risk for exposure to infectious agents from the following: health-care setting, correctional facilities, homeless shelters.</p> <p>Child care settings: wash hands after diaper changing/body fluid contact.</p> <p>Animal contact: exposure possible from veterinary work, pet stores, farms.</p> <p>Gardening/soil contact: avoid gardening/houseplant care/bird-roosting site, soil, cleaning chicken coops. Wear gloves and mask and wash hands after soil contact.</p>	<p>Tuberculosis</p> <p>CMV, cryptosporidiosis, hepatitis A, giardiasis</p> <p>Cryptosporidiosis, toxoplasmosis, salmonellosis, campylobacteriosis</p> <p>Cryptosporidiosis, toxoplasmosis, histoplasmosis, coccidioidomycosis</p>
<i>Food/water</i>	<p>General measures for home or restaurants include the following:</p> <p>Food handlers should practice good hand washing and hygiene.</p> <p>Discard food past expiration date, dented or swollen cans.</p> <p>Maintain adequate refrigeration and cooking temperatures.</p> <p>Control insects and rodents to prevent food contamination.</p> <p>Foods to avoid:</p> <p>Raw/undercooked eggs and foods with raw eggs, such as hollandaise sauce, caesar dressing, mayonnaise, uncooked batters, ice cream, eggnog.</p> <p>Raw/undercooked poultry, meat, seafood.</p> <p>Unpasteurized milk/dairy products and fruit juice, raw seed sprouts.</p> <p>Soft cheeses, which may harbor bacteria: feta, Brie, Camembert, blue veined, queso fresco.</p> <p>Wash produce and avoid unwashed produce on salad bars.</p> <p>Avoid cross contamination of foods with uncooked meat.</p> <p>Cook meat until internal temperature is 180°F (82.2°C) for poultry, 165°F (73.8°C) for red meats, with no trace of pink.</p> <p>Foods to avoid or cook until steaming hot: leftovers, ready-to-eat, delicatessen foods, refrigerated pates, and meat spreads.</p> <p>Water safety:</p> <p>Avoid public drinking fountains.</p> <p>Avoid drinking or swallowing water directly from lakes or rivers.</p> <p>Use safe water supply or boil water 1 minute when unsure.</p> <p>Avoid beverages made from tap water in public places.</p> <p>Drink bottled water purified from reverse osmosis, filtration through absolute 1-µm filter, or distillation (only safe methods). For information, contact www.bottledwater.org.</p> <p>Bottled or canned carbonated soft drinks, commercially packaged nonrefrigerated beverages, pasteurized beverages, and beers are safe.</p>	<p>Foodborne and waterborne infections caused by bacterial, viral, protozoal, or parasitic pathogens</p> <p>Cryptosporidiosis, giardiasis</p>
<i>Sexual</i>	<p>Always use latex condom for every sex act.</p>	<p>STDs, herpes simplex virus, cytomegalovirus, human papillomavirus, resistant HIV strain</p>

(Continued on following page)

TABLE 19.6 PATIENT TEACHING: PREVENTING OPPORTUNISTIC INFECTIONS (Cont'd)

Precaution Category	Reducing Exposure Risk	To Protect From
<i>Injection drug use</i>	Avoid oral-anal contact or use dental dams; use latex gloves for hand-anal contact; wash hands and genitals with warm soapy water after contact. Get hepatitis A vaccine. Get hepatitis B vaccine. Get hepatitis A and B vaccines. Stop using injection drugs and enter substance abuse treatment. If unable to stop, never reuse or share syringes, needles, water, or drug preparation equipment. If shared, use bleach and water to clean equipment. Use sterile syringes from pharmacies or community syringe exchange programs and dispose of safely. Use clean water and equipment and new alcohol swab.	Intestinal infections: amebiasis, hepatitis A, cryptosporidiosis, shigellosis, campylobacteriosis, giardiasis Hepatitis A Hepatitis B Hepatitis A, hepatitis B, hepatitis C, resistant HIV strain
<i>Pet-related</i>	Avoid pet feces/diarrhea; seek veterinary treatment for pet's illness. Counsel on pet contact risks but recognize emotional benefits of pets. Pets should have up-to-date immunizations. Avoid exotic pets. Cat ownership increases risk from litter box cleaning, scratches, bites, licking, fleas. If must clean litter box, wear mask and gloves and wash hands well afterward. Efforts should be made to keep cats indoors to avoid contact with infected prey. Unhealthy birds may transmit infectious organisms.	<i>Cryptosporidium</i> , <i>Salmonella</i> , <i>Campylobacter</i> spp. infection For new pet, avoid those younger than 6 months old (and cats younger than 1 year old); obtain pets from known sanitary source; avoid strays; wash hands after handling pets. Toxoplasmosis, <i>Bartonella</i> spp. infection, salmonellosis, campylobacteriosis
<i>Travel</i>	Avoid reptiles, turtles, chicks, and ducklings. Wear gloves for cleaning aquariums. Consult health-care providers on travel to developing countries. Traveler's diarrhea prophylaxis is not recommended. Carry supply of antimicrobial agent to take for diarrhea. Consider prophylaxis for other types of exposures. Avoid raw fruits, vegetables, raw/undercooked seafood or meat, tap water, ice from tap water, unpasteurized milk/dairy products, items from street vendors. Safe items include steaming-hot foods, self-peeled fruits, bottled (especially carbonated) beverages, hot coffee/tea, beer, wine, and water boiled 1 minute. Avoid soil/sand contact by wearing shoes, using beach towels.	<i>Cryptococcus neoformans</i> , <i>Mycobacterium avium</i> , <i>Histoplasma capsulatum</i> infection Salmonellosis <i>Mycobacterium marinum</i> infection Opportunistic pathogens, foodborne and waterborne infections

CMV = cytomegalovirus; STD = sexually transmitted disease.

Source: Data from U.S. Department of Health and Human Services: 2001 USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus. <http://hivatis.org>, November 28, 2001.

dition that interferes with respiration, the goal is to maintain oxygenation within normal limits and reduce dyspnea. PCP is a respiratory infection with AIDS. (See Table 19.5.) Monitoring the patient's vital signs, including respiratory rate, depth, and rhythm and oxygen saturation, is important. Medications and oxygen therapy are given as ordered. Positioning the patient for comfort is often done by raising the head of the bed. Assisting with activities helps reduce fatigue.

PAIN. Pain may occur from a variety of causes. Treatment is focused on the cause to achieve pain control and relief. Medications may be given as ordered. Timing medication administration prior to planned activities is helpful in

increasing ability to function. Complementary therapy may be used by patients. (See Chapter 4.) Measures such as heat or cold, massage, and frequent position changes may be helpful.

FATIGUE. Many patients with HIV experience fatigue. Other causes of fatigue include infections, medications, anemia, dehydration, depression, and poor nutrition. The patient can help manage fatigue by alternating periods of activity and rest. Tasks that use more energy should be planned at times when the patient is most energetic. Helping a patient prioritize activities is important in planning the best use of the energy available.

Box 19.7**Patient Teaching: Signs and Symptoms of Opportunistic Infections to Report**

Instruct patient to monitor temperature daily and to report the following symptoms to a health care provider immediately:

- New fever higher than 100°F (38.5°C) or a change in fever pattern if low-grade fevers are commonly present
- Cough, shortness of breath, fever, or chest tightness, which may be signs of early pneumonia
- Signs of central nervous system infection, such as severe headache; stiff neck; visual changes; problems with balance, walking, or speech; weakness of an arm or leg; and changes in moods or memory
- Foul-smelling drainage or pus
- Cloudy or foul-smelling urine
- Signs of dehydration, such as a dry mouth, dark concentrated urine, or dizziness when standing
- Diarrhea lasting longer than 48 hours; more than six stools a day; watery, mucous, or bloody stools
- Rashes (possible side effect of medication)
- Sore mouth or tongue, difficulty swallowing, white patches on tongue or back of mouth
- Worsening fatigue
- Change in vision and if floaters develop

IMBALANCED NUTRITION: LESS THAN BODY REQUIREMENTS. Maintaining general health and nutrition is important for a healthy immune system. For patients with HIV, maintaining health is vital. Patients with AIDS often have difficulty maintaining adequate nutrition and preventing weight loss. Many factors interfere with nutrition in HIV/AIDS (e.g., anorexia, oral lesions, nausea and vomiting, diarrhea, or wasting syndrome). The cause needs to be identified for appropriate intervention planning.

The patient's baseline weight is obtained. Then ongoing monitoring of the patient's weight, calorie intake, and intake and output is done. A dietitian is consulted to help plan nutritious and affordable meals. The patient should be on a high-calorie, high-protein diet. Small, frequent meals may be helpful. Vitamins, nutritional supplements, tube feedings, or parenteral nutrition (partial parenteral nutrition [PPN] or total parenteral nutrition [TPN]) may be needed to maintain adequate nutrition. Antiemetics are used to control nausea and vomiting. Medications that help stimulate appetite may be helpful. Easy to prepare meals are helpful when energy is limited. Creative interventions and resources may be needed to ensure the patient receives adequate nutrition. (See Table 19.5.) Along with adequate nutrition, exercise helps maintain muscle mass, promotes relaxation, aids sleep, and gives an individual a sense of control and well-being. An effective exercise program includes exercises that

increase strength, flexibility, and endurance. Becoming physically fit is a lifestyle change that requires dedication.

IMPAIRED ORAL MUCOUS MEMBRANES. Oral or esophageal candidiasis is common. The painful lesions interfere with swallowing and nutrition. In patients with AIDS who smoke there is an increased incidence of oral thrush (candidiasis). Therefore, patients should be encouraged to quit smoking. Antifungal medication is given. Mouth care is very important. A soft toothbrush promotes comfort. Viscous lidocaine can be given to decrease pain during eating.

DIARRHEA. Diarrhea often occurs in the patient with HIV. Diarrhea can be caused by HIV infection, opportunistic infections, or antiretroviral treatments. An antimotility agent (diphenoxylate/atropine [Lomotil]) may be prescribed (except in salmonellosis). Consulting the dietitian may be helpful in making dietary changes that reduce diarrhea (e.g., low-residue diet, no dairy products, no spicy foods, no caffeine or alcohol). Sitz baths may be soothing. Thorough cleansing of the rectal area after each stool is a must. Ointments may be applied to protect and soothe the anal area from excoriation.

IMPAIRED SKIN INTEGRITY. There are many skin conditions that can occur with HIV infection. Medications can cause skin infections that can be life threatening and must be reported immediately. A dermatologist may need to be consulted to help diagnose and treat skin infections.

SOCIAL ISOLATION. Many patients with HIV/AIDS face discrimination, rejection, and isolation. The Americans with Disabilities Act (ADA) makes discrimination toward patients with HIV illegal. Relatives, friends, and others sometimes avoid or refuse to have anything to do with the person with HIV (Box 19.8 Ethical Considerations). Misunderstanding and fear lead to misuse of infection control procedures and increase a patient's isolation. Being knowledgeable about the transmission of HIV allows interaction with the patient to reduce feelings of isolation. Providing patient education to reduce fear of HIV transmission also decreases isolation. Care to maintain confidentiality is essential. Many patients with HIV do not share their diagnosis with family or friends who may visit when they are hospitalized.

RISK FOR SITUATIONAL LOW SELF-ESTEEM. Changes in self-esteem and self-concept occur from several of the effects of HIV infection. Patients often experience changes in their relationships with others and in day-to-day activities such as work. Major weight loss and changes in fat distribution from antiviral treatments, called lipodystrophy, may cause dramatic changes in appearance that alter body image and reduce self-esteem. Nurses can assist patients in maintaining self-esteem and self-concept by ensuring a climate of acceptance and promoting a trusting relationship. Patients should be encouraged to express feelings if ready and to identify positive aspects of self. Emotional and spiritual support of the patient can help improve self-esteem.

Stress impacts health. Having others to talk with and provide support is essential to stress management.

Box 19.8

Ethical Considerations

Caring for a Patient with AIDS

Edward Klee, 28, is hospitalized in a large research hospital in California. He is in the terminal stages of AIDS, with widespread metastatic cancer and lung infections. He wants to see his parents before he dies as he has not seen them for nearly 10 years when he was leaving for college. Edward grew up in a middle-class household deep in the heart of the Bible Belt of Oklahoma. His homosexuality was hidden from his friends, his schoolmates, and especially his family.

Even though he is dying, with no hope of another remission, Edward does not want his parents to know about his homosexuality or that he has a disease that still carries such a stigma. He feels that their rigid religious beliefs may push them towards disowning him. In addition, Edward is terrified of any scene they may make, and he was fearful that such an incident could influence his care. In order to prepare for their visit, Edward asks the licensed practical nurse/licensed vocational nurse (LPN/LVN) who is assigned to care for him to answer any of his parents' questions about his illness by telling them he has leukemia, pneumonia, or another rare disease that they would know nothing about. After the third day of visiting their severely ill son, Edward's parents approached the LPN/LVN, and with a stern tone asked, "Does our son have AIDS?"

- How should the LPN/LVN respond?
- To whom does the LPN/LVN owe the greatest obligation, the patient or his family?
- What principles are in conflict?
- What virtues play a role in this situation?

Use the decision-making model and determine several possible solutions for this situation.

Identifying and maintaining social networks is important. Patients should be taught a variety of relaxation strategies and techniques to reduce stress. Relaxation strategies can range from working on a favorite hobby to talking with friends. Relaxation techniques include progressive muscle relaxation and imagery to aid in relaxation. Stress management techniques are most effective when used every day, not just during times of stress.

DEFICIENT KNOWLEDGE. Extensive teaching is needed for patients to understand this chronic, life-threatening disease that alters everything in their lives. (See also the Prevention section.) Teaching needs to be evaluated for understanding and done as the patient is ready. Adherence to treatment and medication regimens is necessary to prevent infection and prolong the time before AIDS occurs.

MEDICATIONS. It is vital that medication doses not be missed; this must be stressed during patient teaching.

Teaching aids to assist patients in remembering to take their medications is very important. Encourage the patient to take medications exactly as instructed. If a dose is missed, it should be taken as soon as possible unless it is very close to the time of the next dose. Doses should not be doubled. Missing doses of medication could cause therapy failure because viral loads can increase and resistance develops. Tell the patient to consult the physician with any questions or side effects promptly. Many of these medications can cause severe reactions.

FOOD AND WATER SAFETY. Food and water safety is vital to an immunocompromised patient. Bacterial, viral, protozoal, or parasitic pathogens can cause foodborne and waterborne infections. The patient must be taught methods to prevent foodborne and waterborne infections for all phases of handling. (See Table 19.6.) Kitchen counters and food preparation appliances (e.g., cutting boards, can openers) should be disinfected. Freezing does not kill bacteria in foods. Foods should not be thawed at room temperature. Dating and using the oldest foods first is helpful. If symptoms of foodborne or waterborne infection develop (e.g., diarrhea, nausea, vomiting, abdominal cramps, headache, fever), teach patient to report them immediately. In certain areas of the country tap water is not safe. Patients may need to be taught to boil water for drinking and making ice cubes or to drink bottled water.

RESOURCES. Financial resources may need to be addressed so that food and medications can be obtained. Treatment can be expensive and the patient may be unable to work. However, with the new combination antiretroviral therapies, many individuals are now able to continue working longer. Referrals to financial resources and support groups can be important.

COMMUNITY AND HOME HEALTH CARE. During the course of HIV infection, the patient will be primarily at home and in the community. Hospitalization may be needed intermittently for acute illness. If the disease progresses, the patient may require more care from caregivers and home health nurses. The home health nurse provides physical care, establishes a therapeutic relationship with patients with AIDS and their significant others and family/friends, and coordinates care with other health-care team members (Home Health Hints). Caregivers should be assessed for caregiver role strain. Support services should be identified, such as community AIDS organizations, Meals on Wheels, respite care services, community mental health, and Internet support groups. Respite care provides the caregiver time away from the caregiver role to reduce stress. When a patient is terminal, comfort care and emotional support for the family are essential. Hospice care may be used at this time.

Evaluation

Patient goals are met if the patient remains free from infection and maintains desired quality of life and activities as long as possible. As the disease progresses, goals are met if the patient's needs are met and the patient's dignity is maintained.

CRITICAL THINKING

Zoe Sampson

■ Zoe, 22, is diagnosed as HIV positive. She is tearful and asks many questions.

1. How would you answer her questions?
 - a. “Am I going to die?”
 - b. “How is AIDS diagnosed?”
 - c. “Can my boyfriend get it?”
2. What food and water safety methods would you teach her?
3. Years later Zoe loses weight and becomes malnourished. What interventions can you use to promote adequate nutrition?

Suggested answers at end of chapter.

Home Health Hints

- When providing patient care, wash hands frequently, follow standard precautions, and use plastic bags to contain soiled items or clothing.
- Teach patients with AIDS and their families how to properly clean and disinfect the home to prevent infections. The recommended disinfectant is a diluted bleach mixture that contains 1 part household bleach to 10 parts water.

- Wearing gloves, clean body fluid spills with soap and water.
- Flush body fluids, solid waste, and contaminated solutions down toilet.
- Use disinfectant to (a) disinfect spill areas; (b) clean toilet seats and bathroom fixtures; (c) clean inside the refrigerator to avoid mold growth.
- Rinse clothing and then wash separately from other clothes with 1 cup of bleach if soiled with blood, urine, feces, or semen.
- Patients with AIDS do not require separate sets of dishes or silverware. Dishes and silverware are washed in hot, soapy water and rinsed thoroughly or placed in dishwasher.
- Dispose of sharps (e.g., needles, razors) in a rigid labeled container (such as a tin can with a sealable lid). Add 1:10 bleach solution to disinfect. Tape the lid. Place in a bag and dispose of in the trash.
- Contaminated articles are disposed of by bagging in plastic and placing in the trash.
- Teach the family of a patient with AIDS which signs and symptoms to report to the physician or nurse immediately: fever; increased dyspnea; pain; change in sputum production; upper respiratory tract infection; pneumonia; respiratory distress syndrome; diarrhea five times a day or more for 5 days; uncontrolled weight loss greater than 10 pounds in the last month; persistent headaches; falling; seizures; mental status changes, including memory loss and personality changes; rashes and skin changes; difficulty swallowing; and problems with urination.

REVIEW QUESTIONS

1. The nurse would evaluate the patient as understanding modes of HIV transmission if the patient stated that the modes of HIV transmission include which of the following?
 - a. Saliva, tears, fecal-oral contamination
 - b. Close physical contact involving skin surfaces, mosquito bites
 - c. Sharing towels, sharing eating utensils, skin contact
 - d. Unprotected sex with HIV-infected partner, contact with infected blood/products
2. The nurse is teaching a patient about HIV testing. Place HIV diagnostic tests in the sequential order that they are performed.
 - a. Western blot test
 - b. Enzyme-linked immunosorbent assay (ELISA) test
 - c. ELISA test is repeated
3. A patient who is newly diagnosed with HIV infection asks what his future health status will be. The best response for the nurse to give is based on the understanding that HIV disease and AIDS are now characterized as which of the following?
 - a. An acute disease
 - b. A life-ending disease
 - c. A chronically managed disease
 - d. A disease with remissions and exacerbations

Multiple response item. Select all that apply.

4. What should the nurse include in a teaching plan to prevent HIV infection?
 - a. Caregiver may recap used needles
 - b. Abstain from sexual intercourse
 - c. Avoid injection drug use
 - d. Avoid use of male or female condoms
 - e. Autologous blood transfusion
 - f. Test for HIV at time of labor

Multiple response item. Select all that apply.

5. Which of the following should the patient with HIV be taught to do to decrease risk of infections?
 - a. Wash hands before eating
 - b. Wash toothbrush
 - c. Reuse dishes
 - d. Buy prepared deli foods
 - e. Report signs of infection
 - f. May share razor with no visible blood
6. The nurse would recognize that the patient needs further reinforcement of knowledge if the patient stated that one of the goals of highly active antiretroviral therapy is which of the following?
 - a. Reduce the viral load
 - b. Improve survival rates
 - c. Decrease CD4+ T lymphocytes
 - d. Delay the progression of HIV disease
7. The nurse would recognize that the patient is having a reaction to zidovudine (AZT) if which of the following occurred?
 - a. Rash
 - b. Edema
 - c. Abdominal pain
 - d. Blurred vision
8. The nurse is to give lamivudine (3TC) 150 mg PO now and has available a 10 mg/mL oral solution. How many milliliters should the nurse give? _____ mL

SUGGESTED ANSWERS TO**CRITICAL THINKING****■ Zoe Sampson**

1.
 - a. There currently is no cure for HIV/AIDS; however, medications are available that slow the disease's progression and make HIV a manageable chronic illness. Research continues on finding improved treatments and search for a cure.
 - b. AIDS is diagnosed when CD4+ T-lymphocyte counts are below 200 cells per microliter or CD4+ T-lymphocyte percentage is under 14 of total lymphocytes and an opportunistic clinical disease, as defined by the CDC, is present in an HIV-infected person.
 - c. Yes, your boyfriend could become infected through exposure to your blood or vaginal secretions. You need to learn about preventive measures and discuss them with him. If you have had unprotected sex, he should be tested.
2. Food handlers must maintain good hand washing and hygiene practices. Discard food past the expiration date and dented or swollen cans. Ensure adequate refrigeration and cooking. Control insects and rodents to prevent food contamination. Avoid public drinking fountains. Drink purified bottled water if you live in areas of unsafe drinking water. Use a safe water supply or boil water 1 minute when unsure. Avoid unpasteurized milk, other dairy products, and fruit juice and raw seed sprouts. Avoid raw and undercooked eggs, meats, and seafood.
3. Eat three high-calorie, high-protein meals and snacks daily. Drink liquids before meals. Eat a low-residue diet for diarrhea control. Develop easy meal plan. Use antiemetics. Numb painful oral sores. Avoid spicy foods. Refer for food stamps/free meal programs if necessary. Engage in regular exercise.

1. What is the normal anatomy of the cardiovascular system?
2. What is the normal function of the cardiovascular system?
3. What data should you collect when caring for a patient with a disorder of the cardiovascular system?
4. What are the diagnostic tests commonly performed to diagnose disorders of the cardiovascular system?
5. What nursing care should you provide for patients undergoing each of the diagnostic tests?
6. What are common therapeutic measures used for patients with disorders of the cardiovascular system?
7. What are the preoperative and postoperative routines and procedures for cardiac surgery?

REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY

The cardiovascular system consists of the heart, blood, and blood vessels (including arteries, capillaries, and veins). Its function is to pump and distribute the blood throughout the body.

Heart

Cardiac Location and Pericardial Membranes

The heart is located in the mediastinum, the area between the lungs in the thoracic cavity. It is enclosed by three pericardial membranes that make up the pericardial sac. The outermost of these membranes is the fibrous pericardium, which forms a loose-fitting sac around the heart. The second, or middle, layer is the parietal pericardium, a serous membrane that lines the fibrous layer. The third and innermost layer, the visceral pericardium or epicardium, is a serous membrane on the surface of the heart muscle. Between the parietal and visceral layers is serous fluid, which prevents friction as the heart beats.

Cardiac Structure and Vessels

The walls of the four chambers of the heart are made of cardiac muscle (myocardium) and are lined with endocardium, which is smooth epithelial tissue that prevents abnormal clotting. The endocardium also covers the valves of the heart and continues into blood vessels as the lining. The coronary vessels include the arteries and capillaries that circulate oxygenated blood throughout the myocardium and the veins that return deoxygenated blood to the heart's interior chambers. The two main coronary arteries are the first branches of the ascending aorta, just outside the left ventricle (Fig. 20.1).

The upper chambers of the heart are the thin-walled right atrium and left atrium, which are separated by the interatrial septum. The lower chambers are the thicker-walled right and left ventricles, which are separated by the interventricular septum. Each septum is made of myocardium that forms a common wall between the two chambers.

The right atrium receives deoxygenated blood from the upper body by way of the superior vena cava and from the lower body by way of the inferior vena cava. (See Fig. 20.1.) This blood flows from the right atrium through the tricuspid valve into the right ventricle. Backflow during ventricular systole (contraction and emptying) is prevented by the tricuspid, or right, atrioventricular (AV) valve (Fig. 20.2). The right ventricle pumps blood through the pulmonary semilunar valve to the lungs by way of the pulmonary artery. The pulmonary semilunar valve prevents backflow of blood into the right ventricle during ventricular diastole (relaxation and filling).

The left atrium receives oxygenated blood from the lungs by way of the four pulmonary veins. This blood flows through the mitral, or left, AV valve (also called the bicuspid valve) into the left ventricle. The mitral valve prevents backflow of blood into the left atrium during ventricular systole. The left ventricle pumps blood through the aortic semilunar valve to the body by way of the aorta. The aortic valve prevents backflow of blood into the left ventricle during ventricular diastole.

The tricuspid and mitral valves consist of three and two cusps, respectively. These cusps, or flaps, are connective tissue covered by endocardium and are anchored to the floor of the ventricle by the chordae tendineae and papillary muscles. The papillary muscles are columns of myocardium that contract along with the rest of the ventricular myocardium.

FIGURE 20.1 Anterior view of the heart and major blood vessels. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA. Davis, Philadelphia, 2007, p 276.)

FIGURE 20.2 Frontal section of the heart showing internal structures and cardiac blood flow. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA. Davis, Philadelphia, 2007, p 276.)

This contraction pulls on the chordae tendineae and prevents inversion of the AV valves during ventricular systole. (See Fig. 20.2.)

Although each ventricle pumps the same amount of blood, the much thicker walls of the left ventricle pump with approximately six times the force of the right ventricle to distribute the blood throughout the body. This difference in force is reflected in the great difference between systemic and pulmonary blood pressure.

Cardiac Conduction Pathway and Cardiac Cycle

The cardiac conduction pathway is the pathway of electrical impulses that generates a heartbeat. The sinoatrial (SA) node in the wall of the right atrium is a specialized mass of cardiac muscle that depolarizes rhythmically and most rapidly, about 100 times per minute, and therefore initiates each heartbeat. (While at rest, parasympathetic fibers dominate and slow the SA node to about 75 bpm.) For this reason, the SA node is sometimes called the pacemaker, and a normal heartbeat is called a normal sinus rhythm. From the SA node, impulses travel to the AV node located in the lower interatrial septum, to the atrioventricular bundle (bundle of His) in the upper interventricular septum, to the right and left bundle branches in the septum, and to the Purkinje fibers in the rest of the ventricular myocardium. If the SA node becomes nonfunctional, the AV node can initiate each heartbeat, but at a slower rate of 40 to 60 beats per minute. The bundle of His is capable of generating the beat of the ven-

tricles, but at the much slower rate of 20 to 35 beats per minute.

A cardiac cycle is the sequence of mechanical events during one heartbeat. Simply stated, the two atria contract simultaneously, followed a fraction of a second later by the simultaneous contraction of the two ventricles. The contraction, or systole, of each set of chambers is followed by relaxation, or diastole, of the same set of chambers.

The atria in diastole continually receive blood from the veins. As pressure in the atria increases, the AV valves are forced open, causing most of the blood to flow passively into the ventricles. Atrial systole pumps the remaining blood into the ventricles, and then the atria relax. Ventricular systole follows. The pressure in the ventricles causes the AV valves to close and forces the semilunar valves to open. Blood is then pumped into the aorta and pulmonary artery. There is no passive blood flow. Any blood leaving the ventricles must be pumped. Toward the very end of ventricular systole, as the pressure drops, the blood tends to flow backward within the two exiting arteries. It is this backflow of blood that closes the semilunar valves. The ventricles and atria are then all in diastole; the atria continue to fill until pressure opens the AV valves again, and the cycle is repeated.

The events of the cardiac cycle create the normal heart sounds. The first of the two major sounds (the lubb of lubb-dupp) is caused by the closure of the AV valves during ventricular systole. The second sound is created by the closure of the aortic and pulmonary semilunar valves.

Cardiac Output

Cardiac output is the amount of blood ejected from the left ventricle in 1 minute (the right ventricle pumps a similar amount). It is determined by multiplying stroke volume by heart rate. Stroke volume is the amount of blood ejected by a ventricle in one contraction and averages 60 to 80 mL/beat. With an average resting heart rate of 75 beats per minute, an average resting cardiac output is 5 to 6 L (approximately the total blood volume of an individual that is pumped within 1 minute). During exercise, venous return increases and stretches the ventricular myocardium, which in response contracts more forcefully. This is known as Starling's law of the heart, and the result is an increase in stroke volume. More blood is pumped with each beat, and at the same time, the heart rate increases, causing cardiac output to increase to as much as four times the resting level, and even more for athletes.

The ejection fraction is a measure of ventricular efficiency and is usually about 60%. It is the stroke volume divided by total blood in the ventricle (also known as the end-diastolic volume, which is approximately 120 to 130 mL). Lower values indicate that the ventricle is not pumping as forcefully and that more blood remains in the ventricle at the end of systole. The normal end-systolic volume is about 50 to 60 mL.

Regulation of Heart Rate

The heart generates its own electrical impulse, which begins at the SA node. The nervous system, however, can change the heart rate in response to environmental circumstances (Fig. 20.3). In the brain, the medulla contains the cardiovas-

cular centers: the accelerator center and the inhibitory center. Sympathetic nerve impulses—along sympathetic nerves from the thoracic spinal cord to the SA node, AV node, and most of the myocardium—increase rate and force of contraction. Parasympathetic impulses—along the vagus nerve to the SA node, AV node, and atrial myocardium—decrease heart rate.

The information for changes necessary in the heart rate comes to the medulla from proprioceptors and from baroreceptors and chemoreceptors located in the internal carotid arteries and the aortic arch. The baroreceptors, specialized cells in the carotid and aortic sinuses, detect changes in blood pressure. The chemoreceptors are located in the carotid and aortic bodies and are cells specialized to detect changes in the oxygen content of the blood (as well as changes in carbon dioxide and hydrogen ion content). In response to either a drop in blood pressure or a decrease in blood oxygen level, the heart receives sympathetic impulses and beats faster in an attempt to provide sufficient oxygenation for tissues.

Hormones and the Heart

The hormone epinephrine, secreted by the adrenal medulla in stressful situations, is sympathomimetic in that it increases the heart rate and force of contraction and it dilates the coronary vessels. This in turn increases cardiac output and systolic blood pressure.

Aldosterone, a hormone produced by the adrenal cortex, is important for cardiac function because it helps regulate blood levels of sodium and potassium, both of which are needed for the electrical activity of the myocardium. The

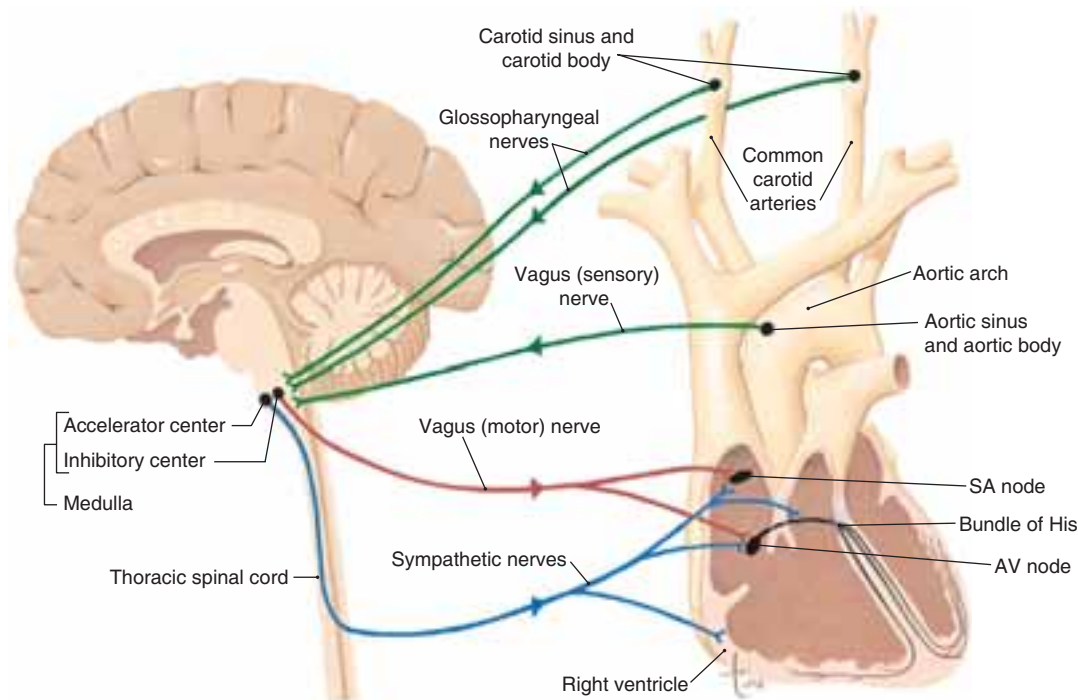

FIGURE 20.3 Nervous system regulation of the heart. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA. Davis, Philadelphia, 2007, p 285.)

blood level of potassium is especially critical because even a small deficiency or excess impairs the rhythmic contractions of the heart.

The atria of the heart secrete a hormone of their own called atrial natriuretic peptide (ANP) or atrial natriuretic hormone (ANH). As its name suggests, ANP increases the excretion of sodium by the kidneys, by inhibiting secretion of aldosterone by the adrenal cortex. Atrial natriuretic peptide is secreted when a higher blood pressure or greater blood volume stretches the walls of the atria. The loss of sodium is accompanied by the loss of more water in urine, which decreases blood volume and therefore blood pressure as well.

Blood Vessels

Arteries and Veins

Arteries and arterioles carry blood from the heart to capillaries. Their walls are relatively thick and consist of three layers. Arteries carry blood under high pressure, and the outer layer of fibrous connective tissue prevents rupture of the artery. The middle layer of smooth muscle and elastic connective tissue contributes to the maintenance of normal blood pressure (BP), especially diastolic BP, by changing the diameter of the artery. The diameter of arteries is regulated primarily by the sympathetic division of the autonomic nervous system. By use of the smooth muscle, the arteries can also alter where the greatest volume of blood is directed. The lining is simple squamous epithelium, called endothelium, which is very smooth to prevent abnormal clotting.

Veins and venules carry blood from capillaries to the heart. Their walls are relatively thin because there is less smooth muscle (veins do not have as important a role in the maintenance of BP as arteries). Sympathetic impulses can bring about extensive constriction of veins, however, and this becomes important in situations such as severe hemorrhage. The lining of veins is, again, endothelium that prevents abnormal clotting; at intervals it is folded into valves to prevent backflow of blood. Valves are most numerous in the veins of the extremities, especially the legs, where blood must return to the heart against the force of gravity.

Capillaries

Capillaries carry blood from arterioles to venules and form extensive networks in most tissues. The exceptions are cartilage, the epidermis, and the lens and cornea of the eye. Their walls, a continuation of the lining of arteries and veins, are one cell thick to permit the exchanges of gases, nutrients, and waste products between the blood and tissues (Fig. 20.4). Blood flow through a capillary network is regulated by a precapillary sphincter, a smooth muscle fiber ring that contracts or relaxes in response to tissue needs. In an active tissue such as exercising skeletal muscle, for example, the rapid oxygen uptake and carbon dioxide production causes dilation of the precapillary sphincters to increase blood flow. At the same time, precapillary sphincters in less active tissues constrict to reduce blood flow. This is important because there is not enough blood in the

body to fill all the capillaries at once; the fixed volume must constantly be shunted or redirected to where it is needed most.

The blood pressure in capillaries is 30 to 35 mm Hg at the arterial end of the network, and it drops to about 15 mm Hg at the venous end. This pressure is low enough to prevent rupture of the capillaries but high enough to permit filtration. Tissue fluid is formed from the plasma in capillaries by the process of filtration. Because capillary blood pressure is higher than the pressure of the surrounding tissue fluid, plasma and dissolved materials such as nutrients are forced through the capillary walls to become tissue fluid. Some of this tissue fluid returns to the capillaries, and some is collected in lymph capillaries. Now called lymph, it too is returned to the blood by the system of lymph vessels. Should blood pressure within the capillaries increase, more tissue fluid than usual is formed, which is too much for the lymph vessels to collect. This is called edema.

Blood Pressure

Blood pressure is the force of the blood against the walls of the blood vessels and is measured in millimeters of mercury (mm Hg), systolic over diastolic. The normal range of systemic arterial pressure is 90 to 135/60 to 85 mm Hg. Blood pressure decreases in the arterioles and capillaries, and the systolic and diastolic pressures merge into one pressure. As blood enters the veins, BP decreases further and approaches zero as it flows into the right ventricle. As mentioned previously, the blood pressure in the capillaries is of great importance, and normal blood pressure is high enough to permit filtration for nourishment of tissues but low enough to prevent rupture.

The arteries and veins are usually in a state of slight constriction that helps to maintain normal blood pressure, especially diastolic pressure. This is called peripheral resistance; it is regulated by the vasomotor center in the medulla, which generates impulses along sympathetic vasoconstrictor nerves to all vessels with smooth muscle to maintain slight constriction. More impulses per second increase vasoconstriction and raise blood pressure; fewer impulses per second bring about vasodilation and lower blood pressure. The information for changes needed in the vessel diameter comes to the medulla from the baroreceptors and chemoreceptors located in the internal carotid arteries and aortic arch and from proprioceptors.

Blood pressure is also affected by many other factors. If heart rate and force increase, blood pressure increases to a limit. If the heart is beating very fast, the ventricles are not filled before they contract, cardiac output decreases, and blood pressure drops. The strength of the heart's contractions depends on adequate venous return, which is the amount of blood that flows into the atria. Decreased venous return results in weaker contractions.

Venous return depends on several factors: constriction of the veins so that blood does not pool in them, the skeletal muscle pumping to squeeze the deep veins of the legs, and the muscles of respiration compressing the veins in the chest

FIGURE 20.4 Structure of an artery, arteriole, capillary network, venule, and vein. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 5. FA. Davis, Philadelphia, 2007, p 298.)

cavity. The valves in the veins prevent backflow of blood and thus contribute to the return of blood to the heart.

The elasticity of the large arteries also contributes to normal blood pressure. When the left ventricle contracts, the blood stretches the elastic walls of the large arteries, which absorb some of the force. When the left ventricle relaxes, the arterial walls recoil or snap back and put pressure on the blood. Normal elasticity, therefore, lowers systolic pressure, raises diastolic pressure, and maintains normal pulse pressure. Pulse pressure is the difference between the systolic and diastolic pressures. The usual ratio of systolic to diastolic to pulse pressure is 3:2:1.

Renin-Angiotensin-Aldosterone Mechanism

The kidneys are of great importance in the regulation of blood pressure. If blood flow through the kidneys decreases, renal filtration decreases and urinary output decreases to

preserve blood volume. Decreased blood pressure stimulates the kidneys to secrete renin, which initiates the renin-angiotensin-aldosterone mechanism (Fig. 20.5). Renin splits the plasma protein angiotensinogen (from the liver) to form angiotensin I, which is changed to angiotensin II by a converting enzyme found primarily in lung tissue. Angiotensin II causes arteriole vasoconstriction and stimulates secretion of aldosterone, both of which raise blood pressure.

Aldosterone, secreted by the adrenal cortex, increases the reabsorption of sodium ions by the kidneys. Water follows the sodium back to the blood; this increases blood volume and blood pressure. Other hormones that affect BP include those of the adrenal medulla: norepinephrine, which causes vasoconstriction throughout the body, and epinephrine, which increases cardiac output and causes vasoconstriction in skin and viscera. Antidiuretic hormone (ADH), from the posterior pituitary, directly increases water reab-

FIGURE 20.5 The renin-angiotensin-aldosterone mechanism.

sorption by the kidneys, thus increasing blood volume and blood pressure. Atrial natriuretic peptide, secreted by the atria of the heart, inhibits aldosterone secretion and thereby increases renal excretion of sodium ions and water, which decreases blood volume and subsequently blood pressure.

Pathways of Circulation

The two pathways of circulation are pulmonary and systemic (see Fig. 20.2). Pulmonary circulation begins at the right ventricle, which pumps deoxygenated blood into the pulmonary artery. The pulmonary artery branches into two arteries, one to each lung. The pulmonary capillaries around the alveoli of the lungs are the site of gas exchange. Oxygenated blood returns to the left atrium by way of the pulmonary veins. The blood pressure in the pulmonary circulation is always low because the right ventricle pumps with only about one-sixth the force of the left ventricle. The pulmonary arterial pressure is approximately 20 to 25 over 8 to 10 mm Hg, and the pulmonary capillary pressure is lower still. This is important to prevent filtration in pulmonary capillaries, which keeps tissue fluid from accumulating in the alveoli of the lungs, causing pulmonary edema.

Systemic circulation begins in the left ventricle, which pumps oxygenated blood into the aorta, the many branches

of which eventually give rise to capillaries within the tissues. Deoxygenated blood returns to the right atrium by way of the superior and inferior vena cava and the coronary sinus. The hepatic portal circulation is a special part of the systemic circulation in which blood from the capillaries of the digestive organs and spleen flows through the portal vein and into the capillaries (sinusoids) in the liver before returning to the heart. This pathway permits the liver to regulate the blood levels of nutrients such as glucose, amino acids, and iron and to remove potential toxins such as alcohol or medications from circulation.

Aging and the Cardiovascular System

It is believed that the “aging” of blood vessels, especially arteries, begins in childhood, although the effects are not apparent until later in life (Fig. 20.6). **Atherosclerosis** is the deposition of lipids in the walls of arteries over a period of years, which can narrow their lumens and form rough surfaces that may stimulate intravascular clot formation. Atherosclerosis decreases blood flow to the affected organ: cerebral flow can diminish by 20% and renal flow by 50% by age 80.¹ With age, the heart muscle becomes less efficient, and there is a decrease in both maximum cardiac output and heart rate, although resting levels may be more than sufficient (Box 20.1 Gerontological Issues). Valves may become thickened by fibrosis, leading to heart **murmur**.

CARDIOVASCULAR DISEASE

According to statistics of the American Heart Association, cardiovascular disease is still the number one killer of people in the United States, being responsible for 1.0 of every 2.6 U.S. deaths.² In 2002, the single leading cause of death in America was coronary heart disease.² About 335,000 people a year die of cardiovascular disease either in the emergency room or without ever reaching the hospital, usually due to a heart attack and ventricular fibrillation or tachycardia.²

In women, the greatest cause of death is cardiovascular disease. The effect of cardiovascular disease in women has been understudied, but more attention is now being focused on this. There is a movement called Go Red for Women to give women encouragement and tools to prevent cardiovascular disease and live healthy. For more information on Go Red for Women, visit www.americanheart.org. Women can further reduce their risk for cardiovascular disease through the American Heart Association’s free program Simple Solutions at www.americanheart.org/simpleolutions.

Lifestyle plays a major role in risk factors for cardiovascular disease. Smoking contributes to approximately one in five cardiovascular disease deaths. Dietary fat intake

atherosclerosis: ather—porridge + sklerosis—hardness

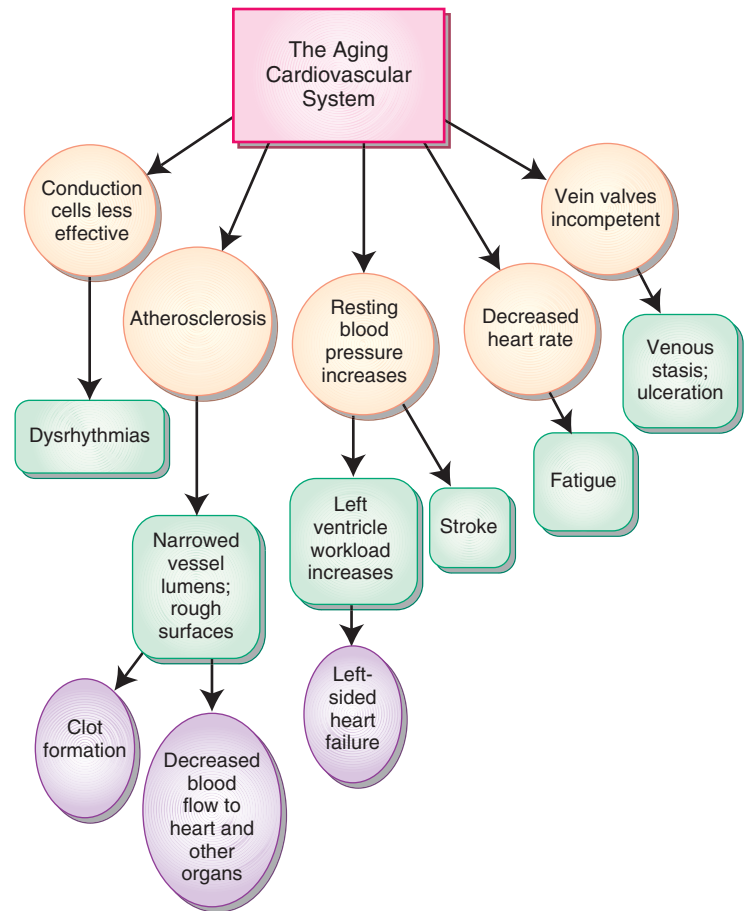

FIGURE 20.6 Aging and the cardiovascular system. This concept map shows the effects the aging process has on the cardiovascular system

Box 20.1

Gerontological Issues

The older adult is at increased risk for developing orthostatic hypotension, which could precipitate a fall. This is often due to a combination of age related changes, immobility, chronic illnesses, and medications.

accounts for approximately 34% of the American diet, which increases cholesterol. Eating two servings weekly of oily fish like tuna or salmon is recommend by the American Heart Association. Exercise needs to be promoted for all, including children, as Americans continue to be sedentary. For more information on cardiovascular disease statistics, visit www.americanheart.org.

NURSING ASSESSMENT OF THE CARDIOVASCULAR SYSTEM

Nursing assessment of the cardiovascular system includes a patient health history and physical examination (Box 20.2 Gerontological Issues). If the patient is experiencing an acute problem, focus on the most serious signs and symptoms and physical assessment data until the patient is stabi-

lized (Table 20.1). An in-depth nursing assessment can be completed when the patient is stable. For stable or chronic cardiac conditions, a complete nursing assessment is done on admission.

Subjective Data

To understand the patient's cardiovascular problems, ask about past and current symptoms, use of prescribed and over-the-counter medications, use of recreational drugs, surgeries, treatments, and such risk factors as diet, activity, tobacco use, and recent stressors. Assessment of symptoms includes asking questions for WHAT'S UP?: where it is, how it feels, aggravating and alleviating factors, timing, severity, useful data for associated symptoms, and perception by the patient of the problem.

Box 20.2

Gerontological Issues

Older adults commonly have signs and symptoms that are not typical of a disorder. For example, the only symptom of myocardial infarction in an older patient may be dyspnea. Chest pain, a typical symptom, may not be present.

TABLE 20.1 ACUTE CARDIOVASCULAR NURSING ASSESSMENT

History	Significance
<i>Allergies</i>	For medication administration, diagnostic dyes
<i>Smoking history</i>	Risk factor for cardiovascular disorders
<i>Medications</i>	Toxic levels; influencing symptoms
<i>Pain</i>	Location—chest, calf; radiation—arms, jaw, neck; description—pressure, indigestion, tightness, burning, angina, myocardial infarction, thrombus, embolism
<i>Dyspnea</i>	Left-sided heart failure; pulmonary edema or embolism
<i>Fatigue</i>	Decreased cardiac output
<i>Palpitations</i>	Dysrhythmias
<i>Dizziness</i>	Dysrhythmias
<i>Weight gain</i>	Right-sided heart failure
Physical Assessment	Possible Abnormal Findings
<i>Vital signs</i>	Bradycardia, tachycardia, hypotension, hypertension, tachypnea, apnea, shock
<i>Heart rhythm</i>	Dysrhythmias
<i>Edema</i>	Right-sided heart failure
<i>Jugular vein distention</i>	Right-sided heart failure
<i>Breath sounds</i>	Crackles, wheezes with left-sided heart failure
<i>Cough, sputum</i>	Acute heart failure—dry cough, pink frothy sputum

Health History

All body systems can be affected by cardiovascular problems. Some symptoms can occur due to more than one cause. For example, shortness of breath can be the result of either heart failure or chronic obstructive pulmonary disease. The health history helps determine the cause of the symptom. For cardiovascular problems, the assessment focuses on the areas listed in Table 20.2.

MEDICAL HISTORY. If previous medical records are available, they can provide objective patient data that can be supplemented with patient responses. If medical records are not available, the patient is asked about previous conditions that could affect the cardiovascular system. A history of childhood illnesses that can lead to heart disease, such as rheumatic fever or scarlet fever, is noted. Other conditions include pulmonary disease, hypertension, kidney disease, cerebral vascular accident or brain attack, transient **ischemic** attack, renal disease, anemia, streptococcal sore throat, congenital heart disease, thrombophlebitis, and alcoholism. Patient allergies, previous hospitalizations, and surgeries are documented. Baseline diagnostic tests are helpful for comparison with current tests. Functional limitations that are related to cardiovascular problems, such as performing activities of daily living (ADLs), walking,

climbing stairs, or completing household tasks, are also assessed.

MEDICATIONS. Medication use is noted. This includes prescription drugs, over-the-counter medications such as aspirin that can prolong clotting time, and recreational drugs. The medication history includes the patient's understanding of the medication and the medication name, dosage, reason for taking, last dose, and length of use.

FAMILY HISTORY. A family history of cardiovascular conditions is assessed because many cardiac problems are hereditary. Health histories of close relatives, such as parents, siblings, and grandparents, are the most significant. For example, those who have had a parent die of sudden cardiac death prior to age 60 are at increased risk for sudden cardiac death.

HEALTH PROMOTION. Risk factors such as diet, activity, tobacco use, and recent stressors for the patient are assessed in the health history. The patient's health promotion activities are noted, especially for risk factors that are modifiable through changes in lifestyle.

Objective Data

Physical Assessment

The patient's general appearance is observed. The patient's level of consciousness, which is an indicator of oxygenation of the brain, is assessed. Height and weight are recorded. Vital signs are measured.

BLOOD PRESSURE. For accurate measurement, the correct size cuff for the patient is used. Normal blood pressure is considered less than 120/80 (see Chapter 21). Readings in both arms are done for comparison. A difference in the readings is reported to the physician. The arm with the higher reading is used for ongoing measurements. If necessary, blood pressure may be measured in the leg using a larger blood pressure cuff. The reading in the leg is normally 10 mm Hg higher than in the arm.

Blood pressure measurements are done with the patient lying, sitting, and standing to detect abnormal variations with postural changes. When the patient sits or stands, a drop in the systolic pressure of up to 15 mm Hg and either a drop or slight increase in the diastolic pressure of 3 to 10 mm Hg is normal. In response to the drop in blood pressure, the pulse increases 15 to 20 beats per minute to maintain cardiac output. Orthostatic hypotension, also referred to as postural hypotension, is a greater than normal change in these pressures and indicates a problem that should be investigated by the physician (Box 20.3). The patient may experience dizziness when changing positions, so fall prevention methods should be used during blood pressure measurement.

PULSES. The apical pulse is auscultated for 1 minute to assess rate and rhythm. Normal heart rate is 60 to 100 beats per minute. In athletic people, the heart rate is often slower, around 50 beats per minute, because the well-conditioned

ischemic: ischein—hold back + haima—blood

TABLE 20.2 CARDIOVASCULAR HISTORY ASSESSMENT

Question	Rationale
	Pain: WHAT'S UP? Format
<ul style="list-style-type: none"> Where is pain? Does it radiate? How does it feel? Discomfort, burning, aching, indigestion, squeezing, pressure, tightness, heaviness, numbness in chest area? Fullness, heaviness, sharpness, throbbing in legs? Aggravating/alleviating factors that increase/relieve the pain? Timing of pain: onset, duration, frequency? Severity of pain? Useful data for associated symptoms? Perception of patient about problem? 	<ul style="list-style-type: none"> Cardiac pain may radiate to shoulders, neck, jaw, arms, or back. Vascular disorders cause extremity pain. Pain can be associated with angina or MI. The quality of pain varies. Venous pain is a fullness or heaviness. Sharpness or throbbing is arterial pain. Activity may cause or increase angina. Rest or medications may relieve angina. Leg activity pain, intermittent claudication, results from decreased perfusion that is aggravated by activity. Rest pain, from severe arterial occlusion, increases when lying. Dangling reduces the pain because blood flow is increased by gravity. Pain may be continuous, intermittent, acute, or chronic. Arterial occlusion causes acute pain. Rate pain on a scale of 0 to 10. Accompanying symptoms and their characteristics guide diagnosis and treatment. Patient's insight to problem is helpful in planning care.
	Level of Consciousness (LOC)
<ul style="list-style-type: none"> What is your name? What is the month? Year? Where are you now? 	<ul style="list-style-type: none"> A lack of oxygen caused by cardiac disease can decrease LOC.
	Dyspnea
<ul style="list-style-type: none"> Are you short of breath? What increases your shortness of breath? What relieves your shortness of breath? 	<ul style="list-style-type: none"> Dyspnea can be present with heart failure that reduces cardiac output, on exertion in angina pectoris or from a pulmonary embolus resulting from thrombophlebitis, heart failure, or dysrhythmias.
	Palpitations
<ul style="list-style-type: none"> Are you having palpitations or irregular heartbeat? Does your heart ever race, skip beats, or pound? 	<ul style="list-style-type: none"> Palpitations can occur from dysrhythmias resulting from ischemia, electrolyte imbalance, or stress. Dizziness can be associated with dysrhythmias.
	Fatigue
<ul style="list-style-type: none"> Have you noticed a change in your energy level? Are you able to perform activities that you would like to? 	<ul style="list-style-type: none"> Fatigue occurs from reduced cardiac output resulting from heart failure. Functional abilities can be limited from fatigue.
	Edema
<ul style="list-style-type: none"> Have you had any swelling in your feet, legs, or hands? Have you gained weight? 	<ul style="list-style-type: none"> Right-sided heart failure can cause fluid accumulation in the tissues. Fluid retention causes weight gain.
	Paresthesia/Paralysis
<ul style="list-style-type: none"> Any numbness, tingling, or other abnormal sensations in extremities? Can you move your extremity? 	<ul style="list-style-type: none"> Numbers and tingling, pins and needles, and crawling sensations are paresthesia. Paralysis is inability to move extremity. Reduced nerve conduction from decreased oxygen supply causes paresthesia and paralysis.

heart pumps more efficiently. Apical pulse rhythm is documented as regular or irregular. The apical rate can be compared with the radial rate to assess equality. If there are fewer radial beats than apical beats, a **pulse deficit** exists and should be reported to the physician.

Arterial pulses are palpated for volume and pressure quality. They are palpated bilaterally and compared for equality. A normal vessel feels soft and springy. A sclerotic vessel feels stiff. The quality of the pulses is described on a

4-point scale as follows: 0 is absent; 1+ is weak, thready; 2+ is normal; and 3+ is bounding. An absent pulse is not palpable. A thready pulse is one that disappears when slight pressure is applied and returns when the pressure is removed. The normal pulse is easily palpable. The bounding pulse is strong and present even when slight pressure is applied. When the normal vessel is palpated, a tapping is felt. In the abnormal vessel that has a bulging or narrowed wall, a vibration is felt, which is called a **thrill**. When aus-

SAFETY TIP

Anticipate potential drops in blood pressure with position changes. Orthostatic, or postural, hypotension is a drop in systolic blood pressure greater than 15 mm Hg, a drop or slight increase in the diastolic blood pressure greater than 10 mm Hg, and an increase in heart rate greater than 20 beats per minute in response to the drop in blood pressure. It can be found in patients of any age but is most commonly found in the older patient. The patient often reports light-headedness or syncope because the drop in pressure decreases the amount of oxygen-rich blood traveling to the brain. The change from a lying to a sitting or a sitting to a standing position may cause the drop in pressure. This blood pressure drop increases the risk of fainting and falling. Factors that can contribute to orthostatic hypotension include fluid volume deficit, diuretics, analgesics, and pain. Use fall precautions for patients at risk of or with orthostatic hypotension.

cultating an abnormal vessel, a humming is heard that is caused by the turbulent blood flow through the vessel. This is referred to as a **bruit**.

RESPIRATIONS. The rate and ease of respirations are observed. Breath sounds are auscultated. Sputum characteristics such as amount, color, and consistency are noted. Pink, frothy sputum is an indicator of acute heart failure. A dry cough can occur from the irritation caused by the lung congestion resulting from heart failure.

INSPECTION. During the health history, inspection begins by noting any shortness of breath when the patient speaks or moves. The patient's skin is noted for oxygenation status through the color of skin, mucous membranes, lips, ear lobes, and nailbeds. Pallor may indicate anemia or lack of arterial blood flow. Cyanosis shows an oxygen distribution deficiency. A reddish brown discoloration (rubor) found in the lower extremities occurs from decreased arterial blood flow. A brown discoloration and cyanosis when the extremity is dependent may be seen in the presence of venous blood flow problems. Hair distribution on the extremities is observed. Decreased hair distribution, thick, brittle nails, and shiny, taut, dry skin occur from reduced arterial blood flow. Venous blood return is assessed by inspecting extremities for varicose veins, stasis ulcers, or scars around the ankles and signs of thrombophlebitis such as swelling, redness, or a hard, tender vein.

The internal and external jugular neck veins are observed for distention. Normally, in the upright position, the veins are not visible. Distention of the veins in an upright position of 45 to 90 degrees indicates an increase in the

Box 20.3

Orthostatic Hypotension Assessment

To assess orthostatic hypotension:

1. Use correct size blood pressure cuff.
2. Explain procedure to patient; determine if patient can safely stand.
3. Have patient lie flat in bed at least 5 minutes prior to readings.
4. Patient should not eat or smoke 30 minutes before readings; patient should not talk during readings and should sit up with legs uncrossed while sitting.
5. Take patient's lying blood pressure and heart rate.
6. Assist patient to sitting position. Ask if dizzy or light-headed with each position change. If yes, ensure safety from fainting or falling. A gait or walking belt can be used. With any position change, if patient experiences additional symptoms with the dizziness and decreased blood pressure and increased heart rate, assist the patient to lie down, take blood pressure, and notify the physician. Consider the possible cause of the orthostatic hypotension (hemorrhaging, dehydration, diuretics) to plan patient care.
7. Wait 3 minutes, and then take patient's sitting blood pressure and heart rate. If patient is dizzy or light-headed, continue sitting position for 5 minutes if tolerated. Do not attempt to bring the patient to standing. Repeat sitting blood pressure. If blood pressure has increased and patient is no longer dizzy, assist patient to stand.
8. Assist patient to stand and take blood pressure and pulse immediately. Then take again in 3 minutes. If blood pressure drops and patient is dizzy or light-headed, do not attempt to ambulate patient.
9. Document all heart rate and blood pressure measurements, including extremity used and patient position when reading was obtained (e.g., right arm lying 132/78, sitting 118/68, standing 110/60). Also document patient tolerance, symptoms, and nursing interventions if symptomatic.
10. Report abnormal findings to physician.

venous volume. This is most commonly caused by right-sided heart failure. To observe for this, the patient is gradually elevated to a 45- to 90-degree position and any distention noted.

Capillary refill time assesses arterial blood flow to the extremities. The patient's nailbed is briefly squeezed, causing blanching, and then released. The amount of time that it takes for the color to return to the nailbed after release of the squeezing pressure is the capillary refill time. Normal capillary refill time is 3 seconds or less. Longer

FIGURE 20.7 Clubbing of the fingers.

times indicate anemia or a decrease in blood flow to the extremity.

Clubbing of the nailbeds occurs from oxygen deficiency over time. It is often caused by congenital heart defects or the long-term use of tobacco. The distal ends of the fingers and toes swell and appear clublike. With clubbing, the normal 160-degree angle formed between the base of the nail and the skin is lost, causing the nail to be flat (Fig. 20.7). Later, the nail base elevates, the angle exceeds 180 degrees, and the nail feels spongy when squeezed.

LEARNING TIP

Six Ps characterize peripheral vascular disease:

- Pain
- Poikilothermia
- Pulselessness
- Pallor
- Paralysis
- Paresthesia (*decreased sensation*)

PALPATION. In addition to palpating the arteries, the thorax can be palpated at the **point of maximum impulse** (PMI). The PMI is palpated by placing the right hand over the apex of the heart. If palpable, a thrust is felt when the ventricle contracts. An enlarged heart may shift the PMI to the left of the midclavicular line.

The temperature of the extremities is palpated bilaterally for comparison. Palpation begins proximally and moves distally along the extremity. In areas of decreased arterial blood flow, the ischemic area feels cooler than the rest of the body because it is blood that warms the body. In the absence of sufficient arterial blood flow, the area becomes the temperature of the environment. This is called **poikilothermy**.

poikilothermy: poikilos—varied + therme—heat

FIGURE 20.8 Pitting edema. Application of pressure over a bony area displaces the excess fluid, leaving an indentation or pit.

A warm or hot extremity indicates a venous blood flow problem.

Edema is palpated in the extremities and dependent areas such as the sacrum for the supine patient (Fig. 20.8). Edema can occur from right-sided heart failure, gravity, or altered venous blood return. The nurse assesses the severity of the edema by pressing with a finger for 5 seconds over a bone, the medial malleolus or tibia, in the area of edema. If the finger imprint or indentation remains, the edema is pitting. Measuring the leg circumference is an accurate method for monitoring the edema.

Homans' sign is an assessment for venous thrombosis; however, in less than 50% of patients with thrombosis, the test is not positive. A positive Homans' sign is pain in the patient's calf or behind the knee when the foot is quickly dorsiflexed with the knee in a slightly flexed position (Fig. 20.9). Homans' sign should not be performed if a positive diagnosis of thrombosis has been made.

PERCUSSION. Percussion is performed by a physician to detect cardiac enlargement. Usually only the left border of the heart can be percussed. The heart is heard as dullness, which is in contrast to the resonance heard over the lungs.

AUSCULTATION. The normal heart sounds heard with a stethoscope placed on the wall of the chest are produced by the closing of the heart valves. These areas indicate where the sounds are best heard because sound in blood-flowing vessels is transmitted in the direction of the blood flow. The first heart sound (S1) is heard at the beginning of systole as “lubb” when the tricuspid and mitral (AV) valves close (Fig. 20.10). The second heart sound (S2) is heard at the start of diastole as “dupp” when the aortic and pulmonic semilunar valves close. The diaphragm of the stethoscope is used to hear the high-pitched sounds of S1 and S2. Extra heart sounds, usually indicating a pathological condition, may be heard with practice. Normally no other sounds are heard between S1 and S2. With the bell of the stethoscope placed

FIGURE 20.9 Assessment of Homans' sign for venous thrombosis. The foot is quickly dorsiflexed with the knee flexed. Calf or knee pain is noted. This assessment should not be performed if a positive diagnosis of thrombosis has been made.

at the apex, a third heart sound (S3) or a fourth heart sound (S4) may be heard. Having patients lean forward or lie on their left side can make the heart sounds easier to hear by bringing the area of the heart where the sound may be heard closer to the chest wall. S3 is normal for children and younger adults. It sounds like a gallop and is a low-pitched sound heard early in diastole. S3 may be heard with left-sided heart failure, fluid volume overload, and mitral valve regurgitation. S4 is also a low-pitched sound, similar to a gallop but heard late in diastole. It occurs with hypertension, coronary artery disease, and pulmonary stenosis.

LEARNING TIP

This sentence can help you remember the heart's auscultation points:

All	(aortic)
People	(pulmonic)
Eat	(Erb's point)
Three	(tricuspid)
Meals	(mitral)

Murmurs are caused by turbulent blood flow through the heart and major blood vessels. A murmur is a prolonged sound caused by a narrowed valve opening or a valve that does not close tightly. A swishing sound that ranges in intensity from faint to very loud is produced. The intensity of the murmur is graded by the physician on a scale of 1 to 6. The timing of the murmur in relationship to the cardiac cycle of systole or diastole is also documented by the physician.

A **pericardial friction rub** occurs from inflammation of the pericardium. The intensity of a rub can range from

FIGURE 20.10 Heart sounds shown on electrocardiogram. S1 is heard at the beginning of systole, and S2 is heard at the beginning of diastole.

soft and faint to loud enough to be audible without a stethoscope. A rub has a grating sound like sandpaper being rubbed together that occurs when the pericardial surfaces rub together during the cardiac cycle. (See the Learning Tip on pericardial friction rub in Chapter 22.) Having the patient sit and lean forward allows a rub to be heard more clearly. The rub is best heard to the left of the sternum using the diaphragm of the stethoscope. A pericardial friction rub may occur after a myocardial infarction or chest trauma.

Diagnostic Studies

Diagnostic test results provide valuable assessment information for the nurse (Table 20.3). These data are combined with the health history and physical assessment to plan care for the patient.

NONINVASIVE STUDIES. Chest X-ray Examination. A chest x-ray examination shows the size, position, contour, and structures of the heart (Fig. 20.11). It shows heart enlargement, calcifications, and fluid around the heart. Heart failure can be confirmed with a chest x-ray examination. Correct placement of pacemaker leads and pulmonary artery catheters in the heart can be confirmed.

Fluoroscopy uses a luminescent x-ray screen to show cardiac structures and pulsations. It is used as a guide when placing cardiac catheters or pacemaker leads.

CRITICAL THINKING

Mrs. Smith

■ Mrs. Smith, age 78, baseline weight 162 pounds, is admitted to the hospital with shortness of breath. Initial assessment findings are BP 152/88, pulse 104, respirations 26, temperature 99.4°F (37.2°C), shortness of breath at rest, shortness of breath increases with activity, ankles swollen, heart tones sound far away, nailbeds are very light pink, no pain, has not eaten well for 2 weeks, 6-pound weight gain in 1 week, sleeps on three pillows, veins in neck are visible on both sides. A diagnosis of acute myocardial infarction with heart failure is made by a physician.

1. Why is Mrs. Smith not having chest pain with a diagnosis of acute myocardial infarction?
2. How should swollen ankles be assessed to provide complete and measurable data?
3. What should be documented for the assessment performed on the swollen ankles?
4. How should the assessment findings for the swollen ankles be documented?
5. How should the assessment findings be documented for the additional symptoms Mrs. Smith has?
6. What is Mrs. Smith's weight in kilograms?

Suggested answers at end of chapter.

SAFETY TIP

Improve the accuracy of patient identification.

Use at least two patient identifiers (neither to be the patient's location) whenever collecting laboratory samples or administering medications or blood products, and use two identifiers to label sample collection containers in the presence of the patient. Processes are established to maintain samples' identities throughout the preanalytical, analytical, and postanalytical processes.

Immediately prior to the start of any invasive procedure, conduct a final verification process to confirm the correct patient, procedure, site, and availability of appropriate documents. This verification process uses active—not passive—communication techniques. The patient's identity is reestablished if the practitioner leaves the patient's location prior to initiating the procedure. Marking the site is required unless the practitioner is in continuous attendance from the time of the decision to do the procedure and patient consent to the initiation of the procedure (e.g., bone marrow collection or fine-needle aspiration). (2006 National Patient Safety Goals from www.jcaho.org)

Cardiac Calcium Scan. A computed tomographic (CT) scan using x-rays shows areas with plaque or calcification (the body deposits calcium to harden plaques, which are not normally found in the coronary arteries). Plaque indicates CAD. Calcium scoring is done to diagnose CAD and

FIGURE 20.11 Normal chest x-ray film. Note white outline of heart borders in center. (From McKinnis, LN: *Fundamentals of Orthopedic Radiology*. FA. Davis, Philadelphia, 1997, p 15.)

determine its severity. This screening test is not routinely done, especially for younger people. Scoring: 0 = no evidence of plaque, low heart attack risk; 1 to 10 10% CAD risk, low risk; 11 to 100 mild hardening, moderate risk; 101 to 400 CAD with possible coronary artery blockage, moderate-high risk, >400 90% chance plaque blocking artery, high risk. Patients are told to avoid caffeine and smoking for 4 hours before the test.

Magnetic Resonance Imaging. A three-dimensional image of the heart is produced by magnetic resonance imaging (MRI). Patients such as those with pacemakers or metal implants, metal shavings, or shrapnel are not candidates for this test. MRI use is currently limited for the heart owing to difficulties in imaging moving parts such as in the heart. Research is ongoing to overcome these obstacles. Cardiac MRI will likely be more common in a few years for things such as diagnosis of a heart attack as it is occurring, which will save valuable time or allow viewing types of plaque formations.

Electrocardiogram. The electrocardiogram (ECG) assesses the electrical activity of the heart from different views. The ECG shows abnormalities related to conduction, rate, rhythm, heart chamber enlargement, myocardial ischemia, myocardial infarction, and electrolyte imbalances. Abnormalities in cardiac function can be detected and the area of abnormality pinpointed with the aid of the different views on the ECG.

(Text continued on page 363)

TABLE 20.3 DIAGNOSTIC TESTS AND PROCEDURES FOR CARDIOVASCULAR SYSTEM

Procedure	Definition/Normal Finding (if applicable)	Significance of Abnormal Findings	Nursing Management
Noninvasive			
<i>Chest x-ray film</i>	Anterior-posterior and left lateral views of chest taken to show heart size and contour and lungs.	Heart enlargement; calcifications; fluid around heart	Assess x-ray history and whether pregnant, Remove metal items.
<i>Magnetic resonance imaging (MRI)</i>	Three-dimensional image of heart. Mainly used in research.	Cardiac abnormalities	Teaching—no discomfort. Assess for metallic items and claustrophobia. Give antianxiety medication as ordered before MRI. Teaching—must lie still in long, small cylinder with loud, pounding sounds. Can talk to technician, listen to music.
<i>Electrocardiogram (ECG)</i>	Electrodes on skin carry electrical activity of heart from different views to show rhythm of heart, size of chambers, and heart damage.	Dysrhythmias; enlarged heart chamber size; myocardial ischemia or infarction; electrolyte imbalances.	Teaching—no discomfort. Explain procedure.
<i>Holter monitor</i>	Normal: Normal Sinus Rhythm. Recording of ECG for up to 48 hours to match abnormalities with symptoms recorded in patient's diary. Normal: Normal sinus rhythm.	Dysrhythmias; myocardial ischemia occurring less often.	Apply electrodes and leads. Teaching—keep accurate diary; push event button for symptoms. No showers or baths. Return visit.
<i>Transtelephonic event recorder</i>	Records ECG events infrequently occurring for transmission over phone to interpreting center for analysis. Pacemaker checks done.	Dysrhythmias; pacemaker malfunction	Teaching—explain use of recorder and how to transmit. Ensure good skin contact for best ECG tracing.
<i>Pressure measurement</i>	Blood pressures taken at several sites along extremity.	Shows area of occlusion or decreased blood flow at rest and with exercise.	Teaching—no discomfort. Explain procedure.
<i>Exercise treadmill test (ETT)</i>	Evaluates effects of exercise on heart and vascular circulation; ECG and vital signs are continuously monitored. Test stopped if symptoms develop.	Dysrhythmias; ischemia	Monitor vital signs and ECG before, during, and after test until stable. Teaching—explain procedure, wear walking shoes and comfortable clothes.
<i>Echocardiogram</i>	Transducer transmits sound waves that bounce off heart to produce heart images and show blood flow. Provides audio and graphic data.	Heart enlargement, coronary artery disease, valvular abnormalities, thickened cardiac walls or septum, pericardial effusion	May be done at bedside. Patient lies on left side. Teaching—no discomfort, gel applied.
<i>Transesophageal echocardiogram</i>	Probe with transducer on end inserted into esophagus, depth and angle directed by physician. Shows clearer images of heart because no lung or rib tissue is crossed. Dye injected for blood flow study.	Heart enlargement, coronary artery disease, valvular abnormalities, thickened cardiac walls or septum, pericardial effusion	Monitor vital signs and oxygen saturation. Encourage patient to relax. Suction continually during procedure. Teaching—NPO 6 hours before test. Sedation and local throat anesthetic given.
Radioisotopes			
	IV injection of radioactive isotopes, which are taken up by heart and scanned with scintillation camera to show cardiac contractility, injury, and perfusion.		Assist patient to lie supine with arms over head for about 30 minutes. Teaching—explain procedure, inform that radioactivity is small and gone within a few hours.

Procedure	Definition/Normal Finding (if applicable)	Significance of Abnormal Findings	Nursing Management
<i>Thallium Imaging</i>	IV injection of thallium 201 to evaluate cardiac blood flow. With exercise, thallium given 1 minute before end of test to circulate thallium. Scan done within 10 minutes and repeated in 2 to 4 hours for comparison.	If thallium not delivered to cardiac cells by good blood flow then see “cold spots” that show ischemia initially or infarcted areas later.	Teaching—explain procedure, inform that radioactivity is small and gone within a few hours. Light meal only between scans.
<i>Dipyridamole thallium imaging</i>	Dipyridamole (Persantine) IV is a vasodilator given to increase blood flow to coronary arteries; test is same as thallium imaging.	If thallium not delivered to cardiac cells by good blood flow then see “cold spots” that show ischemia initially or infarcted areas later.	Teaching—explain procedure, instruct no caffeine or aminophylline 12 hours before. Same as thallium imaging.
<i>Technetium pyrophosphate imaging</i>	Technetium 99m pyrophosphate IV given. Scanned 2 hours later.	Shows hot spot in heart injury area.	Teaching—explain procedure, inform that radioactivity is small and gone within a few hours.
<i>Blood pool imaging</i>	Technetium 99m pertechnetate IV. Serial studies are done over several hours. May be done at bedside.	Studies effects of drugs, recent MI, and congestive heart failure.	Teaching—explain procedure.
<i>Positron emission tomography (PET)</i>	Nitrogen 13-ammonia IV given and scanned for cardiac perfusion. Then fluoro-18-deoxyglucose IV given and scanned for cardiac metabolic function. Exercise may also be used.	In normal heart, scans match; in injured heart, they differ.	Patient’s blood glucose must be 60 to 140 mg/dL for accuracy.
<i>Doppler ultrasound</i>	Sound waves bounce off moving blood, producing recordings. Evaluates PVD.	Decreased blood flow in PVD	Teaching—explain procedure. Must lie still during scan. If exercise used, NPO and no tobacco use.
<i>Plethysmography</i>	After the leg being tested is raised 30 degrees with the patient supine, a pressure cuff is inflated on the leg to distend the veins. Blood flow is measured with electrodes. Cuff is then rapidly deflated and venous volume changes recorded.	Thrombi detected by less venous volume	Teaching—explain procedure. No discomfort. Takes 30 to 45 minutes.
<i>Technetium 99m sestamibi</i>	Technetium 99m sestamibi is given IV and scanned 1.5 to 2 hours later.	Areas of myocardial cell damage take up the radioisotope; when scanned, these areas appear as hot spots.	Explain procedure.
Serum Tests			
<i>Creatine kinase (CK)</i>	Heart, brain, skeletal muscle contain CK enzymes. Normal: male 5 to 55 U/mL; female 5 to 25 U/mL.	Damaged cells release CK. With MI, CK elevates in 6 hours and returns to baseline in 48–72 hours.	Avoid IM injections and take baseline CK before inserting IVs to avoid elevating CK from muscle cell damage. Serial sampling done.
<i>CK-MB</i>	Only heart muscle contains MB isoenzyme. Normal: 0 to 7 IU/L.	Rises with MI in 6 hours and returns to baseline in 72 hours.	Same as CK.
<i>Myoglobin</i>	Protein found in cardiac cells. 99% indicative of MI. Normal: 250 to 450 ng/mL.	Rises in 1 hour after MI and peaks in 4 to 12 hours so must be drawn within 18 hours of chest pain onset.	No special care.
<i>Cardiac troponin I or T</i>	Cardiac cell protein. Normal: Varies by lab; very low levels.	Elevated levels sensitive indicator of MI. Levels elevated up to 7 days.	No special care.

(Continued on following page)

TABLE 20.3 DIAGNOSTIC TESTS AND PROCEDURES FOR CARDIOVASCULAR SYSTEM (Continued)

Procedure	Definition/Normal Finding (if applicable)	Significance of Abnormal Findings	Nursing Management
C-reactive protein	CRP levels can indicate low-grade inflammation in coronary vessels. Low cardiovascular disease risk: <1 mg/L; average risk 10 mg/L–3 mg/L; high risk >3 mg/L	Elevated levels indicate heart attack risk.	No special care
Serum Lipids			
<i>Cholesterol</i>	Measures CAD risk. Normal: 140 to 200 mg/dL.	>200 increased CAD risk.	Fasting not required.
<i>Triglycerides</i>	Elevated in cardiovascular disease. Normal: <150 mg/dL	CAD risk	Eat normal diet for 2 weeks before test. Fasting required for 12 hours. Water allowed but no alcohol.
<i>Phospholipids</i>	May elevate in cardiovascular disease. Normal: 125 to 380 mg/dL.	CAD risk	Same as triglycerides.
<i>Lipoproteins</i>	Electrophoresis done to separate lipoproteins: VLDL, LDL, HDL. HDL protects against CAD; Normal lipoproteins: 400 to 800 mg/dL. Desirable: LDL less than HDL (values vary with age).	Elevated LDL increases CAD risk. LDL <100 desirable; HDL >60	Same as triglycerides.
Invasive			
<i>Angiography</i>	Dye injected into vessels to make them visible on x-rays. Coronary—coronary arteries via cardiac catheter. Peripheral—peripheral arteries or veins.	Assesses vessel patency, injury, or aneurysm.	Precare: Informed consent required. NPO 4 to 18 hours before test. Assess dye allergies. Teaching—sedative and local anesthesia may be used; burning sensation from dye; monitored continuously. Postcare: assess vital signs, circulation mobility sensation, catheter insertion site, or puncture site for hemorrhage, hematoma every 15 minutes for 1 hour, then every 30 minutes to 1 hour. Apply insertion site pressure (dressing, sandbag) as needed. Immobilize extremity for several hours as ordered.
<i>Cardiac catheterization</i>	Catheter inserted into heart for data on oxygen saturation and chamber pressures. Dye may be injected to visualize structures.	Cardiac disease	Same as angiography. Sensory teaching—table is hard, cool cleansing solution used, sting felt from local anesthetic, hear monitor beeping, feel pressure of catheter insertion, dye warm, burning feeling, headache, chest pain briefly, hear camera, feel table move.

Procedure	Definition/Normal Finding (if applicable)	Significance of Abnormal Findings	Nursing Management
<i>Hemodynamic monitoring</i>	Continuous readings of arterial BP, cardiac and pulmonary pressures, CO and Svo obtained with catheter attached to transducer and monitor to diagnose and guide treatment. Normal: BP less than 120/80; right atrial pressure 2 to 6 mm Hg; pulmonary artery systolic pressure/pulmonary artery diastolic pressure 20 to 30/0 to 10; pulmonary artery wedge pressure 4 to 12 mm Hg; CO 4 to 8 L/min; Svo ₂ 60% to 80%.	Blood pressure, cardiac and pulmonary pressure abnormalities.	Informed consent signed for insertion. Continuous assessment to ensure proper placement of catheter is maintained and a permanent catheter wedge does not go undetected. Recording of readings and monitoring of insertion site for signs of infection.
<i>Central venous pressure (CVP)</i>	Catheter inserted into a vein and threaded into vena cava. Normal: 2 to 6 mm Hg.	Monitors CVP, which reflects fluid volume status.	Informed consent signed for insertion. Recording of readings and monitoring of insertion site for signs of infection.

When an ECG is requested, information that aids in its interpretation is provided, including the patient's sex, age, height, weight, blood pressure, and cardiac medications. The patient requires no special preparation but is given an explanation of the procedure and told that the ECG is painless.

To obtain an ECG, electrodes are placed on the skin to transmit electrical impulses to the ECG machine for recording. The electrical impulses from the heart appear as waves on graph paper. One electrode is placed on each limb and several across the chest. The right leg is a ground electrode. One view of the heart using a combination of the electrodes to obtain the view is called a lead. The standard 12-lead ECG, using a combination of the electrodes, provides 12 views of the heart. Eighteen-lead ECGs may also be done.

Signal-averaged ECG. The signal-averaged ECG is used to diagnose whether a patient is at risk of developing ventricular tachycardia and possible sudden death. A computer records low-level signals not detected by a regular ECG. These electrical signals, referred to as late potentials, occur at the end of the QRS wave and into the ST segment. Late potentials place the patient at risk for ventricular dysrhythmias.

Ambulatory Electrocardiogram Monitoring. Continuous monitoring of the ambulatory patient is possible with the use of tape recorders.

Holter Monitoring. A Holter monitor, which weighs 2 pounds, continuously records one lead for up to 48 hours. The patient wears loose-fitting clothing and may only sponge bathe while wearing the monitor. The patient records a diary of activities and symptoms and pushes the event button if symptoms occur. Symptoms are documented for later correlation with the ECG recordings. Dysrhythmias or myocardial ischemia that occurs infrequently can be de-

tected. Recordings are scanned by a computer and interpreted by a physician.

Transtelephonic Event Recorders. This recorder is used for dysrhythmic events that occur so infrequently that they would not likely be captured in 48 hours, or for follow-up evaluation of permanent pacemakers. With this recorder the patient has greater flexibility because the device is worn when needed or when symptoms occur. The disadvantage is that if the event is brief, it may be missed before the recorder is on. When an event is recorded, the patient can transmit it at a convenient time over the telephone for printout and analysis. The telephone mouthpiece is placed over the signal transmitter box for transmission. After transmission, the recording can be erased and the recorder reused.

Pressure Measurement. Pressure readings are done to assess areas of occlusion or narrowing in vessels. Blood pressure readings are taken at intervals along the extremity. Reduced readings are found in areas with blood flow problems.

Tilt Table Test. The tilt table test is used to help diagnose the cause of syncope ("fainting spells"). Heart rate and blood pressure are monitored during a change in position from lying down to standing up.

Exercise Tolerance Testing. The exercise tolerance test, or stress test, measures cardiac function or peripheral vascular disease during a defined exercise protocol (Fig. 20.12). Before the test, patients are given an explanation of the test and told not to smoke, eat, or drink for 2 to 4 hours before the test. They are also instructed to wear comfortable walking shoes, a loose top, and for women a supportive bra. After the test, patients should rest and wait to eat. They should also avoid eating or drinking stimulants such as caffeine and temperature extremes such as going out into cold weather for a few hours after the test.

FIGURE 20.12 Performance of stress test.

Cardiac Stress Test. This test simulates sympathetic nervous system (fight or flight) stimulation. It shows the heart's response to increased oxygen needs. Before the test, baseline vital signs are obtained. Then, while the patient exercises on a treadmill, on a stationary bicycle, or by climbing stairs, vital signs, oxygen saturation, skin temperature, physical appearance, chest pain, and ECG are monitored to help ensure patient safety. The test is completed when the patient reaches peak heart rate (patient's age subtracted from 220), experiences chest pain, is unable to exercise further, or develops vital sign or ECG changes. Vital signs and ECG continue to be monitored after the test until they return to baseline.

The cardiac stress test is used to evaluate coronary artery disease. It aids in diagnosing ischemic heart disease, the cause of chest pain and dysrhythmias. The functional capacity of the heart can also be measured after a cardiac event or to plan a physical fitness or rehabilitation program.

Peripheral Vascular Stress Test. The patient walks for 5 minutes at 1.5 miles per hour on the treadmill. At certain intervals, pulse volume measurements are taken, including baseline resting, during the test, and final resting after the test. This test assesses response to activity. If **claudication** occurs, the test is stopped.

Echocardiogram. An echocardiogram is an ultrasound test that records the motion of the heart structures, including the valves, as well as the heart size, shape, and position. No

claudication: claudicare—to limp

preparation is required for a cardiac ultrasound. This test transmits ultrasonic sound waves into the heart so that the returned echoes can be recorded on videotape as audio and visual information. An ECG is recorded at the same time for comparison purposes. Abnormalities that may be seen on the echocardiogram include heart enlargement, valvular abnormalities, thickened cardiac walls or septum, and pericardial effusion.

Exercise echocardiography diagnoses CAD during exercise-induced cardiac ischemia by detecting cardiac wall motion abnormalities.

Transesophageal Echocardiogram. Transesophageal echocardiogram provides a clearer picture than transthoracic echocardiography. It produces images by using a transducer on a probe that is placed in the esophagus. The images are clearer because lung and rib tissue does not have to be penetrated by the sound waves. The physician controls the position of the probe and takes pictures as it travels within the esophagus. Patients take nothing by mouth (NPO) for about 6 hours before the test, receive a sedative, and have their throat locally anesthetized. After the procedure, patients remain NPO until the nurse has verified (touching the back of the throat with a cotton tip swab) that their gag reflex has returned.

Radioisotope Imaging. For this type of imaging, small amounts of radioisotopes are given intravenously. The patient is then scanned with a gamma camera and a radionuclide image is produced. Radiation exposure is similar to that of other x-ray examinations. These tests can provide information about myocardial ischemia or infarction, cardiac blood flow, and ventricle size and motion.

Thallium Imaging. Thallium 201, a radioactive analog of potassium, is used to detect impaired myocardial perfusion. It is injected intravenously (IV), and muscle cells absorb it. After 10 to 15 minutes the heart is scanned to see where the thallium has concentrated. Four hours later the scan is repeated to look for changes. Healthy myocardial cells with good blood flow take up the thallium. Areas in which the thallium is not seen are referred to as cold spots and indicate ischemia or infarction. The patency of a coronary artery graft may also be assessed with this test. This test is used often because the short half-life of thallium results in lower radiation exposure.

Exercise testing may be combined with thallium injection to detect blood flow changes with activity and after rest. The patient exercises and about 2 minutes before stopping is given thallium. Scans are taken immediately and again in 2 to 4 hours. Cold spots on initial images indicate ischemia. If the cold spots are gone in later images, it indicates exercise-induced ischemia. If the cold spots are still present in later images, they show scarred areas.

If patients are unable to participate in exercise for the thallium stress test, dipyridamole (Persantine) or adenosine, coronary vasodilators, can be given. These drugs simulate the increased blood flow to healthy myocardial cells that occurs with exercise.

Technetium Pyrophosphate Scan. Technetium ^{99m} pyrophosphate is injected for this test. Areas of ischemia or myocardial cell damage take up the radioisotope, and when scanned these areas appear as hot spots. Acute myocardial infarction (MI) size and location can be detected, but old MIs cannot be detected.

Technetium ^{99m} Sestamibi. Technetium ^{99m} sestamibi is given IV and the patient is scanned 1.5 to 2 hours later. Areas of myocardial cell damage take up the radioisotope, and when scanned these areas appear as hot spots.

Blood Pool Imaging. Technetium ^{99m} pertechnetate is injected IV and remains in the bloodstream; it is not taken up by myocardial cells. A camera follows the flow of the radioactivity, which shows ventricular function and wall motion and the ejection fraction of the heart.

Positron Emission Tomography. Positron emission tomography (PET) shows myocardial perfusion and viability with three-dimensional images. Nitrogen 13—ammonia is injected IV first and then scanned to show myocardial perfusion. Next, fluoro-18-deoxyglucose is given intravenously and then scanned to show myocardial metabolic function. If there is ischemia or heart damage, the two scans are different. For example, in ischemia of viable cells, blood flow is decreased but metabolism elevated. Treatment to increase blood flow improves cardiac function in this case. Before the test the patient's blood glucose should be normal, and caffeine and tobacco should be avoided for 4 hours before the test.

Doppler Ultrasound. In this test, sound waves are transmitted to an artery or vein to assess blood flow problems. The sound waves bounce off moving blood cells and return a sound frequency in relationship to the amount of blood flow. With decreased blood flow the sounds are reduced. This test requires no patient preparation, takes about 20 minutes to complete, and is painless.

Plethysmography. With this test, blood volume and changes in blood flow are measured to diagnose deep vein thrombosis and pulmonary emboli and to screen patients for peripheral vascular disease. The leg being tested is raised 30 degrees with the patient supine. A pressure cuff is then inflated on the leg to distend the veins. Blood flow is measured with electrodes, and the cuff is then rapidly deflated and venous volume changes are recorded. Thrombi are detected by reduction in venous volume.

Arterial Stiffness Index (ASI). A newer test measures stiffness of the brachial artery to determine arteriosclerosis and cardiovascular disease risk. The brachial artery correlates with the coronary arteries in regard to the extent of atherosclerosis. The test is done with a device with a blood pressure cuff hooked to a computer. The waveforms during the blood pressure reading are mapped in the computer to provide information on the artery stiffness.

BLOOD STUDIES. Homocysteine. In recent years, homocysteine has been used to predict risk for cardio-

vascular disease when elevated. Homocysteine is an amino acid made in the body that can irritate blood vessels, leading to blockages or clots. Normal levels are 12 mmol/L or less. Often folate, vitamin B₆, and vitamin B₁₂ are not adequate in the diet. Homocysteine levels can be reduced with green leafy vegetables or prescribed folate (folic acid) supplements. For more information, visit <http://www.homocysteine.net>.

C-reactive Protein (CRP). C-reactive protein is a newer test for assessing cardiac disease risk. Elevated cardiac CRP levels can indicate low-grade inflammation in coronary vessels. This can signal increased long-term heart disease risk. CRP is found in small amounts in healthy people. Negative emotions and stress can elevate CRP, increasing cardiac disease risk. Elevated levels indicate risk for myocardial infarction and allow nurses the chance to help patients understand and reduce cardiac risk factors. This test is often done along with cholesterol screening.

Myeloperoxidase Antigen (MPO). Myeloperoxidase antigen (MPO), a leukocyte enzyme, is made when inflammation is present in arteries. Levels are higher in ruptured plaques and can lead to heart attack. Risk of heart attack up to 6 months in advance may be predicted with elevated MPO levels (without the presence of myocardial necrosis) for patients with chest pain. This test may be more predictive than CRP of cardiac risk, especially for use in emergency departments when troponin levels are normal.

Cardiac Troponin. Cardiac muscle contains proteins called troponins, which control the muscle fibers that contract or squeeze the heart muscle. Troponin I and troponin T are highly sensitive indicators of myocardial damage, which is helpful in diagnosing MI. They are proteins found only in cardiac cells. When injured or dead, cardiac cells release these proteins, which results in elevated levels within 4 to 6 hours of damage. These levels peak in 10 to 24 hours and remain elevated for up to 7 days after injury. Troponin T appears slightly earlier than troponin I after cardiac damage. Troponin T is better at showing slight cardiac damage and predicting 30-day mortality for cardiac patients.

Troponin I can also be used to monitor critically ill patients in the critical care setting. Heart damage may be occurring undetected that is delaying recovery. Studies are being done to see if troponin may be useful for ongoing monitoring of cardiac injury so that medications can be given.

Cardiac Enzymes. When heart cells are damaged or die, they rupture and release enzymes into the bloodstream. Levels of these enzymes rise in the serum as a result. A common cardiac enzyme test is creatine kinase (CK), also referred to as creatine phosphokinase (CPK). It is often ordered with troponin tests. Lactic dehydrogenase (LDH), a nonspecific enzyme test, is rarely used today as troponin has basically replaced it. CK enzymes are also found in body cells other than the heart, so a more organ-specific test in which the enzyme's isoenzymes (or different forms) are measured is used.

Creatine Kinase. Creatine kinase (CK) is found in three types of tissue: brain, skeletal muscle, and heart muscle. Isoenzymes of CK contained in these tissues are CK-BB (brain), CK-MM (skeletal muscle), and CK-MB (heart muscle). Levels of CK-MB rise within 4 to 6 hours after cardiac cells are damaged, peak in 12 to 24 hours, and return to normal in 48 to 72 hours. Serial CK levels are drawn at intervals to track trends. It is important to avoid invasive procedures such as IV and intramuscular (IM) injections before drawing the first CK to prevent elevation in the CK levels from cell trauma caused by the procedure. Then medications are often given IV rather than IM to prevent contributing to this elevation.

Myoglobin. Myoglobin is a protein found in skeletal and cardiac muscle and is released into the bloodstream when cell damage occurs. Because myoglobin is not site specific, it can only provide an estimate of damage and is used with other more specific tests such as troponin to diagnosis an MI. Myoglobin levels elevate within 1 hour of an acute MI. Peak levels are reached 4 to 12 hours after an MI, and levels return to normal within 18 hours after the onset of chest pain, so it is a test that must be done early when MI is suspected.

Blood Lipids. Lipids include triglycerides, cholesterol, and phospholipids. Lipoproteins carry these lipids attached to proteins. Triglycerides are found in very low-density lipoproteins (VLDLs). Cholesterol is mainly found in low-density lipoproteins (LDLs). High-density lipoproteins (HDLs) are a mixture of one-half protein and one-half phospholipids and cholesterol.

A lipid profile can screen for increased risk for coronary artery disease. For more information, visit <http://www.nhlbi.nih.gov/guidelines/cholesterol/atglance.pdf>. Patients must fast for 12 hours before the test, and although water is not withheld, alcohol is restricted for 24 hours before the test. High levels of LDLs are linked to an increase in CAD because they circulate cholesterol in the arteries. High-density lipoproteins play a protective role against CAD because they carry cholesterol to the liver to be metabolized. Controlling lipids is very important in reducing CAD (Box 20.4 Cultural Considerations).

INVASIVE STUDIES. Angiography. Arteriography and venography are the two types of angiography (Fig. 20.13).

SAFETY TIP

Improve the effectiveness of communication among caregivers.

For verbal or telephone orders or for telephonic reporting of critical test results, verify the complete order or test result by having the person receiving the order or test result “read back” the complete order or test result. (2006 National Patient Safety Goals from www.jcaho.org)

Box 20.4

Cultural Considerations

Among French Canadians, familial chylomicronemia (hyperlipoproteinemia type I), an autosomal recessive disorder, occurs with the highest frequency worldwide. Familial hypercholesterolemia can lead to coronary thrombosis. Thus, the nurse can improve the health of French Canadians by encouraging early diagnostic workups for familial chylomicronemia and encouraging healthful lifestyles.

Arteriography examines arteries. Venography studies veins. Angiography uses dye injected into the vascular system to visualize the vessels on radiographs. This test is used to assess blood clot formation, to assess peripheral vascular disease (PVD), and to test vessels for potential grafting use.

The patient must be assessed for allergies, give informed consent, be NPO for about 4 hours before the test, and be informed that the dye produces a hot, burning feeling when injected. After the procedure the patient is assessed for several hours. Vital signs, allergic reaction signs, hemorrhage at the injection site, and pulses are monitored.

Cardiac Catheterization. Cardiac catheterization allows the study of the heart’s anatomy and physiology. It is an invasive diagnostic procedure that measures pressures in the heart chambers, great blood vessels, and coronary arteries and provides information on cardiac output and oxygen saturation. Fluoroscopy is used, and dye can be injected once the catheter is in place to visualize the heart chambers and vessels. This procedure is often done before heart surgery.

An informed consent must be obtained. The patient is assessed for allergies to iodine, and procedure dyes and kept NPO before the procedure. Patients should be told that during the test they are awake and a warm, flushing sensation

FIGURE 20.13 Coronary angiography and cardiac catheterization.

may be felt when the dye is injected; the room has a lot of equipment; a movable table is used; the patient's vital signs and ECG are monitored constantly; and the length of the procedure is 2 to 3 hours.

In right-sided catheterization, a catheter with or without a fiberoptic tip is inserted into the basilic or cephalic vein or the femoral vein and advanced into the vena cava. It is then moved through the right chambers of the heart and into the pulmonary artery. The catheter can be wedged momentarily in the artery by inflating the balloon at the tip of the catheter. This position provides the pulmonary artery wedge pressure (PAWP), which reflects pressures in the left side of the heart. Other pressures obtained with right-sided cardiac catheterization are right atrial pressure, which reflects central venous pressure, pulmonary artery systolic and diastolic pressures, cardiac output, and mixed venous oxygen saturation (SVO₂) if a fiberoptic catheter is used.

The left side of the heart can be directly assessed by inserting a catheter into the brachial or the femoral artery. It is advanced against the flow of blood into the aorta, through the aortic valve, and into the left ventricle. Coronary angiography, which visualizes the coronary arteries with dye, can be done with this approach. The catheter is inserted into the opening of the coronary arteries, the dye is injected, and x-ray films are taken. Coronary artery disease can be assessed with coronary angiography.

After the procedure the catheter is removed and firm pressure must be applied to the insertion site for several minutes to prevent hemorrhage or hematoma formation. A pressure dressing or sandbag may be applied to the site when bleeding is stopped and is removed in several hours. Vital signs are assessed according to the physician's orders and the institution's policies. During vital sign checks, the puncture site is assessed and peripheral pulses are verified. The extremity used for insertion must not be moved or flexed for several hours after the procedure. Patients usually may eat and are instructed to drink fluids to help eliminate the dye from the body. If the patient is stable and no significant findings are found, the patient may be discharged.

Complications of cardiac catheterization can be allergic reaction, breaking of the catheter, hemorrhage, thrombus formation, emboli of air or blood, dysrhythmias, MI, cerebrovascular accident (CVA), and puncture of the heart chambers or lungs.

Hemodynamic Monitoring. Bedside monitoring can be done to monitor the pressures in the blood vessels or heart. A catheter attached to a transducer and monitor, called an arterial line, can be inserted into the radial or femoral artery to measure continuous arterial blood pressure.

Ongoing monitoring of cardiac pressures, cardiac output, and central venous pressure (CVP) can be done with either a central catheter or a pulmonary artery catheter. Central venous pressure is measured directly with a central catheter inserted into the vena cava via the brachial, femoral,

FIGURE 20.14 CVP measurement.

subclavian, or jugular vein (Fig. 20.14). It is measured indirectly with the pulmonary artery catheter (Fig. 20.15). The right atrial pressure measurement obtained from the pulmonary artery catheter reflects the pressure in the vena cava. Central venous pressure measures **preload** or fluid volume status; CVP readings used in fluid or diuretic therapy have been primarily replaced by pulmonary artery catheter measurements.

FIGURE 20.15 Pulmonary artery catheter and placement of the inflated balloon in the pulmonary artery.

Electrophysiologic Study. To study the heart's electrical system, one or more catheters with electrodes are inserted via the femoral vein into the right side of the heart. Two to three electrodes are inserted usually. The heart's electrical impulses are then recorded and pacing can also be done. Dysrhythmias can be triggered to help the physician diagnose dysrhythmias. A consent is obtained and the patient is NPO 6 to 8 hours before the test.

THERAPEUTIC INTERVENTIONS FOR THE CARDIOVASCULAR SYSTEM

Exercise

A prescribed walking program helps promote blood flow by contracting the skeletal muscles and may reduce symptoms of peripheral vascular disease. For patients recovering from cardiac surgery or a myocardial infarction, activity is gradually increased. Exercise is very important for optimum cardiac functioning. A cardiac rehabilitation program is usually prescribed, and individualized exercise goals are determined. After discharge from the hospital, exercise three times a week for 20 to 30 minutes is encouraged. Mild stretching should be done before and after the exercise.

Smoking Cessation

Smoking causes vasoconstriction that can last up to 1 hour after the smoking of one cigarette. For patients with cardiac or vascular disease, blood flow is reduced, which can exacerbate symptoms. Patients should be encouraged to stop smoking and should be provided with support information such as cessation programs and support groups. For more information on smoking cessation, visit www.americanheart.org.

Diet

Teaching the patient to eat a healthy, balanced diet is important to help reduce the risk for coronary artery disease. Weight reduction, if needed, is encouraged, as well as increasing physical activity. In May 2001, the National Heart, Lung, and Blood Institute released therapeutic lifestyle changes (TLC) that are recommended to help control CHD risk factors. The TLC diet is low in cholesterol (<200 mg/day) and saturated fats (<7% of calories). Soluble fiber (10 to 25 g/day) and plant stanols/sterols (2 g/day) are also recommended to reduce LDL levels. For more information on the therapeutic lifestyle changes, visit http://hin.nhlbi.nih.gov/cvd_frameset.htm.

A diet low in sodium may be prescribed if excess fluid volume is a problem. (See Chapter 5.) If diuretics are used that promote potassium loss, potassium levels must be monitored and adequate amounts of potassium included in the diet. To reduce fat, red meats, fried foods, whole milk, and cheese should be limited or avoided. Cholesterol can be

reduced by avoiding egg yolks, organ meats, animal fats, and shellfish. Five to six servings of fruits and vegetables should be eaten daily. Increasing fish intake and eating poultry without skin are parts of a healthy diet.

Oxygen

Supplemental oxygen is administered to patients with chest pain to help ensure that the heart receives sufficient oxygen to function. Oxygen may be delivered via a nasal cannula or face mask. The patient must be taught safety precautions necessary for home use of oxygen if it is ordered, such as avoiding open flames and not smoking when the oxygen is in use.

Medications

The primary cardiovascular drugs are cardiac glycosides, vasodilators, antihypertensives, antidysrhythmics, antianginals, anticoagulants, and thrombolytics. They are discussed in further detail where the disorders they are used to treat are discussed (Box 20.5 Nutrition Notes).

Antiembolism Devices

Antiembolism devices improve arterial blood flow and venous return to prevent the formation of blood clots. They are used for patients with peripheral vascular disease, on bedrest, or after surgery or trauma.

Elastic Stockings

Antiembolism stockings apply pressure over the leg to promote the movement of fluid and prevent stasis of fluid. These stockings may be knee or thigh length. They must be applied correctly so that a tourniquet effect is not produced by the stockings. For ease in application, the stocking is turned inside out to the heel, the foot portion is placed on the patient up to the heel, and then the remaining stocking is pulled up over the leg. The tops of the stockings should be 1 to 2 inches below the bottom of the kneecap. They should not roll down or they will cause stasis rather than prevent it. The stockings are removed daily per physician order or agency protocol and the skin inspected for irritation. Elderly patients may require assistance in applying the stockings if they have impaired manual dexterity.

Intermittent Pneumatic Compression Devices

An intermittent pneumatic compression device consists of plastic inflatable stockings that are filled intermittently with air by an attached motor (Fig. 20.16). This device promotes fluid movement by simulating the contraction of the leg muscles to prevent thrombosis development. The compartments in the stockings inflate to 35 to 55 mm Hg of pressure, beginning in the ankle compartment and progressing next to the calf compartment and finally the thigh compartment. The nurse should monitor the device for proper pressure inflation.

Lifestyle and Cardiac Care

To reduce risk factors or promote recovery from cardiovascular disease, lifestyle changes are often needed. Long-

Box 20.5

Nutrition Notes

CYP Enzymes and Fruit Juices

Cytochrome P450 (CYP450) is a superfamily of enzymes found mainly in the liver but also in the gastrointestinal tract, lungs, and kidneys. The isoenzyme CYP3A4, the main form in the small intestine, is estimated to participate in the metabolism of more than 50% of all pharmaceutical agents, a function that may have evolved to protect the body from toxins. After uptake by the intestinal epithelial cells, many substances are metabolized by CYP3A4 or returned to the intestinal lumen by a transporter protein³, thus limiting the amount of the substance available for absorption into the bloodstream. Individuals show a wide variation in the amount of CYP3A4 in the liver and the intestine due to genetic, physiological, and environmental effects so that persons with more of the isoenzyme show greater effects to its inhibition than those with lesser amounts of intestinal CYP3A4.^{3, 4}

Grapefruit juice appears to inhibit intestinal CYP3A4 so that the oral bioavailability of affected drugs is increased dramatically, in some cases sufficient to cause drug toxicity or treatment failure. A single glass (240 mL) of grapefruit juice is enough to produce measurable effects for 24 hours, presumably until the body manufactures more of the enzyme. Applying this knowledge to clinical practice is complicated by the fact that even within a given class of drugs, not all agents are metabolized by CYP3A4. For instance, felodipine (Plendil), diazepam (Valium), and simvastatin (Zocor) interact with grapefruit juice, whereas nifedipine (Procardia), alprazolam (Xanax), and pravastatin (Pravachol) are thought by some to show little or no interaction. Likewise, cyclosporine, an immunosuppressive agent used to prevent transplant rejection, is metabolized by intestinal CYP3A4, and elevated blood levels have occurred when administered with grapefruit juice.⁵

Other fruits may have this same effect which is being studied. Fruits that could have this effect include Seville oranges, lime juice, and tangelos, which are from a form of grapefruit. Other citrus fruit should be safe: lemons, sweet oranges, tangerines, and citrons.

A similar mechanism but a different isoenzyme is proposed to explain an interaction between warfarin (Coumadin) and cranberry juice. Warfarin is mainly metabolized by the cytochrome P450 isoenzyme CYP2C9, and cranberry juice contains flavonoids known to inhibit P450 enzymes. Bleeding problems and hemorrhage have been attributed to this interaction.^{6, 7}

FIGURE 20.16 The Kendall SCD Response Compression system provides sequential personalized compression cycles that minimize stasis and maximize blood flow to prevent thrombosis and pulmonary embolus development. (Courtesy Kendall, Mansfield, MA.)

standing habits are difficult to change. Support groups can offer encouragement that is helpful in promoting a healthy lifestyle. Patients should be referred to community support groups as needed.

Patients recovering from cardiac disorders are often anxious about resuming sexual activity but are embarrassed to discuss it. This is an area that is often overlooked when caring for patients. Sexual counseling should be offered to patients and their partners. Patients often have misconceptions that are unfounded but interfere with resuming their sexual activity. If patients have angina, nitroglycerin can be taken prophylactically before sexual activity. After a myocardial infarction, sexual activity can be resumed in 1 to 2 months or when the patient can climb two flights of stairs without symptoms, as ordered by the physician. Sexual activity is a form of physical activity. Patients should be given information to make an informed decision on when they are ready to resume this activity.

Cardiac Surgery

As heart disease symptoms increase in severity and frequency or the disease process worsens, cardiac surgery may be used as treatment. Although cardiac surgery has become commonplace, it is still a major surgery with numerous complications, as well as physical, emotional, and social stressors.

Preparation for Surgery

For elective heart surgery, patients may be admitted to the hospital on the morning of surgery or 1 to 3 days before the surgery based on their medical history. A nursing assessment is important to provide baseline data that can be used for postoperative comparison and early discharge planning. In addition to routine admission testing, patients with chronic obstructive pulmonary disease (COPD) may have pulmonary function tests and baseline arterial blood gases (ABGs) done (Box 20.6). Patients with carotid bruits have

Box 20.6**Routine Admission Testing**

12-lead electrocardiogram (ECG)
 Chest x-ray exam
 Complete blood cell count (CBC)
 Coagulation studies
 Chemistry profile
 Crossmatched for blood

carotid studies to determine the amount of occlusion in the carotid artery. If the occlusion is significant, a carotid endarterectomy, which removes the plaque on the lining of the blocked or diseased carotid artery, is performed, usually several weeks before having cardiac surgery.

Medications that may increase bleeding or reduce fluid volume may be ordered by the physician to be held before surgery. Drugs that increase bleeding include aspirin, often stopped 3 to 7 days preoperatively; warfarin (Coumadin), often stopped 4 to 5 days preoperatively; and heparin, stopped 4 hours preoperatively. During surgery fluid volume and blood pressure may be decreased by blood loss or medications. Therefore, diuretics, which could further reduce fluid volume and blood pressure, are withheld up to 2 days before surgery. Because the patient takes nothing by mouth (NPO) 8 to 12 hours before surgery, insulin and oral hypoglycemic agents are reduced or withheld the morning of surgery.

Patients recover more quickly and have less postoperative stress when they have thorough preoperative teaching. Explanations of pain management, endotracheal tube (ETT), methods of communicating, ventilator, chest tubes, coughing and deep breathing exercises, intravenous (IV) lines, urinary catheter, incision care, and various equipment alarms are provided to the patient and family. It should be emphasized that patients are not able to talk while the ETT is in place.

Additionally, a preoperative family tour of the patient's initial postoperative unit and the waiting area helps prepare them for the surgical experience. A referral to pastoral care, if desired, can be comforting to the patient and family.

The anesthesiologist assesses the patient before surgery and orders preoperative medications. An antiseptic scrub shower is taken the night before and the morning of surgery. The patient is NPO after midnight the night before surgery.

Cardiopulmonary Bypass

The majority of cardiac surgeries use a cardiopulmonary bypass (CPB) pump in which blood is temporarily diverted away from the heart and lungs to the special pump (Fig. 20.17). This diversion allows for a bloodless and motionless surgical field while the function of the heart and lungs is maintained by the pump. After the **sternotomy** is made, the vena cava and ascending aorta are cannulated (a small tube with multiple holes is placed into each of them). The aorta is cross-clamped between the heart and the cannula by clamping two large hemostats over the aorta in opposite directions. The cannulas are then attached to the pump tubing. Blood then flows from the body through the vena cava cannula to the CPB pump for oxygenation. After the pump oxygenates and removes carbon dioxide from the blood, the blood is returned to the body. The blood flows through the cannula into the ascending aorta, where it then circulates through the body (Fig. 20.18).

Using the CPB pump can have a unique set of complications. Before going on the pump, the patient is anticoagulated with heparin until the partial thromboplastin time (PTT) is five to six times greater than normal. Immediately before the patient comes off the pump, the effects of the heparin are reversed with protamine sulfate (antidote for heparin). Heparin is absorbed and stored in organs and tissue and can be sporadically released hours after surgery. As a result, the patient may have excessive bleeding. The risk of

sternotomy: stern—sternum + otomy—incision into

FIGURE 20.17 Cardiopulmonary bypass pump components.

FIGURE 20.18 Cardiopulmonary bypass pump in use.

an air embolism is minimized by priming the pump with lactated Ringer's solution and maintaining careful observation. The priming solution increases circulating volume, which then results in a shifting of fluid into the interstitial tissue and edema formation. These fluid shifts can continue up to 6 hours after surgery and can cause hypotension.

Methods for providing closed-chest cardiopulmonary bypass and **cardioplegia** are being studied. Instead of opening the chest, small incisions are made in the chest and a

cardioplegia: cardio—heart + plegia—paralysis

video-assisted thoracoscope is inserted and used to perform the entire surgery. This technique of closed-chest surgery, with or without CPB, is termed minimally invasive direct coronary artery bypass (MIDCAB) surgery. When CPB is not used, mechanical devices are used to stabilize the portion of the heart being bypassed while the remainder of the heart continues to beat. Risk for complications associated with MIDCAB are much lower than with the traditional CABG procedure, and the recovery time is often weeks less.

General Procedure for Cardiac Surgery

After the patient is placed on CPB, a cardioplegic solution is infused into the aortic root along with iced saline. This solution is placed around the heart to cause cardiac standstill. When the surgery is completed, the patient's blood is warmed in the CPB circuit and the patient is slowly weaned from CPB. The heart starts beating again after it is warmed and defibrillated. Temporary pacing wires are attached to the heart before the CPB pump is discontinued, so an external temporary pacemaker can be used if bradycardia develops. Once the heart is beating, CPB is stopped. Mediastinal chest tubes are placed to drain remaining blood and fluid from the chest. The sternotomy is closed with wires through the sternum and then sutures for the layers of tissue and skin. While still under anesthesia, the patient is transferred to an intensive care unit (ICU). Patients usually stay in ICU for 1 to 2 days, although those undergoing MIDCAB may not need an ICU stay.

REVIEW QUESTIONS

- The mitral and tricuspid valves prevent backflow of blood from which of the following?
 - Ventricles to atria when the ventricles contract
 - Atria to ventricles when the ventricles relax
 - Ventricles to atria when the atria contract
 - Atria to ventricles when the atria contract
- Which of the following describes the purpose of the endocardium of the heart?
 - Covers the heart muscle and prevents friction.
 - Supports the coronary blood vessels.
 - Lines the chambers of the heart and prevents abnormal clotting.
 - Prevents backflow of blood from atria to ventricles.
- The function of the coronary blood vessels is to do which of the following?
 - Prevent abnormal clotting within the heart.
 - Bring oxygenated blood to the myocardium.
 - Carry deoxygenated blood to the lungs.
 - Carry oxygenated blood to the lungs.
- Which of the following is where the location of the cardiac centers in the nervous system is found?
 - Cerebrum
 - Hypothalamus
 - Spinal cord
 - Medulla
- The functions of angiotensin II are to increase which of the following?
 - Vasodilation and ADH secretion
 - Vasoconstriction and aldosterone secretion
 - Heart rate and vasodilation
 - Heart rate and ADH secretion
- The increase of resting blood pressure with age may contribute to which of the following?
 - Dysrhythmias
 - Thrombus formation
 - Left-sided heart failure
 - Peripheral edema
- Which of the following is a modifiable cardiovascular risk factor that should be noted during patient data collection?
 - Age
 - Gender
 - Ethnic origin
 - Tobacco use

8. If it takes longer than 3 seconds for the color to return when assessing capillary refill, it may indicate which of the following?
 - a. Decreased arterial flow to the extremity
 - b. Increased arterial flow to the extremity
 - c. Decreased venous flow from the extremity
 - d. Increased venous flow from the extremity
 9. Which of the following is an important safety intervention that should be used while assessing a patient for orthostatic hypotension?
 - a. Reality orientation
 - b. Gait or walking belt
 - c. Liquids at bedside
 - d. Standing patient quickly
 10. In which area should the nurse assess a patient who is on bedrest for the presence of edema?
 - a. Arms
 - b. Ankles
 - c. Sternum
 - d. Sacrum
- Multiple response item. Select all that apply.
11. Which of the following should be included in patient teaching for coronary angiography with femoral catheter insertion site?
 - a. Dye injection causes hot, flushing sensation.
 - b. General anesthesia is administered.
 - c. Claustrophobia may be experienced.
 - d. Ambulation is not possible immediately after procedure.
 - e. Allergies are assessed prior to testing.
 12. A high-fiber diet for cardiac patients is recommended for which of the following purposes?
 - a. Increase absorption of nutrients
 - b. Reduce cardiac workload
 - c. Reduce edema development
 - d. Reduce appetite
 13. A patient is scheduled for vascular surgery. The patient is taking digoxin (Lanoxin), furosemide (Lasix), potassium, warfarin (Coumadin) and famotidine (Pepcid). Which medication may be stopped by the physician several days before surgery?
 - a. Digoxin (Lanoxin)
 - b. Furosemide (Lasix)
 - c. Warfarin (Coumadin)
 - d. Famotidine (Pepcid)

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Smith

1. An older patient commonly does not experience typical disorder symptoms. Chest pain is often not present because of reduced nerve sensitivity with aging for an MI. Dyspnea is the classic symptom of MI in the older patient.
2. Inspect both legs to determine edematous areas. Determine location and severity of edema by pressing finger for 5 seconds over the medial malleolus and moving up the leg along the tibia until no edema is found. Assess bilaterally. Measure leg circumference.
3. Document location of edema and whether edema is

nonpitting or pitting. Document findings for both legs.

4. Documentation should state “Bilateral pitting ankle edema” with leg circumference measurement number.
5. Additional symptoms should be documented as follows: Dyspnea at rest that increases with exertion, heart tones clear and distant, nailbeds pale, pain free, poor appetite for 2 weeks, 6-pound weight gain in 1 week, three-pillow orthopnea, bilateral jugular vein distention.
6. Unit Analysis Method:

$$\frac{162 \text{ pounds}}{2.2 \text{ pounds}} \left| \frac{1 \text{ kilogram}}{2.2 \text{ pounds}} \right. = 73.6 \text{ kilograms}$$

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of hypertension?
2. What are the causes and risk factors for hypertension?
3. What are the signs and symptoms of hypertension?
4. What are the current therapeutic interventions for hypertension?
5. What are the classifications of hypertension in adults and recommendations for treatment?
6. How would you classify hypertensive emergency?
7. What are common complications of hypertension?
8. What nursing care will you provide for patients with hypertension?
9. How will you know if your nursing interventions have been effective?

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7)¹ has redefined normal and abnormal blood pressures for adults age 18 years and older, and treatment guidelines for physicians, clinicians, nurses, and community programs to follow (Table 21.1). For more information on the JNC7 guidelines, visit www.nhlbi.nih.gov. More people are now considered hypertensive as well as prehypertensive under these new guidelines. It is important to stay aware of new changes in this area to best serve your patients.

To have a normal blood pressure (BP) both the systolic and diastolic readings taken in a seated position must be below 120/80 (Box 21.1). If either the **systolic blood pressure** is above 119 mm Hg or the **diastolic blood pressure** is above 79 mm Hg, patients are classified in the prehypertensive or hypertensive category that matches their highest reading. **Hypertension**, also known as high blood pressure, is a condition in which the average of at least two or more readings on different dates is above prehypertensive levels of either 120 to 139 over 80 to 89. As we age, the incidence of hypertension increases. Therefore, we can expect to see more cases of hypertension as the population ages and life spans increase. For more information on hypertension, visit www.americanheart.org.

PATHOPHYSIOLOGY OF HYPERTENSION

Normally the heart pumps blood through the body to meet the cells' needs for oxygen and nutrients. As it pumps, the heart forces blood through the blood vessels. The pressure exerted by blood on the walls of the blood vessels is measured

systolic: systole—contraction

diastolic: diastole—expansion

hypertension: hyper—excessive + tensio—tension

Box 21.1

Taking Accurate Blood Pressure Measurements

- Use auscultatory method with properly calibrated and validated blood pressure instrument.
- Seat patient quietly for at least 5 minutes in a chair (not on examination table) with feet on the floor and arm supported at heart level.
- Use appropriate-sized cuff in which cuff bladder encircles at least 80% of arm.
- Take at least two blood pressure measurements.
 - SBP = first of two or more sounds heard
 - DBP = disappearance of sounds
- Provide patients, verbally and in writing, their specific BP reading.

Adapted from JNC 7, 2004.

as blood pressure. Blood pressure is determined by **cardiac output (CO)**, **peripheral vascular resistance (PVR;** the ability of the vessels to stretch), the **viscosity** (thickness) of the blood, and the amount of circulating blood volume. Decreased stretching ability of blood vessels, increased blood viscosity, and/or increased fluid volume may cause an increase in blood pressure.

Several processes influence blood pressure. These processes include nervous system regulation, arterial baroreceptors and chemoreceptors, the renin-angiotensin-aldosterone mechanism, and balancing of body fluids. One way blood pressure is influenced is through adjustment of the CO, which is the amount of blood that the heart pumps out each minute. The heart rate rises to increase CO in

viscosity: viscous—sticky

TABLE 21.1 BLOOD PRESSURE CATEGORIES AND THERAPEUTIC INTERVENTIONS*

BP Category	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)	Recommended Follow-up	Lifestyle Modification	Drug Therapy Without Other Indicators
Normal	<120	<80	2 years	Encourage	None
Pre-hypertension	120–139	80–89	1 year	Yes	None
Stage 1 Hypertension	140–159	90–99	2 months	Yes	Thiazide-type diuretics. Consider ACEI, ARB, BB, CCB, or combination.
Stage 2 Hypertension	≥160	≥100	1 month For BP >180/110 evaluate and seek treatment immediately; then 1 week as needed	Yes	Two-drug combination (usually thiazide-type diuretic and ACEI or ARB, or BB or CCB).

*Treatment is based on highest BP category.

Drug abbreviations: ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, beta blocker; CCB, calcium channel blocker.

Adapted from JNC 7, 2004.

response to either physical or emotional activities that require more oxygen for the organs and tissues. PVR also influences blood pressure; it is the opposition that blood encounters as it flows through vessels. Anything causing blood vessels to become narrower causes an increased PVR. Any time PVR is increased, more pressure is needed to push the blood through the vessel, so blood pressure increases as a result. If PVR is decreased, less pressure is needed. Increased arteriolar PVR is the main mechanism that elevates blood pressure in hypertension.

Factors that impair normal regulation of blood pressure may lead to hypertension. Many of these factors are not well understood. Sympathetic nervous system overstimulation, which causes vasoconstriction, can contribute to hypertension. Alterations in baroreceptors and chemoreceptors may also influence the development of hypertension. For example, baroreceptors may become less sensitive from prolonged increases in vessel pressure and subsequently fail to stimulate vasodilation through vessel stretching. Additionally, increases in hormones that cause sodium retention, such as aldosterone, lead to increased fluid retention. Changes in kidney function that alter the excretion of fluid also result in an increase in overall body fluid that may contribute to hypertension.

Primary Hypertension

Primary, or **essential**, **hypertension** is the chronic elevation of blood pressure from an unknown cause.

Secondary Hypertension

Secondary hypertension has a known cause. In other words, it is a sign of another problem, such as a kidney abnormality, a tumor of the adrenal gland, or a congenital defect of the aorta. When the cause of secondary hypertension is treated before permanent structural changes occur, blood pressure usually returns to normal.

Isolated Systolic Hypertension

Isolated systolic hypertension (ISH) is a systolic pressure of 140 mm Hg or greater and a diastolic pressure of 90 mm Hg or less. This type of hypertension occurs mainly in the elderly, although it can occur at any age (Box 21.2 Gerontological Issues). For people with a systolic pressure higher than 140 mm Hg and a diastolic pressure under

90 mm Hg found on two separate readings, a referral to a physician for further evaluation is recommended. Treatment of ISH is recommended to decrease cardiovascular disease, especially heart failure episodes and risk of stroke. Lifestyle modifications are usually tried first if the systolic elevation is not too severe. If lifestyle modifications fail to reduce the systolic pressure, antihypertensive medication is added.

SIGNS AND SYMPTOMS OF HYPERTENSION

Often hypertension causes no signs or symptoms other than elevated blood pressure readings. As a result, hypertension is referred to as the “silent killer.” Patients with hypertension are often first diagnosed when seeking health care for reasons unrelated to hypertension. In a small number of cases, a patient with hypertension may complain of a headache, bloody nose, severe anxiety, or shortness of breath, although it is usually impossible for a patient to correlate the absence or presence of symptoms with the degree of blood pressure elevation (Box 21.3 Hypertension Summary).

Most signs and symptoms of hypertension stem from long-term damaging effects on the large and small blood vessels of the heart, kidneys, brain, and eyes. These effects are known as target organ disease.

DIAGNOSIS OF HYPERTENSION

Diagnosis of hypertension considers a patient’s risk factors for hypertension, a previous diagnosis of hypertension, presence of signs and symptoms, history of kidney or heart disease, and current use of medications. When the average of

Box 21.2

Gerontological Issues

In the past, it was thought that diastolic pressure was the most important part of blood pressure to control. However, it is now known that after age 55, diastolic pressure falls while systolic pressure continues to rise with age. This means that it is important to control systolic blood pressure, not just diastolic pressure in older adults to prevent heart disease and stroke.

Box 21.3

Hypertension Summary

Signs and Symptoms	Often none Increased blood pressure Headache, bloody nose, severe anxiety, or shortness of breath.
Diagnosis	Prehypertension is greater than systolic of 120 and diastolic of 80. Hypertension is the average blood pressure, for two or more readings on different dates, greater than systolic of 139 and diastolic of 89.
Therapeutic Interventions	Lifestyle modification Antihypertensive medications
Complications	Heart failure, myocardial infarction, stroke, renal failure
Nursing diagnoses	Deficient knowledge Potential ineffective therapeutic regimen management

seated blood pressure is above prehypertensive levels of either 120 to 139 or 80 to 89 on two or more occasions, then hypertension is diagnosed (see Table 21.1). Research has shown that the most effective method for predicting risk for stroke and heart attack are self blood pressure monitoring twice a day for a week.²

Diagnostic Tests

The JNC7 recommends physicians order various routine tests before beginning therapy for high blood pressure to identify damage to organs or blood vessels. Tests recommended by JNC7 include ECG, blood glucose, hematocrit, serum potassium, calcium, lipoprotein profile, high-density and low-density lipoprotein cholesterol (HDL-C and LDL-C, respectively), and triglyceride levels. These tests help determine if target-organ damage has been caused by elevated blood pressure. An example of this is testing for kidney damage with a urinalysis or serum creatinine level.

RISK FACTORS FOR HYPERTENSION

A combination of genetic (nonmodifiable) and environmental (modifiable) risk factors are thought to be responsible for the development of hypertension, although the cause remains unknown. Nonmodifiable risk factors—those that cannot be changed—include a family history of hypertension, age, ethnicity, and diabetes mellitus. Modifiable risk factors—those that can be changed—include blood glucose levels, activity levels, smoking, and salt and alcohol intake. Smoking cessation; reduced salt, caffeine and alcohol intake; weight reduction; improved meal planning; increased physical activity; and managing stress can all help to decrease blood pressure.

Nonmodifiable Risk Factors

Family History of Hypertension

Hypertension is seen more commonly among people with a family history of hypertension. Indeed, people with a family history have almost twice the risk of developing hypertension as those with no family history. People with a family history of hypertension should be encouraged to have their blood pressure checked regularly.

Age

People age differently because of their genetic and environmental risk factors and lifestyle habits. Thus, the results of the aging process may be reflected in wide variations of blood pressure among elderly people. As a person ages, **plaque** builds up in the arteries and the blood vessels become stiffer and less elastic, causing the heart to work harder to force blood through the vessels. These vessel changes increase the amount of work required by the heart to maintain blood flow into the circulation and subsequently blood pressure increases.

Race and Ethnicity

Box 21.4 (Cultural Considerations) discusses hypertension among various ethnic groups.

Diabetes Mellitus

Many adults who have diabetes mellitus also have hypertension. The risk of developing hypertension with a family history of diabetes and obesity is greater than when there is no family history. Lifestyle modifications and adherence to therapy are crucial to prevent the heart attacks, strokes, blindness, and kidney failure associated with high blood glucose and blood pressure levels.

Box 21.4

Cultural Considerations

Hypertension continues to be the most serious health problem for African Americans in the United States. More than 5 million of the 26 million African Americans living in the United States are hypertensive. They suffer higher mortality and morbidity rates related to hypertension and at an earlier age. African Americans from lower socioeconomic backgrounds have higher blood pressure than African Americans from higher socioeconomic backgrounds. Additionally, African Americans are 3.2 times more likely to develop kidney failure related to hypertension than European Americans.

Hypertension among African Americans is usually caused by increased renin activity resulting in greater sodium and fluid retention. Thus, African Americans respond better to diuretics such as furosemide (Lasix) and hydrochlorothiazide (HydroDIURIL) than to beta blockers such as propranolol (Inderal). Hypertension among European-Americans is more often caused by chemical imbalances; thus they respond better to beta blockers.

Chinese people are more sensitive than Caucasians to the effects of propranolol on heart rate and blood pressure, requiring only half the blood level of European Americans to achieve a therapeutic effect. Propranolol is eliminated from the bodies of many Chinese persons at double the rate of European Americans. They are more likely to suffer fatigue as a side effect. Thus, the nurse must carefully monitor the Chinese patient for therapeutic and side effects.

Hypertension among Japanese Americans is primarily related to the high sodium content of the Japanese diet, stress, and a high rate of cigarette smoking.

High rates of hypertension among Koreans and Filipinos are due to the stress of immigration, preserving foods in salt, and using condiments high in sodium.

Modifiable Risk Factors

The JNC7 suggests advising patients with hypertension to use lifestyle modifications. These modifications include weight reduction; adoption of the Dietary Approaches to Stop Hypertension (DASH) eating plan; moderation of dietary sodium, caffeine, and alcohol intake; increased physical activity; and smoking cessation (Box 21.5 Lifestyle Modifications for Hypertension). Lifestyle modifications are often used with antihypertensive drugs to control hypertension and enhance the drug effects (Box 21.6 Nutrition Notes).

Weight Reduction

There is a strong relationship between excess body weight and increased blood pressure. Weight reduction is one of the most important lifestyle modifications to lower blood pressure. The health-care provider and dietitian should be consulted to help the patient develop a weight-reduction plan.

Meal Planning

SALT INTAKE. High blood pressure is associated with a diet high in salt. Patients whose blood pressure can be lowered by restricting dietary sodium are called salt sensitive. This sensitivity is particularly common among African Americans, elderly persons, and patients with diabetes and obesity. Patients with hypertension should be instructed not to add salt while cooking and/or table salt to their food. Processed foods and foods in which salt can be easily tasted (e.g., canned soups, ham, bacon, salted nuts) should also be avoided.

CAFFEINE. Intake of caffeine should be limited as it can increase aortic stiffness. This raises the risk of cardiovascular disease for those with high blood pressure.

INTAKE OF POTASSIUM, MAGNESIUM, AND CALCIUM. The JNC7 recommends a balanced diet that

Box 21.5

Lifestyle Modifications for Hypertension

- Lose weight.
- Limit alcohol intake.
- Get regular aerobic exercise.
- Decrease amount of salt intake.
- Include daily allowances of potassium and calcium.
- Stop smoking.
- Reduce dietary saturated fat and cholesterol.

See Nutrition Notes, Box 21.6

Adapted from The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

Box 21.6

Nutrition Notes

Reducing Blood Pressure with Diet

The Dietary Approaches to Stop Hypertension (DASH) diet reduced blood pressure significantly in **normotensive** people and produced even greater reductions in hypertensive people in the eight week trial. Rather than emphasizing restriction of foods, the DASH diet increases the intake of certain commonly available, not specialty, foods. So that weight loss would not confound the results, participants were given additional calories if they began to lose weight. All the tested diets contained about 3 grams of sodium. Also, everyone was instructed to consume no more than three caffeinated beverages and no more than two standard alcoholic beverages per day to minimize the effects of those substances on the results. On a 2000-calorie diet, an individual following the DASH diet would consume the following:

- 7 to 8 servings of grains, equivalent to 7 to 8 slices of bread
- 4 to 5 servings of vegetables, equivalent to 4 to 5 cups of raw, leafy or 2 to 2 1/2 cups cooked
- 4 to 5 servings of fruits, equivalent to 4 to 5 medium fresh fruits or 1 to 1 1/4 cups dried fruit
- 2 to 3 servings of low-fat or nonfat dairy foods, equivalent to 16 to 24 ounces of milk
- 2 or fewer servings of lean meats, poultry, and fish, equivalent to 6 ounces or less per day
- 4 to 5 servings *per week* of nuts, seeds, and legumes, equivalent to 1 1/3 to 1 2/3 cups nuts or 2 to 2 1/2 cups cooked legumes
- 2.5 servings of fats and oils, equivalent to 2 1/2 teaspoons, preferably monounsaturated oils (canola, olive, peanut oils)

ensures adequate intake of these nutrients. Low levels of these nutrients can contribute to cardiovascular events. Foods rich in potassium include oranges, bananas, and broccoli. Magnesium is found in green vegetables such as spinach, nuts, seeds, and some whole grains. Milk, yogurt, and spinach are rich in calcium. Whenever possible, fresh or frozen foods should be selected rather than canned foods to increase intake of these nutrients.

Alcohol Consumption

The regular consumption of three or more drinks per day can increase the risk of hypertension and cause resistance to antihypertensive therapy. The nurse should counsel hypertensive patients who drink alcohol to consume no more than 1 oz of alcohol per day for men (two drinks) and no more than 1/2 oz per day for women (one drink). One drink should be considered 12 oz of beer, 1.5 oz of 80-

proof liquor, or 5 oz of wine (JNC7). Blood pressure may decrease or return to normal when alcohol consumption is modified.

Exercise

People with sedentary lifestyles have an increased risk of hypertension. Exercise helps prevent and control hypertension by reducing weight, decreasing peripheral resistance, and decreasing body fat. Anyone who is able should participate in regular aerobic physical activity, such as brisk walking, for at least 30 minutes per day on most days of the week. Patients with hypertension should be evaluated by a health-care provider before starting an exercise program.

Smoking

Smoking is a major risk factor for cardiovascular disease. Blood pressure may increase because nicotine constricts the blood vessels. Nurses should counsel patients with hypertension to quit smoking for overall cardiovascular risk reduction benefits. A referral to a smoking cessation program can be helpful in reaching this goal.

CRITICAL THINKING

Mrs. Miller

■ Mrs. Miller, age 54, visits a health clinic because she has a headache every morning. The nurse collects data on Mrs. Miller and finds that she is an office manager, smokes a pack of cigarettes a day, eats fast food for lunch at her desk, has two adult children, is recently divorced, and has two to three alcoholic drinks every evening. Mrs. Miller has been in good health and takes two aspirin tablets for her headaches daily.

1. What are Mrs. Miller's risk factors for hypertension?
2. What is the most significant patient information identified? Why?
3. Why is hypertension referred to as the silent killer?
4. Why should Mrs. Miller be told of the need for lifelong therapy if she is diagnosed with hypertension?

Suggested answers at end of chapter.

THERAPEUTIC INTERVENTIONS

The JNC7 provides guidelines for selecting therapy based on the patient's blood pressure, severity of blood pressure risk factors, and the presence of target-organ disease or cardiovascular disease. The no- or low-risk hypertensive patient's therapy begins with lifestyle modifications. If lifestyle modifications alone do not result in obtaining a blood pressure at the target goal, then drug therapy is recommended. For patients with severe hypertension, high-risk factors, or target-organ disease, drug therapy is started

Box 21.7

Gerontological Issues

Managing Antihypertensive Therapy

For safety, teach older adults who take antihypertensive drugs to rise slowly to prevent the effects of orthostatic hypotension. Dizziness may result, increasing the risk of falling. Deficiencies in fluid volume can be a common problem for older adults as well, and diuretics can contribute to fluid volume deficiencies. Careful fluid balance assessment is important to prevent dehydration. Older adults may be more sensitive to medications, so monitor them carefully for adverse effects. Older patients may need lower dosages of medications.

immediately along with lifestyle modifications. Safe administration of medications is important, especially for the older person (Box 21.7 Gerontological Issues).

Goals of therapeutic interventions are less than 140/90 mm Hg, or less than 130/80 mm Hg for those with diabetes or chronic kidney disease. For most patients with hypertension, initial drug therapy should be thiazide-type diuretics. If the response is inadequate to achieve the blood pressure goal, the dosage may be increased or a second drug from a different class may be added. There are eight categories of medications to treat hypertension: diuretics, alpha-adrenergic blockers, beta blockers, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists (ARB), central acting agents, adrenergic neuron blockers (peripherally acting), and vasodilators. Examples of these medications are given in Table 21.2.

The treatment plan of lifestyle modifications and medications is effective only when patients are motivated to accept the diagnosis of hypertension and include lifelong treatment in their daily routine. Empathy and trust can increase patient motivation. Patients should be instructed that antihypertensive therapy must usually be continued for the rest of their lives. Patients should be reminded that although they may be feeling better with the modifications and medications, the hypertension is still present even if it is well controlled. Patients should be told not to stop taking their medications unless instructed to do so by their health-care provider.

Antihypertensive medications can have unpleasant side effects. Patients should be told what these side effects are and to report them if they do occur, so that medication alterations can be made if possible. Erectile dysfunction can be one of the side effects of these medications. Male patients may be reluctant to discuss this side effect and instead choose to stop the medication. The nurse should be proactive and inform male patients about this side effect so they will understand that if it occurs and is reported, the physician can make adjustments in the medication regimen.

TABLE 21.2 ANTIHYPERTENSIVE MEDICATIONS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
<p>Diuretics Increase urine output by inhibiting sodium and water reabsorption by the kidney. Several types.</p>				Take with food to prevent GI upset. Monitor I&O and weight to determine fluid loss. Assess for improvement of edema in patients with HF and reduced BP in hypertension. Electrolyte imbalances may occur quickly. Teach patient to take during awake hours to prevent excessive urination during sleeping hours.
<p>Thiazide and thiazide-like diuretics Increase urine output by promoting sodium, chloride and water excretion; not immediate effect, most effective in normal renal function; causes loss of sodium potassium, magnesium, calcium saved.</p>	<p>Thiazide: hydrochlorothiazide (HydroDIURIL) chlorothiazide (Diuril) bendroflumethiazide (Naturetin) benzthiazide (Exna) hydroflumethiazide (Saluron, Diucardin) methyclothiazide (Aquatensen, Enduron) polythiazide (Renese-R). Thiazide-like: chlorthalidone (Hygroton) indapamide (Lozol) metolazone (Zaroxolyn, Mykrox) quinethazone (Hydromax)</p>	<p>PO IV form available for chlorothiazide.</p>	<p>Dizziness, fatigue, weakness, hyperkalemia, hypercalcemia, nausea, vomiting, anorexia, hyperglycemia, rash</p>	<p>Blood sugar may increase in diabetics. Teach patient to wear sunscreen and protective clothing to prevent photo-sensitivity. Hypercalcemia could be hazardous to patient on digoxin.</p>
<p>Loop diuretics Act on ascending loop of Henle in kidney to cause sodium and water loss; also causes loss of potassium, magnesium, and calcium.</p>	<p>bumetanide (Bumex) furosemide (Lasix) ethacrynic acid (if allergic to sulfonamides) torsemide (Demadex)</p>	<p>PO/IV/IM</p>	<p>Hyperkalemia, rash, nausea, hyperglycemia, tinnitus, rash, increased uric acid levels.</p>	<p>Contraindicated if allergic to sulfonamides. Teach to use sunscreen to prevent photo-sensitivity. Take with food or milk to prevent GI upset.</p>
<p>Potassium-sparing diuretics Mild diuretic, can be used as combination therapy; promote sodium and water excretion and potassium retention by the kidney.</p>	<p>amiloride (Midamor) triamterene (Dyrenium) spironolactone (Aldactone)</p>	<p>PO</p>	<p>Hyperkalemia, headache, nausea, vomiting, anorexia, diarrhea, rash, itching</p>	<p>Avoid foods rich in potassium such as oranges, bananas, salt substitutes, dried fruits. Triamterene -take after meals for GI upset -may turn urine blue</p>
<p>Sympatholytics: Beta Blockers Decrease sympathetic nervous system resulting in decreased blood pressure, heart rate, contractility, cardiac output, and renin activity.</p>	<p>acebutolol (Sectral) atenolol (Tenormin) betaxolol HCL (Kerlone) carteolol HCL (Cartrol) metoprolol (Lopressor) metoprolol extended release (Toprol XL)</p>	<p>PO IV form available for atenolol, metoprolol, and propranolol</p>	<p>Orthostatic hypotension, decreased heart rate, diarrhea, nausea, vomiting, bronchospasm, blood dyscrasias, and HF</p>	<p>Daily I & O and weight. Check heart rate and blood pressure before administration. Teach patient not to stop drug abruptly to avoid rebound hypertension, angina or dysrhythmias.</p>

(Continued on following page)

TABLE 21.2 ANTIHYPERTENSIVE MEDICATIONS (Continued)

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
	nadolol (Corgard) penbutolol (Levitol) propranolol (Inderal) propranolol long acting (Inderal LA) timolol maleate (Blocadren)			High Alert: IV vasoactive medications are inherently dangerous. Oral and parenteral doses of propranolol are not interchangeable; IV dose is 1/10 the oral dose. Patient harm or fatalities have occurred when switching from oral to IV route.
Alpha₁ blockers Block effects of sympathetic nervous system on smooth muscle of blood vessels resulting in vasodilation and decreased blood pressure.	prazosin (Minipress) terazosin (Hytrin)	PO	Hypotension, increased heart rate, nasal stuffiness, nausea, vomiting, diarrhea	Monitor for hypotension. Teach to make position changes slowly.
Combined alpha and beta blockers Block alpha-adrenergic receptors causing vasodilation and reduced blood pressure; Decrease sympathetic nervous system resulting in decreased heart rate, and contractility.	carvedilol (Coreg) carteolol HCl (Cartol) labetalol (Normodyne)	PO IV form available for labetalol	Dizziness, diarrhea, nausea, vomiting, tinnitus, bradycardia, postural hypotension, sexual dysfunction, high blood sugar	Daily I&O and weight, Assess heart rate prior to administration. Assess edema, neck vein distention, lung sounds. Teach patient not to stop drug abruptly.
Central acting alpha₂ agonists Block effects of sympathetic nervous system centrally.	clonidine* (Catapres) guanabenz acetate (Wytensin) guanfacine HCl (Tenex) methylodopa (Aldomet)	PO Transdermal patch available for clonidine IV methylodopa	Drowsiness, sedation, headache, fatigue, nausea, vomiting, malaise, dry mouth, rash, postural hypotension, palpitations	Assess for edema and/or decreased BP. Suggest gum or hard candy for dry mouth. Teach not to stop drug abruptly.
Adrenergic neuron blockers (peripherally acting) Block norepinephrine release resulting in reduced blood pressure for severe hypertension control.	guanethidine (Ismelin) reserpine (Serpalan)	PO	dizziness, GI upset, edema, headache, dry mouth, orthostatic hypotension, chest pain, bradycardia, dyspnea, muscle pain, depression, difficulty sleeping, sexual dysfunction.	Teach to rise slowly to prevent falls. Teach to chew gum or use hard candy for dry mouth. Reserpine can cause nightmares and suicidal intent.
Angiotension-converting enzyme (ACE) inhibitors Blocks production of angiotension II, a potent vasoconstrictor; Reduces peripheral arterial resistance and blood pressure.	benazepril HCl (Lotensin) captopril (Capoten) enalapril (Vasotec) fosinopril (Monopril) lisinopril ((Prinivil, Zestril) moexipril (Univasc) perindopril (Aceon) quinapril (Accupril) ramipril (altace) trandolapril (Mavik)	PO IV form available for enalapril	Hypotension, increased heart rate, dyspnea, cough, angioedema	Monitor patient for edema with HF and decreased BP with hypertension. Teach patient that sensitivity to sunlight may occur and not to stop agent abruptly.

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Angiotensin II Receptor antagonists (ARB) Block angiotensin II receptors causing vasodilation and reduction in blood pressure.	candesartan (Atacand) eprosartan (Teveten) irbesartan (Avapro) losartan (Cozaar) olmesartan (Benicar) telmisartan (Micardais) valsartan (Diovan)	PO	Dizziness, insomnia, diarrhea, cough	Monitor patient for edema with HF and decreased BP with hypertension. Teach patient sensitivity to sunlight may occur.
Aldosterone receptor antagonist Blocks binding of aldosterone at receptor site to reduce sodium reabsorption and then blood pressure.	eplerenone (Inspra)	PO	Headache, dizziness, angina, hyperkalemia, increased creatinine	Monitor potassium before and during therapy.
Calcium channel blockers Prevent movement of extracellular calcium into the cell which vasodilates.	amlodipine (Norvasc) diltiazem (Cardizem) felodipine (Plendil) isradipine (DynaCirc) nicardipine HCl (Cardene, Cardene SR) nifedipine (Procardia) nisoldipine (Sular, Nisocor) verapamil (CalanSR, Isoptin SR)	PO IV form available for diltiazem, verapamil, nicardipine	Dysrhythmias, edema, headache, fatigue, drowsiness, flushing	Take pulse prior to administration, assess for decreased BP, heart rate dysrhythmias, angina. May increase blood levels of digoxin.
Direct vasodilators Relax smooth muscles of blood vessels causing vasodilation and decreased blood pressure.	hydralazine (Apresoline) minoxidil (Loniten)	PO/IV/IM	Headache, nausea, hypotension or hypertension and changes in heart rhythm	Treat headache with acetaminophen. Monitor for increasing heart rate. Often given with diuretic to reduce edema resulting from water and sodium retention.

HF = heart failure; I&O = input and output; PO = oral; IV = intravenous; IM = intramuscular.

*Clonidine and clonazepam have been identified as potential problematic drug names. (www.jcaho.org, 2006)

LEARNING TIP

Hypertension lifestyle modifications:

- L—Limit salt, caffeine, and alcohol.
- I—Include daily potassium and calcium.
- F—Fight fat and cholesterol.
- E—Exercise regularly.
- S—Stay on your blood pressure regimen.
- T—Try to quit smoking.
- Y—Your medications are to be taken daily.
- L—Lose weight.
- E—End-stage complications will be avoided!

COMPLICATIONS OF HYPERTENSION

Common complications of hypertension include coronary artery disease, atherosclerosis, myocardial infarction (MI), heart failure (HF), stroke, and kidney or eye damage. The

severity and duration of the increase in blood pressure determine the extent of the vascular changes causing organ damage. High blood pressure levels may also result in an increase in the size of the left ventricle, referred to as **hypertrophy**. Elevated blood pressure damages the small vessels of the heart, brain, kidneys, and retina. The results are a progressive functional impairment of these organs, known as target-organ disease.

SPECIAL CONSIDERATIONS

Blood pressure should be well controlled before any invasive procedure. Hypertensive patients are at greater risk for strokes, MI, HF, kidney failure, and pulmonary edema. These patients should be instructed to continue their blood pressure medications until the time of the procedure, unless otherwise directed by their physician or health-care provider. Antihypertensive medications should be resumed as soon as possible after the procedure as directed by the physician.

CRITICAL THINKING

Mrs. Bell

■ Mrs. Bell, 80 years old, is seen in the physician's office. She lives a sedentary lifestyle alone in her own home with a bathroom down the hall from the bedroom. Mrs. Bell's son lives in the same city and visits her often. She has wood floors with throw rugs in the hall and a tile floor in the bathroom. She wears glasses and has a cataract. She has an unsteady gait and nocturia. She is 40 pounds overweight and has a 10-year history of hypertension for which she is taking chlorothiazide (Diuril) and propranolol (Inderal) when she remembers them.

1. What are Mrs. Bell's modifiable and nonmodifiable risk factors for hypertension?
2. Why is Mrs. Bell taking chlorothiazide and propranolol to treat her hypertension?
3. What teaching methods could be used to help ensure that Mrs. Bell will understand and follow her treatment plan?
4. Why should patient safety needs be addressed in the nursing care plan?
5. What safety interventions should the patient and family be taught?
6. Inderal 20 mg PO is ordered now as Mrs. Bell forgot to take her medication. The nurse has on hand Inderal 10-mg tablets. How many tablets should the nurse give?

Suggested answers at end of chapter.

may be given to quickly reduce blood pressure during this crisis.

HYPERTENSIVE URGENCY

The JNC7 considers **hypertensive urgency** to occur in situations when there is severe elevation of BP as in hypertensive emergency but without target-organ dysfunction progression. The patient with hypertensive urgency may experience severe headaches, nosebleeds, shortness of breath, and severe anxiety. Patients experiencing hypertensive urgency can usually be treated with combination oral medication and scheduled for a follow-up visit within several days.

NURSING PROCESS

Nursing Assessment/Data Collection

Assessment of a patient with hypertension includes the patient's health history, blood pressure measurements, medications, and physical assessment (Fig. 21.1). Assessing what hypertensive patients and their families know about hypertension and associated risk factors is essential for planning patient and family education and subsequent lifelong lifestyle modification needs.

Nursing Diagnosis, Planning, Interventions, and Evaluation

Possible nursing diagnosis, planning, interventions, and evaluation must be agreed upon by the patient and the health care team. See Box 21.8 Nursing Care Plan for the Patient with Hypertension.

HYPERTENSIVE EMERGENCY

Hypertensive emergency is a severe type of hypertension characterized by elevations in SBP greater than 180 mm Hg and DBP greater than 120 that are complicated by risk for or progression of target-organ dysfunction (examples include MI, HF, and dissecting aortic aneurysm). Patients who are untreated, fail to comply with antihypertensive therapy, or stop their medication abruptly are at risk for hypertensive emergency. These patients require immediate reduction of BP to prevent or limit damage to target organs. It is recommended that patients with hypertensive crises be admitted to the critical care unit. In some cases, the blood pressure may need to be reduced 25% within 1 hour to prevent organ damage. If the patient is stable, blood pressure is then decreased to 160/100 to 110 in the next 2 to 6 hours. Gradual reduction of the BP is desired to prevent decreased blood flow to the kidneys, heart, and/or brain. An intravenous medication such as nitroprusside (Nipride)

FIGURE 21.1 Nurse obtaining blood pressure measurement. Correct size cuff use is essential for accurate reading.

Box 21.8 NURSING CARE PLAN for the Patient with Hypertension

Nursing Diagnosis: Deficient Knowledge related to disease process and treatment regimen

Expected Outcomes Verbalizes knowledge of disease process and treatment regimen.

Evaluation of Outcomes Is Patient Able to Discuss and Explain Hypertension Disease Process Including its Risk Factors, Complications and Treatment Regimen?

Intervention

Identify patient's readiness and ability to learn.

Provide patient with information concerning disease process including risk factors, complications, and treatment regimen

Rationale

Patient must accept ownership of hypertension diagnosis and be able to receive and understand information given. Determine patient's preferred method of learning.

Patient will be more willing to participate in treatment regimen when able to understand need for changes in behavior.

Evaluation

Does patient verbalize acceptance of hypertension diagnosis?
Does patient demonstrate ability to read, write and retain information?

Is patient able to participate in discussion concerning hypertension disease process including risk factors, complications and treatment regimen?

Nursing Diagnosis: Potential for ineffective therapeutic regimen management related to complexity of therapy, cost of medications, lack of symptoms, side effects of medications, need to alter long-term lifestyle habits, normal blood pressure controlled by therapy.

Expected Outcomes The patient verbalizes ability and willingness to comply with treatment.

Evaluation of Outcomes Is patient able to state how lifestyle will include therapy? Does patient identify and problem solve barriers for therapy?

Intervention

Identify patient's modifiable risk factors and lifestyle modification needs.

Identify factors that are barriers to patient complying with therapy.

Develop plan to overcome barriers. Make referrals as needed.

Rationale

Identifying risk factors is the first step in planning therapy. Patient must understand the relationship of these risk factors with hypertension and complication development.

Factors such as finances, transportation, aging changes, patient motivation, habits, and reading and educational level can be barriers for therapy.

Identified barriers can be overcome with planning and intervention, such as referral to support groups or for financial assistance or prescription delivery service and instructions provided at level of patient's learning ability.

Evaluation

Can patient state rationale for modifying risk factors to prevent complication development?

Are barriers present for patient?

Have barriers been eliminated?

Is patient willing to use referrals?

(Continued on following page)

Box 21.8 NURSING CARE PLAN for the Patient with Hypertension (Continued)

Geriatric

Intervention	Rationale	Evaluation
Assess ability to take medications daily: financially, obtaining refills, understanding directions.	Elderly patients may be on a fixed income, lack transportation, or lack ability to take several medications several times a day. Simplifying this process, to one medication if possible, can increase compliance.	Is patient able to obtain medications? Can patient self-administer medications accurately on daily basis?
Teach patient to take medications as prescribed and not to skip dosages.	Elderly patients may skip dosages to save money, reduce side effects, or reduce need to void.	Does patient take dosages as prescribed? Does patient express concern over cost, side effects, or frequent voiding?
Teach patient to change positions slowly to prevent falls.	Antihypertensive medications can cause hypotension, resulting in dizziness and weakness and possibly leading to falls.	Does patient understand how to change positions slowly? Does patient experience dizziness or weakness?

Home Health Hints

- For meal planning, most patients eat fast foods occasionally. Assist them in choosing foods that are low in fat, sugar, and salt (e.g., choose chicken salads with low-fat dressing or fajitas without sour cream and guacamole).
- Instruct patients and caregivers to avoid frozen dinners and deli meats since many of these are high in sodium.
- Because medication and electrolyte interaction can occur with a salt substitute, which often contains potassium, the physician should be consulted before the patient uses it.
- Teach patients how to read labels for fat and salt content. If patients are on a 2- to 3-g sodium diet, instruct them about eating breads or cereals that contain 200 mg or less of sodium per serving or canned vegetables of 150 mg of sodium per serving. Fresh vegetables are better, but cost and storage must be considered. Providing written suggestions for the caregiver who does the grocery shopping increases compliance with diet therapy.
- Home exercise using weights can be improvised using canned goods and bags of sugar as weights. The amount of weight being used is easily identified for documentation by the labeling on the food item.
- The following suggestions may help a patient decrease or stop smoking: Use cinnamon mouthwash on arising; put away all ashtrays but one and keep it in a place not normally used for smoking; find ways to keep hands busy at times when usually holding cigarette, such as when drinking coffee or alcohol.
- Encourage patients to put “No Smoking” signs on their door to avoid passive smoking.
- Medication compliance can be a challenge for the elderly hypertensive patient. Instruct patients to take medication as prescribed even if they are feeling well or if side effects, which they should report, are present. If the medicines are too expensive for the patient, check with the physician and pharmacist for less expensive alternatives.
- During home visits count the amount of pills in a bottle to assess compliance. Remind the patient to get refills and keep physician appointments by writing them on the calendar.
- Advise patients who are leaving home for the weekend or holidays to refill medicines ahead of time to ensure that they do not run out. The physician can write a prescription for the patient to have for emergency refills.

- Because many of the antihypertensive medicines can cause bradycardia, teach the patient or caregiver to take the patient's pulse and to call the nurse if it is below 60 or the parameters defined by the physician or agency.
- Monitor carefully for symptoms of congestive heart failure when the patient is on beta blockers. This is a side effect that needs to be caught early and reported to the physician.
- Encourage the patient to obtain a home blood pressure monitoring device. Instruct the patient caregiver on proper use and logging the date, time, and reading obtained. The home health nurse should review the log on each visit.
- Patients should be instructed to weigh themselves every morning after voiding, to wear the same amount of clothing each time, and to keep a log for the nurse to review.

REVIEW QUESTIONS

1. Which of the following does the nurse understand as a cause of primary hypertension to plan care for a patient with hypertension?
 - a. It is caused by a tumor of the adrenal gland.
 - b. It is caused by renal artery stenosis.
 - c. It is caused by coarctation of the aorta.
 - d. There is no known cause.
 2. Which of the following is the most important lifestyle modification for the hypertensive patient who is obese?
 - a. Reduce weight.
 - b. Restrict salt intake.
 - c. Increase potassium intake.
 - d. Decrease alcohol intake.
 3. Which of the following does the nurse understand is often the only sign of hypertension?
 - a. Sacral edema
 - b. Elevated blood pressure
 - c. Tachycardia
 - d. Jugular vein distention
- Multiple response item. Select all that apply.
4. Which of the following instructions would be included in dietary education for a patient with high blood pressure?
 - a. Canned fruit and vegetables are best to eat.
 - b. Add salt to food during cooking and just before eating.
 - c. Increase foods high in saturated fat.
 - d. Choose fresh or frozen fruits and vegetables.
 - e. Read food labels.
 - f. Watch for potassium in salt substitutes.
 5. For which of the following blood pressure readings should a 1-year follow-up visit be recommended?
 - a. 108/66
 - b. 116/76
 - c. 138/84
 - d. 142/90
 6. During a health screening a patient's blood pressure is confirmed by two nurses to be 210/120 mmHg. Which of the following interventions should be recommended?
 - a. The patient takes off the rest of the day and rests.
 - b. The patient rest quietly while the nurses calls 911 to request an ambulance.
 - c. The patient should take two doses of blood pressure medication right now.
 - d. The patient may return to work and have blood pressure rechecked in two days.
 7. Which of the following would the nurse expect to find in a patient experiencing the complication of heart failure from hypertension?
 - a. Abnormal hair growth pattern on face.
 - b. Distended jugular veins in semi-Fowler's position.
 - c. Pain in the right hand when writing.
 - d. Depression from taking blood pressure medication.
 8. The nurse should give which of the following instructions to a patient receiving a diuretic?
 - a. Eliminate salt in your diet.
 - b. Change positions slowly.
 - c. Take your medication before bed.
 - d. Empty your bladder after taking the first dose.
 9. At a follow-up visit for a patient with hypertension, which of the following data best indicates that the patient's blood pressure therapy is successful?
 - a. Weight decreased 3 pounds.
 - b. Diary of dietary intake within suggested diet
 - c. BP less than 120/80 mmHg.
 - d. Patient reports walking 30 to 40 minutes daily.

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Miller

1. Risk factors include gender; age; smoking; a diet high in fat, salt, and calories; consumption of two to three alcoholic drinks per evening; and possibly her morning headaches.
2. Morning headaches. Mrs. Miller may be experiencing an episode of hypertensive urgency and should be evaluated immediately by a health-care provider.
3. “Silent killer” refers to the fact that there are often no signs or symptoms associated with hypertension.
4. Lifelong therapy is required because there is no cure for hypertension and complications need to be prevented.

■ Mrs. Bell

1. Nonmodifiable risk factors include age, gender, and history of hypertension. Modifiable risk factors include weight and compliance with antihypertensive therapy.
2. Thiazide diuretics are first-line drugs. Diuretics remove excess salt and water to decrease blood volume and lower blood pressure. Beta blockers stop the beta receptors from receiving the message from the brain for the heart to work harder. Therefore, the heart rate and blood pressure decrease.
3. Assess patient’s reading level and primary language.

Provide patient with written instructions in large letters about medications. Include family members and enlist their support in reinforcing the importance of adhering to the treatment plan.

4. Patient is 80 years old, makes frequent trips to the bathroom related to diuretics, has vision problems, and a side effect of propranolol is weakness and fatigue.
5. Make arrangements for a bedside commode to reduce the distance and urgency to get to the bathroom. Encourage the patient and family to place night-lights in the bedroom, hall, and bathroom. Explain that throw rugs increase the risk of falling and that wood or tile floors can be slippery when wet and hard if a fall occurs. Encourage removal of throw rugs, and suggest carpeting these areas if possible. Suggest the use of safety bars in hall and bathroom for support or other walking aids as needed. If incontinence is a concern, suggest wearing an adult brief to prevent a wet, slippery floor. Suggest discussing with the physician an exercise program to increase strength, such as lifting small, lightweight objects (e.g., soup can), squeezing a rubber ball, or riding an exercise bike if able. These exercises can be done while sitting so they are not a fall-risk activity.
6. Unit Analysis Method:

$$\frac{20 \text{ mg}}{10 \text{ mg}} \left| \frac{1 \text{ tablet}}{10 \text{ mg}} \right. = 2 \text{ tablets}$$

QUESTIONS TO GUIDE YOUR READING

1. What are the pathophysiology, etiology, signs and symptoms, diagnostic tests, therapeutic interventions, and nursing care for rheumatic carditis, infective endocarditis, myocarditis, and pericarditis?
2. What are the pathophysiology, etiology, signs and symptoms, complications, diagnostic tests, therapeutic interventions, and nursing care for dilated, hypertrophic, and restrictive cardiomyopathy?
3. What are the pathophysiology, etiology, signs and symptoms, complications, diagnostic tests, and therapeutic interventions for thrombophlebitis?
4. What are risk factors, prevention measures, and nursing care for thrombophlebitis?

INFLAMMATORY AND INFECTIOUS CARDIAC DISORDERS

The entire heart (**rheumatic carditis**) or layers of the heart (endocarditis, **myocarditis**, and **pericarditis**) can become inflamed or infected (Fig. 22.1).

Rheumatic Carditis

Pathophysiology and Etiology

A serious complication of **rheumatic fever** is rheumatic carditis. The incidence of rheumatic carditis has dropped greatly likely due to antibiotic availability. Rheumatic fever occurs as an autoimmune reaction to an upper respiratory (throat) group A **beta-hemolytic streptococci** infection (Table 22.1). Two to 3 weeks after the streptococcal infection, rheumatic fever occurs. Although rheumatic fever can occur at any age, it typically occurs between ages 5 and 15, and can recur along with rheumatic carditis.

With carditis from rheumatic fever, all layers of the heart become inflamed. Pericardial layers are covered with an exudate and become thickened. As healing takes place, the pericardial sac can be damaged or destroyed by fibrosis. Nodules (Aschoff's bodies) form in myocardial tissue that become scar tissue over time. The endocardium, specifically the mitral valve, is the most seriously affected. Tiny,

myocarditis: myo—muscle kardia—heart + itis—inflammation

pericarditis: peri—around kardia—heart + itis—inflammation

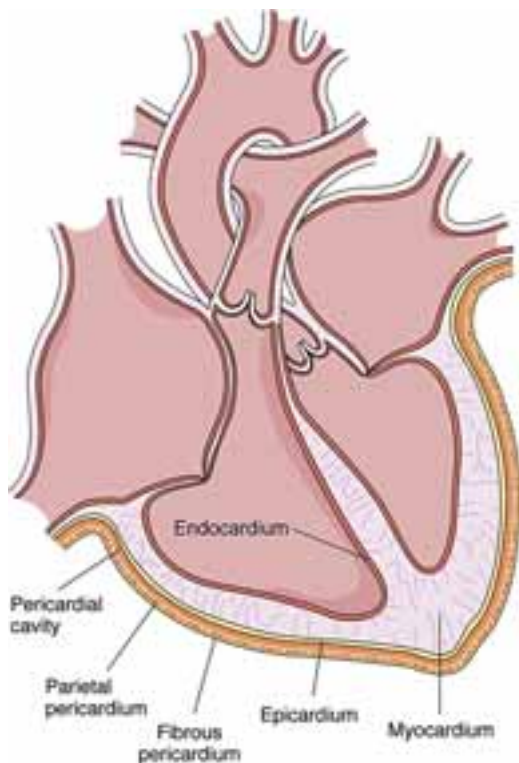

FIGURE 22.1 Layers of the heart.

TABLE 22.1 RHEUMATIC FEVER SUMMARY

Signs and Symptoms	Fever Polyarthritis Subcutaneous nodules Chorea with rapid, uncontrolled movements Rheumatic carditis Arthralgia Pneumonitis
Diagnostic Tests	Throat culture (identifies streptococcal infection) Antistreptolysin O titer level greater than 250 IU/mL. Elevated ESR and WBC
Therapeutic Interventions	Antimicrobial medication Anti-inflammatory medication Control of symptoms Prophylactic antibiotics
Possible Nursing Diagnoses	Acute pain related to joint or cardiac inflammation Anxiety related to disease process Decreased cardiac output related to valvular damage and carditis

ESR = erythrocyte sedimentation rate.

pinhead-size vegetations from blood and fibrin form on the valve leaflets. This can lead to thickening, fibrosis, and calcification of the valve leaflets and support structures. If the valve leaflets do not close completely, regurgitation of blood can occur. If the valve leaflets do not open fully (valvular stenosis), blood movement is impaired and severe heart failure may result.

Signs and Symptoms

Rheumatic carditis signs and symptoms include tachycardia, heart murmur, **pericardial friction rub**, mild to moderate chest pain, heart enlargement, electrocardiographic changes (e.g., PR interval lengthening), and evidence of heart failure.

Prevention

Preventing rheumatic fever by detecting and treating streptococcal infections promptly with penicillin (or erythromycin [Erythromid] for a patient with a penicillin allergy) is important to prevent rheumatic carditis.

Therapeutic Interventions

Activity is limited based on the severity of cardiac involvement. Other treatment for cardiac involvement is based on symptoms.

Nursing Management

A history of recent illnesses (e.g., sore throat, streptococcal infection, or scarlet fever) is obtained from the patient, including past episodes of rheumatic fever, heart disease, joint pain, and current medications. A physical assessment detects murmurs, pericardial friction rub, and heart failure signs (e.g., jugular vein distension, edema, dyspnea, crackles, cough, and fatigue). Vital signs are documented, noting fever and tachycardia.

Nursing care focuses on relieving the patient's pain and anxiety, maintaining normal cardiac function, and educating the patient about the disease. Pain is relieved with analgesics, aspirin, or corticosteroids as ordered. Vital signs are monitored and symptoms of heart failure are reported to the physician. An explanation of the disease and its treatment is provided to promote understanding of acute and lifelong prophylactic treatment. A patient statement of willingness to maintain health supports goal achievement.

Infective Endocarditis

Infective endocarditis (IE) is an infection of the endocardium. Males develop IE more often than females. There is a higher incidence of IE in the older adult. Even with antibiotic treatment, this infection can be fatal related to end-organ failure and other disease processes.

Pathophysiology

Cardiac defects result in turbulent blood flow that erodes the normally infection-resistant endocardium. Infective endocarditis begins when the invading organism (most commonly a bacteria, or maybe fungi) attaches to eroded endocardium where platelets and fibrin deposits have formed a vegetative lesion. Then more platelets and fibrin cover the multiplying organism. This covering protects the microbes, reducing the ability to destroy them. Damage to valve leaflets occurs as the vegetations grow. As blood flows through the heart, these vegetations may break off and become **emboli**.

With bacteremia, bacteria attach mainly to the valves of the heart, although any heart endothelial surface can be infected. Damaged valves from conditions such as mitral valve prolapse with regurgitation, rheumatic heart disease, congenital defects, and valve replacements are especially prone to bacterial invasion. The mitral valve is the valve most commonly infected, with the aortic valve being the second most commonly infected. Heart failure may result from valve damage, especially of the aortic valve.

Etiology

Portals of entry for organisms into the bloodstream result from intravenous (IV) drug use, surgery, dental or invasive procedures, and infections of the skin and gastrointestinal or genitourinary tract. Risk factors include the following:

- IV drug use
- Compromised immune system
- Congenital or valvular heart disease (e.g., mitral valve prolapse with regurgitation, valvular replacement surgery, or rheumatic carditis)
- Gingival gum disease

Prevention

Because dental disease is thought to be a common cause of IE, oral care is an important preventative measure. Additionally, antibiotic therapy before invasive or dental procedures is recommended for high-risk patients with cardiac disease or prior endocarditis.¹ It is important that these patients be taught to inform health-care team members (including their dentists) of their history before a procedure, so that prophylactic therapy can be given if needed.

Signs and Symptoms

Fever (99°F to 103°F [37.2°C to 39.4°C]) is a common sign, although the older adult may be afebrile (Table 22.2). A new murmur is usually heard as valvular damage occurs. Splinter hemorrhages may be seen in the distal nailbed (black or red-brown longitudinal short lines). **Petechiae** (tiny red flat spots) resulting from microembolization of the vegetation may occur on mucous membranes, conjunctivae, or skin (Fig. 22.2). Janeway lesions (small, painless red-blue lesions on palms and soles) are an acute finding. Osler's nodes (small, painful nodes on fingers and toes) from cardiac emboli are a late finding (Fig. 22.3).

Complications

Vegetative emboli can be a major complication of IE. If organ embolization occurs, signs and symptoms that reflect the organ that was affected by the emboli are seen. Brain emboli may produce changes in level of consciousness or

petechiae: petecchia—skin spot

TABLE 22.2 INFECTIVE ENDOCARDITIS SUMMARY

Signs and Symptoms	Fever Murmur Night sweats Fatigue Weight loss Weakness Pain in abdomen, joints, muscles, back Nailbed splinter hemorrhages Petechiae
Diagnostic Tests and Findings	Blood cultures (identify causative organism) Transesophageal echocardiography (identifies vegetations on heart valves) WBC count with differential (identifies elevation)
Therapeutic Interventions	<i>Acute therapy:</i> IV antimicrobial medications such as penicillin, vancomycin, amphotericin B (to cure infection) Antipyretics (to reduce fever) Rest (to decrease cardiac workload) Surgical valve replacement (to restore normal valve function) <i>Prophylactic antibiotic therapy (to prevent infection)</i>
Complications	Emboli Heart failure
Possible Nursing Diagnoses	Acute pain related to fever from cardiac infection Activity intolerance related to reduced oxygen delivery from decreased cardiac output Decreased cardiac output related to impaired valvular function or heart failure Deficient diversional activity related to restricted mobility from prolonged IV therapy Ineffective tissue perfusion related to emboli

FIGURE 22.2 Petechiae. (From Goldsmith, L: *Adult & Pediatric Dermatology*. FA. Davis, Philadelphia, 1997, p 61.)

stroke. Kidney emboli cause pain in the flank area, hematuria, or renal failure. Emboli in the spleen cause abdominal pain. Emboli in the small blood vessels can impair circulation in the extremities. Pulmonary emboli result in sudden dyspnea, cough, and chest pain.

Heart structures can be damaged or destroyed by IE. **Stenosis** (valve narrowing) or regurgitation (valve leakage) of a heart valve may also result. As the infection progresses and causes more damage to heart structures, heart failure may occur. (See Chapter 26.)

Diagnostic Tests

Table 22.2 shows diagnostic tests for IE. Positive blood cultures identify the causative organism of IE, and echocardiography shows cardiac effects.

FIGURE 22.3 Osler's nodes. (From Goldsmith, L: *Adult & Pediatric Dermatology*. Philadelphia, FA. Davis, 1997, p 188.)

Therapeutic Interventions

Initial treatment begins with hospitalization. An antimicrobial drug is selected that will destroy the organism identified by the blood culture. For bacterial infections, penicillin (or vancomycin for those allergic to penicillin) is commonly used. These medications are given intravenously over a period of 4 to 6 weeks, often once a day. A lengthy course of high-dose antibiotics is needed to penetrate the vegetations to reach all the microbes inside to kill them. Rest and supportive symptom care are also used. If afebrile and without complications, the patient is discharged to continue IV antibiotic therapy at home. The patient's response to the drug is monitored via the home care nurse and through laboratory testing. Changes in antibiotics may be made in response to side effects, allergies, organism resistance to the drug, or relapses.

Surgical replacement or repair of valves is usually required for patients with severely damaged heart valves, prosthetic valve infection, recurrent infection, multiple emboli from damaged valves, or heart failure. (See Chapter 24.) Recovery from the disease can be greatly improved with surgery. Antimicrobial therapy continues after surgery.

Nursing Process for the Patient with Infectious Endocarditis

ASSESSMENT/DATA COLLECTION. A patient history is obtained that includes risk factors for IE and recent infections or invasive procedures (Table 22.3). Vital signs are measured and recorded, and heart sounds are auscultated to detect murmurs. Signs of heart failure and emboli are noted. The physician is notified immediately if circulatory impairment, such as cold skin, decreased capillary refill, cyanosis, or absent peripheral pulses in an extremity, or symptoms of organ-related emboli are detected.

NURSING DIAGNOSIS, PLANNING, IMPLEMENTATION, AND EVALUATION.

See Box 22.1 Nursing Care Plan for the Patient with Infective Endocarditis. Teaching about the disease and its treatment provides patients and families with the ability to provide IV antibiotics at home and promotes health maintenance to prevent IE. Good hygiene including dental care is essential. Skin care includes bathing, using proper hand washing technique with soap, avoiding nail biting, not popping pimples or lancing boils, and washing and applying antibiotic ointment to cuts. Brushing with a soft-bristle toothbrush (prevents gum trauma) twice a day reduces plaque formation, which traps bacteria. Twice yearly dental cleaning using prophylactic antibiotics, if indicated, is important. It is essential that patients understand the need to request and take prophylactic antibiotics as needed before invasive procedures. Patients are also taught symptom recognition (e.g., fever, chills, sweats) and seeking of prompt medical care. The patient is educated on the importance of having blood cultures drawn before antibiotics are started. The patient's statement of understanding and a willingness to follow lifestyle changes supports goal achievement.

TABLE 22.3 NURSING ASSESSMENT/ DATA COLLECTION FOR PATIENTS WITH INFECTIVE ENDOCARDITIS

Subjective Data	
Health History	
Infections (rheumatic fever, previous endocarditis, streptococcal or staphylococcal, syphilis)?	
Cardiac disease (valvular surgery, congenital)?	
Childbirth?	
Invasive procedures (surgery, dental, catheterization, IV therapy, cystoscopy, gynecologic)?	
Malaise?	
Anorexia?	
Medications	
Steroids, immunosuppressants, prolonged antibiotic therapy, IV drug use, alcohol abuse?	
Respiratory	
Dyspnea on exertion or when lying (orthopnea)?	
Cough?	
Cardiovascular	
Palpitations, chest pain, fatigue, or activity intolerance?	
Musculoskeletal	
Weakness, arthralgia, myalgia?	
Knowledge of Condition	
Objective Data	
Fever, Diaphoresis	
Respiratory	
Crackles, tachypnea	
Cardiovascular	
Murmurs, tachycardia, dysrhythmias, edema, headache	
Integumentary	
Nailbed splinter hemorrhages, petechiae on lips, mouth, conjunctivae, feet, or antecubital area	
Renal	
Hematuria	
Diagnostic Test Findings	
Anemia, elevated WBC count, elevated ESR, positive blood cultures, ECG showing conduction problems, echocardiogram showing valvular dysfunction and vegetations, chest x-ray exam showing heart enlargement (cardiomegaly) and lung congestion	

ECG = electrocardiogram; ESR = erythrocyte sedimentation rate; WBC = white blood cell.

Pericarditis

Pathophysiology and Etiology

Pericarditis is an acute or chronic inflammation of the pericardium (the sac surrounding the heart). The inflammation creates a problem for the heart as it tries to expand and fill. As a result, ventricular filling is reduced, which then decreases cardiac output and blood pressure. Acute pericarditis can be caused by a variety of factors, including the following:

- Infections: viruses, bacteria, fungi, or Lyme disease
- Drug reactions
- Connective tissue disorders: systemic lupus erythematosus, rheumatic fever, or rheumatoid arthritis
- Neoplastic disease
- Postpericardiotomy (e.g., after cardiac surgery)

CRITICAL THINKING

Mrs. Jones

■ Mrs. Jones, 28 years old, is admitted to the hospital with a fever of 100°F (37°C), chills, fatigue, anorexia, and pain in her joints. A physical assessment reveals splinter hemorrhages in left index finger nailbed and petechiae on her chest. She is diagnosed with a heart murmur and infective endocarditis.

1. Why is a heart murmur heard with endocarditis?
2. What do splinter hemorrhages look like?
3. What do petechiae indicate?
4. How would you document Mrs. Jones's assessment findings?
5. What type of medication would you expect to be ordered to treat the infection?
6. Why does Mrs. Jones have chills if her temperature is elevated?
7. What signs and symptoms might occur if the complications of heart failure develop?
8. Why does Mrs. Jones need to be taught that she needs prophylactic antibiotics before dental or invasive procedures?
9. Tylenol 650 mg q 6 hours for pain is ordered. It comes as 325-mg tablets. How many tablets would be given per dose?

Suggested answers at end of chapter.

- Postmyocardial infarction, 1 to 12 weeks (**Dressler's syndrome**)
- Renal disease or uremia
- Trauma from chest injury or invasive thoracic procedures

Acute pericarditis resolves usually in less than 6 weeks.

Recurrence is possible.

Chronic constrictive pericarditis is the result of fibrous scarring of the pericardium. The heart becomes surrounded by a thickened, stiff sac that limits the stretching ability of the heart's chambers for filling. Heart failure may result. Chronic constrictive pericarditis results from neoplastic disease and metastasis, radiation, or tuberculosis.

Signs and Symptoms

Chest pain is the most common symptom of pericarditis (Table 22.4). The pain is located substernally and over the heart and may radiate to the clavicle, neck, left scapula, or epigastric area. The intense, sharp, creaky, grating pain increases with deep inspiration, coughing, moving the trunk, or lying flat. The pain may be relieved by sitting up and leaning forward. Other symptoms depend on the cause of the pericarditis and may include dyspnea, low-grade fever, and cough. Dyspnea occurs as a result of decreased cardiac output and reduced oxygenation.

The classic sign of pericarditis is a pericardial friction rub, a grating, scratchy, high-pitched sound that is heard

Box 22.1 NURSING CARE PLAN for the Patient with Infective Endocarditis

Nursing Diagnosis: Decreased cardiac output related to impaired valvular function or heart failure

Expected Outcome Has adequate cardiac output as evidenced by vital signs within normal limits, no dyspnea or fatigue.

Evaluation of Outcomes Are patient's vital signs within normal limits with no dyspnea or fatigue?

Interventions

Assess vital signs, murmurs, dyspnea, and fatigue.

Give oxygen as ordered.

Provide rest as ordered.

Elevate head of bed 45 degrees.

Rationale

Vital signs, dyspnea, and fatigue are indicators of cardiac output decline.

Supplemental oxygen provides more oxygen to the heart.

Cardiac workload and oxygen needs are reduced with rest.

Venous return to heart is reduced and chest expansion improved.

Evaluation

Are vital signs within normal limits with no dyspnea or fatigue?

Are breathing pattern and oxygen saturation within normal limits?

Are vital signs within normal limits and no fatigue reported?

Are vital signs within normal limits and respirations easy?

Nursing Diagnosis: Activity intolerance related to reduced oxygen delivery from decreased cardiac output

Expected Outcomes Patient will state less fatigue in response to activity.

Evaluation of Outcomes Does patient report less fatigue? Is patient able to participate in desired activities?

Interventions

Assist with activities of daily living (ADLs) prn.

Provide rest and space activities.

Rationale

Assistance conserves energy.

Cardiac workload and oxygen needs are reduced with rest.

Evaluation

Are ADLs completed?

Does patient report less fatigue?

Nursing Diagnosis: Deficient diversional activity related to restricted mobility from prolonged intravenous therapy

Expected Outcomes States participation in satisfying diversional activities.

Evaluation of Outcomes Does patient participate in diversional activities? Does patient state satisfaction with activities?

Interventions

Assess patient's preferred activities and hobbies.

Plan patient's schedule around relaxing and fun activities.

Use pet therapy.

Provide a mix of physical, mental, and social activities on a rotating schedule.

Rationale

Activity preference should be known to plan satisfactory diversional activities.

Self-esteem is fostered with increased patient control.

Individuals who can interact with pets live longer and healthier.

Rotating stimulating activities and visitors will keep patient interested and avoid fatigue.

Evaluation

Are patient's preferred activities known?

Does patient offer input into scheduled care? Is input followed?

Does patient state enjoyment of pet therapy?

Does patient state satisfaction in activities with no fatigue?

TABLE 22.4 PERICARDITIS SUMMARY

Signs and Symptoms	Chest pain Dyspnea Low-grade fever Cough
Diagnostic Tests	Pericardial friction rub Complete blood cell count Electrocardiogram Echocardiogram MRI CT
Therapeutic Interventions	Anti-inflammatory medication Corticosteroids Pericardiocentesis Pericardial window
Complications	Pericardial effusion Cardiac tamponade
Possible Nursing Diagnoses	Acute pain related to inflammation of pericardium Anxiety related to disease process Decreased cardiac output related to cardiac constriction

when a rub is present. The rub is a result of friction from the inflamed pericardial and epicardial layers rubbing together as the heart fills and contracts. Depending on the severity of the pericarditis, the rub may be faint when auscultated or loud enough to be audible without auscultation. The rub may be heard intermittently or continuously. It is usually heard over the lower left sternal border of the chest during each heartbeat. It is present in approximately 50% of those with pericarditis.

Chronic constrictive pericarditis produces the signs and symptoms of right-sided heart failure. Atrial fibrillation may also be seen in some patients with chronic constrictive pericarditis.

LEARNING TIP

To simulate the sound of a pericardial friction rub, hold the diaphragm of a stethoscope against the palm of one hand; listen through the stethoscope as you rub the index finger of the opposite hand over the knuckles of the hand holding the diaphragm. The sound you hear is similar to that of a pericardial friction rub.

Diagnostic Tests

Table 22.4 lists diagnostic tests for pericarditis. The electrocardiogram reveals ST-T wave elevation in all leads. Echocardiogram results show **pericardial effusions**. Serum laboratory tests focus on causes of the pericarditis, such as an elevated white blood cell (WBC) count, indicating a bacterial or viral infection, or elevated blood urea nitrogen or creatinine levels, indicating uremia. Fluid obtained during

pericardiocentesis is examined to diagnose the cause. In chronic constrictive pericarditis, computed tomography (CT) or magnetic resonance imaging (MRI) may show a thickened pericardium.

Therapeutic Interventions

If the patient is unstable, prompt intervention is required, such as an emergency pericardiocentesis. When the patient's blood pressure and heart rate are stable and adequate, the cause is determined so that appropriate treatment can be administered, such as antibiotics for bacterial infections. Bedrest is used to reduce the heart's workload during acute symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin (Indocin) are given to resolve inflammation and reduce pain. Corticosteroids may be used when NSAIDs are not effective. Hemodialysis is used to treat uremic pericarditis.

Chronic effusive pericarditis can be treated with a pericardial window to allow continuous drainage of pericardial fluid into the pleural space. A pericardial window is created surgically by removing a portion of the outer pericardial layer.

Chronic constrictive pericarditis is treated with **pericardiectomy**, which is the surgical removal of the entire tough, calcified pericardium. Pericardiectomy relieves constriction of the heart and allows normal filling of the ventricles.

Complications

A pericardial effusion (build-up of fluid in pericardial space) is the most common complication of pericarditis. A rapidly developing effusion, such as one occurring from trauma, can produce symptoms at smaller amounts of fluid than slowly developing effusions, such as pericarditis from tuberculosis, with larger amounts of fluid. The increasing fluid presses on nearby tissue. Pressure on lung tissue can produce dyspnea, cough, and tachypnea. The heartbeat sounds distant. The body's compensatory mechanisms attempt to maintain blood pressure.

As the fluid accumulation grows, **cardiac tamponade**, another complication of pericarditis, can occur. Cardiac tamponade is a life-threatening compression of the heart by fluid accumulated in the pericardial sac. Cardiac output drops and to compensate, heart rate increases. Then blood pressure falls as compensatory mechanisms fail. The patient shows symptoms of decreased cardiac output, such as restlessness, confusion, tachycardia, and tachypnea. Jugular vein distention is present from increased venous pressure, and heart sounds are distant. Cardiac tamponade requires immediate treatment with pericardiocentesis to puncture the pericardium with a 16-gauge needle and remove the excess fluid in the pericardial sac (Fig. 22.4). After the procedure, the patient is monitored for complications, such as dys-

pericardiocentesis: peri—around + kardia—heart + centesis—puncture

cardiac tamponade: kardia—heart + tamponade—plug

FIGURE 22.4 Pericardiocentesis.

rhythmias, laceration of a coronary artery, or laceration of the myocardium or pneumothorax.

Nursing Management

A patient history is obtained that includes any cardiac disease, recent infections, and current medications. Chest pain, pericardial friction rub, heart sounds, and signs of heart failure are noted. Vital signs are documented, noting fever and tachycardia.

Nursing care focuses on relieving the patient's pain and anxiety and maintaining normal cardiac function. Symptoms are monitored to detect complications. Pain, which may be severe, is relieved by giving NSAIDs or corticosteroids as ordered. Allowing the patient to assume a position of comfort by sitting up and leaning forward also relieves pain. Maintenance of normal cardiac function includes monitoring vital signs and observing for the presence of symptoms of cardiac tamponade or heart failure. The detection of these symptoms is immediately reported to the physician. Teaching the patient about pericarditis and its treatment relieves anxiety and allows a feeling of control by allowing the patient to make knowledgeable health-care decisions.

Myocarditis

Pathophysiology and Etiology

In myocarditis, inflammation of the myocardium occurs. The amount of muscle destruction and necrosis that occurs

as a result of myocarditis determines the extent of damage to the heart. The heart may enlarge in response to the damaged muscle fibers, although most cases of myocarditis are benign, with few signs or symptoms.

Myocarditis is a rare condition that most commonly develops following a viral infection. Other causes are bacteria, parasites, fungi, rickettsiae, spirochetes, medications, lead toxicity, autoimmune factors, human immunodeficiency virus (HIV), rheumatic fever, systemic lupus erythematosus, pericarditis or infective endocarditis, or cardiac transplant rejection.

Signs and Symptoms

Signs and symptoms of myocarditis vary from none to severe cardiac manifestations. Fatigue, fever, pharyngitis, malaise, dyspnea, palpitations, muscle aches, gastrointestinal (GI) discomfort, and enlarged lymph nodes may occur early from a viral infection. Cardiac manifestations such as chest discomfort, pain, or tachycardia may occur about 2 weeks after a viral infection. Occasionally, sudden death may occur.

Diagnostic Tests

A percutaneous endomyocardial biopsy during the first 6 weeks of inflammation is the preferred diagnostic test for myocarditis, although it is positive only about 30% of the time. MRI and gallium-67 scanning are helpful. An electrocardiogram (ECG) shows dysrhythmias, commonly sinus tachycardia.

Therapeutic Interventions

Interventions to reduce the heart's workload are essential and include bedrest and limited activity. Administration of oxygen treats hypoxia. Exercise increases myocardial inflammation and mortality and should be avoided until symptoms improve and inflammation is gone. Treatment is aimed at the cause, if known, such as antibiotics for bacterial infections. The use of alcohol and tobacco should be avoided. Heart failure is treated with medication to strengthen the heart's contractility and slow the heart's rate, which reduces the heart's workload and oxygen needs. With myocarditis, the heart is sensitive to digoxin, which may be used to treat heart failure, and toxicity may occur even with small doses. The patient should be monitored closely for signs of digoxin toxicity, which may include anorexia, nausea, vomiting, bradycardia, dysrhythmias, or malaise. The use of immunosuppressive therapy is being investigated and may result in new treatment options in the future.

Nursing Management

Recent illnesses, toxin exposure, cardiac diseases, activity tolerance, and current medications are documented. Vital signs and signs of heart failure, such as jugular vein distention, peripheral edema, crackles, and dyspnea are noted.

Nursing care is aimed at the patient's maintenance of normal cardiac function by monitoring vital signs and symptoms and administering medications as ordered. Interventions to reduce fatigue include providing assistance as

needed, having frequent rest periods, and teaching energy conservation methods. Reducing the patient’s anxiety and increasing the patient’s knowledge can be achieved through teaching about the disease. Determining diversional activities with the patient for times when activity is restricted further reduces anxiety.

Cardiac Trauma

Two types of cardiac trauma can occur: nonpenetrating and penetrating. Nonpenetrating injuries, or contusions, occur from blunt trauma such as motor vehicle accidents or contact sports in which direct compression or force is applied to the upper torso. Contusions may vary from small bruises to hemorrhage.

There may be few or no external injuries indicating traumatic cardiac injury. The patient may be asymptomatic or exhibit signs and symptoms identical to a myocardial infarction. In severe contusions, laboratory results may show elevated creatine kinase MB (CK-MB) or troponin-I levels.

If bleeding occurs into the pericardial sac, cardiac tamponade (compression of the heart from the blood collecting in the sac) may occur (discussed above). If signs of shock occur, a pericardiocentesis must be performed. With its own pressure, the tamponade may seal the area of bleeding, so no cardiac decompensation occurs. In this case, only bedrest and observation are required. There are no long-term effects with most contusions. With severe contusions, however, scarring and necrosis of the myocardium may decrease cardiac output and increase the risk for cardiac rupture.

Penetrating traumas may be an external injury to the chest, such as a stab or gunshot wound, or an internal injury, such as invasive lines that penetrate the cardiac muscle. Complications vary depending on the size, location, and cause of injury. Tamponade occurs from bleeding into the pericardial sac if the pericardium is sealed off by clot formation. A hemothorax develops if blood drains into the pleural space in the chest. A pneumothorax occurs if air collects in the pleural space. Signs and symptoms of hemorrhage and myocardial ischemia may be noted. Cardiac trauma treatment usually requires surgery to repair the damage so that hemostasis can be regained.

Cardiomyopathy

Cardiomyopathy is an enlargement of the heart muscle. There are three types of cardiac structure and function abnormalities in cardiomyopathy: (1) dilated, (2) hypertrophic, and (3) restrictive (Fig. 22.5). A consequence of all types of cardiomyopathy can be heart failure (Fig. 22.6), myocardial ischemia, and myocardial infarction due to reduced cardiac output. There is currently no cure for cardiomyopathy. The greatest advancement for the cardiomyopathies has been in genetic research that has identified potential causes of these diseases. This research will help lead to better diagnosis and treatment in the future.

cardiomyopathy: kardia—heart + myo—muscle + pathy—disease

FIGURE 22.5 Comparison of the normal heart structure with each type of the cardiomyopic heart structure.

Dilated Cardiomyopathy

In dilated cardiomyopathy, the size of the ventricular cavity enlarges with reduced cardiac output. Contractile function decreases as the myocardial tissue is destroyed. Blood

FIGURE 22.6 All types of cardiomyopathies can lead to heart failure.

moves more slowly through the left ventricle, which often results in blood clot formation. Dilated cardiomyopathy is the most frequent type of cardiomyopathy and one of the most frequent causes of heart failure. Dilated cardiomyopathy may be hereditary, follow infectious myocarditis, or be caused by chronic alcohol or cocaine use, HIV, thiamine or zinc deficiencies, infections, or other causes.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is enlargement of the cardiac muscle wall, often of the septum and left ventricle. The hypertrophy may occur asymmetrically. It can be a hereditary disorder that is transmitted as a dominant trait. Hypertrophic cardiomyopathy causes the ventricular wall to be rigid, which decreases ventricular filling. If an enlarged septum obstructs the outflow of blood through the aortic valve, it is known as obstructive hypertrophic cardiomyopathy. Death occurs suddenly and is likely due to an abnormal heart rhythm. Genetic research is focusing on the mutant genes associated with the disease, which will guide future diagnosis and therapy.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy impairs ventricular stretch and limits ventricular filling. Cardiac muscle stiffness is present with no ventricular dilation, although systolic emptying of the ventricle remains normal. Restrictive cardiomyopathy is the rarest form of cardiomyopathy. It may be caused by infiltrative diseases such as amyloidosis that deposit the protein amyloid within the myocardial cells, making the muscle stiff and resistant to stretching for easy ventricular filling. Treating the underlying cause may help reduce heart damage. Visit the American Heart Association at www.americanheart.org for more cardiac information.

Signs and Symptoms

Manifestation of cardiomyopathy depends on the type of abnormality. Most patients show varying degrees of signs and symptoms of heart failure (Table 22.5). With dilated cardiomyopathy, left ventricular and then right-sided heart failure with a poor prognosis are seen. Dyspnea on exertion, orthopnea, fatigue, and sometimes atrial fibrillation occur. In hypertrophic cardiomyopathy, exertional dyspnea related to the obstruction of cardiac output is the most common symptom. Angina is not common, but atypical chest pain that occurs at rest and is not relieved with nitrates may occur. With restrictive cardiomyopathy, heart failure symptoms (Chapter 26) result from the ventricles' inability to fill during diastole. Syncope, arrhythmias, and thrombi may occur.

Diagnostic Tests

Cardiomegaly is seen on a chest x-ray examination. Echocardiography shows muscle thickness and chamber size to differentiate between the types of cardiomyopathy. Changes related to enlarged chamber size, tachycardia, and dysrhythmias can be seen on the ECG. Cardiac catheteriza-

TABLE 22.5 CARDIOMYOPATHY SUMMARY

Signs and Symptoms	Angina Arrhythmias Dyspnea Fatigue Syncope

Possible Nursing Diagnoses	Decreased cardiac output related to impaired myocardial function Activity intolerance related to cardiac insufficiency Anxiety related to disease process

tion with angiocardiology may also be useful. Cardiovascular magnetic resonance is a newer tool that is being used that has greater accuracy in diagnosing cardiomyopathy.

Therapeutic Interventions

Treatment is palliative and aimed at managing heart failure and the underlying cause if known for both dilated and restrictive cardiomyopathies (see Chapter 26). In dilated cardiomyopathy, treatment focuses on the symptoms of heart failure seen. Angiotensin-converting enzyme (ACE) inhibitors, beta blockers, diuretics, and digoxin may be given to increase cardiac output. Biventricular pacing and implantable defibrillators may be used. Therapy is not very useful for restrictive cardiomyopathy. Diuretics or nitrates may be used to relieve venous congestion that occurs due to heart failure. However, a fine balance is needed when using these drugs so that preload is not reduced too greatly, which would worsen symptoms. Anticoagulants are given to prevent emboli formation in patients with atrial fibrillation. Antidysrhythmics or cardioversion are used for dysrhythmias.

For obstructive hypertrophic cardiomyopathy, beta blockers (propranolol) and calcium channel blockers (Calan) are given to slow the heart rate to allow more filling time and lessen the strength of the heart's contraction. An antiarrhythmic agent such as disopyramide (Norpace) may be used. Patients must remain hydrated at all times to maintain cardiac output.

In obstructive hypertrophic cardiomyopathy, digoxin and vasodilators are avoided because they can increase the

cardiomegaly: kardia—heart + mega—large

obstruction. Strenuous exercise and athletic sports are restricted to prevent sudden death. Lower levels of exercise may be allowed. For patients in whom medical therapy is not effective, atrioventricular (AV) sequential pacemakers, implantable automatic defibrillators, or invasive procedures are considered. For those without obstruction, fewer treatment options exist. Diuretics are used to reduce elevated pressures along with beta blockers and calcium channel blockers.

If medical therapy is not successful, surgery is considered. For hypertrophied muscle, surgery to remove part of the ventricular septum (**myectomy**) is done to allow greater outflow of blood. Another option especially for those who are not candidates for surgery is septal ablation. In septal ablation, alcohol is delivered via a catheter to necrose and reduce septal heart wall thickness. The CorCap™ Cardiac Support Device, an investigational device, is a polyester mesh stocking that is pulled over the bottom portion of the heart through a surgical chest incision (Acorn Cardiovascular, St. Paul, Minn.). It becomes part of the heart as tissue grows around it. The stocking provides support for the heart and also reshapes the heart to its more normal shape and size, which reduces heart failure symptoms. Cardiomyoplasty is an experimental surgical approach for dilated cardiomyopathy when heart transplant is not an option (see Fig. 26.6). The heart's contraction strength is aided by the patient's latissimus dorsi muscle, which has been wrapped around the heart. For severe heart failure, primarily in those with dilated cardiomyopathy, a heart transplant may be the only hope for survival. A ventricular assist device may be used until a donor is found. Many patients die while waiting for a donated heart because donated organs are limited.

Nursing Management

A patient history is obtained that includes signs and symptoms and assessment of family support systems because of the chronic nature of the disease. A physical assessment is done, noting vital signs and any signs or symptoms of heart failure.

Nursing care focuses on maintaining normal cardiac function, increasing activity tolerance, relieving anxiety, and educating the patient about the disease and its treatment. Patients with cardiomyopathy can be very ill. Careful monitoring is done to detect complications, such as heart failure, emboli, or dysrhythmias. The physician is immediately notified of problems. Home health care is often used for these patients to maintain their functional ability and reduce hospitalizations.

Maintenance of normal cardiac function includes monitoring vital signs and symptoms of heart failure. Increasing activity tolerance includes planning rest periods, scheduling activities in small amounts, avoiding tiring activities, and providing small meals that require less energy to digest than large meals. Patients are taught to avoid alcohol because it decreases cardiac function.

Reducing anxiety is important and can be accomplished by providing explanations for procedures, as well as educating the patient about the disease and its treatment. This may allow patients to feel in control of their lives by being able to make knowledgeable decisions about their health care. Methods to incorporate necessary lifestyle changes such as avoiding fatigue and scheduling rest periods can be helpful. Emotional support is greatly needed by these patients and their families because of the chronic nature of this disease.

Patient and Significant Other Education

Patients need to be taught the importance of medication compliance to prevent heart failure. The patient and family should have emergency telephone numbers readily available. Families should learn cardiopulmonary resuscitation (CPR). In terminal stages of the disease, the patient and family should be informed about the availability of hospice care and be emotionally supported during the grieving process.

VENOUS DISORDERS

Thrombophlebitis

Thrombophlebitis is the formation of a clot and inflammation within a vein. The clot usually forms first and then inflammation occurs. Thrombophlebitis is the most common disorder of veins, with the legs being most often affected. Any superficial or deep vein in the body can be involved. Deep vein thrombosis (DVT) is the most serious form of thrombophlebitis because pulmonary emboli can result if the thrombus detaches. (See Chapter 28.)

Pathophysiology

A venous thrombus is made up of platelets, red blood cells, white blood cells, and fibrin. Platelets attach to a vein wall and then a tail forms as more blood cells and fibrin collect. As the tail grows, it drifts in the blood flowing past it. The turbulence of the blood flow can cause parts of the drifting thrombus to break off and become emboli that travel to the lungs.

Etiology

Three factors, Virchow's triangle, are involved in the formation of a thrombus: stasis of blood flow, damage to the lining of the vein wall, and increased blood coagulation (Table 22.6). Venous stasis occurs when blood flow is reduced, veins are dilated, muscle contractions are decreased, or vein valves are faulty. When the wall of a vein is damaged, it provides a site for a thrombus to form. Intravenous therapy and venipuncture cause trauma to the vein, and IV catheters in place longer than 48 to 72 hours increase the risk of inflammation and thrombus. Increased coagulation of the blood promotes thrombus formation. Patients on oral anticoagu-

myectomy: myo—muscle + ectomy—cutting out

thrombophlebitis: thromb—lump (clot) + phleb—vein + itis—inflammation

TABLE 22.6 PREDISPOSING CONDITIONS FOR THROMBOPHLEBITIS (VIRCHOW'S TRIANGLE)

Condition	Type	Example
<i>Venous Stasis</i>	Reduction of blood flow Dilated veins Decreased muscle contractions	Shock, heart failure, myocardial infarction, atrial fibrillation Vasodilators Immobility, sitting for long periods as in traveling, fractured hip, paralysis, anesthesia, surgery, obesity, advanced age
<i>Venous Wall Injury</i>	Faulty valves	Varicose veins, venous insufficiency Venipuncture, venous cannulation at same site for >48 hours, venous catheterization, surgery, trauma, burns, fractures, dislocation, IV medications (potassium, chemotherapy drugs, antibiotics, IV hypertonic solutions), contrast agents, diabetes, cerebrovascular disease
<i>Increased Coagulation of Blood</i>		Anemia, malignancy, antithrombin III deficiency, oral contraceptives, estrogen therapy, smoking, discontinuance of anti-coagulant therapy, dehydration, malnutrition, polycythemia, leukocytosis, thrombocytosis, sepsis, pregnancy

lants that are abruptly stopped experience increased clotting of the blood. Smoking, oral contraceptive use, and estrogen therapy also increase blood coagulation. Hematological disorders can also lead to altered blood coagulation and increased risk of thrombus formation.

Prevention

Identification of risk factors for thrombosis (Table 22.6) and patient education promote the use of interventions (discussed below) to prevent thrombosis. Because the elderly are at increased risk for thrombus formation, a family member should be instructed along with the elderly person in techniques that may be difficult for the elderly person to perform. Dehydration, which is common in the elderly population, should be avoided to reduce thrombus risk.

IMMOBILITY. People with sedentary jobs that require long periods of sitting, standing, or traveling long distances should change positions, perform knee and ankle flexion exercises, or walk at regular intervals to prevent stasis of blood. Patients on bedrest should have legs elevated above the level of the heart if possible and turn every 2 hours to prevent pooling of blood. Postoperatively or in times of bedrest, active or passive range-of-motion exercises should be done to increase blood flow. Postoperatively, early ambulation is a major preventive technique for thrombosis. Patients' pain should be controlled to facilitate their ability to participate in early ambulation. Deep breathing aids in improving blood flow in the large thoracic veins. Smoking should be avoided because nicotine causes vasoconstriction.

PROPHYLACTIC ANTIEMBOLESM DEVICES. Patients with peripheral vascular disease, those on bedrest, and those who have had surgery or trauma may use antiembolism devices to improve blood flow. Knee- or thigh-length elastic stockings apply pressure to the leg. They must be applied correctly to avoid a tourniquet effect. Older patients with decreased manual dexterity may need assistance. The skin should be inspected daily for irritation under the stockings as ordered. Sequential compression devices (SCD) fill

intermittently with air to move venous blood in the legs by simulating contraction of the leg muscles. They may be used in combination with elastic stockings. Research that compares the various preventive measures for DVT and rates of DVT in surgical patients has shown that the lowest incidence of DVT occurs with elastic stockings and SCDs used together.

PROPHYLACTIC MEDICATION. Low molecular weight heparin (LMWH) is given postoperatively to prevent thrombosis (e.g., enoxaparin [Lovenox] subcutaneously [Table 22.7]). LMWH is more effective for orthopedic patients. Anticoagulation tests are not monitored with LMWH due to the predictability of its dose related response. Subcutaneous heparin may also be used postoperatively to prevent thrombosis. Platelet counts must be monitored with either LMWH or heparin to detect heparin induced thrombocytopenia.

Oral anticoagulants such as warfarin (Coumadin) can be used in the high-risk patient to decrease thrombosis. The **international normalized ratio (INR)** measures the effectiveness of warfarin therapy. The INR uses a standardized testing reagent. This means that it can be used around the world with no variation in results as occurs with prothrombin time (PT). Prothrombin time was previously the most commonly used test; however, PT control values can vary from laboratory to laboratory. INR is reported along with the prothrombin time. These values should correspond in meaning (i.e., normal, subtherapeutic, therapeutic, toxic). INR should be used; however, some practitioners still order PT, so a discussion of how to interpret the PT is presented for your understanding. For more information on these medications, visit www.fda.gov/cder/drug/default.htm.

INTRAVENOUS THERAPY. Monitoring of venous IV sites should be performed according to institutional policy time frames to detect signs of thrombophlebitis. Venous cannula sites should be changed regularly according to institutional guidelines (e.g., every 48 to 72 hours) to prevent thrombus formation.

TABLE 22.7 ANTICOAGULANT MEDICATIONS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Anticoagulants Inhibit clot formation to prevent new clot formation.				
Coumarins Inhibit liver synthesis of vitamin K dependent clotting factors: II, XII, IX, X.				
	dicumarol (Bishydroxycoumarin) warfarin (Coumadin)	PO	Hemorrhage or bleeding. Risk increased with NSAIDs.	Monitor PT/INR regularly. Acetaminophen (Tylenol) used instead of aspirin during therapy. Antidote: Oral or parental vitamin K.
Heparins Bind to antithrombin III, which then inhibits fibrin formation.				
	heparin sodium (Lipo-Hepin)	IV SubQ	Itching, burning, bleeding, hemorrhage, ecchymosis, severe hypotension.	Antidote: Protamine sulfate. Do not give IM due to pain and hematoma. Monitor PTT: 1.5–2 times control. Monitor platelet count as may decrease. Monitor for bleeding. Teach patient to report bleeding.
Low Molecular weight heparins (LMWH) Bind with antithrombin III inhibiting making of factor Xa and the formation of thrombin.				
	ardeparin (Normiflo) dalteparin sodium (Fragmin) enoxaparin (Lovenox) www.lovenox.com	SubQ	Bleeding rare.	Monitoring of aPTT not needed. Teach patient to give injection (pre-filled syringes available) typically in abdomen. Treatment is usually 7–14 days.
Thrombolytics Promote fibrinolysis to break down fibrin in blood clot.				
	tissue plasminogen activator (t-PA, alteplase) streptokinase (Streptase, Kabikinase) urokinase (Abbokinase)	IV	Allergic reaction (especially streptokinase), hemorrhage, hypotension (streptokinase)	Monitor for bleeding, vital signs, signs of allergic reaction. Use bleeding precautions (avoid needle sticks). Teach patient to report side effects. Avoid use of ASA, NSAIDs. Aminocaproic acid (Amicar) is antidote.

LEARNING TIP

Before administering anticoagulants, laboratory values must be assessed to ensure patient safety. INR normal and desired therapeutic values for the patient's disorder are provided on the laboratory report. These INR values do not require calculation of a therapeutic range because the values are given on the report. Compare the patient's INR value with the desired INR value to determine if it is safe to give the warfarin.

Understanding that INR is the preferred test for warfarin effectiveness, you may still want to know how to calculate a therapeutic range for prothrombin time. Prothrombin times are measured in seconds. The normal value range gives the seconds required for a fibrin clot to form during the test. If a patient is on warfarin, the purpose is to increase the time (seconds) it takes the blood to clot. It is therefore expected that the prothrombin time will be elevated by warfarin therapy.

Because a therapy, warfarin, is being given, a prothrombin time range that safely considers the expected effects of the warfarin is needed. This is called the therapeutic range (i.e., a low and a high value). Warfarin's therapeutic range is 1.5 to 2 times the normal prothrombin time range. To monitor the patient's therapeutic prothrombin time, compare the patient's result with the therapeutic range that you calculate. For example:

Patient's value on warfarin: 16 seconds (sec.)

Normal prothrombin time range: 9 to 12 seconds

To calculate therapeutic range,

multiply

$$\begin{array}{r} 1.5 \\ \times 9 \text{ sec.} \\ \hline \end{array} \qquad \begin{array}{r} 2 \\ \times 12 \text{ sec.} \\ \hline \end{array}$$

The therapeutic range is: 13.5 sec. to 24 sec.

Compare the patient's value of 16 seconds with the therapeutic range of 13.5 to 24 seconds to determine that the patient is safely within the therapeutic range.

TABLE 22.8 THROMBOPHLEBITIS SUMMARY

Signs and Symptoms	Superficial veins: redness, warmth, swelling, and tenderness Deep veins: swelling, edema, pain, warmth, venous distention, and tenderness
Diagnostic Tests	Venous duplex ultrasound Magnetic resonance venography
Therapeutic Interventions	Superficial veins: warm, moist heat; analgesics; NSAIDs; compression stockings Deep veins: LMWH; heparin; warfarin; bedrest with extremity elevation above the level of the heart for 5–7 days; warm, moist heat; compression stocking therapy; thrombolytic therapy; thrombectomy; vena cava filter
Complications	Pulmonary embolism Chronic venous insufficiency Varicose veins Recurrent deep vein thrombosis
Possible Nursing Diagnoses	Acute pain related to inflammation of vein Impaired skin integrity related to venous stasis Anxiety related to uncertain prognosis of disease

Signs and Symptoms

Up to 50% of patients have no symptoms with thrombophlebitis in the legs. For others, the symptoms vary according to the size and location of the thrombus (Table 22.8). If adequate collateral circulation is present near the involved area, symptoms may be reduced. For some patients a pulmonary embolus is the only evidence of a DVT.

SUPERFICIAL VEINS. Thrombophlebitis in a superficial vein may produce redness, warmth, swelling, and tenderness in the area around the site of the thrombus. The vein feels like a firm cord, which is referred to as induration. The saphenous vein is the most commonly affected vein in the leg. Varicosity of the vein is usually the cause. In the arm, IV therapy is the most common cause.

DEEP VEINS. In a deep vein thrombus of the leg (femoral vein), swelling, edema, pain, warmth, venous distention, and tenderness with palpation of the calf may be present in the affected leg. Obstruction of blood flow from the leg causes edema and varies with the location of the thrombus. An elevated temperature may also be present. Pain in the calf with sharp dorsiflexion of the foot, a classic indication known as a positive Homans' sign, is present in less than 50% of those with thrombophlebitis and is not specific to DVT. Once a DVT is positively diagnosed, it is important to avoid performing Homans' sign because it may cause the clot to become dislodged. Cyanosis and edema may occur if the large veins such as the vena cava are involved.

Complications

The most serious complication of deep vein thrombophlebitis is pulmonary embolism, which is a life-threatening emergency (see Chapter 28). Another complication,

chronic venous insufficiency, results from damage to the valves in the vein and causes venous stasis. Signs and symptoms from venous insufficiency that may appear years after a thrombus include edema, pain, brownish discoloration and ulceration of the medial ankle, venous distention, and dependent cyanosis of the leg. This condition can be difficult to treat.

Therapeutic Interventions

Diagnostic tests are done to guide treatment, with venous duplex ultrasound being the primary test used (see Table 22.8). The goals of treatment are to relieve pain and prevent pulmonary emboli, thrombus enlargement, and further thrombus development. Superficial thrombophlebitis is treated with warm, moist heat, analgesics, NSAIDs, and compression stockings.

Patients with a proximal DVT may be treated at home if they do not have pulmonary embolism, cardiovascular or pulmonary disease, obesity, or renal failure and are able to comply with follow-up care. A LMWH (e.g., enoxaparin, dalteparin, or ardeparin) is given subcutaneously daily or twice a day while oral warfarin is started (see Table 22.7). Both are taken until the INR is within therapeutic range (about 5 days); the LMWH is then stopped.

For some DVTs, a hospital stay may be required. Treatment includes bedrest with leg elevation above heart level for 5 to 7 days, warm, moist heat, elastic stocking (initially on unaffected leg only until acute symptoms are gone on affected leg), and anticoagulants. A continuous heparin IV infusion is usually started for up to 10 days to prevent further enlargement of the thrombus and development of new thrombi; it has little effect on the existing clot, which the body dissolves over time. An oral anticoagulant, warfarin, is begun 4 to 5 days before the heparin is stopped. When the therapeutic INR goal is reached, the heparin is stopped. Warfarin is continued for several months. For second DVT episodes, lifelong warfarin therapy is used. In some cases of massive DVT, thrombolytic therapy (tissue plasminogen activator, streptokinase) may be used to dissolve the clot, but there is a high risk of bleeding with these drugs. New research is looking at an oral thrombin inhibitor which will have fewer side effects than warfarin.

Surgical treatment is used to prevent pulmonary emboli or chronic venous insufficiency when anticoagulant therapy cannot be used or the risk of pulmonary emboli is great. Venous thrombectomy removes the clot through a venous incision. In some cases, a vena cava filter is placed into the inferior vena cava through the femoral or right internal jugular vein (Fig. 22.7). Once in place, it is opened and attaches to the vein wall. The filter traps clots traveling toward the lungs without hindering blood flow.

Nursing Process for the Patient with Thrombophlebitis

ASSESSMENT/DATA COLLECTION. A patient history is obtained that includes recent IV therapy or use of contrast dyes, surgery, extremity trauma, childbirth, bedrest, recent long trip, cardiac disease, recent infections, and current

FIGURE 22.7 Vena cava filter placed in the inferior vena cava to prevent emboli from reaching the lungs.

medications. A physical assessment is done noting pain, fever, tenderness, positive Homans’ sign, redness, warmth, swelling, edema, and a firm, cordlike vein in the affected extremity. Daily measurements are taken of bilateral thighs and calves and recorded to monitor swelling. Coagulation tests are monitored. Signs of a pulmonary embolism, such as dyspnea, tachycardia, tachypnea, blood-tinged sputum, chest pain, or changes in level of consciousness are immediately reported to the physician.

NURSING DIAGNOSIS, PLANNING, INTERVENTIONS, AND EVALUATION. See Box 22.2 Nursing Care Plan for the Patient with Thrombophlebitis for specific nursing interventions. Teaching the patient about the disease and treatment is important to reduce anxiety about complications and to enhance compliance with treatment to prevent complications (Box 22.3 Education for Patients Receiving Anticoagulant Therapy).

Box 22.2 NURSING CARE PLAN for the Patient with Thrombophlebitis

Nursing Diagnosis: Acute pain related to inflammation of vein

Expected Outcome Reports satisfactory pain relief.

Evaluation of Outcome Does patient report satisfactory pain relief?

Interventions

- Assess pain using rating scale such as 0–10.
- Provide analgesics and NSAIDS as ordered.
- Apply warm, moist soaks.
- Maintain bedrest with leg elevation above heart level.

Rationale

- Self-report is the most reliable indicator of pain.
- Pain is reduced when inflammation is decreased.
- Heat relieves pain and vasodilates, which increases circulation to reduce swelling. Moist heat penetrates more deeply.
- Elevation decrease swelling, which reduces pain.

Evaluation

- Does patient report pain using scale?
- Is patient’s rating of pain lower after medication?
- Does patient report increased comfort with warm, moist soaks? Is swelling reduced?
- Is swelling reduced?

Nursing Diagnosis: Impaired skin integrity related to venous stasis

Expected Outcome Skin remains intact without edema.

Evaluation of Outcome Does patient’s skin remain intact? Is edema present?

Interventions

- Assess skin for edema, skin color changes, and ulcers. Measure extremities.
- Elevate legs.
- Fit and apply elastic stockings after edema reduced as ordered.
- Teach patient to avoid crossing legs or wearing constricting clothes.

Rationale

- Assessment will detect signs of skin integrity impairment and extremity swelling.
- Elevation decreases swelling.
- Elastic stockings are fitted after edema is reduced to avoid constriction. They increase venous blood flow to reduce swelling.
- Crossing legs and constrictive clothes impair venous return.

Evaluation

- Are skin changes seen? Do daily measurements show a change in swelling?
- Is swelling reduced?
- Is swelling reduced?
- Does patient state understanding of teaching?

Box 22.3**Education for Patients Receiving Anticoagulant Therapy**

Anticoagulants prolong the time it takes blood to clot, so it is important to prevent injury and to recognize and report signs of bleeding to the physician.

To Prevent Injury

- Wear shoes or slippers; avoid going barefoot.
- Use an electric razor to shave.
- Use a soft toothbrush.

Signs of Bleeding to Report to Physician

- Easy bruising
- Nosebleeds
- Bleeding that does not stop
- Blood in urine
- Blood in sputum
- Blood in stools or black stools

Additional Instructions

- Avoid use of aspirin/NSAIDs because they further prolong clotting time.
- Have your lab work done as prescribed by your physician to monitor your clotting time and medication dosage.

**Home Health Hints**

- Encourage the patient to move frequently since immobility can contribute to thrombophlebitis.
- If the patient is bed bound, instruct both the patient and caregiver on simple active and passive ROM. If

necessary, consider involving occupational and physical therapy. Working collaboratively with therapy, an appropriate activity program can be planned.

- On admission, measure the patients mid calves so you have a baseline size. Reassess measurements during each visit. Subtle changes in measurement can indicate a potential problem.
- Following cardiovascular surgeries, patients are at a high risk for the development of thrombophlebitis. They are also at risk for developing an incisional infection, pneumonia, or pulmonary emboli. Report any abnormal findings.
- Home health nurses can assist patients to develop energy-conserving techniques by being observant of their lifestyles. For instance, notice the room and chair that they spend most of the day in. Television trays and baskets can be used to hold items they may need or want, such as water pitcher and glass, TV remote, reading material, paper and pen, mail, medicines, telephone and phone book, snacks, washcloth, or tissues. Answering the door should be done by the caregiver. When the patient is alone, a note can be placed on the door with instructions; however, the instructions should not convey that the patient is alone.
- Other techniques to conserve energy are putting a carrying pouch on the front bar of a walker to carry items such as a portable phone or tissues and, if the house has stairs, putting a chair at the top and bottom of the stairs so the patient can rest.
- When a patient with venous circulation problems is sitting in a recliner with the leg rest up, the nurse should note whether pressure is being applied on the popliteal area or calf muscle. The angle of the recliner and the patient's height affect the position of the pressure. A small, flat pillow is placed underneath the knees and lower legs to open the angle and relieve the pressure.

REVIEW QUESTIONS

1. The nurse evaluates the patient as understanding how to prevent rheumatic fever if the patient states that rheumatic fever can be prevented by treating streptococcal infections with which of the following?
 - a. Penicillin
 - b. Prednisone
 - c. Cortisone
 - d. Cyclosporine
2. For patients recovering from infective endocarditis, discharge teaching to prevent recurrence should include which of the following?
 - a. Proper use of isolation techniques
 - b. Keeping vaccinations up to date
 - c. Need to obtain annual flu injection
 - d. Need for antibiotics before invasive procedures
3. The nurse is planning care for a patient with cardiomyopathy. For which of the following complications of cardiomyopathy should the nurse collect data?
 - a. Thrombophlebitis
 - b. Heart failure
 - c. Rheumatic fever
 - d. Pulmonary embolism

Multiple response item. Select all that apply.

4. Which of the following signs and symptoms indicates to the nurse the presence of a deep vein thrombus in the patient's leg?
 - a. Calf swelling
 - b. Crackles
 - c. Jugular vein distention
 - d. Positive Homans' sign
 - e. Warmth
5. The nurse is to give warfarin (Coumadin). Which of the following laboratory tests should the nurse review before giving the medication?
 - a. International normalized ratio
 - b. Partial thromboplastin time
 - c. Plasma fibrinogen level
 - d. Bleeding time

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Jones

1. A heart murmur is heard from damaged heart valves.
2. Splinter hemorrhages appear as black or red lines in the nails.
3. Petechiae indicate that tiny pieces of a lesion on the endocardium or valves have broken off and become microemboli.
4. Subjective assessment findings might include patient statements such as, "I have pain in my joints and am chilled" or "I am fatigued and have no appetite." Objective findings are as follows: temperature 100°F (37°C), red splinter hemorrhages in left index finger nailbed, many petechiae on chest.
5. Expected medications include IV antibiotics.
6. Removing blankets to decrease fever results in chills and shivering, which further increases body temperature from the heat generated by muscular activity during shivering. Therefore, Mrs. Jones should be kept covered to prevent chills.
7. For left-sided heart failure, crackles, wheezes, cough, or dyspnea might be seen. In right-sided heart failure, peripheral edema or jugular vein distention could be present.
8. Prophylactic antibiotics are needed to prevent another episode of infective endocarditis, which can result from bacteria entering the circulation during the invasive procedure, attaching to areas of the endocardium damaged from the current infection, and growing.
9. 2 tablets

QUESTIONS TO GUIDE YOUR READING

1. What are the etiologies, signs, symptoms, and therapeutic interventions of coronary artery disease, angina pectoris, and myocardial infarction?
2. What data should you collect and what nursing care will you provide for patients with coronary artery disease, angina pectoris, or myocardial infarction?
3. What are therapeutic interventions for coronary artery disease, angina pectoris, and myocardial infarction?
4. What are the etiologies, signs, and symptoms for each of the peripheral vascular disorders?
5. What are therapeutic interventions for each peripheral vascular disorder?
6. What nursing care will you provide for patients with each peripheral vascular disorder?

Cardiovascular disorders are the leading cause of disability and death in the United States. Diseases of the heart and peripheral vessels can affect quality of life and alter the ability of the individual to perform tasks of everyday living. Long-term disability can place a burden on families and businesses and can create high insurance costs. Many factors leading to cardiovascular diseases can be controlled or modified. Education is important in preventing and treating occlusive cardiovascular diseases.

According to the American Heart Association, in 2003 6,500,000 people had angina with 400,000 new cases of stable angina and 150,000 cases of unstable angina occurring each year.¹ Seven million two hundred thousand people have had heart attacks. One in three adults has cardiovascular disease (CVD). Two of three women develop CVD, which occurs about 10 years later than in men, often after menopause. CVD is the number one killer in the United States and the leading killer of women, with 500,000 women dying each year.

ARTERIOSCLEROSIS

Arteriosclerosis is part of the aging process in which the intimal lining of the artery wall loses elasticity and weakens. This weakening is due to the high pressure that carries blood within arteries. Arteriosclerosis may be called hardening of the arteries, although the arteries are actually weakened.

ATHEROSCLEROSIS

Atherosclerosis is the formation of **plaque** within the arterial wall. Arteriosclerosis and **atherosclerosis** are conditions that may begin in early childhood and progress without symptoms through adult life.

Pathophysiology

Atherosclerosis is a multistep process that affects the inner lining of the artery (Fig. 23.1). The first step in the development of atherosclerosis is injury to the endothelial cells that line the walls of the arteries. This injury causes inflammation and immune reactions. Damage to the endothelium stimulates the growth of smooth muscle cells. These cells secrete collagen and fibrous proteins. Lipids, platelets, and other clotting factors accumulate. Scar tissue replaces some of the arterial wall. An early indication of injury is a fatty streak on the lining of the artery. This build-up of fatty deposits is known as plaque. Plaque is composed of smooth muscle cells, fibrous proteins, and cholesterol-laden foam cells. Plaque has irregular, jagged edges that allow blood cells and other material to adhere to the wall of the artery. The portion of the plaque that faces the bloodstream develops a fibrous cap, a firm shell that often contains calcium.

arteriosclerosis: arterio—artery + sklerosis—hardness

FIGURE 23.1 (Top) Cross-section of normal coronary artery. (Bottom) Coronary artery with atherosclerosis narrowing the lumen.

Over time this build-up becomes calcified and hardened, causing turbulence that damages cells and increases the build-up within the vessel. Sometimes the plaque's fibrous cap tears or ruptures and a blood clot forms. This blood clot can completely block the coronary artery, or it may break loose and lodge within a smaller artery leading to the heart. The vessel may also become stenosed (narrowed) by plaque build-up. This build-up of plaque may cause partial or total occlusion of the artery resulting in reduced blood flow. The area distal to the occlusion may become ischemic as a result. Atherosclerosis often progresses asymptotically through adult life. However, it is often noted when the patient has symptoms of ischemic coronary syndromes, stroke, transient ischemic attack (TIA), and peripheral artery disease.

Causes

Risk factors for atherosclerosis can be divided into two categories: those that can be modified and those that cannot. Nonmodifiable risk factors include:

- Age
- Gender
- Ethnicity
- Genetics: predisposition for **hyperlipidemia**

Modifiable risk factors include:

- Diabetes mellitus
- Hypertension
- Smoking
- Obesity

hyperlipidemia: hyper—above + lipos—fat + emia—blood

- Sedentary lifestyle
- Increased serum homocysteine levels (an amino acid)
- Increased serum iron levels
- Infection
- Depression
- Hyperlipidemia
- Excessive alcohol intake

Signs and Symptoms

Atherosclerosis is not usually symptomatic until later stages of development, often when a major portion of the lumen of a blood vessel is occluded (Box 23.1). If symptoms do occur, they may include chest pain or dizziness caused by decreased blood supply and oxygen to the heart. Other symptoms noted may include diaphoresis, shortness of breath, nausea, weakness, and fatigue. Reduced blood flow in the extremities is reflected by pallor in the nailbeds, a reddish purple color in the lower extremities, thickened nails, dry skin, or loss of hair on the extremities. Peripheral pulses may be diminished or absent. Skin temperature in the

extremities is cooler, and there is prolonged capillary refill (greater than 3 seconds). A carotid bruit (abnormal sound on auscultation) indicates atherosclerosis in the carotid artery. Sometimes symptoms occur only with exertion. In some people, symptoms occur at rest.

Diagnostic Tests

Cholesterol and triglycerides are often elevated in patients with atherosclerosis. (See Table 20.3.) Total cholesterol levels above 200 mg/dL increase risk of myocardial infarction. Low-density lipoproteins (LDLs) increase **coronary artery disease** (CAD) risks, but **high-density lipoproteins** (HDL) are protective against CAD. A premature risk factor is a high Lp(a) cholesterol (a genetic variation of plasma LDL). C-reactive protein can indicate low-grade inflammation in coronary vessels and long-term heart disease risk. (See Chapter 20.)

Blood glucose levels should also be checked because elevated levels may increase the risk for atherosclerosis. Radiological studies of the arteries can be performed to show narrowed or occluded vessels. (See Chapter 20.)

Therapeutic Interventions

A healthy lifestyle that includes good nutrition and exercise, cholesterol screening, frequent check-ups, and medications are helpful in controlling arteriosclerosis and atherosclerosis.

Diet

Saturated fats are the primary cause of increased cholesterol levels, which promote arteriosclerosis and atherosclerosis. Because the formation of plaque within arteries is primarily caused by fatty deposits, an adherence to a low-fat diet is recommended (Box 23.2 Nutrition Notes). The liver is capable of producing cholesterol from saturated fats even when the dietary intake of fats is low. The American Heart Association has complete guidelines and diets for decreasing fat and cholesterol intake. For more information, visit <http://www.americanheart.org>.

Smoking

The risk of developing CAD is two to six times higher in cigarette smokers than in nonsmokers. Risk is proportionate to the number of cigarettes smoked. Smoking contributes to a loss of high-density lipoproteins (HDLs). These proteins are considered the best cholesterol to have in the body to decrease the risk of cardiovascular disorders. The rate of progressive damage to blood vessels is increased with smoking. Smoking also causes vasoconstriction, which leads to **angina pectoris** and cardiac dysrhythmias. The benefits of smoking cessation are dramatic and almost immediate. Education about the risks of smoking and exposure to second-hand smoke should be presented to patients. The American Cancer Society has many programs to help patients quit smoking. For more smoking cessation information, visit <http://www.cancer.org>.

angina pectoris: angina—to choke + pectora—chest

Box 23.1

Atherosclerosis Summary

Signs and Symptoms

Asymptomatic until later stages

Vascular

- Capillary refill greater than 3 seconds
- Diminished peripheral pulses
- Dry skin
- Loss of hair on extremities
- Pallor in nail beds
- Thickened nails
- Leg cramps

Cardiac

- Chest pain
- Diaphoresis
- Dizziness
- Fatigue
- Nausea
- Shortness of breath
- Weakness
- Arterial bruits

Diagnostic Tests

- Cholesterol
- Triglycerides
- Arteriogram

Therapeutic Interventions

- Diet—low fat, low cholesterol
- Smoking cessation
- Increased exercise—walk 30 minutes daily

Nursing Diagnoses

- Deficient knowledge related to self-care and health promotion
- Pain related to reduced vascular or coronary artery blood flow

Box 23.2

Nutrition Notes

Controlling Blood Cholesterol with Diet

Two-thirds of the body's cholesterol is produced by the liver and intestines. Most people can produce less cholesterol or increase its excretion in response to high levels of dietary cholesterol, but others respond weakly, a phenomenon that may be genetically based. Although only foods of animal origin contain cholesterol, some vegetable oil products contain *trans* fats, potent risk factors for cardiovascular disease. About 63% to 75% of *trans* fat intake comes from baked goods, fried fast foods, and other prepared foods rather than from margarines (Ascherio, Katan, and Stampfer, 1999). *Trans* fats are on labels beginning 2006.

Manufacturers of certain foods may make health claims that the food *as part of a diet low in saturated fat and cholesterol* may reduce the risk of heart disease. The Food and Drug Administration has approved such health claims for omega-3 fatty acids (salmon, lake trout, tuna, and herring), psyllium (e.g., Kellogg's Bran Buds), and soy protein.

The National Cholesterol Education Program therapeutic lifestyle changes (TLC) diet for individuals at increased risk of heart disease is based on the following:

Saturated fat and <i>trans</i> fats	Less than 7% of total calories
Dietary cholesterol	Less than 200 milligrams per day
Moderate physical activity	To use 200 calories per day

For patients with diabetes or metabolic syndrome, unsaturated fats may be prescribed as follows:

Monounsaturated fat	Up to 20% of total calories
Polyunsaturated fat	Up to 10% of total calories

After 6 weeks on the above program, the following may be added:

Fiber	20 to 30 grams per day
Plant stanols/sterols*	2 grams per day

After another 6 weeks, cholesterol-lowering medication may be prescribed.

*These compounds in plants, which structurally resemble cholesterol but are not absorbed in the human body to any extent, actually inhibit the absorption of cholesterol. Table spreads and salad dressings containing plant sterols are commercially available. In a rare autosomal recessive disorder called sitosterolemia, both cholesterol and plant sterols are absorbed at a high rate and are not removed effectively by the liver, resulting in accelerated atherosclerosis and premature coronary artery disease (Lee, Lu, and Patel, 2001).

Exercise

Increased activity raises HDL levels (the desirable cholesterol). Increasing physical activity may also lower insulin resistance and facilitate weight loss. Over time, exercise also leads to the development of **collateral circulation**, which allows blood to flow around occluded sites. Before beginning an exercise program, the patient should consult a physician.

Medications

Lowering lipid levels is the major treatment for atherosclerosis (Table 23.1). When dietary control is not effective, medication is also used. It may take 4 to 6 weeks before lipid levels respond to drug therapy. If one drug does not control the lipids, another drug can be added. High doses of statins, which lower lipid levels, are being researched to see if they significantly reduce the risk of heart attack.

Complications

Complications of atherosclerosis include CAD, MI (discussed below), and TIA or stroke (see Chapter 49).

CORONARY ARTERY DISEASE AND ACUTE CORONARY SYNDROME

Coronary artery disease is a term applied to obstructed blood flow through the coronary arteries to the heart muscle. The primary cause of coronary artery disease is atherosclerosis. The term *acute coronary syndrome (ACS)* is used to encompass the continuum of coronary artery disease, such as unstable angina, non-ST elevation myocardial infarction, and ST elevation. (See Chapter 25 for ST definition.) If blood flow reduction resulting from CAD is severe and prolonged, a **myocardial infarction** (MI, heart attack) can occur, causing irreversible damage.

Pathophysiology and Etiology

As discussed in the sections on atherosclerosis and arteriosclerosis, an accumulation of fatty deposits and minerals in the coronary arteries, called an **atheroma** or plaque, leads to stenosis and eventually occlusion of the artery. In CAD, blood flow to the myocardium is reduced. The arteries are unable to dilate to meet increased metabolic needs. When myocardial oxygen demands are not met, ischemia results, which can cause chest pain. The pain associated with CAD occurs from a lack of oxygen to the myocardium from CAD and is called angina pectoris.

Prevention

Risk factors for CAD are listed in Table 23.2. If coronary artery disease is not prevented or treated early, it can progress to more serious cardiac disorders. These include angina, myocardial infarction, heart failure, cardiac dysrhythmias, and even sudden death. The appropriate management of risk factors can prevent, modify, or retard the progression of atherosclerosis and coronary artery disease.

TABLE 23.1 LIPID-LOWERING DRUGS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Statins				
First-line drugs to reduce low-density lipoprotein by reducing cholesterol synthesis	Atorvastatin (Lipitor)	PO	Impaired liver function Rhabdomyolysis— Lethal breakdown of skeletal muscle	Tell patient to take in the evening when cholesterol synthesis is highest. Teach patient to report any muscle pain. Monitor liver function studies.
	Fluvastatin (Lescol XL)			
	Lovastatin (Mevacor)	PO		
	Pravastatin (Pravachol)	PO		
	Simvastatin (Zocor)			
Fibrates				
Reduce triglycerides	Fenofibrate (Tricor) Clofibrate (Atromid) Gemfibrozil (Lopid)	PO	Heartburn Gallstones	Tell patient to take 30 minutes before morning and evening meal. May increase the effects of anticoagulants and hypoglycemia.
Bile Acid Sequestrants				
Lower cholesterol by binding bile acids, so stored cholesterol is used to make more bile acids	Colestipol (Colestid)	PO	Headache, heartburn, constipation, gas	Fruits and vegetables high in fiber should be added to diet to reduce constipation and other GI effects noted with bile acid sequestrants. May interfere with absorption of digoxin, thiazides, and beta blockers.
	Colesevelam HCl (WelChol, Sankyo)	PO		
	Cholestyramine (Questran)	PO		
Niacin				
Prevents conversion of fats into very-low-density lipoproteins. First antilipid agent used	Niacin (nicotinic acid) Niaspan (extended-release niacin)	PO	Gastritis Gout Flushing	Take aspirin 30 minutes prior to taking drug to reduce flushing.
	Zetia (Ezetimibe) (intestinal cholesterol absorption inhibitor)			Tell patient to take with liquids and meals and to take other drugs 1 hour before or 4 hours after. Tell patient to take with meals or milk to avoid GI upset. Used with diet, exercise, and smoking cessation therapy to lower lipids.

Therapeutic Interventions

Most risk factors for heart disease are related to lifestyle and environmental factors. The guidelines for prevention of heart disease by the American Heart Association target the risk factors that have the potential for change. Educating patients on cessation of smoking, dietary changes, controlling hypertension, maintaining weight, and diabetes can decrease their risk of CAD. Dietary changes are made to reduce saturated fats to less than 10% of daily food intake. Cholesterol intake on the Step 1 diet is less than 300 mg per day and less than 200 mg per day on the step 2 diet. Medication may be given to reduce cholesterol levels. Low-dose aspirin and anticoagulants are used to prevent the formation of a thrombus.

Percutaneous Transluminal Coronary Angioplasty

Percutaneous transluminal coronary angioplasty (PTCA) is a minimally invasive procedure that helps reduce symptoms of CAD (Fig. 23.2). In a cardiac catheterization laboratory, a catheter with a balloon tip is inserted usually via the femoral artery and advanced into the heart. However, the radial artery has also been used with fewer complications like bleeding. Once the blocked coronary artery is entered, the balloon on the catheter is inflated and the atherosclerotic plaque is compressed. This results in a dilated vessel being able to deliver more oxygen-rich blood to the myocardium. The patency of the vessel is restored. The symptoms of CAD are usually reduced, but the underlying progression of ath-

TABLE 23.2 RISK FACTORS FOR CORONARY ARTERY DISEASE

<i>Risk Factors that Cannot Be Changed</i>	
Heredity	CAD risk factors can run in families.
Ethnicity	African Americans have a higher incidence of atherosclerosis.
Gender	Men have more risk factors and higher incidence of CAD.
Age	Men have increased incidence after age 50. Women have increased incidence after menopause.
<i>Risk Factors that Can Be Changed or Controlled</i>	
Smoking	Causes vasoconstriction and increases myocardial oxygen demand. Decreases HDL.
Hypertension	Vasoconstriction increases myocardial oxygen demand.
Elevated serum cholesterol	Level above 240 mg/dL increases the risk of developing CAD.
Diabetes	Increases the risk of hypertension, obesity, and elevated blood lipids.
Obesity	Increases heart workload and risk of hypertension, diabetes, glucose intolerance, hyperlipidemia.
Stress	Increases heart workload and risk for hypertension.
Elevated serum homocysteine	Increases CAD risk. Foods that contain folic acid (fruits, green leafy vegetables) reduce homocysteine levels.
Sedentary lifestyle	Increases obesity, hypertension, hyperlipidemia.
Excessive alcohol use	Raises blood pressure leading to heart failure, increase triglycerides, cause irregular heart beats.

**FIGURE 23.2** Percutaneous coronary angioplasty opens narrowed coronary arteries.

erosclerosis continues. Reocclusion of the artery often occurs within a few months. Over time, PTCA may need to be repeated. Angioplasty can be done with or without the placement of stents (discussed below), but it is often more successful when stents are used.

Coronary Atherectomy

Coronary atherectomy is used to cut and remove plaque from atherosclerotic coronary arteries. The catheter has a central rotating blade that shaves off the plaque and contains it for removal and pathological analysis. Calcium channel blockers are given before the procedure to prevent vasospasms from the vibrating cutter. To prevent clot formation, an antiplatelet agent is given after the procedure.

Coronary Artery Stents

Coronary artery stents are used to prevent closure of a coronary artery from an atherosclerotic lesion. Stents are put in place during an angioplasty. A stent is an expandable metal mesh tube that is implanted at the site of blockage in the coronary artery. A stent provides support to a coronary artery wall at the area of stenosis to keep blood flowing through the artery. Different types of materials, such as bioabsorbable materials or stainless steel mesh, and designs, such as self-expanding or balloon expandable, are used to make stents (Fig. 23.3). Complications associated with stent placement include **thrombosis**, bleeding from anticoagulation, stent occlusion, or coronary artery dissection. Some stents are coated with medication (drug-eluting stents) that can be released at the implantation site to reduce the risk of restenosis. After the procedure, medications are given to help prevent clot formation. Antiplatelets (such as aspirin, clopidogrel bisulfate [Plavix], ticlopidine [Ticlid], or enoxa-

**FIGURE 23.3** Insertion of a coronary artery stent: (A) A balloon catheter with a collapsed stent is advanced to the location of a coronary artery lesion. (B) The balloon is inflated, which expands the stent and compresses the lesion to increase the artery opening. (C) The balloon is then deflated and removed, leaving the expanded stent in place to prevent the artery from closing.

parin [Lovenox]) and anticoagulants (warfarin [Coumadin]) may be used. Aspirin can be used long term, but the other medications may only need to be used for several weeks until the stent is covered with tissue and the risk of clot formation is over. Fondaparinux (Arixtra) is a new anticoagulant that inhibits factor Xa only. A daily subcutaneous injection of 2.5 mg is given.

Myocardial Revascularization—Coronary Artery Bypass Graft

Coronary artery bypass graft (CABG) surgery is a procedure used to increase blood flow and oxygen to the myocardium and alleviate anginal symptoms. During bypass surgery, a blood vessel from the leg or chest is used to reroute blood around a segment of a coronary artery that is narrowed by atherosclerosis. Significant occlusions in the coronary arteries are bypassed with vein or artery grafts (Fig. 23.4). One or more vessel bypasses can be performed during the procedure. The saphenous vein from the leg or an internal mammary artery from the chest wall is generally used. The right gastroepiploic artery (RGEA), a branch of the gastro duodenal artery, and the inferior epigastric artery (IEA) have also been used for repeat CABG operations.

While the sternotomy is made, the vein graft is being removed from the body. The graft is flushed with a heparinized solution to check for leaks, and then set aside for use during the surgery. The patient is then placed on cardiopulmonary bypass (CPB) (see Chapter 20). After cardiac standstill occurs, one end of the graft is **anastomosed** (joined) to the coronary artery distal to the occlusion while the proximal end of the graft is anastomosed, usually to the ascending aorta.

Resecting the mammary arteries for grafting is more difficult and time consuming than resecting the saphenous vein, but their patency is longer. The proximal end of the artery is left attached to its origin, and the distal end is anastomosed to the coronary artery distal to the occlusion. See Box 23.3 Patient Perspective.

Minimally invasive direct visualization coronary artery bypass graft (MIDCABG) is a technique that is done without the use of cardiopulmonary bypass. Several small incisions

are used to access the coronary arteries instead of a sternotomy. This technique uses a thoracoscope to mobilize the internal mammary artery (IMA) or the left internal mammary artery (LIMA). Single-vessel disease patients may take advantage of this new technique. The main disadvantage of MIDCAB is that it cannot be used to treat several diseased vessels, especially if arteries on both the left and right sides of the heart are blocked. The limited number of small incisions made using MIDCAB makes it difficult to treat more than two coronary arteries during the same surgery.

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization is an option for patients who are not candidates for angioplasty or coronary

CRITICAL THINKING

Mr. Jones

■ Mr. Jones is transferred to the nursing unit 12 hours after a quadruple CABG. Preoperative vital signs were blood pressure 164/88, apical pulse 62 regular, respiratory rate 8, temperature 98.4°F (36.9°C). Assessment findings are blood pressure 100/56, apical pulse 105 and irregular, respiratory rate 28 and shallow, temperature 99.8°F (37.7°C), lung sounds diminished with crackles in bilateral bases, pedal pulses weak bilaterally, chest and leg dressings dry and intact, and no urinary catheter. Mr. Jones is being monitored for first postoperative voiding.

1. Which findings may indicate pulmonary problems?
2. List four nursing interventions for the altered pulmonary status.
3. What are three reasons why the apical pulse could be elevated?
4. What are two reasons why the blood pressure could be low?

Suggested answers at end of chapter.

transmyocardial: trans—across + myo—muscle + cardial—heart

FIGURE 23.4 Myocardial revascularization: coronary artery bypass graft surgery.

Box 23.3

Patient Perspective

Keith: Coronary Artery Bypass Graft

I was 72 when I had coronary artery bypass surgery. I had some very minor symptoms, and a heart catheterization showed significant coronary artery blockage. I ended up having five bypass grafts performed. It was a long surgery. I felt disoriented for several days afterward—mostly while I was in the intensive care unit.

I felt absolutely no pain of any type after surgery. However, I have had a strange sensation in my legs at the incision sites ever since surgery, but not pain! I also have experienced no depression and have assumed an attitude that I am in better condition than before surgery, so why should I worry?

I was provided with excellent care at home after discharge from the hospital. The nursing and rehab personnel were outstanding. I had a capable visiting nurse, physical therapist, or occupational therapist practically every day. Physical therapy was difficult at first but shortly became routine and easy.

My experience during cardiac rehab was outstanding. I had three sessions per week for 12 weeks. I have always exercised a lot, so I had no problems attaining the exercise levels suggested. It was a very positive experience, and I enjoyed the association with others in the same situation. We even staged a graduation when we finished. I wore a tuxedo jacket with my gym shorts! Since completing my rehab, I have religiously maintained a minimum 40-minute exercise schedule three times per week. I do this because I want to stay healthy for a long time.

The only negative aspect I experienced was a minor stroke during surgery. As a result, my balance is not as good as I would like. I need to be more careful, particularly when running or bike riding. Perhaps this is just older age, but it started just after surgery, so that is the reason I assume it is due to the minor stroke.

The impact on my life and family has been minimal. The primary change is being more conscious of my diet and an emphasis on exercise. Otherwise, I live pretty much the same as before.

artery bypass surgery. Carbon dioxide laser revascularization uses a high-powered carbon dioxide laser to create approximately 40 transmural channels directly in the myocardium. The laser is synchronized to fire on the R wave of the electrocardiogram (ECG). This minimizes dysrhythmias and ensures that the ventricle is at rest and full of blood. The channels created allow blood to flow into the ischemic areas. This enables oxygen-rich blood to flow directly into ischemic myocardium. Optimal results are seen in about 3 to 12 months after the procedure. Over time the

ischemic myocardial tissue is reperfused as a new system of circulation develops. Anginal pain is decreased and cardiac function may be improved.

Nursing Process: The Patient with Atherosclerosis and Coronary Artery Disease

Assessment/Data Collection

A health history is obtained regarding the patient's risk for atherosclerosis and coronary artery disease. Data collected would include nonmodifiable risk factors such as age, race, gender, ethnicity, and family history and modifiable risk factors such as smoking, diabetes, hypertension, obesity, physical inactivity, infection, depression, drug use, alcohol use, and cocaine use. A history of chest pain, fatigue, or activity intolerance is noted. Current medications, including over-the-counter and prescription drugs are documented as well as allergies to medications. Height, weight, and diet history as well as laboratory values for lipids and cholesterol are recorded.

Nursing Diagnosis, Planning, and Implementation

Deficient knowledge related to ineffective management of regimen for atherosclerosis or coronary artery disease

EXPECTED OUTCOME: The patient will report understanding and management of atherosclerosis and coronary artery disease.

- Identify cognitive or physical impairments *that would interfere with the patient's ability to learn desired information.*
- Include significant other as appropriate *to support patient during learning.*
- Collect data on the patient's present understanding of atherosclerosis and CAD *to determine baseline knowledge.*
- Collect data on the patient's readiness to learn and desired learning needs and feelings about incorporating lifestyle changes into daily routine *to prioritize teaching topics.*
- Determine cultural beliefs *as they may influence learning.*
- Provide for the physical comfort of the patient during teaching *to increase learning.*
- Use appropriate teaching tools to meet individual learning needs of the patient *such as pamphlets, diagrams, or other written materials in simple language.*
- Use an interpreter as needed and provide written materials in the patient's native language *to facilitate understanding.*
- Explain pathophysiology of atherosclerosis and CAD to patient.
- Explain to patient how to control risk factors and manage symptoms of CAD including the following as appropriate: weight reduction plans, stress management, smoking cessation, cardiovascular fitness, low-fat diet, smoking cessation, increasing activity level, hypertension, and diabetes management.

- Explain action, side effects, and importance of taking medications as prescribed *to prevent complications*.
- Teach to consult health-care provider prior to taking over-the-counter preparations *that may interfere with desired effects of medication regimen*.
- Provide information about community resources *that can assist in making life-style changes such as weight loss, smoking cessation, stress management, and exercise*.
- Teach to monitor blood pressure and heart rate as appropriate and to report chest pain or dyspnea, *which may point to the presence of complications from CAD*.
- Assist the learner to plan how to incorporate information into daily life *to increase likelihood change will occur*.
- Encourage questions and allow the patient the opportunity to verbalize new information and skills *to enhance learning*.
- Document teaching and evaluation of patient knowledge.

See Box 23.4 Nursing Care Plan for the Patient Undergoing Cardiac Surgery for additional nursing care.

Evaluation

Interventions are successful if the patient has an increased understanding of atherosclerosis, CAD, and their management and states he or she will modify risk factors of CAD.

ACUTE CORONARY SYNDROMES

Acute coronary syndromes are a group of conditions that are caused by a lack of oxygen to the heart muscle. These conditions may include unstable angina, non-Q wave myocardial infarction, and ST-segment elevation myocardial infarction. Patients with acute coronary syndromes are at high risk for myocardial infarction and death.

Angina Pectoris

Pathophysiology

Angina pectoris (chest pain) is a symptom of ischemia and is the primary symptom of coronary artery disease and heart attack. When an increased workload is placed on the heart, as in exercise or strenuous activity, there is an increased demand for oxygen. Normally, when the heart needs more oxygen, the coronary arteries dilate to carry more blood. However, with CAD, the narrowed vessels are unable to dilate and supply the heart with this extra blood and oxygen. This inability to supply more blood and oxygen causes myocardial ischemia and chest pain. Chest pain results from the ischemia but usually lasts only for a few minutes, especially if activity is stopped. If adequate blood supply to the myocardium is restored with rest, no myocardial damage usually occurs.

LEARNING TIP

Angina pectoris is not a disease. It is a symptom of coronary artery disease. Ischemia results from a lack of oxygen and blood flow to the heart muscle. Ischemia = pain or angina.

Signs and Symptoms

Anginal pain manifests itself in several ways. Patients often describe the pain as heaviness, tightness, squeezing, vise-like, or crushing pain in the center of the chest. The pain can radiate down one or both arms, with pain in the left arm being more common, into the shoulder, neck, jaw, or back. Patients may also describe heaviness in their arms or a feeling of impending doom. During the episode of pain, the patient may be pale, diaphoretic, or dyspneic. The pain is usually brought on by exertion and subsides with rest. It can be relieved with a vasodilator medication such as nitroglycerin (NTG). Episodes of chest pain may increase in frequency and severity over time. If patients do not heed this warning to stop their activity and rest, they may be at risk for a myocardial infarction or sudden death. Any event that increases oxygen demand can cause an anginal attack. Most often precipitating events include large meals, exercise, cold, stimulant drugs such as cocaine or amphetamines, and emotional tension. Often angina may occur in the morning hours between 6:00 a.m. and noon when the patient arises and the heart experiences increased workload. Women often exhibit atypical symptoms that should be recognized as being cardiac related so that treatment is sought.

Types

STABLE ANGINA. Stable angina is chest pain that occurs with moderate exertion in a pattern that is familiar to the patient. The pain is predictable and can usually be managed with nitroglycerin and rest. The atherosclerotic arteries cannot dilate to increase blood flow to the myocardium. When increased physical activity and stress place an added demand on the heart, the patient develops midsternal chest pain. The pain of stable angina usually subsides when the activity is stopped.

VARIANT ANGINA (PRINZMETAL'S ANGINA). The pain of variant angina is similar to the pain in stable angina except it has a longer duration and may occur at rest. The pattern of occurrence is often cyclical, with the pain presenting about the same time each day. This type of angina is often caused by coronary artery spasms and usually does not cause damage to the myocardium. Accelerating or “crescendo” pattern of chest pain lasts longer than in stable angina.

UNSTABLE ANGINA. Unstable angina occurs in patients with worsening CAD and is noted by its changing pattern. Rest does not decrease the chest pain of unstable angina. This pain may even occur when the patient is at rest. The

Box 23.4 NURSING CARE PLAN for the Patient Undergoing Cardiac Surgery

Nursing Diagnosis: Acute Pain Related To Sternotomy, Leg Incisions, Internal Mammary Artery Resection, Or Pericarditis

Expected Outcomes Patient will state pain is relieved or tolerable. Patient is able to rest and perform respiratory treatments.

Evaluation of Outcomes Does patient state pain is within acceptable levels? Is patient able to rest and perform respiratory therapies?

Interventions

- Assess characteristics of pain with each episode.
- Splint chest incision with all movement and coughing and deep breathing.
- Encourage patient to report pain even when pain is mild.
- Turn, reposition every 2 hours.
- Offer back rubs frequently.
- Instruct patient to take a deep breath before movement and exhale slowly during movement.

Rationale

A thorough description is needed to determine cause and plan actions. Stabilizes sternum and incision to increase comfort.

It is easier to keep pain under control when mild.

Changes muscle position, relieving stiffness.

Relaxes tense muscles retracted during operation.

Keeps muscles relaxed, minimizing tension with guarding and pain.

Evaluation

Does patient describe pain on scale of 0 to 10?

Can patient splint chest incision independently?

Does patient report pain when mild?

Is patient comfortable without stiffness?

Is patient able to rest comfortably?

Can patient perform coughing and deep breathing techniques as instructed?

Nursing Diagnosis: Decreased cardiac output related to myocardial depression, hypothermia, bleeding, unstable dysrhythmias, or hypoxemia

Expected Outcomes Patient will remain free of major side effects of pharmacological support. Patient will maintain vital signs within normal limits (WNL), palpable peripheral pulses, urine output greater than 30 mL/hr, and normal sinus rhythm.

Evaluation of Outcomes Is patient free of major side effects? Are vital signs WNL?

Interventions

- Monitor vital signs.
- Check peripheral circulation.
- Monitor intake and output.
- Listen to lung sounds and note character of sputum.
- Monitor temperature closely while rewarming the patient.
- Note shivering.
- Monitor chest tube drainage for increase or sudden decrease.
- Monitor ECG.

Rationale

Trends reflect problems.

Mottling or weak pulses may indicate poor cardiac output (CO).

Fluid deficit or excess can alter CO.

Wet lung sounds may indicate heart failure or pulmonary edema.

Febrile state increases heart rate and myocardial oxygen consumption.

Shivering increases the blood pressure, decreasing CO and increasing risk for bleeding.

Drainage >200 mL/hr may lead to hypovolemia and a decrease in CO.

Premature ventricular contractions and atrial fibrillation decrease CO.

Evaluation

Are vital signs WNL?

Do peripheral pulses remain strong with normal skin color, temperature, capillary refill?

Does total intake equal output?

Are lungs clear?

Does temperature remain less than or equal to 98.6°F (37°C)?

Is patient's shivering controlled?

Is patient free from cardiac tamponade and hypovolemia?

Does patient remain in normal sinus rhythm or controlled dysrhythmia?

(Continued on following page)

Box 23.4 NURSING CARE PLAN for the Patient Undergoing Cardiac Surgery (Continued)

Interventions

- Monitor electrolytes.
- Monitor ABGs.

Rationale

Low calcium and magnesium and high potassium decrease contractility and CO.
Acidosis decreases heart function, and a low CO may lead to further acidosis.

Evaluation

Are electrolytes WNL?
Are ABGs WNL?

Nursing Diagnosis: Risk for infection related to inadequate primary defenses from surgical wound

Expected Outcomes Patient will remain free from infection.

Evaluation of Outcomes Does patient remain free from infection?

Interventions

- Observe incision for signs and symptoms of infection.
- Monitor drainage and maintain drains.
- Maintain sterile technique for dressing changes.
- Monitor and report abnormal findings for temperature, lung sounds, sputum, and urine consistency.
- Encourage coughing and deep breathing and incentive spirometer use.

Rationale

Redness, warmth, fever, and swelling indicate infection.
Drains remove fluid from the surgical site to prevent infection development.
Sterile technique reduces infection development.
Low-grade or high-grade fever, crackles, yellow-green sputum color, or cloudy urine can indicate infection.
Lung infections can be prevented with lung expansion and secretion removal.

Evaluation

Are signs and symptoms of infection present?
Are drainage amount and color normal for procedure? Are drains functioning?
Is incision free of signs and symptoms of infection?
Is the patient's temperature WNL and are lung sounds, sputum, and urine clear?
Does patient perform coughing and deep breathing and use incentive spirometer?

episodes of chest pain with unstable angina increase in frequency and severity, placing the patient at risk for myocardial damage or sudden death. Symptoms of angina usually occur when an artery is narrowed by at least 60% to 70%. Women may experience anginal pain as chest pain, jaw pain, or heartburn or have symptoms different than those thought of as being typical of angina. These symptoms include fatigue, nausea, and breathlessness.

SILENT ISCHEMIA. Many people may have myocardial ischemia without chest pain or symptoms of angina. This is called silent ischemia. Ischemia with or without pain usually has the same prognosis. The older adult and people with hypertension or diabetes are most often noted to have silent ischemia.

Diagnostic Tests

Diagnostic tests of cardiovascular system function are discussed in Chapter 20. Tests commonly done for acute coronary syndromes include electrocardiogram, exercise electrocardiogram, graded exercise testing, stress echocar-

diography, chemical stress testing, radioisotope imaging, and coronary angiography (see Table 20.3).

BIOLOGICAL MARKERS. When cardiac cells become damaged they release enzymes and other molecules into the blood stream that can be measured: troponin, creatine kinase, myoglobin (see Table 20.3). C-reactive protein levels are elevated in the presence of inflammation. Myeloperoxidase is an enzyme produced by activated white blood cells. Myeloperoxidase levels are elevated in the presence of unstable atherosclerotic plaque. Elevated levels of these markers can help detect a heart attack in patients with severe chest pain. Often these markers identify individuals who may have otherwise been misdiagnosed such as the elderly and women.

New marker tests are being developed that may in the future benefit the patient with acute coronary syndrome. One test on the horizon is the albumin cobalt-binding test. This test can be used with ECG findings and troponin levels to increase the accuracy of cardiac disease diagnosis.

Therapeutic Interventions

Treatment for angina is directed at relieving and preventing anginal episodes that could lead to a myocardial infarction. The risk factors identified for the patient determine the course of treatment. Weight reduction; a low-fat, low-cholesterol diet; and stress reduction may help slow disease progression. Most patients with angina are placed on medication that reduces oxygen demand and increases oxygen supply to the myocardium. The three major groups of medication used for angina are vasodilators, calcium channel blockers, and beta blockers (Table 23.3).

For those with unstable angina, taking the Fab Four of cardiac drugs has been shown to be beneficial for heart health.² The Fab Four include antiplatelets, statins, ACEIs, and beta blockers. A drug from each of these drug classes should be taken by patients. These drugs when taken together have a synergistic effect in fighting plaque, which means they have a greater positive result for the patient. Generic drugs are available in these drug classes, making the four-drug combination affordable with remarkable benefits. However, research has shown that not all eligible patients are prescribed each of these medications. Patient teaching can include the need to ask the health-care provider about these drug classes to ensure they receive the ones for which they are eligible.

VASODILATORS. Nitroglycerin (a nitrate) is the drug of choice for acute anginal attacks. Nitrates dilate coronary arteries to increase oxygen to the myocardium, and dilate peripheral vessels so the heart does not have to work so hard to pump blood into them. NTG can be administered sublingually, orally, transdermally, intravenously, or as a lingual spray. When administered sublingually, NTG may relieve chest pain within 1 to 2 minutes (Box 23.5 Key Points for Using Sublingual Nitroglycerin). Newer guidelines tell people at home to call 911 immediately if after one tablet and 5 minutes the pain is not relieved *and* symptoms of a myocardial infarction are occurring.

Long-acting nitrates are used to prevent chest pain rather than treat acute pain, and can be given orally, in ointment, or by transdermal patches. A problem with long-acting nitrates is the development of a tolerance to the drug. To prevent tolerance, the patch or ointment is usually removed at bedtime and reapplied in the morning, giving the patient an 8- to 12-hour nitrate-free period. Headaches may be experienced when nitrates are first begun. This side effect usually subsides after a week or two.

CALCIUM CHANNEL BLOCKERS. Calcium is required for electrical excitability of cardiac cells and contraction of the myocardium and vascular smooth muscle. Calcium channel blockers relax vascular smooth muscle, which leads to decreased peripheral vascular resistance (afterload) and decreased myocardial oxygen demand. These drugs dilate main coronary arteries, increasing the myocardial oxygen supply. Nifedipine (Procardia) and verapamil (Calan, Isoptin) are potent inhibitors of coronary artery spasms and are used to treat variant (Prinzmetal's) angina.

SAFETY TIP

Those who take nitrates should not use drugs such as sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra) for erectile dysfunction because these types of drugs dilate blood vessels and may cause a significant drop in blood pressure if used together.

Calcium channel blockers are also used to decrease systolic and diastolic blood pressures and to slow the heart rate. These drugs are commonly given in conjunction with other vasodilators and beta blockers. Because these drugs are slow acting, they are ineffective in relieving acute anginal attacks. Side effects of calcium channel blockers are usually mild and include constipation, fluid retention, headache, and dizziness.

Beta Blockers. Beta blockers decrease heart rate, lower blood pressure, and prevent release of rennin. This results in decreased workload on the heart to help prevent anginal attacks. Because of these decreased effects, beta blockers should be used with caution in patients with any degree of heart failure because it makes heart failure worse. There are nonselective and selective types of beta-adrenergic blockers. People with asthma or chronic obstructive pulmonary disease (emphysema, bronchitis, and bronchiectasis) should avoid nonselective beta-adrenergic blockers because they cause bronchoconstriction. Metoprolol and atenolol are more cardioselective and can be used in patients with asthma and chronic obstructive pulmonary disease (COPD). Beta blockers are not effective for coronary artery spasms.

LEARNING TIP

To help you identify beta blockers, remember that their generic names end with *-olol*.

Angiotensin-Converting Enzyme Inhibitors (ACEIs). ACEIs block production of angiotension II, which is a potent vasoconstrictor. This action reduces peripheral arterial resistance, which lowers blood pressure. Some patients taking an ACEI may develop a cough. If this occurs, they should inform their health care provider so that the medication can be changed.

Statins. Cholesterol and inflammation in artery walls are involved in atherosclerosis development. Statins lower cholesterol levels by reducing cholesterol production in the liver (see Table 23.1). They also reduce inflammation and CRP levels, which improves patient outcomes in CAD. Statins are used to prevent and treat atherosclerosis and the disorders caused by it.

(Text continued on page 418)

TABLE 23.3 PHARMACOLOGICAL TREATMENT FOR ANGINA PECTORIS

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antiplatelets Inhibit platelet activation, adhesion, or procoagulant activity	Aspirin	PO	Increased risk of bleeding including hemorrhagic stroke	Enteric coated may be given for daily dosing.
Statins See Table 23.1				
Nitrates: Vasodilators Relax smooth muscle in blood vessel walls. Produces vasodilation, which relieves cardiac workload. Preload and afterload reduction. Reduces oxygen consumption of myocardium.	Nitrates/nitroglycerin (Nitrostat, NitroQuick)	Sublingual	Hypotension Headache Contraindicated in head trauma, hypotension, uncorrected hypovolemia	Take apical pulse the AP and BP pre and post administration. Caution patient to rise slowly because of orthostatic hypotension, especially with sublingual nitroglycerin. Document onset, type, radiation, location, and duration of chest pain. Place tablet in buccal pouch to lessen burning sensation under the tongue. If chest pain is not relieved call the physician, or emergency medical assistance. Tablets should be replaced every 3 to 6 months. Check expiration date. Do not remove tablets from bottle. Vasodilators become inactive when exposed to light, air, heat, and moisture. Tell the patient a burning or tingling sensation may be felt under the tongue with sublingual nitroglycerin.
	Isosorbide dinitrate (Isordil), Isosorbide monitrate (ISMO)	Oral or Sublingual	Hypotension Transient flushing of face and neck Dizziness if standing Orthostatic hypotension Nausea Vomiting Restlessness	Tolerance may occur with repeated prolonged therapy. High dose may produce severe headache. Elderly may be more sensitive to drug dosing. Instruct the patient to rise slowly from a lying position. Caution against using one brand of drug to another. Avoid alcohol during therapy. Alcohol intensifies the drug's hypotensive effect.
	Nitroglycerin (Transderm Nitro, Nitro-Bid) Nitroglycerin patch (Nitro-Dur, Nitrek)	Transdermal	Hypotension Transient flushing of face and neck Dizziness if standing Orthostatic hypotension Nausea Vomiting Restlessness	Remove patch before defibrillation. Rotate application sites. Apply the patch to a clean, dry, hairless area. Tolerance may develop.
Angiotensin-Converting Enzyme Inhibitors Block the production of angiotension II, a potent vasoconstrictor. Reduces peripheral arterial resistance, pulmonary capillary wedge pressure, improves cardiac output and exercise tolerance.	captopril (Capoten), lisinopril (Prinivil, Zestril), ramipril (Altace)	PO	Persistent cough may develop in 20% of patients. Hyperkalemia may develop in patients with diabetes mellitus or renal impairment.	Angioedema, swelling of the face and lips may occur. Agranulocytosis and neutropenia may be noted in patients with concurrent collagen vascular disease including scleroderma and systemic lupus erythematosus, and impaired renal function. Take baseline blood pressure before each dose. Give 1 hour before meals; food delays absorption.

(Continued on following page)

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Calcium Channel Blockers Prevent the movement of extracellular calcium into the cell. The result is dilation of peripheral arteries, decreased myocardial contractility, and depressed conduction system. The result is decreased workload of the heart. In variant angina these drugs reduce coronary artery spasm.	Diltiazem (Cardizem, Dilacor XR), amlodipine (Norvasc)	Oral	Headache Peripheral edema Dysrhythmias Flushing Dizziness Atrioventricular blocks Nausea Constipation	Assess apical pulse and blood pressure prior to administration. If blood pressure is less than 90 systolic or heart rate is less than 50, call the physician. Assess liver and renal function tests during therapy. Administer before meals and at bedtime.
	Nifedipine (Procardia)	Oral	Headache Peripheral edema Dysrhythmias Flushing Dizziness Atrioventricular blocks Abdominal discomfort	Grapefruit juice may alter absorption. Take apical pulse and blood pressure prior to administration. Monitor liver and renal function tests during therapy.
	Verapamil (Calan, Isoptin, Covera-HS)	Oral IV	Headache Peripheral edema Dysrhythmias Flushing Dizziness Atrioventricular blocks	Not removed by hemodialysis. Monitor heart rate and blood pressure. Monitor for constipation. If blood pressure is less than 90 systolic or heart rate is less than 50, call the physician.
Beta Blockers Cause a decrease in heart rate, blood pressure, cardiac output, and suppress renin activity. They decrease myocardial contractility and oxygen demand. Decreases the risk of sudden death and may reduce ventricular remodeling.	Propranolol (Inderal)	Oral		
	Metoprolol succinate (Lopressor, Toprol XL)	Oral, IV		
	Atenolol (Tenormin)	Oral	Cold extremities, constipation, diarrhea, diaphoresis, dizziness, fatigue, and nausea. Abrupt withdrawal may result in diaphoresis, palpitations, headache, and tremors. May precipitate thyroid storm in persons with thyrotoxicosis. Hypoglycemia may occur in patients with previously controlled diabetes. Thrombocytopenia.	Warn the patient not to get up quickly. Avoid salt and alcohol. Take the apical pulse and blood pressure immediately prior to administration. If pulse is less than 60 beats per minute, or blood pressure less than systolic 90 mm Hg, withhold the medication and notify the physician. Use cautiously in patients with diabetes. Beta blockers are contraindicated in patients with asthma, heart block, bradycardia, or pulmonary conditions with bronchoconstriction. Do not stop abruptly.
Anti-Ischemic Agent New class of antianginal agent for use as combination therapy for those not responding to other antianginal agents. Action not fully known.	Ranolazine (Ranexa)	PO	Prolongs QT interval. Dizzy, headache, constipation, nausea.	May not be as effective in women.

Box 23.5**Key Points for Using Sublingual Nitroglycerin (NTG)**

- Carry NTG at all times.
- Keep NTG tightly sealed in the original container.
- Replace NTG every 6 months for maximum effect.
- Take NTG before an activity known to cause chest pain.
- Sit or lie down when taking NTG if possible
- Take one NTG tablet and repeat every 5 minutes up to three doses if pain is not relieved. If pain is unrelieved after one dose and other symptoms of myocardial infarction are present, call 911 for emergency medical care.
- Tingling should be felt under the tongue when NTG is used.
- NTG may cause a headache.
- NTG may cause light-headedness; rise slowly to prevent falls.

Antiplatelets. Aspirin, clopidogrel (Plavix), and ticlopidine (Ticlid) are commonly used antiplatelets that help prevent cardiovascular events. Aspirin is the one most often prescribed and may be used in combination with another antiplatelet. Patients with unstable angina, stent placement, or heart attack are given antiplatelets.

Nursing Process for the Patient with Angina

ASSESSMENT/DATA COLLECTION. Assess the patient's description of pain. Note the type, location, and pain radiation to other areas of the body. Note skin color and temperature. Note any factors that may make the pain worse or better. This will provide information to determine improvement or lack of improvement in pain. Ask how long the patient has had angina, triggering activities, and how the pain has been relieved in the past. Note the presence of dyspnea, labored respirations, diaphoresis, or nausea. Obtain vital signs, blood pressure, apical pulse, respiration, and oxygen saturation to provide a baseline of the patient status.

NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION. **Acute pain related to reduced coronary artery blood flow and increased myocardial oxygen needs causing an imbalance between oxygen supply and demand**

EXPECTED OUTCOME: The patient reports an absence of pain.

- Ensure vascular access established. *Intravenous access may be necessary to use to administer drugs for pain relief.*
- Consult physician for pain management.
- Obtain a 12-lead ECG as ordered *to determine ischemia or injury of the myocardium with evaluation of the ST segment.*

- Administer analgesics or aspirin as prescribed *to provide pain relief.*
- Administer oxygen as ordered via nasal cannula *to increase oxygen availability to myocardium.*
- Administer sublingual NTG as ordered. *Notify the physician if pain is unrelieved after three doses of nitroglycerin or as prescribed, or vital signs change.*
- Remain with the patient and reassess the pain in 5 minutes after the administration of medication. *A patient who is experiencing chest pain should never be left alone.*
- *Chest pain unrelieved by nitrates may represent unstable angina or myocardial infarction.*
- Notify physician of ECG changes. *ST segment changes may indicate a myocardial infarction.*
- Offer the patient assurance and emotional support *to decrease anxiety. Emotional support is important because patients and their families are often afraid that the patient may die.*
- Promote rest and decrease anxiety for the patient with chest pain.
- Document patient data in the medical record *to communicate patient's problem and outcome.*

Evaluation

Interventions are successful if the patient is pain free.

Myocardial Infarction

A myocardial infarction (MI), commonly known as a heart attack, results in the death of heart muscle. The affected myocardial cells in the heart are permanently destroyed. An MI occurs from a partial or complete blockage of a coronary artery, which decreases the blood supply to the cells of the heart supplied by the blocked coronary artery. The extent of the cardiac damage varies depending on the location and amount of blockage in the coronary artery. This is a potentially devastating condition. The ability of the heart to contract, relax, and propel blood throughout the body requires healthy cardiac muscle. When the patient has an MI, part of the heart muscle no longer functions as it should. Cardiac conduction, blood flow, and function can be dramatically altered by an MI.

Those with MIs are typically men over 40 with atherosclerosis development. Although MIs can occur at any age in men or women, women who smoke and use oral contraceptives are at greater risk for MI.

Pathophysiology

Myocardial infarction does not happen immediately. Ischemic injury evolves over several hours before complete necrosis and infarction take place. The ischemic process affects the subendocardial layer, which is most sensitive to hypoxia. This process leads to depressed myocardial contractility. The body's attempt to compensate for decreased cardiac function triggers the sympathetic nervous system to increase heart rate. The change in heart rate increases myocardial oxygen demand, further depressing the myocardium.

FIGURE 23.5 Myocardial infarction. Areas of ischemia, injury, and necrosis caused by a blockage in the left anterior coronary artery.

Prolonged ischemia can produce severe cellular damage and necrosis of cardiac muscle. Once necrosis takes place, the contractile function of the muscle is permanently lost. The heart has a zone of ischemia and injury around the necrotic area (Fig. 23.5). The zone of injury is next to the necrotic area and is susceptible to becoming necrosed. If treatment is initiated within the first hour of symptoms of the MI, the area of damage can be minimized. Around the injury zone is an area of ischemia and viable tissue. If the heart responds to treatment, this area can rebuild and maintain collateral circulation. If prolonged ischemia takes place, the size of the infarction can be quite large. The size of the infarction depends on how quickly the blood supply from the blocked artery can be restored.

The area that is affected by an MI depends on the coronary artery involved and the extent of occlusive coronary disease (Fig. 23.6). Being familiar with the anatomy of the heart and the area of the MI helps the nurse anticipate dysrhythmias, conduction disturbances, and heart failure, which are the major complications of MIs (Table 23.4).

The anterior interventricular branch of the left coronary artery is the area that feeds the anterior wall of the heart, which also includes most of the left ventricle. An occlusion in this area causes an anterior wall MI. When the left ventricle is affected, there can be severe loss of left ventricular function, leading to severe changes in the hemodynamic status of the patient.

The right coronary artery (RCA) feeds the inferior wall and parts of the atrioventricular node and the sinoatrial node. An occlusion of the RCA leads to an inferior MI and abnormalities in impulse formation and conduction. Serious dysrhythmias can occur early in an inferior MI that may be life threatening.

The left circumflex coronary artery feeds the lateral wall of the heart and part of the posterior wall of the heart. A lesion in the circumflex leads to a lateral wall infarction of the left ventricle.

Signs and Symptoms

Chest pain is a classic symptom of an MI. The pain begins suddenly and continues without relief with rest or NTG. The pain in the center of the chest is usually described as crushing, viselike, or as if an elephant is standing on the chest. The pain may radiate to the back, one or both arms and shoulders, neck, or jaw. The pain can imitate indigestion or a gallbladder attack with abdominal pain and vomiting. Other classic MI symptoms include shortness of breath, dizziness, nausea, and sweating (Box 23.6 Myocardial Infarction Summary). When listening to lung sounds, crackles or wheezing may be heard. The pulse may be rapid or irregular, and an extra heart sound (referred to as S3 or S4) may be present. The presence of an extra heart sound can mean ventricular failure is imminent.

People often deny or fail to recognize that they are having an MI because they experience atypical MI symptoms or their symptoms are similar to other mild conditions such as

FIGURE 23.6 (A) Coronary arteries, frontal view. (B) Coronary arteries, posterior view.

TABLE 23.4 COMPLICATIONS OF MYOCARDIAL INFARCTION

Complication	Types or Symptoms	Interventions
Dysrhythmias	Premature ventricular contractions, ventricular tachycardia, ventricular fibrillation, heart block	Continuous cardiac monitoring Protocols for treatment of dysrhythmias (see Chapter 25)
Cardiogenic shock	Decreased blood pressure; increased heart rate; diaphoresis; cold, clammy, gray skin	Immediate initiation of treatment to decrease infarct size, control pain and dysrhythmias Thrombolytic therapy Dopamine and dobutamine
Heart failure/pulmonary edema	Dizziness, orthopnea, weight gain, edema, enlarged liver, jugular venous distention, crackles	Correct underlying cause, relieve symptoms, increase cardiac contractility, administer furosemide (Lasix) and digoxin
Emboli	Dependent on location of emboli.	Anticoagulants to prevent; supportive symptom treatment.
Ventricular aneurysms, rupture of muscles or valves of the heart, septal rupture Pseudoaneurysm	Signs of cardiogenic shock, death	Mortality rate high; immediate treatment of MI to limit extent of damage
Pericarditis (inflammation of the heart muscle)	Chest pain, increased with movement, deep inspiration, or cough; pericardial friction rub (fine grating sound)	Relieved when sits up and leans forward Anti-inflammatory drugs (aspirin, indomethacin [Indocin])

LEARNING TIP

To remember what coronary artery occlusion results in a specific MI location, use coast-to-coast U.S. location initials such as those given below. You can personalize the locations with initials of landmarks familiar to you.

Location	Coronary Artery	Resulting MI Location
Los Angeles	Left anterior descending	Anterior
Cedar Point	Circumflex	Posterior
Rhode Island	Right	Inferior

indigestion. Patients have reported that the symptoms of an MI that they experienced were not what they expected. If people expect to have the dramatic heart attack symptoms seen on television (which are usually not the same as those in real life) and they do not, they are likely to wait to seek treatment. People often wait 2 to 24 hours before seeking medical care, yet the first hour after symptom onset is crucial for seeking the newer reperfusion treatments that restore blood flow, minimize tissue damage, and save lives.

Because so few patients arrive at the emergency room quickly enough to benefit from newer treatments, the National Heart, Lung, and Blood Institute (NHLBI) and the American Heart Association launched a major new heart attack education campaign on 9-11-01 called “Act in Time to Heart Attack Signs.” The purpose of this campaign is to educate people on the importance of recognizing heart attack symptoms, working with a physician to create a heart attack survival plan, and calling 911 as soon as symptoms begin. For more information on the Act in Time to

Heart Attack Signs, visit <http://www.nhlbi.nih.gov/actintime/>, <http://www.4woman.gov/faq/h-attack.htm>, and www.americanheart.org.

The National Heart Attack Alert Program (NHAAP) is another public education program developed by the NHLBI. The message of this program is symptom recognition and “60 minutes to treatment” to improve survival and reduce tissue damage. For more information, visit <http://www.nhlbi.nih.gov/about/nhaap>.

Women and Heart Health

Heart disease remains the leading cause of death in women in the United States. American women are six times more likely to die of heart disease than breast cancer. Heart disease kills more women than all cancers combined in the over 65-year-old group. Ethnicity is also a factor among women. African American women are more likely than Caucasian women to develop heart disease. Women tend to have an acute myocardial infarction at an older age than men. Women also have a higher mortality rate and are more likely to have complications such as ventricular fibrillation and heart failure than men.

Women often have classic chest pain but they are also likely to have other symptoms as well that men do not typically have. Research is focusing on understanding women and cardiac disease. Atypical symptoms reported by women may include extreme fatigue, epigastric pain, jaw pain, indigestion, nausea and vomiting, dyspnea, shortness of breath, or cramping in the chest. A high percentage of women (more than 50%) noted prodromal symptoms a month before an acute MI. These symptoms include unusual fatigue, sleep disturbances, and shortness of breath. Less than 30% complained of chest discomfort. Delay in seeking care has also been identified in women. Women also often do not associate their symptoms with a heart attack because they believe it is a male disease. Women with atypical symptoms usually

Box 23.6

Myocardial Infarction Summary

Signs and Symptoms

Classic

Crushing, viselike chest pain with radiation to arm, shoulder, neck, jaw, or back
Shortness of breath
Dizziness
Nausea
Sweating

Atypical

Absence of chest pain
Fatigue
Cramping in chest
Anxiety
Feeling of impending doom
Falling

Symptoms More Common in Women

Epigastric or abdominal pain
Chest discomfort, pressure, burning.
Arm, shoulder, neck, jaw, or back pain.
Discomfort/pain between shoulder blades
Shortness of breath
Fatigue
Indigestion or gas pain
Nausea or vomiting

Diagnostic Tests

ECG
CBC
Serum cardiac troponin I or T
Serum myoglobin
Serum CK-MB
Serum magnesium and potassium
Vital signs, oxygen saturation, intake and output

Therapeutic Interventions

Medications
Oxygen
Fab Four cardiac medications— aspirin, statin, ACEI, beta blocker
Platelet aggregation inhibitor (Plavix)
Morphine sulfate
Thrombolytics
Anticoagulants
Antidysrhythmics
Nitrates
Vasodilators
Fluid restriction
Low-sodium diet advanced to diet as tolerated; no caffeine
Bedrest with bedside commode/bathroom privileges
Daily weights
Cardiac rehabilitation
Percutaneous coronary interventions
Intracoronary stents
Myocardial revascularization—CABG

Complications

Dysrhythmias
Heart failure
Cardiogenic shock
Valvular insufficiency

Possible Nursing Diagnoses

Acute pain
Anxiety
Decreased cardiac output
Deficient knowledge

delay treatment, and when treated have less aggressive management which leads to increased mortality.

Gerontological Implications

With age the heart has decreased elasticity and decreased ability to respond to changes in pressure. This causes increases in the resistance to its pumping action and therefore increases the workload of the myocardium to perfuse the body. Elderly patients should be taught never to neglect symptoms of shortness of breath, fatigue, fast or slow heartbeats, or chest discomfort. Some myocardial infarctions occur without the presence of pain. This is referred to as a silent MI and occurs most often in the older adult. It may also occur in those with diabetes regardless of age. When pain is not present, the only symptom may be a sudden onset of shortness of breath or fainting, restlessness, or a fall experienced by the patient. Atypical presentation of MI symptoms is normal in the elderly patient, especially in those older than age 85. Because the older adult has had more time to develop collateral circulation than younger people, they often do not have as many complications with an MI.

In the elderly, revascularization therapies such as angioplasty and bypass surgery seem to be superior in improving quality of life without increasing mortality risk. Statin therapy has also shown to reduce mortality in those over 80 years of age.

Diagnostic Tests

Patients with a strong familial history of MI should be considered at risk until an MI is ruled out. The most useful indicators of an MI are patient history, ECG, and serum cardiac troponin I or T, myoglobin, and CK-MB levels. (See Chapter 20.) Magnesium levels are also checked, especially for those on diuretic therapy. Before thrombolytic or heparin therapy, prothrombin time (PT) and partial thromboplastin time (PTT) are determined. The ECG usually shows the area that has infarcted, as well as the ischemic areas of the heart. Myocardial damage is seen as ST-segment elevation, the presence of a Q wave, or T-wave abnormalities (Fig. 23.7). Serial ECGs are done to monitor changes indicating damage or ischemia.

Therapeutic Interventions

Treatment should be sought within 5 minutes for any unrelieved chest pain. The American Heart Association recommends chewing one uncoated adult aspirin at the onset of chest pain. Delays in seeking care can limit treatment options and result in more cardiac damage (Box 23.7 Preventing Delays in Myocardial Infarction Treatment). Patients need to be educated that “time is muscle.” As time passes during an MI, more muscle is lost. Patients should not drive themselves to the hospital if they are having chest pain. Emergency medical care (911 or local emergency services number) should be called.

The presence of chest pain indicates a lack of oxygen to the myocardium. Patients reporting chest pain are treated as if they have an MI until it has been proven otherwise

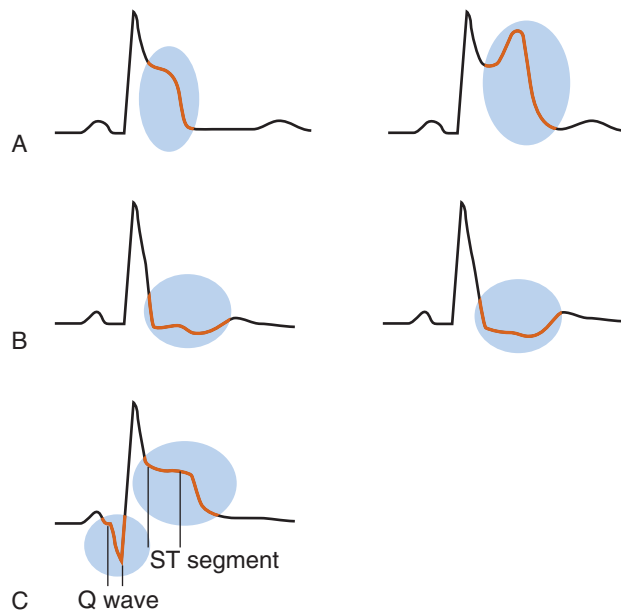

FIGURE 23.7 ECG changes during myocardial infarction. (A) Injury: ST-segment elevation. (B) Ischemia: ST-segment inversion. (C) Necrosis: large Q wave and ST-segment elevation.

through testing. Treatment is given to increase oxygen supply to the heart muscle.

OXYGEN. Oxygen is administered immediately, usually at 2 L per minute via nasal cannula. Oxygen therapy may be limited to the first 6 hours in stable patients. Too much oxygen may lead to systemic vasoconstriction, which may increase myocardial workload. Arterial blood gases (ABGs) are drawn to determine the patient’s oxygen needs. Oxygen saturation should be monitored and kept above 94%. Oxygen can be administered via mask if higher concentrations are needed. Mechanical ventilation can be provided when indicated by ABGs.

MEDICATION. Table 23.5 summarizes pharmacological treatment of myocardial infarction. The Fab Four cardiac

Box 23.7

Preventing Delays in Myocardial Infarction Treatment

- Understand symptoms and “time is muscle” principle.
- Develop an action plan and rehearse it.
- Understand normal emotional responses of anxiety, denial, or embarrassment.
- Educate family to follow action plan.
- Establish protocols in workplaces for employees experiencing myocardial infarction.
- Establish emergency room policies that reduce delays, such as having equipment and medication readily available.

TABLE 23.5 PHARMACOLOGICAL TREATMENT FOR MYOCARDIAL INFARCTION

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Antiplatelets				
Inhibit platelet activation, adhesion, or procoagulant activity	Aspirin	PO Chew if MI symptoms.	Increased risk of bleeding including hemorrhagic stroke	Should be given as soon as ACS or MI is suspected. Enteric coated may be given for daily dosing.
	Ticlopidine (Ticlid)	PO	May cause diarrhea and other gastrointestinal distress.	Teach patient to take drug with food. Also report any unusually bleeding or bruising.
	Clopidogrel (Plavix)	PO	May cause diarrhea and other gastrointestinal distress.	Teach patient to take drug with food. Also report any unusually bleeding or bruising.
Analgesics				
Opioids that bind with opioid receptors in the central nervous system	Morphine sulfate	IV push	Use cautiously in patients with COPD. May cause respiratory depression, hypotension, and bradycardia. May cause constipation.	Reduces preload and afterload. Decreases anxiety. Slows respiratory rate. Decreases myocardial oxygen demand. Monitor RR, HR, and BP prior to and after administration. Monitor vital signs for 10 minutes after IV administration.
Nitrates: Vasodilators				
Relax smooth muscle in blood vessel walls. Produce vasodilation, which relieves cardiac workload. Preload and afterload reduction. Reduce oxygen consumption of myocardium.	Nitroglycerin (Nitro-stat, Nitro Quick)	Sublingual	Hypotension Headache Contraindicated in head trauma, hypotension, uncorrected hypovolemia	Assess the AP and BP before and after administration. Document onset, type, radiation, location, and duration of chest pain. Place tablet in buccal pouch to lessen burning sensation under the tongue. Tablets should be replaced every 3 to 4 months. Check expiration date.
	Nitrolingual translingual spray	Sublingual spray	Hypotension Headache Contraindicated in head trauma, hypotension, uncorrected hypovolemia	Do not shake aerosol canister prior to administration of lingual spray.
	Isosorbide dinitrate (Isordil, Iso-Bid)	Sublingually PO	Hypotension Transient flushing of face and neck Dizziness if standing Orthostatic hypotension Nausea Vomiting Restlessness	Tolerance may occur with repeated prolonged therapy. High dose may produce severe headache. Elderly may be more sensitive to drug dosing. Instruct the patient to rise slowly from a lying position. Avoid alcohol during therapy. Alcohol intensifies the drug's hypotensive effect.
	Isosorbide mononitrate (Imdur)	PO	Hypotension Transient flushing of face and neck Dizziness if standing Orthostatic hypotension Nausea Vomiting Restlessness	Tolerance may occur with repeated prolonged therapy. High dose may produce severe headache. Elderly may be more sensitive to drug dosing. Instruct the patient to rise slowly from a lying position.

(Continued on following page)

TABLE 23.5 PHARMACOLOGICAL TREATMENT FOR MYOCARDIAL INFARCTION (Continued)

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
	Nitroglycerin patch (Nitro-Dur, Nitrek)	Transdermal	Hypotension Transient flushing of face and neck Dizziness if standing Orthostatic hypotension Nausea Vomiting Restlessness	Caution against using one brand of drug to another. Avoid alcohol during therapy. Alcohol intensifies the drug's hypotensive effect. Remove patch before defibrillation. Rotate application sites. Apply the patch to a clean, dry, hairless area. Tolerance may develop.
Thrombolytics				
Dissolve blood clots in blood vessels or in catheters in the body such as dialysis catheters.	alteplase (Activase, tissue plasminogen activator [t-PA]), anistreplase (Eminase), reteplase (Retavase), streptokinase (Streptase)	IV	Bleeding, stroke, dysrhythmias may occur when blood flow is reestablished.	Thrombolytic drugs are most effective when administered within 6 hours of coronary event. Indicated when a patient has unrelieved chest pain for 30 minutes with nitrates, and ischemia on ECG. Prior to use INR, aPTT, platelet count and fibrinogen levels should be checked. Avoid venipunctures after administration.
Anticoagulants				
Heparin inactivates clotting factors IX, X, XI, and XII. It inhibits the conversion of prothrombin to thrombin to prevent thrombus formation.	Heparin sodium: dose regulated by activated partial thromboplastin time (aPTT). aPTT should be 1.5 to 2.5 times the control or baseline value. Normal control is 25 to 35 seconds. enoxaparin (Lovenox):	IV, SC		Contraindicated in peptic ulcer disease, blood dyscrasias, recent eye surgery. Low molecular weight heparins cannot be used unit for unit as regular heparin. They can be used to prevent embolus and may be used in out patient settings. Platelets counts should be monitored.
Low doses of heparin are given to prevent DVT and pulmonary embolism.	aPTT is not necessary for low molecular weight heparins.			
Beta blockers				
Decrease heart rate, blood pressure, cardiac output, and suppress renin activity. They decrease myocardial contractility and oxygen demand. Decrease the risk of sudden death and may reduce ventricular remodeling.	atenolol (Tenormin), metoprolol (Lopressor, Toprol XL), propranolol (Inderal)	IV or PO	Diminished sexual activity, fatigue, weakness, difficulty sleeping, bradycardia, depression, hypotension, nasal congestion, nausea.	Take the apical pulse and blood pressure immediately prior to administration. If pulse is less than 60 beats per minute, or blood pressure less than systolic 90 mm Hg, withhold the medication and notify the physician. Use cautiously in patients with diabetes. Beta blockers are contraindicated in patients with asthma, heart block, bradycardia, or pulmonary conditions with bronchoconstriction. Do not stop abruptly.

Medication Class/Action	Examples	Route	Side Effects	Nursing Implications
Angiotensin-converting enzyme inhibitors Block the production of Angiotension II, a potent vasoconstrictor. Reduce peripheral arterial resistance, pulmonary capillary wedge pressure. Improve cardiac output and exercise tolerance.	captopril (Capoten), lisinopril (Prinivil, Zestril), ramipril (Altace)	PO	Persistent cough may develop in 20% of patients. Hyperkalemia may develop in patients with diabetes mellitus or renal impairment.	Angioedema, swelling of the face and lips may occur. Agranulocytosis and neutropenia may be noted in patients with concurrent collagen vascular disease including scleroderma and systemic lupus erythematosus, and impaired renal function. Obtain baseline blood pressure before each dose. Give 1 hour before meals; food delays absorption.
Statins See Table 23.1				
Antidysrhythmics bolus or infusion Inhibit ventricular arrhythmias. Depolarization, automaticity, and excitability of the ventricle during diastole is decreased by direct action.	lidocaine (Xylocaine)	IV	High doses can produce cardiac depression. Potential exists for malignant hyperthermia. CNS toxicity may occur. Seizures, respiratory depression, and somnolence may occur.	Obtain baseline vital signs, ECG, and serum electrolytes. Elderly more sensitive to side effects. Therapeutic serum level is 1.5 to 6 µg/mL. Monitor level of consciousness. Drowsiness may signal high lidocaine blood levels.
Additional Medications as needed:				
Antiemetics	Specific for drugs given	PO/IV	May be drug specific.	Controls nausea/vomiting, anxiety, gastric upset, and constipation.
Anxiolytics				
Antacids				
Stool softeners				

drugs—antiplatelets, statins, ACEIs, and beta blockers—should be considered for use as discussed in the section on angina to improve patient outcomes.

Analgesics. Analgesics are given for relief of chest pain. Morphine sulfate is the most commonly used narcotic for several reasons. It is usually given in increments of 2 to 8 mg intravenously every 5 to 15 minutes until pain is relieved. The patients should be monitored for hypotension, respiratory depression, oversedation, and morphine sensitivity. In addition to pain relief, morphine helps decrease anxiety, opens bronchioles, and reduces preload and afterload, which can help increase blood supply and oxygen to the myocardium.

Vasodilators. NTG sublingually, topically, or by intravenous (IV) drip can be administered for vasodilation to supply more blood to the myocardium to reduce pain and the workload of the heart. In the acute phase, the IV route is usually used. Nitrates should not be given if the patient has a systolic blood pressure less than 90 mm Hg or 30 mm Hg or more below baseline, severe bradycardia less than 50 beats per minute, or if the patient has taken a phosphodiesterase inhibitor for erectile dysfunction. Catastrophic hypotension may result.

Thrombolytics. Thrombolytic therapy is used to dissolve a blood clot that is occluding a coronary artery. Many communities allow initiation of thrombolytic therapy by paramedics in the field. Studies have revealed a decreased incidence of mortality and morbidity and less extensive tissue damage when thrombolytic treatment is used. Thrombolytic therapy must be started within a specified time range from the onset of symptoms, usually within 1 to 6 hours, before necrosis results. Aim for a “door to needle” interval of under 30 minutes for patients who are candidates of thrombolytic therapy.

Glycoprotein 11b/111a inhibitors (abciximab, tirofiban) may be used as an adjunct to thrombolysis or PTCA in patients with acute myocardial infarction. These drugs work by inhibiting platelet aggregation.

ACTIVITY. Initially patients are kept on bedrest with a bedside commode for bowel movements to decrease myocardial oxygen demand. Then activity is advanced gradually as tolerated.

GLUCOSE CONTROL. Recent research indicates that maintaining blood glucose levels within a range of 70 to 100 mg/dL significantly reduces mortality for critically ill patients. Protocols to regulate blood sugar are determined by

the institution. Insulin infusions may be given until the patient's blood glucose is within the targeted range.

DIET AND WEIGHT LOSS. During the acute phase of an MI, small, easily digested meals are served. Caffeine is restricted because it increases heart rate and causes vasoconstriction. Fluids may be restricted if the patient is in heart failure as well. Initially a low-sodium clear liquid diet may be ordered. Then a low-fat, low-cholesterol, and low-sodium diet may be ordered. The number of grams of sodium is prescribed by the physician. If the patient is obese, weight loss is desirable to reduce cardiac workload. A dietitian can work with the patient and family to devise a weight-loss diet for the patient.

SMOKING. Smoking should be avoided, and patients are instructed on the hazards of continuing to smoke. Referral to a tobacco cessation program can be made. The nurse needs to work with patients to help them understand and accept lifestyle changes.

VENTRICULAR ANEURYSM REPAIR. Ventricular aneurysms may occur after an MI. Indications that a ventricular aneurysm requires surgery include persistent angina, symptoms of heart failure, large aneurysms impeding the function of the heart, left ventricular failure, or tachy-dysrhythmias. Once the patient is on CPB, an incision is made exposing the heart and then the aneurysm is resected (cut out), leaving a fibrous border (Fig. 23.8). The ventricle is wiped clean and irrigated to ensure all thrombi are removed. The opening is then closed with sutures or patched with a graft. Air that entered the ventricle while it was open is aspirated, and the surgery continues as described in the general surgery procedure section.

Nursing Process for the Patient Experiencing Myocardial Infarction

ASSESSMENT/DATA COLLECTION. A thorough history is obtained to identify risk factors that may contribute to a myocardial infarction. All patients admitted with chest pain are treated as having a possible MI until it has been ruled out. Continuous cardiac monitoring, serial ECGs, and laboratory values help identify life-threatening dysrhythmias and determine the degree of cardiac damage. Controlling chest pain immediately helps diminish anxiety and the negative physiological effects pain has on the body.

NURSING DIAGNOSIS, PLANNING, IMPLEMENTATION, AND EVALUATION. See Box 23.8 Nursing Care Plan for the Patient with Myocardial Infarction.

Patient Education

Teaching about the therapeutic regimen includes information about the disease, medications, diet, activity, and rehabilitation needs that may require lifestyle changes. Diet, stress reduction, a regular exercise program, cessation of smoking if necessary, and following a medication schedule require extensive patient and family teaching. This disease can affect all aspects of a patient's lifestyle. Issues about

- 1: Aneurysm is cut and closed.
- 2: Patch inserted inside incision, then closed.

FIGURE 23.8 Ventricular aneurysm repair.

family and job roles and sexual activities need to be addressed. Patients need time to understand information that has been presented and should be encouraged to express any questions, needs, or fears.

Cardiac Rehabilitation and Exercise

Cardiac rehabilitation is begun when the patient's acute symptoms are relieved. The purpose of cardiac rehabilitation is to improve cardiac function and assist the patient to return to as normal a life as possible. Cardiac rehabilitation protocols are used in many institutions. The first two phases of rehabilitation occur in the hospital. Activities for each hospital day, such as types and amounts of self-care and activity, are specified in protocols. The third phase begins with hospital discharge and focuses on returning to prior levels of activity and function. Outpatient programs are often ordered for patients in this phase. In this phase, patients are encouraged to maintain optimum physical fitness and to continue healthy lifestyles that include exercise and losing weight to maintain an ideal body weight.

(Text continued on page 430)

Box 23.8 NURSING CARE PLAN for the Patient with Myocardial Infarction

Nursing Diagnosis: Acute pain related to decreased coronary blood flow causing myocardial ischemia

Expected Outcomes Patient will exhibit signs of decreased pain. Patient will exhibit signs of relaxation.

Evaluation of Outcomes Does patient state pain is reduced?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Monitor location, duration, intensity, and radiation of pain; use a scale of 0 to 10. • Monitor blood pressure, pulse, and respiration. • Obtain ECG as ordered. • Administer oxygen as ordered. 	<p>Identifies type and severity of pain.</p> <p>Vital signs may elevate with episodes of pain.</p> <p>Identifies location of infarction or ischemia.</p> <p>Helps prevent hypoxia.</p>	<p>What is pain level, location, duration, intensity, and radiation?</p> <p>Are vital signs within normal limits?</p> <p>Is ECG normal?</p> <p>Are ABGs within normal limits? Is oxygen saturation greater than 90%?</p> <p>Does patient report pain?</p>
<ul style="list-style-type: none"> • Instruct patient to report pain at first onset. • Instruct patient to rest during pain. • Remain with patient during chest pain until it is relieved. • Assist with alternative pain relief measures: related to positioning, diversional activities, relaxation techniques. • Medicate as ordered. 	<p>Helps control pain quickly to prevent further ischemia.</p> <p>Activity increases oxygen demand and can increase chest pain.</p> <p>Provides comfort and reassurance to decrease anxiety and fear.</p> <p>These measures help decrease painful stimuli, allowing the patient to focus on other things.</p> <p>Helps eliminate pain.</p>	<p>Does patient remain quiet and relaxed?</p> <p>Are anxiety and fear decreased?</p> <p>Does patient express relief and decreased stress?</p> <p>Is pain relieved?</p>
Geriatric		
<ul style="list-style-type: none"> • Monitor and ensure that older patient's pain is relieved. 	<p>Pain is not an expected part of the aging process as many believe.</p>	<p>Does patient report pain is relieved?</p>

Nursing Diagnosis: Decreased cardiac output related to ischemia or infarction, changes in heart rate and rhythm, and decreased contractility

Expected Outcomes Patient will maintain adequate cardiac output and tissue perfusion. Patient will exhibit signs of improved cardiac output and tissue perfusion.

Evaluation of Outcomes Does patient have heart rate greater than 60 and less than 100, blood pressure greater than 90/60 and less than 140/90, and urine output greater than 30 mL/hr?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Monitor blood pressure, heart rate, and urine output. • Listen to lung sounds. • Monitor peripheral circulation, pulses, capillary refill, edema, color, and temperature. • Monitor ECG. 	<p>Indirect indicators of cardiac output.</p> <p>Crackles indicate heart failure.</p> <p>Indicators of adequate tissue perfusion.</p> <p>Identifies dysrhythmias.</p>	<p>Are indicators within normal limits?</p> <p>Are lungs clear?</p> <p>Does patient have strong peripheral pulses, capillary refill less than 3 seconds, no edema, warm skin, pink nailbeds?</p> <p>Is patient's ECG within normal limits?</p>

(Continued on following page)

Box 23.8 NURSING CARE PLAN for the Patient with Myocardial Infarction (Continued)

Interventions

- Administer medications as ordered by physician, such as vasodilators, beta blockers, calcium channel blockers, and cardiac glycosides.
- Promote and provide for adequate rest, quiet environment, bedrest; place in semi-Fowler's position.

Rationale

Helps improve contractility, cardiac output, and tissue perfusion.

Decreases cardiac workload and stress and allows for improved breathing.

Evaluation

Does patient show signs of improved contractility, increased cardiac output, and tissue perfusion?

Is patient relaxed?

Geriatric

- Observe for atypical pain such as jaw pain or no pain with dyspnea or fatigue.
- Observe patient carefully for side effects of medications.

In acute MI older adults may have not had typical chest pain or have a silent MI.

Older patients are more likely to have medication toxicity owing to reduced renal and hepatic function.

Does patient have atypical symptoms of MI?

Does patient exhibit toxic side effects of medications?

Nursing Diagnosis: Fear related to threat of death, changes in lifestyle, chest pain, and procedures

Expected Outcome Patient verbalizes reduced fear. Patient demonstrates effective coping mechanisms.

Evaluation of Outcomes Does patient verbalize reduced fear?

Interventions

- Assess level of fear and note non-verbal communication.
- Ask the patient's usual coping pattern.
- Orient the patient and family to surroundings and equipment, oxygen, cardiac monitoring, IVs, and explain procedures.
- Assure patient he/she will be closely monitored.
- Allow patient to verbalize fear of dying.
- Provide diversional materials such as newspapers, music, and television.
- Offer family support.

Rationale

Controlling anxiety will reduce sympathetic activity that may intensify condition.

This allows building on patient's strengths.

Information may promote trust and reduce emotional stress.

Assurance of detection for prompt treatment of any complications will reduce fear.

Ventilation helps identify and reduce fear.

Diversion can be relaxing and prevent feelings of isolation.

Significant others often ignore their own needs, experience anxiety and need support, including ongoing information and explanations, being allowed to stay with the patient, and being involved in the patient's care. Nurses need to help spouses or significant others meet their own needs, so that they are better able to support the patient.

Evaluation

Does patient report fear or have signs of being fearful?

What are patient's coping techniques?

Does patient state understanding of environment and equipment?

Does patient state less fear due to continuous monitoring?

Is patient able to verbalize fears?

Does patient report that use of diversional activities reduces fear?

Does family verbalize ability to offer support to patient without anxiety?

Geriatric

Provide protective, safe environment with consistent caregivers	Older adults adapt to change with more difficulty during illness than younger adults	Is continuity of care provided? Does patient report less fear?
---	--	---

Nursing Diagnosis: Activity intolerance related to imbalance between oxygen supply and demand, weakness, and fatigue.

Expected Outcomes Patient tolerates progressive activity as evidenced by heart rate, blood pressure, pulse oximetry, and respiratory rate within normal limits.

Evaluation of Outcomes Is patient's heart rate, blood pressure, pulse oximetry, and respiratory rate within normal limits with progressive activity?

Interventions

Obtain patient's vital signs before activity.

Observe patient during and after activity and document abnormal responses to activity which include: increased heart rate over 120 beats per minute or 20 beats over resting heart rate, increased blood pressure over 20 mm Hg systolic during activity, chest pain, dizziness, skin color changes, diaphoresis, dyspnea, dysrhythmias, excessive fatigue, and ST segment changes on ECG.

Position patient for comfort and ease in breathing.

Maintain progression of activities as ordered by physician or cardiac rehabilitation program.

Stage One activities—ADLs, dangle at bedside for 15 minutes, use commode with assistance

Stage Two activities—Out of bed to chair for 30 to 60 minutes, partial bath, ROM.

Slow the pace of care.

Refer patient to cardiac rehabilitation as able.

Encourage families to allow patient to be independent in activities.

Rationale

Identifies baseline data comparison with activity.

Observation allows detection of abnormal responses to stop activity.

Semi-Fowler's position is usually preferred by patients having respiratory distress. When patients are sitting upright in bed, supporting their arms on pillows reduces the workload of the heart by eliminating the force of gravity on unsupported arms.

The patient should have increasing activity to condition the myocardium.

Geriatric

Allow patient extra time to complete activity to reduce cardiac demand and fatigue.

Older adults with CAD in exercise programs benefit comparably with younger persons in similar situations.

Families may believe being sedentary is helpful to the patient.

Evaluation

What are vital signs?

Are vital signs within normal limits?

Is activity tolerated without symptoms?

Is patient able to breathe easily?

Is patient able to progress activity?

Is patient able to complete care without symptoms or fatigue?

Does patient participate in cardiac rehab?

Do families encourage patient to be as active as able?

CRITICAL THINKING

Mrs. Sims

■ Mrs. Sims, age 43, is admitted to the intensive care unit with a diagnosis of atypical chest pain. She has a history of midsternal chest cramping. The pain is radiating to her left and right shoulders and down her left arm. Her pain increases with activity and decreases with rest. She smokes one and a half packs of cigarettes per day and is 50 pounds overweight. The cardiac monitor shows normal sinus rhythm without dysrhythmias. She has NTG sublingual ordered prn for chest pain.

One hour after admission, Mrs. Sims reports midsternal chest pain radiating to left neck and jaw. The cardiac monitor shows sinus tachycardia with occasional premature ventricular contractions (PVCs). Her blood pressure is 100/70, respirations are 20 and unlabored, and skin is warm and dry.

1. What actions should you take?
2. What is happening to Mrs. Sims?
3. How is angina differentiated from an MI?
4. What are four indicators of an MI?
5. What medical interventions can be used for an MI?
6. What education is indicated for Mrs. Sims?

Suggested answers at end of chapter.

collateral circulation has developed and can supply some blood to the occluded area. Symptoms depend on the artery occluded, the tissue supplied by that artery, and whether collateral circulation is present.

There are six clinical signs of acute arterial occlusion, known as the six *Ps*: pain, pallor, pulselessness, paresthesia (numbness), paralysis, and poikilothermia (temperature). The patient experiences pain, numbness, and decreased movement in the extremity, which is pale and without pulses distal to the occlusion. The extremity feels cold because blood normally provides warmth. If treatment is not initiated immediately, ischemia occurs and can progress to tissue necrosis and gangrene development within hours.

Therapeutic Interventions

Early treatment is necessary to protect and save the affected limb. Anticoagulant therapy is started immediately. Intravenous heparin is the treatment of choice to prevent further clotting. Heparin has no effect on existing clots. An initial IV bolus of heparin, usually 5000 IU, is given. An IV infusion is then started as ordered. The patient remains on heparin therapy for several days. Daily PTTs are monitored to maintain therapeutic heparin levels. After 3 to 7 days, warfarin (Coumadin) is added. Warfarin, an oral anticoagulant, takes 3 to 5 days to reach therapeutic levels. The heparin is continued until a therapeutic warfarin level is reached. To monitor warfarin's effects, international normalized ratios (INRs) and PTs are done daily, and adjustments in warfarin doses are made based on the results.

For patients with severe occlusions, especially if the risk of limb loss is imminent, surgery or thrombolytic agents are used to save the extremity. During an emergency embolectomy or thrombectomy, the artery is cut open, the emboli or thrombus is removed, and the vessel is sutured closed. Thrombolytic agents dissolve the thrombus or embolus.

Peripheral Arterial Disease

Peripheral arterial disease (PAD) is a disorder of the arterial circulation usually caused by chronic, progressive narrowing of arterial vessels that lead to obstruction or occlusion. PAD usually affects the lower extremities. Peripheral arterial disease is sometimes referred to as lower extremity arterial disease (LEAD). Atherosclerosis is the leading cause of occlusive disease. Peripheral arterial disease can be described as organic or functional. Organic disease is caused by structural changes from plaque or inflammation in the blood vessels. Functional disease is a short-term localized spasm in the blood vessel as noted in Raynaud's disease. It is estimated that eight to 12 million people have PAD.

Pathophysiology

The purpose of the arterial system is to delivery oxygen-rich blood to the vascular beds. Anything that impedes this flow causes an imbalance in supply and demand for oxygen. Decreased nutrition, cellular waste accumulation, and the development of ischemia occur at the area distal to the

PERIPHERAL VASCULAR SYSTEM

Peripheral vascular disease (PVD) may be either arterial or venous in origin. PVD is very common in people who are older or diabetic. It is important for the nurse to understand if the origin of the problem is arterial or venous to prevent serious complications from occurring.

Arterial Thrombosis and Embolism

Pathophysiology

Acute arterial occlusions are often sudden and dramatic. Occlusions are most common in the lower extremity; but may occur in the upper extremity as well. A thrombus (blood clot) adheres to the vessel wall. Acute arterial thrombi occur where there is injury to an arterial wall, sluggish flow, or plaque formation secondary to atherosclerotic changes. Other causes of arterial thrombosis are polycythemia, dehydration, and repeated arterial needle sticks. If a thrombus breaks off and travels, it becomes an **embolism** that occludes an arterial vessel that is too small to allow it to pass. Some of the causes of an arterial embolism are dysrhythmias, prosthetic heart valves, and rheumatic heart disease.

Signs and Symptoms

Usually there is an abrupt onset of symptoms with acute arterial occlusion. If a patient also has chronic arterial insufficiency, the symptoms may not occur as rapidly because

CRITICAL THINKING

Mrs. May

■ Mrs. May is admitted with severe rheumatoid arthritis, which has left her immobile for 7 months. She is returning to her room following a whirlpool treatment when she suddenly reports severe pain in her left groin.

1. What is your first action?
2. After assessing Mrs. May, what action should be taken next?
3. What are the possible causes of these sudden symptoms?
4. How would you document Mrs. May's symptoms?
5. What would the immediate interventions be?
6. What medical interventions would you anticipate?
7. What surgical procedure may need to be done if the risk of losing the limb is imminent?

Suggested answers at end of chapter.

obstruction. With the increased debris and sluggish flow, thrombosis and embolism become major problems.

The body has several mechanisms to attempt to compensate for reduced blood flow, including peripheral vasodilation, anaerobic metabolism, and development of collateral circulation. However, these mechanisms are not intended to meet the ongoing blood supply needs of the body. It takes time for collateral circulation to develop, blood vessels eventually reach their limit of dilation, and anaerobic metabolism is only a very short-term compensatory mechanism. Eventually this lack of blood supply produces signs of ischemia, and if not corrected, ulceration, gangrene, and necrosis of the extremity occur; amputation of the limb may then become necessary.

Signs and Symptoms

Many people with PAD, especially women, have no symptoms. Symptoms often occur late in the course of PAD when diminished blood flow begins to produce changes in the extremities that symptoms occur. Pain in the calves of the lower extremities associated with activity or exercise, called **intermittent claudication**, is a common symptom of arterial occlusive disease. When blood supply to the muscles is decreased, the muscles are unable to receive adequate oxygen and ischemia develops. As ischemia increases, the muscle develops a cramping-type pain that usually subsides when the activity is stopped. As PAD progresses, the pain is present even at rest, thus indicating severe arterial occlusion.

Skin color changes are associated with decreased blood supply. The extremity is pale when the leg is elevated. If the leg is in a dependent position, it becomes reddish purple or cyanotic. The extremity is cool to touch even in warm environments. There may be hair loss on the lower calf, ankle, and foot. Other findings include dry, flaky, scaly, pale, or mottled skin. The toenails may be thickened. As occlusion

of the arteries progresses, there are diminished or absent arterial pulses. Pulses should be palpated in both legs. The loss of circulation leads to tissue death and gangrene.

Diagnostic Tests

Noninvasive studies can be used to diagnose occlusive disorders. The ankle-brachial (arm) blood pressure index is used to determine pressures in the upper and lower extremities. Normally, blood pressure readings in the thigh and calf are higher than those in the upper extremities. With the presence of arterial disease, these pressures are lower than the brachial pressure. Normally the ankle pressure is equal to or greater than the brachial pressure. When an occlusion occurs in the lower extremities, the pressures between the upper and lower extremities become unequal. A Doppler ultrasound measures the velocity of the blood flow. Magnetic resonance imaging (MRI) can give definitive images of blood vessels and degrees of arterial closure. Plethysmography and angiography can also be used to evaluate arterial flow in lower extremities (see Chapter 20).

Therapeutic Interventions

Conservative treatment is initiated with mild to moderate occlusive disease. This includes patients who experience pain on activity that ceases with rest. This type of patient usually receives medication for vasodilation and diet management if necessary. Surgical intervention is used for the patient who experiences pain at rest or who has leg ulcers that do not heal. Surgical treatment includes endarterectomy to remove atherosclerotic lesions or grafting to bypass the occluded area. See vascular surgery section later in this chapter.

DIET. To help control atherosclerosis development, the diet should be low fat, low cholesterol, and low calorie if the patient is overweight. Teaching the patient to avoid red meats, fried foods, whole milk, and cheese is important. Avoiding high-cholesterol foods, such as egg yolks, organ meats, animal fats, and shellfish, helps lower lipid levels.

MEDICATIONS. Drug therapy is geared toward the symptoms and causes of the occlusive disease. The same drugs used to decrease cholesterol and lipid levels in atherosclerosis are used with occlusive disease. Vasodilators can be used, but their effectiveness is not the same for all patients. Pentoxifylline (Trental) or cilostazol (Pletal) is used for patients with occlusive disorders who experience intermittent claudication. This drug makes red blood cells more flexible to improve perfusion. The major side effect is gastrointestinal upset, so it should be taken with meals. Thrombolytic therapy is used when an occlusion is caused by a thrombus or an embolus.

INVASIVE THERAPIES. Percutaneous transluminal angioplasty (PTA) can be used to dilate a narrowed peripheral vessel. It is similar to PTCA, which was discussed earlier. Complications that can occur with this procedure are a ruptured artery as a result of the stretching caused by the balloon and clot formation. Peripheral atherectomy is

another invasive procedure used to remove plaque from atherosclerotic arteries. Intravascular stents can also be used to maintain patency of the artery. After stent placement, patients are given platelet aggregation inhibitors.

Raynaud's Disease

A vasoconstrictive response causing ischemia from exposure to cold and stress is known as **Raynaud's disease**. It occurs more often in women who live in cold climates. Raynaud's disease primarily affects the hands but can also occur in the feet, ears, or nose. To be diagnosed with Raynaud's disease, the patient must experience intermittent attacks of ischemia for at least 2 years.

Pathophysiology

Raynaud's disease is characterized by spasms of small arteries in the digits. These spasms prevent arterial blood from perfusing the fingertips and sometimes the toes. The spasms can occur unilaterally and in one or two digits, but most often they occur bilaterally and in all digits. Raynaud's disease may be seen with collagen diseases such as rheumatoid arthritis, scleroderma, and systemic lupus erythematosus.

Signs and Symptoms

The hands, when exposed to cold, exhibit vascular spasms and a marked decrease in blood flow to the tissues. The resulting effect in the tissues is ischemic pain. After several minutes of ischemia, hyperemia occurs. Hyperemia is intense reddening of the hands from dilation of all the vessels of the hands. Pain becomes more intense at this time. Patients with Raynaud's disease go through various phases which include blanching of the skin, pain, and reddening of the skin. This disease can progress over time; the vessels remain constricted and the severe decrease in blood flow can lead to fingers becoming gangrenous and necrotic.

Therapeutic Interventions

Conservative treatment is attempted first. The patient is instructed to keep the hands warm. Gloves should be worn when going outside, cleaning a refrigerator, or preparing cold foods. Patients are instructed in the importance of protecting the hands from injury and avoiding things that contribute to vasoconstriction, such as smoking, alcohol, and caffeine. Reducing stress levels can also help prevent vasoconstriction. Immersing the hands in warm water may decrease the vasospasm. Vasodilators are sometimes prescribed to help the patient avoid peripheral vasoconstriction. Low doses of nifedipine or long-acting nitrates can be used.

To treat Raynaud's disease surgically, the sympathetic reflex must be blocked. This is accomplished by interrupting the sympathetic nerve impulses from the spinal cord to the hand, which is known as sympathectomy.

Nursing Management

Education is the primary goal for patients with Raynaud's disease. Teaching the patient to protect the hands is very important. Stressing the use of gloves in cold climates, reducing vasoconstrictive activity, and decreasing stress levels helps reduce the number and severity of attacks.

Thromboangiitis Obliterans (Buerger's Disease)

Buerger's disease is a recurring inflammation of small and medium arteries and veins of the lower extremities. The disease is usually the result of occlusion of the vessels by thrombus formation. The cause is unknown, but heavy cigarette smoking is a major contributing factor. Some studies indicate an autoimmune response to tobacco products as a possible cause. The disorder is more prevalent in young men between the ages of 25 and 40 years.

The inflammation and irritation of the vessels contribute to the development of vasospasms. These vasospasms lead to an obstruction in blood flow. The tissues become hypoxic, and the development of ischemic pain can occur. Left untreated, this ischemia can lead to ulceration and gangrene.

Intermittent claudication and other symptoms of occlusive disease are common in patients with Buerger's disease. Other symptoms include numbness or decreased sensation and cool extremities. Lower extremities can be red or cyanotic when in a dependent position, and pulses may be diminished. Depending on the degree of ischemia, ulceration or gangrene may be present.

Because the primary contributing factor is smoking, there is an urgency in helping the patient to cease smoking. The patient must be made aware of the effect smoking has on the body and that the disease will progress and further damage other vessels. Therapy and nursing care for Buerger's disease is the same as those used for other arterial occlusive diseases. The use of calcium channel blockers such as diltiazem (Cardizem) promotes vasodilation and may help with intermittent claudication. Careful inspection of the lower extremities for signs of breakdown is important, so early treatment can begin.

Nursing Process: The Patient with Peripheral Arterial Disorders

ASSESSMENT/DATA COLLECTION. When dealing with patients having arterial occlusive disorders, monitoring peripheral circulation is most important. Careful assessment of pulses, capillary refill, temperature, color, and presence of edema helps identify patients at risk for complications. Absent pulses are reported immediately. Skin that is shiny and hairless points to chronic diminished blood flow to the extremity. Laboratory blood testing is not necessary to test for peripheral arterial disease; but a lipid panel, and serum glucose can identify diabetes which is a significant risk factor for PAD. The presence of any skin lesions and ulcerations is noted.

NURSING DIAGNOSIS, PLANNING, IMPLEMENTATION, AND EVALUATION. See Box 23.9 Nursing Care Plan for the Patient with Peripheral Arterial Occlusive Disorders.

Aneurysms

An **aneurysm** is a bulging, ballooning, or dilation at a weakened point of an artery. The artery diameter is often

Box 23.9 NURSING CARE PLAN for the Patient with Peripheral Arterial Occlusive Disorders

Nursing Diagnosis: Acute pain related to impaired circulation to extremities causing intermittent or continuous pain

Expected Outcomes Patient will report that pain is controlled at acceptable level.

Evaluation of Outcomes Does patient report relief from pain by nonpharmacological or pharmacological methods?

Interventions	Rationale	Evaluation

(Continued on following page)

Box 23.9 NURSING CARE PLAN for the Patient with Peripheral Arterial Occlusive Disorders (*Continued*)

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Check skin for intactness, healed areas, signs of ulceration or infection. 	Chronic arterial occlusion leads to decreased blood flow, resulting in tissue damage and poor wound healing.	Is skin intact?
<ul style="list-style-type: none"> • Place extremities lower than heart, feet on floor in sitting position, head of bed elevated on blocks. 	Dependent position increases blood flow to the legs and feet.	Does patient have adequate tissue perfusion signs?
<ul style="list-style-type: none"> • Avoid bending knees, pillows under knees, prolonged sitting, or crossing legs. 	These activities impede blood flow to extremities.	Does patient exhibit understanding of improving blood flow?
<ul style="list-style-type: none"> • Inspect lower extremities frequently. Clean feet with mild soap; dry carefully. Protect from injury. 	Cleaning prevents trauma to feet, protecting feet from things that can lead to ulcerations.	Is patient free from trauma or breaks in skin of the lower extremities?
<ul style="list-style-type: none"> • Encourage use of well fitting shoes. 	Prevents irritation and tissue breakdown leading to ulcer.	Does patient verbalize shoes fit well?
<ul style="list-style-type: none"> • Refer to progressive activity program. 	Gradual progressive exercise promotes collateral circulation.	Does patient participate in exercise program?
<ul style="list-style-type: none"> • Keep extremity warm using socks and blankets. 	Prevents vasoconstriction and promotes comfort.	Are extremities warm?

Nursing Diagnosis: Activity intolerance related to activity pain and diminished blood flow

Expected Outcomes Patient will report that pain is relieved during desired activities.

Evaluation of Outcomes Does patient participate in activities without pain?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Begin walking program: Start on flat surface. Walk 30 minutes per day. 	Promotes collateral circulation without greatly increasing oxygen demand.	Does patient participate in walking program?
<ul style="list-style-type: none"> • Walk every day increasing the distance in small increments until experiencing claudication. Walk one half city block after pain begins per physician order. Stop and rest until pain subsides. 	Walking through the pain will promote collateral circulation. Pain should subside with rest.	Does patient increase distance with claudication? Does pain stop with rest?

Nursing Diagnosis: Deficient knowledge: peripheral arterial disease related to complications, medications, or postoperative care.

Expected Outcomes Patient and family will verbalize self care measures to control disease and prevent complications.

Evaluation of Outcomes Does patient and family verbalize understanding of teaching?

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Ask patient's and family's knowledge of the physiology of the disease, and treatment and preventive techniques. 	This will determine educational topics.	What is patient's and family's baseline knowledge of PAD?

Interventions

- Describe peripheral arterial disease, symptoms, diagnosis, treatment, complications to patient and his family.
- Teach healthy lifestyle and risk factor control: Smoking cessation, low fat diet, walking programs, hyperlipidemia, diabetes and hypertension control.

Explain daily foot care:

- Inspect feet for ingrown toenails, redness, sores, or blisters, wash feet with warm soap and water, dry with gentle patting, lubricate skin to prevent cracking, wear clean socks. Do not walk barefoot and inspect inside of footwear for foreign objects before inserting foot. Explain prescribed drug treatment protocols.

Rationale

The patient should understand PAD to help control disorder.

Healthy lifestyle promotes circulation and decreases functional impairment and pain.

Daily foot care and reporting problems promptly can help prevent complications of PAD.

Ulceration of the toes may follow trauma if foreign object is walked on, which can result in infection.

Medication explanation can help patient comply with therapy.

Evaluation

Does patient and family verbalize understanding of PAD?

Is patient willing and able to incorporate healthy lifestyle into daily routine?

Does patient state will perform daily foot care and verbalize understanding?

Does patient verbalize understanding of need to protect feet?

Does patient verbalize understanding of medications?

increased by 50 percent. The cause is unknown, but anything that weakens the artery wall or causes loss of elasticity in the artery can cause an aneurysm. Atherosclerosis, hypertension, smoking, trauma, and congenital abnormalities are risk factors for an aneurysm. Heredity may also play a role. Aneurysms can occur in any artery in the body but are common in the abdominal aorta, which is the focus of the rest of this discussion.

An abdominal aortic aneurysm (AAA) is often silent if it is less than 4 cm. Most people do not even know that they have an AAA. Men older than age 50 are at the highest risk of death from an AAA. The incidence of AAA increases with age. Survival improves with elective surgery rather than emergency surgery after the aneurysm ruptures.

Types

There are different types of aneurysms (Fig. 23.9). A fusiform aneurysm is the dilation of the entire circumference of the artery. A saccular aneurysm is a bulging on only one side of the artery wall. A dissecting aneurysm occurs when a cavity is formed from a tear in the artery wall, usually the intimal (inner) layer. The layers of the artery are then separated as blood is pumped into the tear with each heartbeat, expanding the cavity, which is then prone to rupturing.

Signs and Symptoms

Usually there are few if any symptoms (Box 23.10 Aneurysm Summary). As the AAA grows, symptoms may develop. Back or flank pain is the classic symptom; the pain is caused by the aneurysm pressing against nerves of the vertebrae. Depending on the location and size of the

FIGURE 23.9 Types of aneurysms. (A) *Fusiform*. The entire circumference of the artery is dilated. (B) *Saccular*. One side of artery is dilated. (C) *Dissecting*. A tear in the inner layer causes a cavity to form between the layers of the artery and fill with blood. The cavity expands with each heartbeat.

aneurysm, there may be complaints of abdominal pain, a feeling of fullness, or nausea caused by pressure on the intestines. The pain may mimic pain associated with any abdominal or back disorder. Changing positions may temporarily relieve the symptoms. Because the symptoms are vague, they are often not associated with an AAA. There may be a pulsating mass in the abdomen caused by an AAA that is discovered only during routine physical or x-ray examination.

Severe, sudden back, flank, or abdominal pain and a pulsating abdominal mass can indicate that the aneurysm may be about to rupture. With rupture, the patient's blood pressure may drop and signs of shock may be present.

Box 23.10**Aneurysm Summary**

Signs and Symptoms	Back pain Flank pain Abdominal fullness Nausea Pulsating mass in abdomen Severe sudden back pain with rupture Shock from blood loss
Diagnostic Tests	Ultrasound Chest x-ray MRI CT scan Aortography
Therapeutic Interventions	Observe for growth of aneurysm Maintain blood pressure Surgical repair and graft
Complications	Rupture Shock Hemorrhage
Possible Nursing Diagnoses	Acute pain Risk for deficient fluid volume Risk for ineffective tissue perfusion

Immediate surgery is needed for a ruptured AAA. The mortality rate is high with a ruptured aneurysm.

Diagnostic Tests

Computed tomography (CT) and abdominal ultrasound are the most common diagnostic tools used to confirm the presence of an aneurysm. Small aneurysms may be watched over time to see if they enlarge. Aortography can be performed when surgical intervention is considered to identify the size and exact location of the aneurysm.

Therapeutic Interventions

Medical treatment consists of medication to maintain lower blood pressures because patients with aneurysms often have hypertension. If the blood pressure is allowed to get too high, it can cause the arterial wall to rupture. Surgical treatment—a bypass graft—is performed when the patient is experiencing pain or showing signs of circulatory compromise. An aneurysm that is larger than 5 cm requires surgery. The risk of rupture is greatest when the aneurysm reaches 5 cm or greater.

A conventional open surgical repair or newer endovascular grafting may be done for an AAA. Endovascular grafting involves the transluminal placement (through the femoral artery) and attachment of a sutureless aortic endograft or stent-graft prosthesis at the site of the AAA. In the endograft procedure, a balloon catheter positions and opens

the graft. The graft remains attached to the inner wall of the aorta when the catheter is withdrawn. Blood flow continues through the aorta, bypassing the aneurysm. Another method uses a stent-graft that opens to fit the diameter of the aorta to reduce pressure on the aneurysm. Endovascular surgery requires less hospitalization time and a quicker recovery.

Nursing Process

ASSESSMENT/DATA COLLECTION. Careful monitoring of a patient with an AAA is necessary. Understanding must be assessed so patients know their medications and the importance of taking antihypertensives as prescribed. Stress may be a risk factor that should be addressed. Lifting heavy objects can increase pressure within the artery and may be restricted even in the individual being treated with more conservative measures. Postoperatively, the patient should avoid lifting heavy objects (see Home Health Hints).

NURSING DIAGNOSIS, PLANNING, IMPLEMENTATION, AND EVALUATION. See Box 23.11 Nursing Care Plan for the Patient After Vascular Surgery (page 439).

Varicose Veins

Varicose veins are elongated, tortuous, dilated veins. The exact cause is unknown. The condition tends to be familial. Varicose veins are divided into primary and secondary varicosities.

Pathophysiology

Primary varicosities are believed to be caused by a structural defect in the vessel wall. Along with the defect, the dilation of the vessel can lead to incompetent venous valves. The valves help prevent blood from refluxing. If reflux occurs, it can cause further dilation of the vessel. The superficial veins are the vessels most often involved in primary varicosities.

Secondary varicosities are caused by an acquired or congenital pathological condition of the deep venous system. This produces dilation of collateral and superficial veins. As a result, there is an interference of blood return to the heart, which leads to stasis, or pooling, of the blood in the deep venous system. This increases the pressure within the system, pushing blood into the collateral vessels and producing varicosities in the superficial veins.

Causes

A number of factors can lead to varicose veins. The wall defects have been identified as a familial tendency and may be inherited. Any factor that may contribute to increasing hydrostatic pressure within the leg, such as prolonged standing, pregnancy, and obesity, may promote venous dilation. Incompetent valves within the veins can cause blockage of blood flow and lead to dilated veins.

Signs and Symptoms

The most common manifestation is the disfigurement of the lower extremity with primary varicosities. There may be dull pain, especially after prolonged standing. This usually can be relieved by walking or elevating the extremity. With secondary varicosities, the pain and disfigurement may be

more severe. There can be development of edema or ulceration if circulation is severely compromised.

Therapeutic Interventions

The primary goals are to improve circulation, relieve pain, and avoid complications. Treatment is usually not indicated if the problem is only cosmetic. Conservative treatment is geared to reduction of factors that contribute to varicose veins. Elastic compression stockings should be used as ordered. Injection sclerotherapy or lasers treat superficial varicosities. Surgical intervention is radiofrequency ablation stripping the vein to remove incompetent valves. Surgery is performed when venous insufficiency cannot be controlled or prevented with conservative treatment.

Venous Insufficiency

Venous insufficiency is a chronic condition. Damaged or aging valves within the veins interfere with blood return to the heart, causing pooling of blood in the lower extremities. Chronic venous insufficiency can lead to venous stasis ulcers.

Venous Stasis Ulcers

PATHOPHYSIOLOGY. Venous stasis ulcers are the end result of chronic venous insufficiency. Dysfunctional valves in the venous system prevent or reduce venous blood return. As venous pressure increases, venous stasis occurs. Over time the congestion and decreased venous circulation lead to changes in the lower extremities. There may be edema and a brownish discoloration of the leg and foot, with the surrounding skin hardened and leathery in appearance. The brown color occurs when veins rupture, releasing red blood cells into the tissues; the red blood cells then break down and stain the tissue brown.

Stasis ulcers develop from the increased pressure and rupture of small veins. Signs of skin breakdown are most commonly seen at the medial malleolus of the ankle. Stasis ulcers are a serious complication of venous insufficiency that are difficult to cure and can affect the patient's quality of life.

THERAPEUTIC INTERVENTIONS. The focus of treatment is to decrease edema and heal skin ulcerations. Compression wraps such as elastic stockings or bandage wraps are necessary to decrease edema. Elastic wraps should be started at the foot, with greater tension applied there, and wrapped up the leg. Rewrapping the elastic bandage twice a day is necessary. It is important to ensure that the wraps are not too tight at the top, which prevents return of blood to the heart.

Bedrest and elevation of legs and feet above the heart are important to assist with drainage of lower extremities. Patients are advised not to keep legs dependent and to avoid long periods of standing or sitting to prevent increased pressure and pain. The foot of the bed should be elevated 5 to 6 inches. Additionally, patients should be encouraged to exercise and walk often during nonacute episodes. Patients should be taught not to cross their legs or wear constrictive clothing that would decrease venous blood return to the heart.

Skin ulcers are usually cultured and treated with topical antibiotics if needed. Wound care can be chronic and challenging. (See Chapter 54.) An Unna boot, which is a gauze dressing coated with zinc oxide, calamine, and glycerin, may be used to promote healing in severe ulcers. Zinc promotes wound healing and can be soothing. The Unna boot is applied snugly and provides compression therapy as well. It is changed every 2 to 7 days. Skin grafting may be necessary if ulcerations are severe or do not heal.

NURSING PROCESS: THE PATIENT WITH A VENOUS DISORDER.

Assessment/Data Collection. Risk factors for varicose veins are identified. Symptoms and concerns about body image are noted. Leg appearance, presence of edema, and ulcerations are noted. Patient-coping skills are assessed to determine patient's ability to cope with chronic ulcers that may affect quality of life. Baseline knowledge of contributing factors for venous disorders is determined for teaching plans.

Nursing Diagnosis, Planning, and Implementation. Acute pain related to edema and increased pressure

EXPECTED OUTCOME: The patient reports pain is at a tolerable level.

- Use rating scale such as 0 to 10 to identify pain level *to provide consistency in pain reporting.*
- Elevate legs above heart level (such as in a reclining chair) and avoid long periods of standing *to reduce pooling of fluid.*
- Apply compression therapy as ordered *to promote drainage and reduce edema.*
- Administer analgesics as prescribed *to provide pain relief.*

Impaired tissue integrity related to chronic venous congestion

EXPECTED OUTCOME: The patient has intact tissue integrity.

- Assess and document size, shape, and depth of wound *to evaluate healing of wound over time.*
- Provide a comprehensive plan for wound care including methods of pressure relief from edema, treatments, and nutrition as ordered *to ensure that quality wound care is provided.*
- Provide wound care as ordered.

Ineffective health maintenance related to deficient knowledge of venous disease

EXPECTED OUTCOME: The patient will report understanding and management of his or her venous disorder.

- Assess the patient's present understanding of the disease *to determine baseline knowledge.*
- Explain to patient how to control risk factors and prevention of varicose veins: weight reduction, elevation of the extremities, walking, and exercise *help increase muscle strength and contraction.*
- Explain tight-fitting clothes at tops of legs or waist should not be worn *to prevent venous occlusion.*

- Encourage to wear support hose with varicose veins *to assist blood flow return to the heart.*
- Explain need to avoid heating devices *because of decreased sensitivity and risk of burns.*
- Encourage questions and allow the patient the opportunity to verbalize new information and skills *to enhance learning.*
- Document teaching and evaluation of patient knowledge.

See also Box 23.11 Nursing Care Plan for the Patient After Vascular Surgery.

Evaluation. Interventions are successful if the patient reports understanding of venous disease and prevention. Interventions are successful if the patient reports pain is at acceptable level.

Vascular Surgery

Vascular impairments requiring surgery may be acute or chronic and involve arteries, veins, or lymphatic vessels. When intermittent claudication becomes severe or disabling or when the limb is at risk for amputation, then surgical vascular grafting may be done.

Nursing Process: Preoperative Vascular Surgery

ASSESSMENT/DATA COLLECTION. A baseline assessment is important for postoperative comparison and discharge planning. Pain control needs and circulatory status are assessed. Diagnostic test (CBC, electrolytes, PT, PTT, and bleeding time) results are reviewed and typing and crossmatching of blood to be placed on hold is performed.

NURSING DIAGNOSES. The nursing diagnoses for preoperative vascular surgery may include:

- Acute or chronic pain related to ischemia of tissue distal to occlusion or aneurysm
- Anxiety related to unknown outcome, pain, powerlessness, or threat of death
- Deficient knowledge: preoperative and postoperative procedures related to unfamiliar process.

See Chapter 11 for further preoperative nursing process information.

Embolectomy and Thrombectomy

When an artery becomes completely occluded by an embolus or thrombus, it is considered a surgical emergency. Emergency embolectomy is the procedure of choice only if the affected extremity is viable.

Surgical removal to restore blood flow and oxygenation to the tissue distal to the occlusion is imperative to decrease ischemia and necrosis. Fogarty catheters (long narrow catheters with an inflatable balloon tip) are used to remove the thrombus or embolus. A small incision is made in the blood vessel near the occlusion, and the catheter tip is inserted past the occlusion. The balloon is inflated, and the catheter with the occlusive material is drawn back through the incision. The blood vessel and wound are sutured as circulation is assessed.

Vascular Bypasses and Grafts

Vascular bypass surgery involves the use of either autografts, such as the patient's own saphenous vein, or a synthetic graft material. The graft is anastomosed to the artery proximal to the occlusion and tunneled past the occlusion, where the distal end of the graft is anastomosed to the artery (Fig. 23.10). The graft is assessed for hemostasis and function, and then the wound is sutured closed.

Repair of a diseased area of a blood vessel, such as an aortic abdominal aneurysm, is performed with resection of the diseased area and replacement with a graft (aortic aneurysmectomy). This is usually an elective procedure. However, if an aneurysm is dissecting or ruptures, it is a surgical emergency.

Newer techniques are being used for bypass surgery. One technique uses video-assisted aortofemoral bypass without laparotomy. This method reduces length of hospital stay and patient recovery times.

Endarterectomy

Arteriosclerotic plaques are dissected from the lining of the arterial wall and removed in a procedure called an **endarterectomy**. This is most commonly performed on the carotid artery but may be done on peripheral arterial vessels as well. To control blood flow, the artery is clamped on both sides of the occlusion, and an incision is made into the artery. The plaque within the artery is removed with forceps. The artery is irrigated to remove any further debris and then closed with sutures. The clamps are removed, and the skin

FIGURE 23.10 Aortic-femoral bypass.

endarterectomy: end—inside + arter—artery + ectomy—excision

Box 23.11 NURSING CARE PLAN for the Patient After Vascular Surgery

Nursing Diagnosis: Acute pain related to surgical incision and reperfusion of tissue

Expected Outcomes Patient will state that the pain is relieved or is tolerable. Patient will rest comfortably, perform respiratory treatments as necessary, and perform activities of daily living (ADLs).

Evaluation of Outcomes Does patient state pain is relieved or acceptable? Is patient able to rest and participate in respiratory treatments and ADLs?

Interventions

- Ask severity of pain, as well as all other qualities.
- Ask patient to rate pain after analgesic is given.
- Notify physician if pain is unrelied.

Rationale

Peripheral vascular surgery pain is usually mild, and severe pain may indicate reocclusion. Major vascular surgery pain is severe.
Pain relief is individualized.
Different analgesic may be needed to give relief.

Evaluation

Does patient state pain is at a tolerable level with a patent vessel?

Does patient state pain is controlled at a tolerable level?
Are patient's pain relief needs met?

Geriatric

Interventions

- Ensure that older patient's pain is relieved.
- Use opioid pain medications cautiously. Consider reducing frail older patient's first opioid dose by 25%–50%, and increase as safe and needed and as ordered.

Rationale

Pain is not a normal part of aging, and elderly patients need and are entitled to adequate pain relief.
Older patients are more susceptible to peak effects and duration of analgesia of opioids.

Evaluation

Does patient rate pain as none or at a tolerable level using a scale of 0 to 10?
Are patient's vital signs and sedation levels within normal limits (WNL)?

Nursing Diagnosis: Ineffective tissue perfusion related to hypotension, hypothermia, emboli, vascular spasm, or reocclusion

Expected Outcomes Patient will have palpable peripheral pulses: adequate capillary refill; and normal color, temperature, motor, and sensory function of extremities. Patient will have reactive pupils and baseline cognitive function.

Evaluation of Outcomes Is patient's circulatory status WNL? Does patient have reactive pupils and baseline cognitive function intact?

Interventions

- Monitor circulation, movement, and sensation to extremities every 1 to 4 hours.
- Mark location of pulses on affected extremity.
- Perform neurological checks every 2 to 4 hours (carotid).
- Perform circulation or neurological check between nurses when changing caregiver.
- Measure abdominal girth every shift (abdominal aortic surgery).

Rationale

Early detection of spasm or reocclusion minimizes risk of ischemia and necrosis.
Allows for quick location of pulses.
Allows early detection of complications.
Subtle changes can be detected and new caregiver has baseline for comparison.
Increasing girths may indicate bleeding into abdomen.

Evaluation

Does graft or vessel remain patent?

Are pulses located easily?

Are major neurological or circulatory problems detected?
Is baseline assessment done?

Does abdominal girth remain unchanged?

(Continued on following page)

Box 23.11 NURSING CARE PLAN for the Patient After Vascular Surgery (*Continued*)

Interventions	Rationale	Evaluation
<ul style="list-style-type: none"> • Take temperature every 4 hours. 	May indicate infection or hypothermia with need for further warming.	Does patient remain normothermic?
<ul style="list-style-type: none"> • Monitor CBC as ordered. 	RBC count, hemoglobin, and hematocrit decrease with insidious bleeding into abdomen or significant hematoma formations.	Is CBC WNL?
<ul style="list-style-type: none"> • Avoid constricting measures on affected extremity: knee gatch of bed, adhesive tape, tight dressings. 	Prevent further decrease in blood flow to compromised extremity.	Is blood flow to affected extremity maintained?
<ul style="list-style-type: none"> • Auscultate AV shunts and grafts for bruits and palpate for thrills. 	Any decrease or cessation of bruit or thrill indicates occlusion.	Does AV shunt or fistula remain patent?

incision is closed. A drain may be placed to help prevent hematoma formation.

Angioplasty

Minimally invasive techniques can also be used to open plaque-blocked arteries. These techniques include balloon or laser angioplasty. A flexible laser-tipped catheter is inserted into an artery and advanced to the site of the blockage. The laser sends out pulsating beams of light, which vaporize the plaque. This procedure is used for patients with smaller occlusions in the distal superficial femoral, proximal popliteal, and common iliac arteries.

Stents

Stents are placed inside an artery to provide support to the artery walls and keep them open. Stents are placed in a procedure similar to percutaneous transluminal coronary angioplasty (PTCA) discussed earlier. Stents may also be used in combination with other procedures such as angioplasty.

Complications of Vascular Surgery

Bleeding and hemorrhage can occur with all vascular surgeries. Drainage can be expected with most surgeries. Drainage is usually small when peripheral vessels are involved. But with involvement of the great vessels, drainage is usually heavier and drains are often placed to prevent swelling and hematoma formation. If hemorrhage occurs, manual pressure is applied to the site of bleeding and the physician notified immediately.

Reocclusion is possible with any vascular surgery. If thrombi or emboli develop and block blood flow, it is a surgical emergency. Extensive surgeries may also result in significant blood loss, leading to fluid volume deficit or shock.

Postoperative Therapeutic Intervention

Frequent assessments are ordered postoperatively. Neurovascular checks of extremities every 1 to 4 hours are usually ordered. The incisional area is monitored for hematoma

formation. Abdominal girth measurements (for aortic aneurysm repair) are ordered. An increase in abdominal girth may indicate hemorrhage. Any abnormal change is reported immediately to the physician. A loss of a pulse can indicate that circulation has been impaired in the vessel. The patient's need to return to surgery is anticipated if signs of impaired circulation are found.

CBC, INR, PT, PTT, and electrolytes may be ordered daily. Intake and output monitoring may be initially ordered hourly, then every 4 to 8 hours. Imbalances in fluid status should be reported. IV crystalloid solutions, volume expanders, or blood may be ordered for fluid deficits.

Nursing Process: The Patient After Vascular Surgery

ASSESSMENT/DATA COLLECTION. On transfer postoperatively to either the ICU or surgical unit, the patient is positioned comfortably and a head-to-toe assessment is performed and documented. Abnormal findings are reported to the physician. Once a patent airway is ensured, vital signs are monitored according to institutional policy or more frequently if they are unstable. The patient's pain level is rated on a scale of 0 to 10. All IVs and drains are monitored. Measurement of intake and output is usually done hourly. Laboratory tests are also monitored.

Initially, neurovascular checks are performed hourly for aortic or extremity vascular surgery. Neurovascular checks include extremity movement and sensation, presence of numbness or tingling, pulses, temperature, color, and capillary refill (less than 3 seconds normally). Peripheral pulses are palpated, or assessed with Doppler ultrasound if not palpable, marked, and compared with the unaffected extremity to detect deficits. If a pulse is absent or weak or the extremity is cool or dusky, the physician is notified immediately. A return to surgery for an embolectomy or other procedure is anticipated.

NURSING DIAGNOSIS, PLANNING, IMPLEMENTATION, AND EVALUATION. See Box 23.11 Nursing Care Plan for the Patient After Vascular Surgery.

NURSING CARE TIP

Neurovascular checks refer to the assessment of an extremity. (Neurological checks refer to assessment of the central nervous system.) The following are areas to examine on an extremity when doing neurovascular checks. They are identified under the category for which they provide information:

Neurological	Vascular
Movement	Pulses
Sensation	Capillary refill
Numbness	Color (nailbed or skin)
Tingling	Temperature

CRITICAL THINKING

Mr. Jangles

■ You are caring for Mr. Jangles, age 63, who has just returned from surgery after an embolectomy of the right lower leg. He has a history of insulin-dependent diabetes mellitus, hypertension, renal insufficiency, and a myocardial infarction 2 weeks ago. He is 6 feet tall and weighs 316 pounds.

1. What are four priority assessment areas for you to perform for Mr. Jangles?
2. What other information might you want to know regarding Mr. Jangles's medical history?
3. List three priority nursing diagnoses for Mr. Jangles.
4. State one outcome for each nursing diagnosis.
5. What are nursing interventions for each nursing diagnosis that you will perform?

Suggested answers at end of chapter.

LYMPHATIC SYSTEM

The lymphatic system returns fluid from other tissues in the body to the bloodstream. It is a pumpless system with one-way valves that return the fluid to the heart. Any interruption in the flow of lymph results in edema.

Lymphangitis

Lymphangitis is a bacterial infection of the lymphatic channels. The infection can occur in the arms or legs and is commonly caused by *Staphylococcus* or *Streptococcus* bacteria. It is a serious infection that can cause sepsis and be fatal.

Signs and Symptoms

Symptoms include painful red streaks in the extremity. Fever and chills may be present. Lymph nodes in the area of infection can be enlarged and painful.

Therapeutic Interventions

Therapy is initiated with a broad-spectrum antibiotic as the drug of choice. The use of heat on the extremity, as well as elevating it, can help improve circulation. Physicians may order the use of pneumatic pressure devices to help alleviate congestion.

Nursing Process: Lymphangitis

ASSESSMENT/DATA COLLECTION. Frequent monitoring of the affected area for edema and skin breakdown is needed to prevent complications from edema. The nurse monitors the size of the extremity and notifies the physician of any increase in size or possible spread of infection. Pain level and fever are monitored.

Nursing Diagnosis, Planning, and Implementation

Acute pain related to tissue damage and edema from infection

EXPECTED OUTCOME: The patient reports an absence or acceptable level of pain.

- Explain and have patient use pain rating to report pain level for consistency.
- Administer analgesics as prescribed to provide pain relief.
- Re-check pain level 30 to 60 minutes after analgesic given.
- Position extremity for comfort and elevate to reduce edema, which can cause pressure and pain.

Risk for excess fluid volume related to congested lymph nodes from infection

EXPECTED OUTCOME: The patient has no evidence of edema.

- Apply heat on the extremity as ordered to increase circulation and reduce edema.
- Elevate extremity to help improve circulation and prevent edema.

EVALUATION. Interventions are successful if the patient reports pain is at acceptable level and no edema is present.

Home Health Hints

Cardiac

- Both patients and caregivers can experience stress and frustration related to cardiovascular disease. Patients who have undergone open heart surgery may experience feelings of powerlessness, depression, and anger. The home health nurse can be instrumental in helping the family deal with these life changing illnesses. Appropriate interventions include:
 - Have a home health social worker visit a postsurgical cardiac patient. This can be useful to help the patient and family plan for lifestyle changes to reduce anxiety and environmental stress.
 - The ability of the patient caregiver to provide necessary care should be assessed. The support and resources available to the caregiver should be explored to prevent caregiver role strain.
 - The need for caregiver respite care should be assessed, especially over time. If respite care is needed, assist the caregiver in identifying respite care resources in the family or community.
 - Assist the caregiver to identify a plan to distribute the care workload among family members, if possible.
 - Teach the caregiver stress management techniques to use. This can include deep breathing exercises, reading a book, meditation, massage therapy, guided imagery, exercise, socializing with friends, and/or working on a favorite hobby.

- After open heart surgery, many patients suffer from depression. If your patient appears withdrawn, offers limited eye contact during interaction, and seems uninterested with following through on postoperative instructions, discuss with the patient how they feel they have changed since having surgery. Report concerns to the patient's physicians; antidepressants might be helpful during this time. Also identify community resources that are available such as a support group and offer that information to your patient.
- Chest pain from esophageal reflux can mimic cardiovascular symptoms. The home health nurse should ask if the pain is related to consuming large meals, lying down, or bending over; or if it is relieved with antacids or food. Inform the physician of these findings.

Vascular

- Instruct the patient that if pain develops in the lower extremities during exercise to stop and rest.
- It is important to monitor peripheral pulses and capillary refill to ensure adequate tissue perfusion. Report absence pulses or sluggish capillary refill to the patient's physician.
- Patients with peripheral vascular disorders are at a high risk for developing lower extremity wounds that are often slow to heal. Instruct the patient to report changes in skin color; insect bites, and/or rashes to his or her physician.

REVIEW QUESTIONS

1. Which of the following is a risk factor that can be controlled to prevent the development of cardiovascular disease?
 - a. Family history of cardiovascular disease
 - b. Hypertension
 - c. Ethnicity
 - d. Family history of diabetes mellitus
2. Which of these assessment findings is an atypical symptom of a myocardial infarction when chest pain is not present?
 - a. Fatigue
 - b. Dizziness
 - c. Sweating
 - d. Nausea
3. Which of the following is the purpose of CABG surgery?
 - a. Cure coronary artery disease
 - b. Increase blood flow to the myocardium
 - c. Prevent spasms of the coronary arteries
 - d. Decrease blood flow to the coronary arteries
4. Which of the following is a classic symptom of peripheral arterial occlusive disease?
 - a. Angina
 - b. Edema

- c. Intermittent claudication
 - d. Stasis ulcers
5. The nurse is caring for a patient who has peripheral arterial disease. Which of the following statements by the patient indicates understanding of how to manage the pain of peripheral arterial disease?
- a. "I will lie down frequently."
 - b. "I will use a reclining chair."
 - c. "I will sit with my legs down."
 - d. "I will do knee flexion exercises."
6. A patient who had a myocardial infarction is to receive aspirin, 5 grains PO, now. How many milligrams of aspirin will the nurse give?
_____mg

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Sims

1. Place on bedrest, administer oxygen via nasal cannula at 2 L per minute, assess blood pressure and pulse, administer nitroglycerin sublingual as ordered, obtain ECG, and notify physician.
2. She may be having an anginal attack versus acute MI.
3. Nitroglycerin usually stops chest pain associated with angina. Rest may also alleviate chest pain. Neither nitroglycerin nor rest will relieve the pain of an acute MI.
4. Indicators of an MI include patient history, ECG changes with ST segment elevation, elevated troponin I, and CK-MB elevation.
5. Medical interventions may include nitroglycerin drip, morphine, anticoagulant therapy (heparin), and thrombolytic agents to dissolve the clot. A cardiac catheterization can determine which coronary artery is blocked. Angioplasty or a coronary artery bypass graft may be done to reroute blood.
6. Educate Mrs. Sims about the risks of smoking and being overweight.

■ Mrs. May

1. Monitor the patient's left leg for color, temperature, capillary refill, and pulses: femoral, popliteal, dorsalis pedis, and posterior tibial. Compare findings with findings in the right leg.
2. If unable to palpate pulses, use a Doppler ultrasound that enhances sound to locate pulses.
3. The patient's symptoms could be caused by an embolism above left femoral artery.
4. To document finding, you would obtain more assessment data. A sample of SOAP charting for your additional findings is given:
S: "I have a severe pain in my left groin that just started. It is at 9."
O: Grimacing, moaning, and holding left upper leg. Left leg cool, color pale, nail beds pale, capillary refill 10 seconds, unable to palpate pulses. Faint femoral and popliteal pulse, no dorsalis pedis or posterior tibial pulse heard with Doppler. Right leg warm, pink, capillary refill 3 seconds, with all pulses palpable.

A: Ineffective tissue perfusion

P: Notify physician stat.

5. Immediate interventions include complete bedrest, protecting the leg, and notifying the physician.
6. Medical interventions could include medication for pain and use of an anticoagulant, such as heparin. If no pulses are present, a thrombolytic agent, such as streptokinase or tissue plasminogen activator, which dissolves already formed clots, may be ordered. Surgery is possible.
7. Thrombolectomy or embolectomy may be necessary to save the limb.

■ Mr. Jangles

1. Priority assessments include respiratory status, circulatory status of right leg and foot, vital signs, and pain level.
2. A medical history should include Mr. Jangles's usual blood sugar values, insulin dose, ambulation aids, gait, knowledge base regarding his various disease processes, and what led to this hospitalization.
3. (a) Priority nursing diagnoses include pain related to surgery of right lower leg; (b) ineffective tissue perfusion related to embolectomy of right lower leg, renal insufficiency; (c) risk for injury related to leg surgery, diabetes, obesity.
4. Outcomes include (a) verbalizes relief of pain; (b) maintains adequate tissue perfusion as evidenced by palpable peripheral (pedal) pulses, warm and dry skin; (c) remains free from injury.
5. Nursing interventions include the following: (a) Position (especially right leg) for comfort; keep the right leg slightly elevated; educate the patient regarding the need to ask for pain medication before pain is too severe; educate the patient regarding the need to take pain medication to minimize the negative physiological effects of pain; monitor pain on a pain scale; evaluate the effectiveness of medication using the same pain scale, report ineffective pain measures. (b) Check pedal pulses, surgical dressing, pedal sensation and movement, and color, initially and every hour; report changes; check capillary refill; monitor for pain in extremities; monitor for edema in extremities; keep leg elevated slightly. (c) Make sure the nursing call light is within reach; provide assistance with ambulation; use walking aids.

Nursing Care of Patients with Cardiac Valvular Disorders

LINDA S. WILLIAMS

KEY TERMS

annuloplasty (AN-yoo-loh-PLAS-tee)
commissurotomy (KOM-i-shur-AHT-oh-mee)
insufficiency (IN-suh-FISH-en-see)
murmur (MUR-mur)
regurgitation (ree-GUR-ji-TAY-shun)
stenosis (ste-NOH-sis)
valvotomy (val-VAH-tuh-mee)
valvuloplasty (VAL-vyoo-loh-PLAS-tee)

QUESTIONS TO GUIDE YOUR READING

1. What is the pathophysiology, etiology, signs and symptoms, and diagnostic tests for each of the valvular disorders?
2. What nursing care would you provide for a patient with a valvular disorder?
3. Why are prophylactic antibiotics prescribed for some patients with valvular disorders?
4. What are the differences between commissurotomy, annuloplasty, and valve replacement?
5. What postoperative complications can occur for the two types of cardiac valve replacements?

In the normal heart, blood flows in one direction because of the presence of heart valves. There are four valves in the heart: mitral, tricuspid, pulmonic, and aortic (see Fig. 20.2). The chordae tendineae and papillary muscles are attachment structures for both the mitral and tricuspid valves. They ensure that the valves close tightly. The pulmonic and aortic valves do not have these attachment structures.

Damage to the valves or their surrounding structures can result in abnormal valvular functioning (Fig. 24.1). The valves of the left side of the heart are most commonly affected and are discussed in this chapter. Forward blood flow can be hindered if the valve is narrowed, or stenosed, and does not open completely. If the valve does not close completely, blood backs up, which is referred to as **regurgitation** or **insufficiency**. The abnormal blood flow increases the workload of the heart and increases the pressures in the affected heart chamber.

Valvular damage may occur from congenital defects, rheumatic fever, or infections. Congenital defects occur mainly in children, and rheumatic heart disease occurs mainly in adults. Prophylactic antibiotic therapy helps prevent rheumatic fever and subsequent rheumatic heart disease and is recommended to prevent valvular disease.

LEARNING TIP

The opening of a stenosed valve and an insufficient valve look very similar, and the results of extra blood building up in a chamber are the same (see Fig. 24.1). However, the problem is different. Remember what the defect is in each disorder to understand why the blood is building up in a chamber.

A valve that does not open fully (stenosed) does not allow a chamber to empty normally. Blood builds up in that chamber as a result. For example, mitral **stenosis** does not allow the left atrium to empty easily, so blood builds up in the left atrium.

A valve that does not close fully (insufficient) allows blood to flow back into the chamber that emptied. Blood builds up in that chamber as a result. For example, mitral insufficiency allows blood to backflow from the left ventricle into the left atrium after the left atrium has emptied, so blood builds up in the left atrium.

VALVULAR DISORDERS

Mitral Valve Prolapse

Pathophysiology

During ventricular systole, when pressure in the left ventricle rises, the flaps of the mitral valve normally remain closed and stay within the atrioventricular junction. In mitral valve prolapse (MVP), however, one or both flaps bulge backward into the left atrium during systole. This is due to one flap

being too large or a defect in the chordae tendineae that secures the valve to the heart wall. If the bulging flaps do not fit together, mitral regurgitation can occur with varying degrees of severity. Increased pressure on the papillary muscles results in ischemia within the muscle, causing further dysfunction of the mitral valve.

Etiology

In some people, MVP is a hereditary collagen tissue disorder, although the cause is unknown. Infections that damage the mitral valve, ischemic heart disease, or cardiomyopathy

regurgitation: re—again + gurgitare—to flood

insufficiency: in—not + sufficiens—sufficient

stenosis: stenosis—narrow

FIGURE 24.1 Openings of stenosed and insufficient valves compared with a normal valve.

may cause it. MVP is the most common form of valvular heart disease. It typically occurs in women mainly from 15 to 30 years of age who are thin and have slight chest deformities. Over age 50, males are frequently affected with more severe effects.

Signs and Symptoms

Most patients with MVP do not have symptoms and prognosis is very good (Table 24.1). The degree of MVP sever-

ity ranges from a **murmur** to chordae tendineae rupture with mitral regurgitation. The murmur, which is best heard at the apex, begins midsystolic and becomes more intense until the end of systole. If symptoms do occur, they may include atypical chest pain not related to exertion, dysrhythmias such as premature ventricular contractions causing palpitations, dizziness or syncope, fatigue, dyspnea, or anxiety. Emboli and infective endocarditis with mitral regurgitation are concerns.

TABLE 24.1 CARDIAC VALVULAR DISORDERS SUMMARY

Valve Disorder	Signs and Symptoms	Diagnostic Tests	Complications	Therapeutic Interventions	Nursing Interventions
<i>Mitral Valve Prolapse</i>	None Murmur Chest pain Palpitations Dizziness Syncope Fatigue Dyspnea	Echocardiography Cardiac catheterization	Emboli Infective endocarditis	None Beta blockers Antidysrhythmics Valvuloplasty Valve replacement	Activity intolerance Decreased cardiac output

Box 24.1**Diagnostic Tests for Cardiac Valvular Disorders**

History and physical examination
 Electrocardiogram
 Chest x-ray examination
 Echocardiography
 Cardiac catheterization

Diagnostic Tests

Auscultation for a click or murmur, caused by the stress on the chordae tendineae or valve leaflets when they prolapse, is the first diagnostic step for MVP. Other diagnostic tests are used when MVP is suspected (Box 24.1 Diagnostic Tests for Cardiac Valvular Disorders). A normal electrocardiogram (ECG) is usually seen with MVP, although inverted T waves may be seen. A two-dimensional echocardiogram can show valve abnormalities and Doppler echocardiogram identifies mitral regurgitation from MVP. For more severe cases, cardiac catheterization, an invasive test, can show the bulging flaps of the mitral valve on a coronary angiogram.

Therapeutic Interventions

Unless patients have severe mitral regurgitation, MVP is a benign disorder. No treatment is needed unless symptoms are present (Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders). The severity of MVP and symptoms produced determine the treatment used. A healthy lifestyle, including a good diet, exercise, stress management, and avoidance of stimulants and caffeine, can be important to prevent symptoms. Beta blockers for those with rapid heart

rates reduce heart rate and may relieve chest pain. Antidysrhythmic agents may need to be considered. Surgical repair or replacement of the valve can be done for severe cases of MVP (Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders and the section on Surgical Interventions).

Complications

Rare complications include dilation of the left side of the heart, heart failure, infective endocarditis, and emboli. Preventive antibiotic therapy before invasive procedures may be needed for some patients with thickened mitral valves to prevent endocarditis.¹ Aspirin or anticoagulants may be ordered to help prevent emboli.

CRITICAL THINKING**Mrs. Tepley**

■ Mrs. Tepley, age 32, has mitral valve prolapse and reports palpitations whenever she experiences stress. She drinks three cups of coffee daily. Today, she is admitted for an outpatient cystoscopy.

1. What might you hear when auscultating Mrs. Tepley's heart sounds?
2. Why does Mrs. Tepley experience palpitations?
3. What medication might you expect to be ordered preoperatively for Mrs. Tepley?
4. Why does Mrs. Tepley need to be informed that she may need prophylactic antibiotics before invasive procedures?
5. What other information does Mrs. Tepley need to manage her MVP?

Suggested answers at end of chapter.

Mitral Stenosis**Pathophysiology**

Mitral stenosis results from thickening of the mitral valve flaps and shortening of the chordae tendineae, causing narrowing of the valve opening. Older patients with mitral stenosis usually have calcification and fibrosis of the mitral valve flaps. The narrowed opening obstructs blood flow from the left atrium into the left ventricle. The left atrium enlarges to hold the extra blood volume caused by the obstruction. As a result of this increased blood volume, pressure rises in the left atrium. Pressures then rise in the pulmonary circulation and the right ventricle as blood volume backs up from the left atrium. The right ventricle dilates to handle the increased volume. Eventually the right ventricle fails from this excessive workload, reducing the blood volume delivered to the left ventricle and subsequently decreasing cardiac output.

Etiology

The major cause of mitral stenosis is rheumatic fever, with symptoms often taking two to four decades to appear after the illness. It is a continuous and progressive disease. Since rheumatic fever is declining in developed nations less mitral

stenosis is being seen in those countries. It is still a problem in underdeveloped areas where rheumatic fever still occurs. Less common causes include congenital defects of the mitral valve, tumors, rheumatoid arthritis, systemic lupus erythematosus, calcium deposits, and rheumatic endocarditis.

Signs and Symptoms

At first, patients may be asymptomatic (see Table 24.1). A click or low-pitched murmur may be heard. The murmur presents as a rumbling sound over the apex during diastole and is more pronounced right before systole. Then mild symptoms progressing to more severe symptoms develop. Pulmonary symptoms are most commonly seen. Exertional dyspnea, cough, and hemoptysis are the major symptoms. Fatigue and intolerance to activity result from decreased cardiac output. Palpitations from atrial flutter or fibrillation caused by atrial enlargement and chest pain from decreased cardiac output may be experienced. Complications from emboli formed from the stasis of blood in the left atrium include stroke and seizures. If the right ventricle fails, symptoms related to heart failure are seen (see Chapter 26).

Diagnostic Tests

Mitral stenosis is diagnosed with data from the patient history and physical examination and findings from diagnostic tests (see Box 24.1 Diagnostic Tests for Cardiac Valvular Disorders). The ECG shows enlargement of the left atrium and right ventricle and changes in the P waveform. Atrial flutter or fibrillation may be seen. A chest x-ray examination confirms enlargement of the affected heart chambers. Transthoracic two-dimensional color flow Doppler echocardiography and Doppler ultrasound are the noninvasive gold standard for evaluation of valvular disease. They show the narrowed mitral valve opening and decreased motion of the valve. Transesophageal echocardiography can be used if transthoracic images are not effective. A cardiac catheterization is typically done only if needed to validate unclear echocardiography results for preoperative evaluation or postprocedure for symptom recurrence.

Therapeutic Interventions

Individualized prophylactic antibiotic therapy may be given to prevent endocarditis.¹ Anticoagulants are given to patients with atrial fibrillation to prevent development of emboli from stasis of blood in the atrium. If heart failure develops, symptoms are treated with medications such as digitalis and diuretics and other therapies used for heart failure (see Chapter 26).

For less severe cases, percutaneous balloon **valvuloplasty**, which uses a balloon to dilate the stenosed heart valve, is done in a cardiac catheterization laboratory (Fig. 24.2). One approach for valvoplasty is to insert a balloon catheter via the venous circulation into the right atrium. Then the catheter is threaded through a small hole pierced into the right atrial septum that emerges into the left atrium and is then passed through the mitral valve. Inflation of the balloon within the mitral valve opens the stenosed valve flaps. Complications may include dysrhythmias, emboli,

FIGURE 24.2 Percutaneous balloon valvuloplasty.

hemorrhage, and cardiac tamponade. There are fewer complications with balloon valvuloplasty than with surgery.

Surgical treatment can include **commissurotomy** or **annuloplasty**, both forms of valvular repair (valvuloplasty) or valve replacement (see Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders and the discussion on Surgical Interventions). Mitral valve replacement is used for more severe cases and when symptoms of ventricular failure develop. These procedures may require the use of cardiopulmonary bypass. In commissurotomy, the valve flaps that have adhered to each other and closed the opening between them, known as the commissure, are separated to enlarge the valve opening. Annuloplasty is the repair or reconstruction of the valve flaps or annulus. It may involve the use of prosthetic rings. Valve replacement with prosthetic valves has been done since 1952. Valve replacement uses mechanical or biological valves from animal or human tissue (Fig. 24.3).

Mitral Regurgitation

Pathophysiology

Mitral regurgitation, or insufficiency, is the incomplete closure of the mitral valve leaflets. It allows backflow of blood into the left atrium with each contraction of the left ventricle. This blood is then extra volume that is added to the incoming blood from the lungs. With chronic mitral regurgitation, the increase in blood volume dilates and increases pressure in the left atrium. In response to the extra blood volume delivered by the left atrium, the left ventricle compensates by dilating. If the compensatory mechanism of dilation is inadequate, pressures rise in the pulmonary circulation and then in the right ventricle as blood vol-

commissurotomy: commissura—joining together +
tome—incision

annuloplasty: annulus—ring + plasty—formed

FIGURE 24.3 Valve prosthesis. An SJM Masters Series valve. (Courtesy St. Jude Medical, Inc., St. Paul, MN.)

ume backs up from the left atrium. The left ventricle and eventually the right ventricle may fail from this increased strain.

Etiology

The major cause of mitral regurgitation is rheumatic heart disease. Other causes include endocarditis, rupture or dysfunction of the chordae tendineae or papillary muscle, MVP, cardiomyopathy, annulus calcification, or congenital defects.

Signs and Symptoms

Initially, patients may be asymptomatic (see Table 24.1). The symptoms of chronic mitral regurgitation are similar to those of mitral stenosis. The murmur begins with S1 (first heart sound) and continues during systole up to S2 (second heart sound). Exertional dyspnea and fatigue occur slowly. Palpitations and an irregular pulse due to atrial fibrillation may result. Weakness from decreased cardiac output occurs if the left ventricle begins to fail.

If acute mitral regurgitation develops, such as in papillary muscle rupture following myocardial infarction, pulmonary edema and shock symptoms will be exhibited.

Diagnostic Tests

The ECG shows enlargement of the left atrium and left ventricle and changes in the P waveform. Atrial flutter or fibrillation may be seen. A chest x-ray examination confirms hypertrophy of the affected heart chambers. Two-dimensional or Doppler echocardiography shows left atrial enlargement and regurgitation of blood. Transesophageal echocardiography can also be used to identify causes. Cardiac MRI may be used for some people to determine treatment approaches. Cardiac catheterization further identifies regurgitation effects.

Therapeutic Interventions

Without symptoms, there is no general medical treatment. Prophylactic antibiotic therapy may be given to prevent infectious endocarditis before invasive procedures.¹ Angiotensin-converting enzyme (ACE) inhibitors are often used to reduce afterload. If atrial fibrillation with rapid heart rate is present, it can be controlled with digitalis, calcium channel blockers, or beta blockers. Emboli occur less frequently, but anticoagulation is still prescribed. Symptoms of heart failure are treated with therapies for heart failure (see Chapter 26). When symptoms develop or surgery is indicated to prevent further left ventricular dysfunction, mitral valve repair or replacement is done (Fig. 24.4). For acute mitral regurgitation, emergency surgery may be needed (see Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders and the discussion on Surgical Interventions).

Aortic Stenosis

Pathophysiology

Blood flow from the left ventricle into the aorta is obstructed through the stenosed aortic valve. The opening of the aortic valve may be narrowed from thickening, scarring, calcification, or fusing of the valve's flaps. To compensate for the difficulty in ejecting blood into the aorta, the left ventricle contracts more forcefully. In chronic stenosis, the left ventricle hypertrophies to maintain normal cardiac output. With increased narrowing of the valve opening, the compensatory mechanisms are unable to continue and the left ventricle fails to move blood forward. This results in decreased cardiac output and heart failure.

Etiology

The major causes of aortic stenosis are congenital defects or rheumatic heart disease. Mitral valve stenosis is often also

FIGURE 24.4 Mitral valve replacement with ball valve prosthesis.

present when the cause is rheumatic heart disease. Calcification of the aortic valve can be related to aging and is seen after the age of 50.

Signs and Symptoms

It may take many years or decades before signs or symptoms of aortic stenosis are observed (see Table 24.1). When symptoms do occur, evaluation is essential because the disease can progress dramatically. If the mitral valve is also diseased, signs and symptoms may appear earlier.

Angina pectoris is a primary symptom that occurs as a result of the increased oxygen needs of the hypertrophied myocardium. The extra workload of the left ventricle and the hypertrophy of the cardiac muscle require more oxygen. Angina results if these oxygen needs are not met. In the young patient, angina indicates severe obstruction.

Other signs and symptoms include a murmur, syncope from dysrhythmias or decreased cardiac output, and heart failure signs and symptoms. The murmur is a systolic murmur that begins just after the first heart sound, increasing in intensity till midsystole, then decreasing and ending right before the second heart sound. Orthopnea, dyspnea on exertion, and fatigue are indicators of left ventricular failure. Progressive heart failure can result in pulmonary edema and right-sided heart failure.

Diagnostic Tests

ECG usually shows enlargement of the left ventricle and left atrium. A chest x-ray examination confirms hypertrophy of the left ventricle and calcification of the aortic valve. Left atrial enlargement may be seen but occurs primarily when mitral stenosis is also present. Two-dimensional and Doppler echocardiography show thickening of the left ventricular wall, impaired movement of the aortic valve, and the severity of the disease. Serial echocardiography (e.g., annually or less often) may be recommended for those with moderate or severe disease. Cardiac catheterization will show elevated left ventricular pressure and decreased cardiac output.

Therapeutic Interventions

Generally, the treatment of choice is valve replacement because of the risk of sudden death when severe symptoms are present (see Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders and the section on Surgical Intervention). Mechanical valves are often chosen for middle-aged adults and require lifelong anticoagulation. For older adults, biological valves (porcine or bovine) are usually used as they do not require anticoagulation therapy and last about 12 years. **Valvotomy** may be considered for young adults but is not used for older adults due to early restenosis. Prophylactic antibiotics are considered before invasive procedures.¹ Heart failure symptoms are treated carefully. Medications that reduce the contractility of the heart and subsequently cardiac output are avoided to prevent further failure.

Aortic Regurgitation

Pathophysiology

The aortic valve cusps may be scarred, thickened, or shortened in chronic aortic regurgitation. A backflow of blood

CRITICAL THINKING

Mrs. Hesche

■ Mrs. Hesche, age 72, has aortic stenosis and is admitted to the hospital with angina. She had an episode of syncope 2 days ago. She reports that she tires easily.

1. Mrs. Hesche asks what aortic stenosis is. What will you tell her and how will you document it?
2. Why might Mrs. Hesche be experiencing angina?
3. What nursing care related to safety needs are important to include in Mrs. Hesche's plan of care?
4. What nursing diagnosis and care are relevant for Mrs. Hesche's report of being tired?
5. Digoxin (Lanoxin) 0.25 mg is prescribed for Mrs. Hesche. It is time to give her digoxin and you have available digoxin 0.125 mg tablets. How many tablets will you give?

Suggested answers at end of chapter.

from the aorta into the left ventricle occurs if the aortic valve cusps do not close completely. The left ventricle's blood volume increases with this backflow of blood that is in addition to the normal flow of blood from the left atrium. To handle the increased volume, the left ventricle compensates with dilation and hypertrophy to deliver a stronger contraction. This stronger contraction ejects more blood volume with each beat to maintain cardiac output. Over time the heart's contraction is not effective and the left ventricle fails, causing a cardiac output drop and pulmonary edema.

Etiology

Rheumatic heart disease (which is becoming less common) is the usual cause of aortic regurgitation. Other causes include congenital defects, syphilis, severe hypertension, and rheumatoid arthritis. An acute cause of aortic regurgitation may be endocarditis or aortic dissection.

Signs and Symptoms

No symptoms may be apparent for many years with chronic aortic regurgitation (see Table 24.1). Initially, the patient may report feeling a forceful heartbeat which is more pronounced lying down. Also, palpitations and pounding in the head may be experienced. Then exertional dyspnea, fatigue, and worsening levels of dyspnea (orthopnea, paroxysmal nocturnal dyspnea) occur after years of progressive valvular dysfunction. A murmur is heard during diastolic after the second heart sound. The palpated pulse is forceful and then quickly collapses (Corrigan's pulse). The diastolic blood pressure decreases to widen the pulse pressure. This compensates for an increase in systolic blood pressure. Angina pectoris may occur late. The angina is atypical, often happening at rest or at night along with diaphoresis, when a lower pulse rate results in delivery of less oxygen to the myocardium. Eventually heart failure symptoms develop if the left ventricle fails.

In acute dysfunction, profound symptoms of pulmonary distress, chest pain, and shock symptoms occur. The prognosis is poor.

Diagnostic Tests

The ECG shows left ventricle hypertrophy, ST segment depression, and T wave inversion in some leads (see Chapter 25). A chest x-ray confirms hypertrophy of the left ventricle and aorta. With severe regurgitation, left atrial enlargement may also be seen. An echocardiogram and Doppler echocardiography show an enlarged left ventricle and severity of aortic regurgitation. Cardiac catheterization reveals elevated left ventricular diastolic pressure and, with dye injection, shows the regurgitation of blood into the left ventricle.

Therapeutic Interventions

Surgical valve replacement is the treatment of choice prior to heart failure development (see Box 24.2 Therapeutic Interventions for Cardiac Valvular Disorders and the Surgical Interventions section). Treatment with digitalis, diuretics, and vasodilator therapy such as ACE inhibitors and nifedipine (Procardia) may be useful for some patients to reduce systolic blood pressure and subsequently cardiac workload until surgery is needed. Prophylactic antibiotic therapy may be given before invasive procedures.¹ If dysrhythmias develop, they are promptly treated. Acute aortic regurgitation requires immediate surgery.

Nursing Diagnoses, Planning, Interventions, and Evaluation

The major nursing diagnoses for all valvular disorders are the same and include those for heart failure as well if heart failure symptoms are present. See Box 24.3 Nursing Care Plan for the Patient with Cardiac Valvular Disorders.

Patient Education

Education, an important nursing intervention, promotes understanding of the valvular disorder, health maintenance, prevention of complications, and early recognition of symptoms, so medical care can be sought. For older adult patients, it is important to include caregivers or family members in teaching sessions to assist with understanding of the information being taught. Teaching is provided for medications the patient is taking. If the patient is on anticoagulants for atrial fibrillation or mechanical valve replacement, a Medic Alert identification should be used and monthly appointments to check international normalized ratio (INR) values should be kept.

Information on endocarditis prevention is essential for patients with most valvular problems. Damaged cardiac valves are prone to developing infection from organisms such as *Streptococcus viridans* or *Staphylococcus epidermidis*. During invasive procedures in which bleeding is possible, these organisms can enter the circulation, attach to damaged valves, and multiply. Patients should be taught the possible need for prophylactic antibiotics before invasive procedures, including dental work or surgery, to prevent endocarditis.¹ Patients should consult their physician about the need for prophylactic antibiotics.

NURSING PROCESS FOR THE PATIENT WITH A VALVULAR DISORDER

Nursing Assessment/Data Collection

A history that includes information presented in Table 24.2 is obtained. Vital signs are measured and recorded. Heart sounds are auscultated to detect murmurs. Any signs and symptoms of heart failure are noted (see Chapter 26).

CARDIAC VALVULAR SURGICAL INTERVENTIONS

There are several types of heart valve repairs and replacements. Technological advances have created less invasive

TABLE 24.2 NURSING ASSESSMENT FOR PATIENTS WITH CARDIAC VALVULAR DISORDERS

Subjective Data	
Health History	Infections—rheumatic fever, endocarditis, streptococcal or staphylococcal, syphilis Congenital defects
Respiratory	Cardiac disease—myocardial infarction, cardiomyopathy Dyspnea at rest, on exertion, when lying, or that awakens patient? Cough or hemoptysis?
Cardiovascular Medications Knowledge of Condition Coping skills	Any palpitations, chest pain, dizziness, fatigue, activity intolerance?
Objective Data	
Respiratory Cardiovascular	Crackles, wheezes, tachypnea Murmurs, extra heart sounds, dysrhythmias, edema, jugular vein distention, Corrigan’s pulse, increased or decreased pulse pressure
Integumentary Diagnostic Test Findings	Clubbing; cyanosis; diaphoresis; cold, clammy skin; pallor

Box 24.3 NURSING CARE PLAN for the Patient with Cardiac Valvular Disorders

Nursing Diagnosis: Decreased cardiac output related to valvular stenosis or insufficiency or heart failure

Expected Outcomes Patient has adequate cardiac output as evidenced by vital signs within normal limits (WNL), no dyspnea or fatigue.

Evaluation of Outcomes Does patient have vital signs WNL with no dyspnea or fatigue?

Interventions

Assess vital signs, chest pain, and fatigue.

Give oxygen as ordered.

Provide bedrest or rest periods as ordered.

Elevate head of bed 45 degrees.

Rationale

Vital signs, chest pain, and fatigue are indicators of cardiac output decline.

Supplemental oxygen provides more oxygen to the heart.

Cardiac workload and oxygen needs are reduced with rest.

Venous return to heart is reduced and chest expansion improved.

Evaluation

Are vital signs WNL with no chest pain or fatigue?

Is breathing pattern normal?

Are vital signs WNL and no fatigue reported?

Are vital signs WNL and respirations easy?

Geriatric

Assess for cardiac medication side effects and teach patient side effects to report.

Toxic side effects are more common owing to altered metabolism and excretion of medications in the elderly.

Are side effects present for medications patient is taking?

Does patient understand side effects to report?

Nursing Diagnosis: Activity intolerance related to decreased oxygen delivery from decreased cardiac output

Expected Outcomes Patient will show normal changes in vital signs with less fatigue in response to activity.

Evaluation of Outcomes Does patient have normal changes in vital signs with activity? Does patient report decreased fatigue with activity?

Interventions

Assist as needed with activities of daily living (ADLs).

Provide rest and space activities.

Rationale

Energy is conserved with ADL assistance.

Cardiac workload and oxygen needs are reduced with rest.

Evaluation

Are all ADLs completed?

Are vital signs WNL with activity?

Is patient able to perform activities when allowed extra time?

Geriatric

Slow pace of care and allow patient extra time to perform activities.

Ensure safety when mobilizing elderly patient.

Elderly patients can often perform activities if allowed time to slowly perform them and rest at intervals.

Orthostatic hypertension is common in the elderly.

Does blood pressure remain WNL when changing position?

Does patient ambulate without injury?

options than the traditional open cardiac surgery with cardiopulmonary bypass (CPB) for valve repair and replacement. New percutaneous approaches are being researched such as a transseptal stitch repair and coronary sinus tucking that reduces mitral annular size. A minithoracotomy can be used to repair or replace valves such as the mitral valve. Robotic devices are being trialed that can reduce incision size even more. Less invasive surgery means a quicker recovery, less pain and healing time. It is a good surgical option for older adults who meet the criteria.

Heart Valve Repairs

A **commissurotomy** is a heart valve repair for a stenosed valve. For commissurotomy, the patient is placed on CPB and an atriotomy (incision into the atrium) is made to expose the valve (see Chapter 20). The valve cusps are either incised with a knife or broken apart with a dilator. The atrium is sewn closed, CPB is discontinued, and surgery continues as described in the general surgery procedure section. Commissurotomy is most commonly performed on the mitral valve.

A balloon valvotomy is a procedure that repairs a stenosed heart valve. The balloon catheter is inserted through a diseased valve and then inflated to open the stenosed valve.

Another type of valve repair is **annuloplasty**, which repairs the annulus of a valve. The mitral valve is the most common valve repaired in this way. Sutures or a ring may be placed in the valve annulus to improve closure of the leaflets. Similar procedures are used on the tricuspid valve; however, the aortic valve is not readily repaired in this manner.

Heart Valve Replacement

Valves used for cardiac valve replacement may be either mechanical or biological. There are three types of mechanical valves: caged ball, monoleaflet, and bileaflet (Fig. 24.5). Mechanical valves are durable but create turbulent blood flow. The turbulent flow can lead to clot formation, requiring lifelong anticoagulant therapy. Biological (tissue) valves come from three sources: porcine (pig), bovine (cow), or allograft (human donor) (Box 24.4 Cultural Considerations). Allografts are available in limited numbers because they rely on donors. Visit www.lifenet.org for more information on allografts and www.sjm.com to view heart valves. Tissue valves have a very low incidence of thrombus formation and do not require lifelong anticoagulant therapy, but do not last as long as mechanical valves. Selecting the type of valves to use depends on several factors. If anticoagulation is a concern, then biologic valves may be preferred especially for the older adult or women considering pregnancy.

For mitral valve replacement (MVR), a left atriotomy is made after the patient is on CPB. For an aortic valve replacement (AVR), an incision is made above the right coronary artery in the aorta. Then in either valvular procedure, the diseased valve is excised and the new valve sutured

A. Caged ball valve

B. Monoleaflet

C. Bileaflet

FIGURE 24.5 Types of mechanical heart valves.

in place. The incision is closed, and surgery then continues as described in the general surgery procedure section.

Valve Replacement Complications

In tissue valves, degenerative changes and calcification can occur, leading to valve failure. For mechanical valves, the most common complication is thrombus formation. An embolism can occur when thrombi form on the mechanical valve and then break off. Embolism rarely occurs with tissue valves and is prevented with anticoagulant therapy for mechanical valves. When the patient is on warfarin, ongoing monitoring of international normalized ratio (INR) is important. The general target for INR with certain aortic valve replacements is 2.0 to 3.0, and 2.5 to 3.5 with mitral or aortic valve replacement along with thromboembolic risks.

Other complications include anemia and endocarditis. Anemia is due to hemolysis of red blood cells (RBCs) as they come in contact with mechanical valve structures. In

Box 24.4

Cultural Considerations

Cardiac Valves

Because the pig is considered a dirty animal to religious Jews and Muslims, only bovine, synthetic, or human valves should be used for these patients. Likewise, because the cow is sacred among Hindus, only porcine, synthetic, or human valves should be used for Hindu patients.

endocarditis, microorganisms tend to grow on the valve leaflets or the sewing ring of mechanical valves. These growths can make valves incompetent or break off to become emboli.

NURSING PROCESS FOR THE PREOPERATIVE CARDIAC SURGERY PATIENT

Assessment/Data Collection

A baseline assessment is important for postoperative comparison and to begin discharge planning. Pain control needs and circulatory status are essential items. Results of diagnostic laboratory tests, x-ray examinations, and other studies are reported if abnormal. Typing and crossmatching of ordered units of blood is done and placed on hold.

Nursing Diagnoses, Planning, Interventions, and Evaluation

See Nursing Process for Preoperative Patients in Chapter 11.

NURSING PROCESS FOR THE POSTOPERATIVE CARDIAC SURGERY PATIENT

After cardiac surgery, the patient goes to the intensive care unit (ICU) for about 1 to 2 days for close observation and cardiac monitoring. Tubes are removed as the patient's status allows. Then the patient is transferred to a stepdown or general surgical unit for continued cardiac monitoring as recovery continues.

Assessment/Data Collection

The patient is accompanied to the ICU by the anesthesiologist, who gives the nurse a report of the procedure, complications, and hemodynamic and ventilatory management of the patient. The patient is connected to a cardiac monitor and mechanical ventilator. The mechanical ventilator is used for 4 to 24 hours. The patient is placed under a warming device, such as a light or blanket. A head-to-toe assessment of the patient, including dressings, tubes, and IV lines, is performed. The patient may have several tubes that require monitoring including a chest tube, nasogastric tube, and a urinary catheter. Of importance are signs of awakening, shivering, pain, lung and heart sounds, and palpation of the entire chest and neck to detect crepitus (air in the subcutaneous tis-

sue from opening the chest). Trends in the patient's cardiac output are monitored. Body temperature is continuously monitored until warming measures are discontinued, which occurs when the core body temperature nears 37°C (98.6°F). While patients are being rewarmed, they are assessed for shivering, which may be felt as a fine vibration at the mandibular angle of the jaw. Shivering greatly increases cardiac oxygen needs. Paralyzing agents given with narcotics eliminate shivering. Blood is drawn for a CBC, electrolytes, coagulation studies, and arterial blood gases.

After the initial transfer assessment, vital signs, oxygen saturation, and cardiac pressures are monitored and recorded every 15 to 30 minutes, with decreasing frequency as the patient stabilizes. Body temperature is monitored continuously while warming measures are used. The patient is warmed slowly to avoid peripheral vasodilation and onset of signs and symptoms of shock. Intake and output are measured and vital signs are checked. A 12-lead electrocardiogram (ECG) is done to detect perioperative myocardial infarction. A chest x-ray examination is done to check central line and endotracheal tube placement and to detect a pneumothorax or hemothorax, diaphragm elevation, or mediastinal widening from bleeding. At this point, the family may see the patient, and patient care is explained.

Awakening with many questions, strange auditory and tactile sensations, and the inability to speak are very frightening and frustrating to the patient. Keeping eye contact with the patient and using touch appropriately can be very soothing to the patient. If lip reading is unsuccessful, use simple closed-ended questions, nonverbal gestures, communication boards, and magic slates. Give explanations regarding procedures in simple terms.

After cardiac surgery, pain is monitored in relation to the patient's preoperative anginal or infarction-associated pain. Chest pain after surgery can be frightening for patients. Knowing that chest pain can occur from the surgical incision rather than the heart is important to the patient. Otherwise the patient may not associate surgical chest pain with the incision and instead think the pain is anginal or myocardial infarction pain.

Nursing Diagnoses, Planning, Interventions, and Evaluation

Nursing diagnoses for postoperative cardiac surgery are discussed in Box 24.5 Nursing Care Plan for the Postoperative Patient Undergoing Cardiac Surgery. Additional general postoperative nursing care is discussed in Chapter 11.

Box 24.5 NURSING CARE PLAN for the Postoperative Patient Undergoing Cardiac Surgery

Nursing Diagnosis: Pain related to sternotomy, or pericarditis

Expected Outcomes Patient will state pain is relieved or tolerable. Patient is able to rest and perform respiratory treatments.

Evaluation of Outcomes Does patient state pain is within acceptable levels? Is patient able to rest and perform respiratory therapies?

Interventions

- Ask about characteristics of pain with each episode.
- Splint chest incision with all movement and coughing and deep breathing.
- Encourage patient to report pain even when pain is mild.
- Turn, reposition every 2 hours.
- Offer back rubs frequently.
- Instruct patient to take a deep breath before movement and exhale slowly during movement.

Rationale

A thorough description is needed to determine cause and plan actions. Stabilizes sternum and incision to increase comfort. It is easier to keep pain under control when mild. Changes muscle position, relieving stiffness. Relaxes tense muscles retracted during operation. Keeps muscles relaxed, minimizing tension with guarding and pain.

Evaluation

Does patient describe pain on scale of 0 to 10? Can patient splint chest incision independently? Does patient report pain when mild? Is patient comfortable without stiffness? Is patient able to rest in comfort? Can patient perform coughing and deep breathing techniques as instructed?

Nursing Diagnosis: Decreased cardiac output related to myocardial depression, hypothermia, bleeding, unstable dysrhythmias, or hypoxemia

Expected Outcomes Patient will remain free of major side effects of pharmacological support. Patient will maintain vital signs within normal limits (WNL), palpable peripheral pulses, urine output greater than 30 mL/h, and normal sinus rhythm.

Evaluation of Outcomes Is patient free of major side effects? Are vital signs WNL?

Interventions

- Monitor vital signs.
- Monitor peripheral circulation.
- Monitor intake and output.
- Listen to lung sounds and note character of sputum.
- Monitor temperature closely while rewarming the patient.
- Monitor for shivering.
- Monitor chest tube drainage for increase or sudden decrease.
- Monitor ECG.
- Monitor electrolytes.
- Monitor ABGs.

Rationale

Trends reflect problems. Mottling or weak pulses may indicate poor cardiac output (CO). Fluid deficit or excess can alter CO. Wet lung sounds may indicate heart failure or pulmonary edema. Febrile state increases heart rate and myocardial oxygen consumption. Shivering increases the blood pressure, decreasing CO and increasing risk for bleeding. Drainage >200 mL/hr may lead to hypovolemia and a decrease in CO. Premature ventricular contractions and atrial fibrillation decrease CO. Low calcium and magnesium and high potassium decrease contractility and CO. Acidosis decreases heart function, and a low CO may lead to further acidosis.

Evaluation

Are vital signs WNL? Do peripheral pulses remain strong with normal skin color, temperature, capillary refill? Does total intake equal output? Are lungs clear? Does temperature remain less than or equal to 98.6°F (37°C)? Is patient's shivering controlled? Is patient free from cardiac tamponade and hypovolemia? Does patient remain in normal sinus rhythm or controlled dysrhythmia? Are electrolytes WNL? Are ABGs WNL?

(Continued on following page)

BOX 24.5 NURSING CARE PLAN for the Postoperative Patient Undergoing Cardiac Surgery (Continued)

Nursing Diagnosis: Risk for infection related to inadequate primary defenses from surgical wound

Expected Outcomes Patient will remain free from infection.

Evaluation of Outcomes Does patient remain free from infection?

Interventions

- Use good hand hygiene and cleanse stethoscope with alcohol between patients.
- Observe incision for signs and symptoms of infection.
- Monitor drainage and maintain drains.
- Maintain sterile technique for dressing changes.
- Monitor and report abnormal findings for temperature, lung sounds, sputum, and urine consistency.

Rationale

- Hands and stethoscopes can carry infectious agents.
- Redness, warmth, fever, and swelling indicate infection.
- Drains remove fluid from the surgical site to prevent infection development.
- Sterile technique reduces infection development.
- Low-grade (immunosuppressed) or high-grade fever, crackles, yellow-green sputum color, or cloudy urine can indicate infection.

Evaluation

- Are infectious preventive techniques used?
- Does patient remain free from infection?
- Are signs and symptoms of infection present?
- Are drainage amount and color normal for procedure? Are drains functioning?
- Is incision free of signs and symptoms of infection?
- Is the patient's temperature WNL and are lung sounds, sputum, and urine clear?

REVIEW QUESTIONS

1. The nurse is evaluating patient teaching for mitral valve prolapse. The patient shows understanding of the prognosis of MVP by stating which of the following?
 - a. "The prognosis is poor."
 - b. "There are often no symptoms."
 - c. "Heart failure often occurs."
 - d. "Symptoms then quickly progress."
2. Which of the following symptoms would the nurse identify as a priority to report for a patient with aortic stenosis?
 - a. Angina
 - b. Peripheral edema
 - c. Headache
 - d. Weight loss
3. A patient just diagnosed with aortic regurgitation asks what this means. Which of the following is the nurse's best response for describing what occurs in aortic regurgitation?
 - a. "Backflow of blood into the right ventricle."
 - b. "Backflow of blood into the left ventricle."
 - c. "Impaired emptying of the right ventricle."
 - d. "Impaired emptying of the left ventricle."
4. A patient with mitral stenosis develops atrial fibrillation. Which of the following medications does the nurse understand is given to the patient to prevent embolitic complications from atrial fibrillation?
 - a. Bumetanide (Bumex)
 - b. Furosemide (Lasix)
 - c. Penicillin (Bicillin)
 - d. Warfarin (Coumadin)
5. A patient is scheduled for cardiac valve testing. Which of the following tests would the nurse explain will show the cardiac valves and how they function?
 - a. ECG
 - b. Chest x-ray examination
 - c. Echocardiogram
 - d. Cardiac catheterization
6. The nurse is planning care for a patient having a cardiac valve replacement. With which type of valve will the patient be on anticoagulant therapy to prevent thrombus formation?
 - a. Mechanical valve
 - b. Porcine valve
 - c. Allograft valve
 - d. Bovine valve

Multiple response item. Select all that apply.

7. A patient with mitral regurgitation receives antibiotic prophylaxis. Which of these patient statements would indicate the need for further explanation by the nurse?
 - a. “I am at less risk for developing endocarditis.”
 - b. “The antibiotics I take prevent further heart valve damage.”
 - c. “The antibiotics I am taking are to prevent a heart infection.”
 - d. “Invasive procedures put me at risk of endocarditis which the antibiotics are to prevent.”
 - e. “The antibiotics I take are to prevent a cold.”

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ Mrs. Tepley

1. You might hear a murmur.
2. Stress and caffeine increase the occurrence of palpitations.
3. Prophylactic antibiotics might be ordered preoperatively.
4. She might need prophylactic antibiotics to prevent infective endocarditis, which can result from bacteria entering the circulation during invasive procedures, attaching to the damaged valve, and growing.
5. To help manage her condition, Mrs. Tepley needs a definition of MVP, stress management techniques, to know she should reduce caffeine intake (e.g., with decaffeinated coffee), and to understand symptoms of endocarditis to report to her physician.

■ Mrs. Hesche

1. In aortic stenosis, the valve is narrowed, which makes it more difficult for blood to leave the left ventricle and go into the aorta. This means there can be less blood flow to the body.

Documentation: S: “What is aortic stenosis?”
 O: Listened attentively during explanation that in aortic stenosis the valve is narrowed making it more difficult for blood to leave left ventricle to go to aorta. This means there can be less blood flow to the body. A: Interested in learning more about diagnosis.
 P: Provide more information

2. Angina results if the heart’s oxygen needs are not met because of reduced cardiac output.
3. Nursing care should include fall precautions due to syncope and fatigue.
4. Diagnoses and care include the following: Self-care deficits related to fatigue, so plan for meeting ADL needs. Activity intolerance related to fatigue, so plan rest periods between activity and monitor vital signs with activity.
5. You should give 2 tablets. An example of solving this problem is:

Unit Analysis Method

$$\frac{0.25 \text{ milligrams}}{0.125 \text{ milligrams}} \left| \frac{1 \text{ tablet}}{1} \right. = 2 \text{ tablets}$$

QUESTIONS TO GUIDE YOUR READING

1. How does electrical activity flow through the heart?
2. What are the five steps used for dysrhythmia interpretation?
3. What are current medical treatments for each of the cardiac dysrhythmias?
4. What are types and uses of cardiac pacemakers?
5. What nursing care would you provide for patients with dysrhythmias or a pacemaker?

CARDIAC CONDUCTION SYSTEM

The heart's electrical conduction system initiates an impulse whose purpose is to stimulate the cardiac muscle to contract (Fig. 25.1). This electrical activity can be viewed on a cardiac monitor or recorded on an **electrocardiogram (ECG)** tracing. The activity seen on the ECG does not necessarily mean that the heart has contracted in response to the electrical impulse. The patient's vital signs and pulses verify that contraction occurs.

Located in the upper posterior wall of the right atrium is the **sinoatrial (SA) node**. The SA node is the primary pacemaker of the heart. It normally fires at a rate of 60 to 100 beats per minute (bpm). As a protective mechanism if the SA node does not function properly, other areas of the heart can initiate impulses to keep the heart beating. If the SA node fails, the **atrioventricular (AV) node** initiates an impulse at 40 to 60 bpm. This is referred to as a **nodal or junctional rhythm**. The body can usually function adequately with this rhythm. If the AV node is unable to initiate an impulse, then the ventricles take over at 20 to 40 bpm. When the ventricles initiate the impulse, the heart's rhythm is third-degree or complete heart block, or **ventricular escape rhythm**. Ventricular rhythms are the heart's last attempt to compensate for loss of SA and AV node impulse

initiation. The ventricular rate of 20 to 40 bpm is not adequate to meet the body's oxygen needs, so the patient begins to show signs of inadequate cardiac output such as dyspnea, abnormal vital signs, and changes in level of consciousness. Treatment is usually necessary to reestablish a normal heart rate as soon as possible.

Normally after the SA node fires, the impulse travels across both atria, stimulating them to contract. This is known as **atrial systole**. This atrial contraction propels blood out of the atria and into the relaxed ventricles during **ventricular diastole**. The impulse then travels down the atria to the AV node where it is delayed briefly. Next it travels down the **bundle of His**, which divides into right and left bundle branches. From there the impulse quickly travels through the Purkinje fibers, stimulating both ventricles to contract. This contraction is known as **ventricular systole**.

Cardiac Cycle

A cardiac cycle is the period from the beginning of one heartbeat to the beginning of the next. The cardiac cycle is the electrical representation of the impulse that stimulates contraction and then relaxation of the atria and ventricles. Within the normal cardiac cycle, there is a P wave, a QRS complex, and a T wave (Fig. 25.2).

FIGURE 25.1 Conduction pathway of the heart. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 5. FA. Davis, Philadelphia, 2007.)

FIGURE 25.2 Components of the cardiac cycle. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed. 5. FA Davis, Philadelphia, 2007.)

ELECTROCARDIOGRAM

The electrical activity of the heart can be viewed with ongoing cardiac monitoring or by obtaining an ECG reflecting the activity just at that moment. Leads placed on the patient allow different views of the heart to be seen. A 12-lead ECG provides 12 different perspectives of the heart, while an 18-lead ECG allows 18 views. Waveforms change in appearance in the different leads. For continuous monitoring, lead II is the most commonly used. In lead II, the waveforms can be expected to be upright.

Specialized training usually by physicians is required to interpret ECGs for normal and abnormal function. By learning characteristics of a normal heart rhythm and rules

LEARNING TIP

Think of a 12- or 18-lead ECG as if you had a camera that you were using to take pictures or views of an object such as an apple. To obtain views that showed you all the sides of the apple—front, side, back, side—you would take a picture and then move the camera a little to get the view next to the one you had just taken. You would continue moving the camera until you had worked your way around the apple. This would then give you a complete view of the entire apple. This is what an ECG does for viewing the heart.

FIGURE 25.3 Electrocardiogram recording paper time intervals.

for common **dysrhythmias**, you will be able to report rhythm changes to your supervisor or physician.

Electrocardiogram Graph Paper

The intervals of each of the components of a cardiac cycle can be measured on the ECG graph paper on which the rhythm is recorded. The graph paper is calibrated in a grid with small squares divided into heavy lined blocks of 25 (five squares wide and five squares high; Fig. 25.3). Each small box is 0.04 seconds wide. There are five small squares, which equal 0.20 seconds of time, between two horizontally heavy vertical black lines (see Fig. 25.3). The height of waveforms (amplitude) is measured vertically. Each small square is 1 mm. Ten millimeters is the standard height that the ECG uses to measure patient waveforms.

When the ECG is on but there is no electrical activity detected, a straight line is produced. This **isoelectric line** occurs when there are no positive or negative electrical wave deflections. Cardiac cycle impulses (seen as waves), depending on how they travel through the heart, are either upright (positive) or downward (negative) from the isoelectric line on the ECG graph paper.

COMPONENTS OF A CARDIAC CYCLE

P Wave

The P wave is the first wave of the cardiac cycle and represents **atrial depolarization**. When the SA node fires, the P wave normally appears rounded and symmetrical. There is

dysrhythmia: dys—difficult or abnormal + rhythm—rhythm

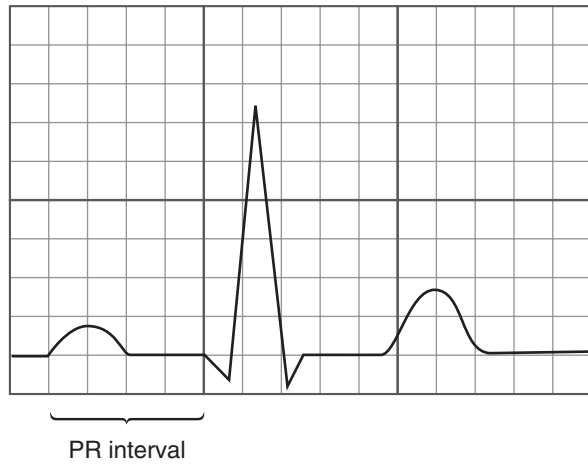

FIGURE 25.4 PR interval.

LEARNING TIP

To make measuring waves easier:

- Identify the isoelectric line as you measure waveform tracings to help you determine the type of wave. Use a straight edge resting below the line to see any waves above the line; then rest the straight edge above the line to see any waves that fall below the line.
- Try to find a wave that starts at the beginning of one small box (Fig. 25.4). If the wave starts or ends in the middle of a box, count it as one-half of a box, which is 0.02 seconds.

one P wave in a normal cardiac cycle. Disorders that change atrial size cause alterations in P wave shape and size.

PR Interval

The PR interval represents the time it takes the electrical impulse to travel down the atrium to the AV node. It starts at the beginning of the P wave and ends at the beginning of the QRS complex. Counting the number of small boxes horizontally that the interval covers determines the length of the PR interval (see Fig. 25.4). The normal PR interval is 0.12 to 0.20 second.

QRS Complex

The QRS complex represents ventricular depolarization and is composed of three waves, the Q, R, and S. The Q wave is the first downward deflection after the P wave but before the R wave. The R wave is the first upward deflection after the P wave. The last part of the QRS complex is the S wave, which is the second negative deflection after the P wave when a Q wave is present or the first negative deflection after the R wave (see Fig. 25.2). The S wave ends when it returns

FIGURE 25.5 (A) QRS complex with a Q wave. (B) QRS complex without a Q wave. (C) QRS complex without a Q or an S wave.

to the isoelectric line (this is why locating the isoelectric line is helpful when first learning to identify waves). It is important to note that all three waves are not always present in every QRS complex. Even with absent waves, the QRS is still referred to as the QRS complex and can be considered normal (Fig. 25.5).

Atrial repolarization occurs during the interval of the QRS but is not seen because of the more powerful ventricular activity. The presence of the P wave in the following cardiac cycle indicates that atrial repolarization has occurred.

QRS Interval

To measure the QRS interval, count the number of boxes from the wave that begins the QRS complex to the end of the wave that completes the QRS complex. For example, when a Q, R, and S are present, measure from the beginning of the Q wave to the end of the S wave (Fig. 25.6). If there is only an R present, measure from the beginning of the R to the end of the R. The normal QRS interval is <0.12 seconds.

T Wave

The T wave represents **ventricular repolarization**, the resting state of the heart, when the ventricles are filling with blood and preparing to receive the next impulse. The T wave starts at the next upward (positive) deflection, after the QRS complex, and ends with a return to the isoelectric line. The T wave can be a downward deflection after the QRS complex in some ECG leads, or it can indicate ischemia of the heart (Fig. 25.7).

FIGURE 25.6 QRS interval. This QRS interval covers two and one-half boxes. Each full box is 0.04 seconds. One-half box is 0.02 seconds; $2.5 \times 0.04 = 0.10$ seconds.

FIGURE 25.7 (A) T wave with positive deflection. (B) T wave with inverted, negative inflection, indicating ischemia.

FIGURE 25.8 Various locations where U waves may appear.

FIGURE 25.9 ST segment.

FIGURE 25.10 ST segment inverted or depressed.

FIGURE 25.11 ST segment elevated.

U Wave

The U waveform is usually not present. It is seen in patients with hypokalemia, which is a low serum potassium level. It occurs shortly after the T wave and can distort the configuration of the T wave (Fig. 25.8).

ST Segment

The ST segment reflects the time from completion of a contraction (depolarization) to recovery (repolarization) of myocardial muscle for the next impulse. The ST segment starts at the end of the QRS and ends at the beginning of the T wave (Fig. 25.9). The ST segment is examined for patients experiencing chest pain. Changes in the ST segment can indicate the presence of ischemia or an injury pattern suggestive of myocardial damage. If a patient has ischemia, the ST segment can be inverted or depressed (Fig. 25.10). With cardiac injury, the ST segment elevates from the isoelectric line (Fig. 25.11).

INTERPRETATION OF CARDIAC RHYTHMS

Five-Step Process for Dysrhythmia Interpretation

An orderly, systematic method for interpreting ECG rhythms should be used to increase understanding of items to examine and ensure nothing is overlooked. Five steps are examined in this process (Table 25.1). The findings of these five steps allow interpretation of the ECG rhythm according to the rules for each dysrhythmia. A 6-second ECG strip is used when interpreting rhythms. (See Fig. 25.3.)

Step 1. Regularity of the Rhythm

The regularity or rhythm of the heartbeat can be determined by looking at the R-R interval on the ECG (Fig. 25.12). The same spacing between each R-R interval, with a variation of no greater than two small boxes, is seen in a normal rhythm. To determine the regularity of a rhythm, count the number of small boxes between every R wave, which normally should remain the same, or use a caliper to measure the R-R interval.

A caliper is a small, two-sided, movable metal instrument with a sharp point at the end of each side. It is V-shaped when spread apart to measure distances. To use a caliper for measuring, one point is placed at the top of an R wave and the other point is spread apart until it rests on the top of the next R wave. Then, without changing the distance between the caliper points, the caliper is moved from one R wave to the next across the ECG tracing (also known as a strip) to see if the distance remains the same for each R-R interval. If the distance is the same, the rhythm is regular. If the distance changes, the rhythm is irregular. An irregular rhythm can be regularly irregular, which means it has a predictable pattern of irregularity, or irregularly irregular, without any pattern of irregularity.

LEARNING TIP

If a caliper is not available, a piece of paper can be placed on the ECG strip. A mark can be made on the paper at the top of one R wave and another mark made on the paper at the top of the next R wave. The marks on the paper can then be moved across the R-R intervals on the strip (just as caliper points would be) to determine whether the rhythm is regular or irregular.

Step 2. Heart Rate

After the rhythm regularity is determined, the heart rate is counted. One of the two following methods may be used.

1. Six-second method: The 6-second method is used for irregular rhythms. It may also be used when a rapid estimate of a regular rhythm is needed,

although it is not the most accurate method for regular rhythms. At the top of ECG graph paper there are vertical marks at 3-second intervals (see Fig. 25.3). Count the number of R waves in a 6-second strip and multiply the total by 10 (the number of 6 seconds in a minute) to obtain the beats per minute (6 seconds \times 10 = 60 seconds or 1 minute) (Fig. 25.13).

- Count the number of small (0.04-second) boxes between two R waves and divide that number into 1500. This gives the bpm, because 1500 small boxes equal 1 minute (Fig. 25.14). This method is used only for regular rhythms and is very accurate.

Step 3. P Wave

The P waves on the ECG strip are examined to see if (1) there is one P wave in front of every QRS, (2) the P waves are regular, and (3) the P waves all look alike. (See Fig. 25.1.) If all the P waves meet these criteria, they are considered normal. If they do not, further examination of the strip is necessary to determine the dysrhythmia.

Step 4. PR Interval

All PR intervals are measured to determine whether they are normal and constant. If the PR is found to vary, it is important to note whether there is a pattern to the variation.

Step 5. QRS Complex

The QRS intervals are measured to determine whether they are all normal and constant. Then the QRS complexes are examined to see if they all look alike.

TABLE 25.1 FIVE-STEP PROCESS FOR DYSRHYTHMIA INTERPRETATION

After answering the questions listed here, you should be able to name the patient's dysrhythmia.

Step	Topic	Assessment Questions
1	Regularity of rhythm	<ul style="list-style-type: none"> Is the rhythm regular? Irregular?
2	Heart rate	<ul style="list-style-type: none"> Is there a pattern to the irregularity?
3	P waves	<ul style="list-style-type: none"> What is the heart rate? Is there one P wave for every QRS complex? Are the P waves regular and constant? Do the P waves look alike? Are the P waves upright and in front of every QRS complex?
4	PR interval	<ul style="list-style-type: none"> Is the PR interval normal? Is the PR interval constant or varying?
5	QRS interval	<ul style="list-style-type: none"> Is the QRS interval normal? Is the QRS interval constant? Do the QRS complexes all look alike?

NORMAL SINUS RHYTHM

Description

Normal sinus rhythm is the normal cardiac rhythm (Fig. 25.15). It begins in the SA node and has complete, regular cardiac cycles.

FIGURE 25.12 Normal cardiac waves are equal distances apart. (A) R-R waves. (B) P-P waves.

FIGURE 25.13 Counting R waves in a 6-second strip. There are six R waves in this 6-second strip, and $6 \times 10 = 60$ beats per minute.

FIGURE 25.14 Heart rate. Count small boxes and divide by 1500 or count large boxes and divide by 300. Count number of large boxes between two R waves and divide into 300; five large boxes, $300/5 = 60$ beats per minute.

FIGURE 25.15 Normal sinus rhythm.

Normal Sinus Rhythm Rules

1. Rhythm: regular
2. Heart rate: 60 to 100 bpm
3. P waves: rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: <0.12 seconds

DYSRHYTHMIAS

Two terms are used for rhythm disturbances: *arrhythmia* and *dysrhythmia*. An arrhythmia is an irregularity or loss of rhythm of the heartbeat, and a dysrhythmia is an abnormal, disordered, or disturbed rhythm. These two terms are used interchangeably, but dysrhythmia is the most accurate term for the discussion of abnormal rhythms. For more information about cardiac care for dysrhythmias, visit the American Heart Association website at www.americanheart.org.

Several mechanisms can cause irregularity or dysrhythmia. Two examples of these mechanisms are a disturbance in the formation of an impulse and a disturbance in the conduction of the impulse. When impulse formation is disturbed, the impulse may arise from the atria, the AV node, or the ventricles. This disturbance can be seen as an increased or decreased heart rate, early or late beats, or atrial or ventricular fibrillation. With a disturbance in conduction there may be normal formation of the impulse, but it becomes blocked within the electrical conduction system, resulting in abnormal conduction (as in heart block or bundle branch blocks).

Dysrhythmias Originating in the Sinoatrial Node

Rhythms arising from the SA node are referred to as sinus rhythms. The SA node, being the pacemaker of the heart, fires normally at 60 to 100 bpm. Disturbances in conduction

from the SA node can cause irregular rhythms or abnormal heart rates. Dysrhythmias arising from the SA node are rarely dangerous. Patients, especially those with heart, lung, or kidney disease, who cannot tolerate a rapid or slow heart rate may require treatment.

LEARNING TIP

The origin and type of a problem are used to name a dysrhythmia. Let us name a slow dysrhythmia that originates in the SA node. The origin is *sinus* and the type of problem (slow) is *bradycardia* = *sinus bradycardia*. The term *normal* is not used since there is a problem. So what would a fast dysrhythmia originating in the SA node be called? Yes, it is *sinus tachycardia*.

Sinus Bradycardia

DESCRIPTION. Bradycardia is a slower than normal heart rate. Sinus bradycardia has the same cardiac cycle components as a normal sinus rhythm. The only difference between the two is a slower heart rate caused by fewer impulses originating from the SA node (Fig. 25.16). Can you see that the name *sinus bradycardia* tells you this difference? The name says the impulse is coming from the sinus node (sinus) but at a slower rate than normal (bradycardia). See, it is easy to understand what is happening in the dysrhythmia when you look at what the name tells you.

CAUSES. Medications such as digoxin (Lanoxin), myocardial infarction (MI), and electrolyte imbalances can cause bradycardia. Well-conditioned athletes also can have slower heart rates because their hearts work more efficiently.

bradycardia: bradys—slow + kardia—heart

FIGURE 25.16 Sinus bradycardia.

SINUS BRADYCARDIA RULES

1. Rhythm: regular
2. Heart rate: less than 60 bpm
3. P waves: smoothly rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: <0.12 seconds

SIGNS AND SYMPTOMS. Sinus bradycardia rarely produces symptoms unless it is so slow that it reduces cardiac output. Symptoms consist of fatigue or fainting episodes.

THERAPEUTIC INTERVENTIONS. Treatment is usually not required if the patient is asymptomatic. The patient is observed for symptoms, and the underlying cause is determined for correction. Oxygen and intravenous (IV) access may be started. If bradycardia is due to a heart block dysrhythmia, insertion of a cardiac pacemaker may be required. If the patient is symptomatic, therapeutic interventions may include atropine sulfate, transcutaneous pacing, dopamine, epinephrine, or isoproterenol. Medications are given IV by a registered nurse for immediate effect. The treatments increase the heart rate for a short time until a cause can be determined and treated.

Sinus Tachycardia

DESCRIPTION. Tachycardia is defined as a heart rate greater than 100 beats per minute. Sinus tachycardia has the same components as a normal sinus rhythm except the heart rate is faster (Fig. 25.17). More impulses originating from the SA node than normal cause this.

CAUSES. Sinus tachycardia causes include physical activity; hemorrhage; shock; medications such as epinephrine, atropine, or nitrates; dehydration; fever; MI; electrolyte imbalance; fear; and anxiety. Tachycardia occurs as a compensatory mechanism for hypoxia when more cardiac output is needed to deliver oxygen to organs and tissues.

SINUS TACHYCARDIA RULES

1. Rhythm: regular
2. Heart rate: 101 to 180 bpm
3. P waves: rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: <0.12 seconds

SIGNS AND SYMPTOMS. Sinus tachycardia may not produce symptoms. If the heart rate is very rapid and sustained for long periods, the patient may experience angina or dyspnea. Older patients may become symptomatic more rapidly than younger patients (Box 25.1 Gerontological Issues). Patients with MI may not tolerate a rapid heart rate and have more severe symptoms since cardiac workload is increased.

THERAPEUTIC INTERVENTIONS. Treatment depends on the cause and symptoms. Medications such as digoxin, calcium channel blockers (verapamil [Calan]), or beta blockers (propranolol [Inderal]) may be used to slow the heart rate. Oxygen may also be prescribed to ensure an

adequate supply for the heart. The treatment goal is to decrease the heart's workload and resolve the cause, which then usually corrects the tachycardia. For example, if the patient is hemorrhaging, immediate intervention is needed to stop the bleeding and restore normal blood volume. Once normal blood volume is restored, the heart rate should return to normal.

**LEARNING TIP**

Tachycardia is often the first sign of hemorrhage. It is a compensatory mechanism to maintain cardiac output. If a patient develops sudden tachycardia, consider whether hemorrhage could be the cause, such as in postoperative patients, patients with gastrointestinal bleeding or cancer, or trauma patients. The bleeding may be external, or it may be internal and therefore not visible. Apply pressure to the site if the bleeding is obvious. Monitor the patient and report the tachycardia and any obvious bleeding promptly.

Dysrhythmias Originating in the Atria

As previously discussed, all areas of the heart can initiate an impulse. The SA node is the primary pacemaker, but if the atria initiate impulses faster than the SA node, they become the primary pacemaker. Atrial rhythms are usually faster than 100 bpm and can exceed 200 bpm. When an impulse originates outside the SA node, the P waves produced look different from the rounded P waves from the SA node (flatter, notched, or peaked), which indicates that the SA node is not controlling the heart rate. These atrial impulses travel to the ventricles to initiate a normal QRS complex after each P wave.

**LEARNING TIP**

- If a QRS complex measures less than 0.12 seconds and there is a dysrhythmia present, the problem originated above the ventricles. This is known as a supraventricular (above the ventricle) dysrhythmia.
- Ventricular originating dysrhythmias produce wide QRS complexes that are greater than 0.11 seconds.

Premature Atrial Contractions

DESCRIPTION. The term *premature* refers to an “early” beat. When the atria fire an impulse before the SA node fires, a premature beat results. If the underlying rhythm is sinus rhythm, the distance between R waves is the same

FIGURE 25.17 Sinus tachycardia.

except where the early beat occurs. When looking at the ECG strip, a shortened R-R interval is seen where the premature beat occurs. The R wave preceding the premature atrial contraction (PAC) and the PAC's R wave are close together, followed by a pause, with the next beat being regular (Fig. 25.18).

CAUSES. Causes of PACs include hypoxia, smoking, stress, myocardial ischemia, enlarged atria in valvular disorders, medications (such as digoxin), electrolyte imbalances, atrial fibrillation onset, and heart failure.

PREMATURE ATRIAL CONTRACTIONS RULES

1. Rhythm: premature beat interrupts underlying rhythm where it occurs
2. Heart rate: depends on the underlying rhythm; if normal sinus rhythm (NSR), 60 to 100 bpm
3. P waves: early beat is abnormally shaped
4. PR interval: usually appears normal, but premature beat could have shortened or prolonged PR interval
5. QRS interval: <0.12 seconds (indicates normal conduction to ventricles)

SIGNS AND SYMPTOMS. Premature atrial contractions can occur in healthy individuals, as well as in the patient with a diseased heart. No symptoms are usually present. If

many PACs occur in succession, the patient may report the sensation of palpitations.

THERAPEUTIC INTERVENTIONS. PACs are usually not dangerous, and often no treatment is required other than correcting the cause. Frequent PACs indicate atrial irritability, which may worsen into other atrial dysrhythmias. Quinidine or procainamide can be given to a patient having frequent PACs to slow the heart rate.

Atrial Flutter

DESCRIPTION. In atrial flutter, the atria contract, or flutter, at a rate of 250 to 350 bpm. The very rapid P waves appear as flutter, or F waves, on ECG and appear in a saw-toothed pattern. Some of the impulses get through the AV node and reach the ventricles, resulting in normal QRS complexes. There can be from two to four F waves between QRS complexes. If impulses pass through the AV node at a consistent rate, the rhythm is regular (Fig. 25.19). The classic characteristics of atrial flutter are more than one P wave before a QRS complex, a saw-toothed pattern of P waves, and an atrial rate of 250 to 350 bpm.

CAUSES. Causes of atrial flutter include rheumatic or ischemic heart diseases, congestive heart failure (CHF), hypertension, pericarditis, pulmonary embolism, and post-operative coronary artery bypass surgery. Many medications can also cause this dysrhythmia.

Box 25.1

Gerontological Issues

Dysrhythmia Risk

Factors that increase the risk of dysrhythmias in older adults include the following:

- Digitalis toxicity (most common)
- Hypokalemia
- Acute infection
- Hemorrhage
- Angina
- Coronary insufficiency (exercise, stress)

Dysrhythmias that occur most often in older adults include the following:

- Atrial fibrillation (atria beating 400 to 700 times per minute)
- Sick sinus syndrome (alternating episodes of bradycardia, normal sinus rhythm, tachycardia, and periods of long sinus pause)

- Heart block (delayed or blocked impulses to the atria or ventricles)

Age-related effects of dysrhythmias include the following:

- Weakness
- Fatigue
- Forgetfulness
- Palpitations
- Dizziness
- Hypotension
- Bradycardia
- Syncope

Older adults are especially sensitive to changes in heart rate that increase the heart's workload. Whenever the heart works harder, as in tachycardia, the cardiac cells require more oxygen to function properly. Older patients have less ability to adapt to sudden changes or stressors, and they may not be able to tolerate tachycardia for very long. Any new-onset tachycardia in an older patient should be reported promptly.

FIGURE 25.18 Premature atrial contractions (PAC).

ATRIAL FLUTTER RULES

1. Rhythm: atrial rhythm regular; ventricular rhythm regular or irregular depending on consistency of AV conduction of impulses
2. Heart rate: ventricular rate varies
3. P waves: flutter or F waves with saw-toothed pattern
4. PR interval: none measurable
5. QRS complex: <0.12 seconds

SIGNS AND SYMPTOMS. The presence of symptoms in atrial flutter depends on the ventricular rate. If the ventricular rate is normal, usually no symptoms are present. If the rate is rapid, the patient may experience palpitations, angina, or dyspnea.

THERAPEUTIC INTERVENTIONS. The ventricular rate and cardiac output guide treatment. The goal is to control the ventricular rate and convert the rhythm. A rapid ventricular rate or symptoms of decreased cardiac output require **cardioversion** (electrical shock). If the rate is greater than 150 bpm, immediate cardioversion is needed. Medications that may be used to control the rate include calcium channel blockers and beta blockers. For rhythm conversion, digoxin can be used to slow conduction through the AV node and increase cardiac contractility. Other medications, such as quinidine, procainamide, or propranolol, can also be used to slow the heart rate.

Atrial Fibrillation

DESCRIPTION. In atrial fibrillation, the atrial rate is extremely rapid and chaotic. An atrial rate of 350 to 600 bpm can occur. However, the AV node blocks most of the impulses, so the ventricular rate is much lower than the atrial rate. There are no definable P waves because the atria are fibrillating, or quivering, rather than beating effectively. No P waves can be seen or measured. A wavy pattern is produced on the ECG. Because the atrial rate is so irregular and only a few of the atrial impulses are allowed to pass through the AV

node, the R waves are irregular. The ventricular rate varies from normal to rapid.

Atrial fibrillation can be self-limiting, persistent, or permanent. A complication of this dysrhythmia is an increased risk of thrombus formation in the atria from blood stasis caused by poor emptying of blood from the quivering atria (Fig. 25.20). This can result in stroke or pulmonary emboli.

CAUSES. Causes of atrial fibrillation include aging, rheumatic or ischemic heart diseases, heart failure, hypertension, pericarditis, pulmonary embolism, and post-operative coronary artery bypass surgery. Medications can also cause this dysrhythmia.

ATRIAL FIBRILLATION RULES

1. Rhythm: irregularly irregular
2. Heart rate: atrial rate not measurable; ventricular rate under 100 is controlled response; greater than 100 is rapid ventricular response
3. P waves: no identifiable P waves
4. PR interval: none can be measured because no P waves are seen
5. QRS complex: 0.06 to 0.10 seconds

LEARNING TIP

Atrial fibrillation is easy to identify based on its two classic characteristics: a lack of identifiable P waves and an irregularly irregular rhythm (R waves).

SYMPTOMS. With atrial fibrillation, most patients feel the irregular rhythm. Many describe it as palpitations or a skipping heartbeat. When checking a patient's radial pulse, it may be faint because of a decreased stroke volume (volume of blood ejected with each contraction). If the ventricular rhythm is rapid and sustained, the patient can go into left ventricular failure.

FIGURE 25.19 Atrial flutter.

FIGURE 25.20 Atrial fibrillation.

THERAPEUTIC INTERVENTIONS. Treatment is based on the patient's stability. If the patient is unstable, cardioversion is done immediately to try to return the heart to normal sinus rhythm. If the patient is stable, medications to restore and maintain a normal sinus rhythm and control the ventricular rate may be used. The ventricular rate may be controlled with such medications as digoxin, beta blockers, or calcium channel blockers. Medications approved by the Food and Drug Administration to convert atrial fibrillation and maintain a normal sinus rhythm include dofetilide, quinidine, flecainide, propafenone, and ibutilide IV. Anticoagulant therapy (aspirin for low-risk patients, warfarin for those at high risk), which can be long term or lifelong, is given to reduce thrombi. International normalized ratio (INR) and prothrombin time levels must be carefully monitored for patients on warfarin. Chemical or electrical cardioversion may be performed to convert the rhythm after sufficient anticoagulation (about 3 weeks). If known, the underlying cause of the atrial fibrillation should also be treated.

Dual-chamber pacing for those with sinus node problems or biatrial pacing, as well as pacemaker recognition of atrial fibrillation, helps to prevent this dysrhythmia. Implantable cardioverter defibrillators (ICDs) can deliver a shock activated by the physician or patient to end the atrial fibrillation. Because this is a planned event, medications for comfort can be taken by the patient before the shock.

For patients with atrial fibrillation who do not respond to medications, **ablation** procedures may be performed

ablation: ab—away from + lat—carry

(discussed later). A surgical procedure can be performed if other treatments fail. The maze procedure was first done as open heart surgery, but a percutaneous, nonsurgical catheter maze procedure may be used to eliminate the risks of open heart surgery. In the open heart maze procedure, incisions are made in the atria that create a “maze,” or route, for electrical impulses to travel through to the AV node. These impulses cannot go off course because scar tissue surrounds the incision sites. In many cases, this cures atrial fibrillation. However, some patients may need continued medications or a pacemaker following this procedure.

Ventricular Dysrhythmias

Premature Ventricular Contractions

DESCRIPTION. Premature ventricular contractions (PVCs) originate in the ventricles from an ectopic focus (a site other than the SA node). The ventricles are irritable and fire prematurely, before the SA node. When the ventricles fire first, the impulses are not conducted normally through the electrical pathway. This results in a wide (greater than 0.11 seconds), bizarre QRS complex on an ECG (Fig. 25.21).

PVCs can occur in different shapes. The shape of the PVC is referred to as **unifocal** (one focus) if all the PVCs look the same because they come from the same irritable ventricular area. **Multifocal** PVCs do not all look the same because they are originating from several irritable areas in the ventricle. There can be several repetitive cycles or patterns of PVCs:

- **Bigeminy** is a PVC that occurs every other beat (a normal beat and then a PVC) (Fig. 25.22).

FIGURE 25.21 Premature ventricular contractions. (A) Unifocal PVCs arise from one area and look the same. (B) Multifocal PVCs arise from different foci and may look different.

FIGURE 25.22 Bigeminal premature ventricular contractions.

- **Trigeminy** is a PVC that occurs every third beat (two normal beats and then a PVC).
- **Quadrigeminy** is a PVC that occurs every fourth beat (three normal beats and then a PVC).
- When two PVCs occur together, they are referred to as a couplet (pair).
- If three or more PVCs occur in a row, it is referred to as a run of PVCs or ventricular tachycardia.

CAUSES. Use of caffeine or alcohol, anxiety, hypokalemia, cardiomyopathy, ischemia, and MI are common causes of PVCs.

PREMATURE VENTRICULAR CONTRACTION RULES

1. Rhythm: depends on the underlying rhythm; PVC usually interrupts rhythm
2. Heart rate: depends on underlying rhythm
3. P waves: absent before PVC QRS complex
4. PR interval: none for PVC
5. QRS complex: if PVC, is greater than 0.11 seconds; T wave is in the opposite direction of QRS complex (i.e., QRS upright, T downward or QRS downward, T upright)

SIGNS AND SYMPTOMS. PVCs may be felt by the patient and are described as a skipped beat or palpitations. With frequent PVCs, cardiac output can be decreased, leading to fatigue, dizziness, or more severe dysrhythmias.

THERAPEUTIC INTERVENTIONS. Treatment depends on the type and number of PVCs and whether symptoms are produced. A few PVCs do not usually require treatment. However, if the PVCs are more than six per minute, regularly occurring, multifocal, falling on the T wave (known as “R-on-T phenomenon,” which can trigger life-threatening dysrhythmias), or caused by an acute MI, they can be dangerous. Antidysrhythmic drugs that depress myocardial activity are used to treat PVCs. Examples of drugs that may

be given intravenously by the registered nurse and then followed by a continuous IV drip are procainamide (Procan) and lidocaine (Xylocaine).

Ventricular Tachycardia

DESCRIPTION. The occurrence of three or more PVCs in a row is referred to as **ventricular tachycardia (VT)** (Fig. 25.23). VT results from the continuous firing of an ectopic

CRITICAL THINKING

Mrs. Mae

■ Mrs. Mae, age 70, is 5 days post-MI without complications. You assist her back to bed at 1400 hours after she ambulates. Her oxygen is on at 2 L/min via nasal cannula. Her vital signs are 126/78, 82, 18. She has no pain and says she feels good after walking. The cardiac monitor shows normal sinus rhythm with PVCs of less than six per minute. Her vital signs are now 132/84, apical 92 irregular, 22. She reports no pain but says, “I can feel my heart skipping, it takes my breath away.” You call the RN while staying with the patient for reassurance.

1. What should you do first?
2. What should you do regarding the dysrhythmia?
3. What might be some of the causes for this dysrhythmia?
4. What symptoms, if any, would you expect to be present?
5. What would you do if symptoms were present?
6. What type of orders would you anticipate from the physician?
7. How would you document your findings?

Suggested answers at end of chapter.

FIGURE 25.23 Ventricular tachycardia.

ventricular focus. During VT, the ventricles rather than the SA node become the pacemaker of the heart. The pathway of the ventricular impulses is different from normal conduction, producing a wide (greater than 0.11 seconds), bizarre QRS complex.

CAUSES. Myocardial irritability, MI, and cardiomyopathy are common causes of VT. Respiratory acidosis, hypokalemia, digoxin toxicity, cardiac catheters, and pacing wires can also produce VT.

VENTRICULAR TACHYCARDIA RULES

1. Rhythm: usually regular, may have some irregularity
2. Heart rate: 150 to 250 ventricular bpm; slow VT is below 150 bpm
3. P waves: absent
4. PR interval: none
5. QRS complex: greater than 0.11 seconds

SIGNS AND SYMPTOMS. The seriousness of ventricular tachycardia is determined by the duration of the dysrhythmia. Sustained VT compromises cardiac output. Patients are aware of a sudden onset of rapid heart rate and can experience dyspnea, palpitations, and light-headedness. Angina commonly occurs. The severity of symptoms can increase rapidly if the left ventricle fails and complete cardiac arrest results.

THERAPEUTIC INTERVENTIONS. If the patient is pulseless or not breathing, cardiopulmonary resuscitation

(CPR) and immediate defibrillation are required. Current advanced cardiac life support (ACLS) protocols for VT treatment should follow.

If the patient is stable, medications can be tried first, such as amiodarone, procainamide, sotalol, lidocaine, phenytoin, or beta blockers following ACLS protocols. Magnesium can be used to help stabilize ventricular muscle excitability if the patient's magnesium level is low.

Ventricular Fibrillation

DESCRIPTION. Ventricular fibrillation occurs when many ectopic ventricular foci fire at the same time. Ventricular activity is chaotic with no discernible waves (Fig. 25.24). The ventricle quivers and is unable to initiate a contraction. There is a complete loss of cardiac output. If this rhythm is not terminated immediately, death ensues.

CAUSES. Hyperkalemia, hypomagnesemia, electrocution, coronary artery disease, and MI are all possible causes of ventricular fibrillation. Placement of intracardiac catheters and cardiac pacing wires can also lead to ventricular irritability and then ventricular fibrillation.

VENTRICULAR FIBRILLATION RULES

1. Rhythm: chaotic and extremely irregular
2. Heart rate: not measurable
3. P waves: none
4. PR interval: none
5. QRS complex: none

SIGNS AND SYMPTOMS. Patients experiencing ventricular fibrillation lose consciousness immediately. There are no heart sounds, peripheral pulses, or blood pressure. These are all indicative of circulatory collapse. Additionally, respiratory arrest, cyanosis, and pupil dilation occur.

THERAPEUTIC INTERVENTIONS. Immediate defibrillation is the very best treatment for terminating ventricular fibrillation. Each minute that passes without defibrillation reduces survival. CPR is started until the defibrillator is available. Automatic external defibrillators (AEDs) provide quick access to easily used technology for defibrillation (see defibrillation section). Endotracheal intubation and ventilation support respiratory function. Medications are given

CRITICAL THINKING

Mrs. Parker

■ You are caring for Mrs. Parker, age 66, on the cardiac medical unit. She had an MI and several episodes of ventricular tachycardia while she was in the ICU before transferring to your unit. At 1600 hours you find her unresponsive, with no palpable pulses and shallow respirations and in VT on the ECG. Vital signs are BP 80/40, P 150, R 6.

1. Why are there no palpable pulses?
2. What is occurring to the heart when it is in VT?
3. What action should you take?
4. How will you document your findings?

Suggested answers at end of chapter.

hyperkalemia: hyper—above + kalium—potassium + emia—blood

hypomagnesemia: hypo—below + magnes—magnesium + emia—blood

FIGURE 25.24 Ventricular fibrillation.

FIGURE 25.25 Asystole.

according to ACLS protocols and may include epinephrine, vasopressin, amiodarone, lidocaine, magnesium, and procainamide.

Asystole

DESCRIPTION. Asystole (the silent heart) is the absence of electrical activity in the cardiac muscle. It is referred to as cardiac arrest. A straight line appears on an ECG strip (Fig. 25.25). Ventricular fibrillation usually precedes this rhythm and must be reversed immediately to help prevent asystole.

CAUSES. Ventricular fibrillation and a loss of a majority of functional cardiac muscle due to an MI are common causes of asystole. Hyperkalemia is another cause of asystole.

ASYSTOLE RULES

1. Rhythm: none
2. Heart rate: none
3. P waves: none
4. PR interval: none
5. QRS complex: none

THERAPEUTIC INTERVENTIONS. CPR is started immediately. ACLS protocols for asystole are used. Endotracheal intubation to support respirations is performed. Transcutaneous pacing is considered, then epinephrine and atropine are administered.

CRITICAL THINKING

Mr. Peet

■ You are making rounds. When you enter Mr. Peet's room, you note that he is having difficulty breathing and is unresponsive.

1. What are your initial actions?
2. What should you do after assessing and finding no pulse or respirations?
3. What is your responsibility during a cardiac/respiratory arrest code?

Suggested answers at end of chapter.

CARDIAC PACEMAKERS

Pacemakers can be external and temporary or internal and permanent (Fig. 25.26). They are used to override dysrhythmias or to generate an impulse when the heart is beating too

slowly. Transcutaneous pacemakers are used in emergency situations because they are quick and easy to apply. Impulses are delivered to the heart through the skin from the external generator via electrodes that are attached to the chest and back.

Temporary pacemakers are used for bradycardias or tachycardias that do not respond to medications or cardioversion. They may also be used after an MI to allow the heart time to heal when the diseased myocardium is unable to respond to or is not receiving electrical conduction because of damage within the system. The temporary pacemaker becomes the electrical conduction system and stimulates the atria and ventricles to contract to maintain cardiac output. Temporary pacemakers can be inserted during valve or open heart surgery or in the cardiac catheterization laboratory or critical care unit at the bedside as emergency treatment until surgery can be scheduled to insert a permanent pacemaker.

Permanent pacemaker insertion is a surgical procedure in which **fluoroscopy**, a screen that shows an image similar to a radiograph, is used. The pacemaker generator is implanted subcutaneously and attached to one or two leads (insulated conducting wires) that are inserted via a vein into the heart. The lead can then deliver the impulse directly to the heart wall. A single-lead pacemaker paces either the right atrium or right ventricle depending on its chamber placement. Dual-chamber pacemakers have two leads, with one in the right atrium and the other in the right ventricle.

FIGURE 25.26 Insertion of dual-chamber permanent pacemaker.

This allows pacing of both chambers. Usually pacemakers are set at a prescribed rate of 72 bpm. Activity-responsive pacemakers provide a rate range (e.g., 60 to 115 bpm) in response to a person's activity level. This provides the patient with greater flexibility for increasing cardiac output when needed, such as during exercise.

When a patient is in a paced rhythm, a small spike is seen on the ECG before the paced beat. This spike is the electrical stimulus. It can precede the P wave, QRS complex, or both depending on what is being paced (Fig. 25.27). Patients may have all paced beats (100% paced), a mixture of their own beats and paced beats, or all of their own beats. Pacemakers should not fire when patients have their own beats.

Problems that can occur with pacemakers include the following:

- Failure to sense the patient's own beat
- Failure to pace because of a malfunction of the pulse generator
- Failure to capture, which is a lack of depolarization

Nursing Care for Patients with Pacemakers

Patients are placed on a cardiac monitor and rest for several hours after insertion of a pacemaker. The patient's apical pulse is monitored frequently to detect changes in the heart rhythm. Irregular heart rhythms or a rate slower than the

pacemaker's set rate can indicate pacemaker malfunction. The dressing at the pacemaker insertion site is monitored every 2 to 4 hours for signs of bleeding. Any change in heart rhythm, complaints of chest pain, or changes in vital signs must be reported immediately. Patients may have a sling on the operative side arm for 24 to 48 hours to help prevent dislodgement of the pacemaker lead from the cardiac wall. The patient may remain in the hospital for a short stay.

Patient education for pacemaker care before discharge includes the following:

- Incision care. The patient should check the incision daily and report evidence of inflammation or infection (redness, swelling, warmth, tenderness, pain, fever, or discharge) to a physician. A hard ridge may form over the incision that will disappear with healing.
- Methods for taking a radial pulse. The patient should call a physician if the pulse is slower than the pacemaker's set rate.
- The patient should report symptoms of dizziness, fainting, irregular heartbeats, or palpitations.
- The patient should understand the importance of wearing medical alert jewelry and carrying a pacemaker information card.
- The patient should avoid radiation, magnetic fields (e.g., magnetic resonance imaging [MRI], industrial

FIGURE 25.27 (A) Atrial-only pacemaker. (B) Ventricular-only pacemaker. (C) AV sequential pacemaker that paces both atrial and ventricular chambers.

magnets), high voltage (e.g., power plant, arc welding, high-tension wires), antitheft devices, and large running motors (e.g., distributor coil of running engine).

- The patient will need to tell airport security about the pacemaker, because it may trigger metal detectors (they do not harm the pacemaker).
- Grounded appliances (usually includes microwave ovens) and office equipment are safe to use.
- The patient must avoid lifting more than 10 pounds, making major arm movements, or participating in contact sports for 6 weeks after surgery. Normal activity is usually resumed after 6 weeks.
- The patient must keep scheduled appointments with the physician. Periodic pacemaker checks will be done by the physician or over the telephone. Reprogramming of the pacemaker can be done by the physician if needed.

CRITICAL THINKING

Mr. Treacher

■ Mr. Treacher, age 58, underwent pacemaker placement 6 days ago and is being transferred to the medical floor. After transfer, his vital signs are 138/72, 72 bpm, and 100% paced rhythm. Thirty minutes later, he says that he feels weak and tired. His vital signs are now 100/60, 60 bpm, and irregular.

1. What is your first action?
2. What actions should be taken next?
3. What might be happening to Mr. Treacher?
4. What interventions should you anticipate next?

Suggested answers at end of chapter.

DEFIBRILLATION

Defibrillation is a lifesaving procedure used for lethal dysrhythmias. It delivers an electrical shock to reset the heart's rhythm. It is used to terminate pulseless ventricular tachycardia or ventricular fibrillation. Self-adhesive pads, conductive jelly, or saline pads are placed on the patient's chest to prevent electrical burns from the defibrillator and promote conduction of the electrical charge. After the defibrillator is charged, the paddles are pressed firmly and evenly against the chest wall at the second intercostal space, right of the sternum and on the anterior axillary line at the fifth intercostal space (Fig. 25.28).

If the paddles are not pressed firmly against the chest wall during defibrillation, burns or electrical arcing can result when the shock is delivered. For safety, the person defibrillating must announce “clear.” The phrase “One. I’m

FIGURE 25.28 Placement of defibrillator paddles on chest.

clear. Two. You're clear. Three. All clear” is suggested. No one, including the person defibrillating, should touch the bed or patient during this time to avoid also being shocked. ACLS protocols specify guidelines for resuscitation. If the first shock is unsuccessful, a total of three shocks can be given initially, at increasing energy levels (200, 300, 360 joules).

A defibrillator may have a synchronization mode that allows R waves, if present, to be sensed so that an electrical shock can be delivered at an appropriate time in the cardiac cycle. This timing is important to prevent a more life-threatening dysrhythmia from developing. When defibrillation of a pulseless ventricular dysrhythmia is desired, the synchronize mode must be off (unsynchronized cardioversion). In this mode the charge is immediately released when the trigger is pressed. In the synchronized mode (synchronized cardioversion) there is a delay in the release of the charge while the R wave is sensed for appropriate timing.

After successful defibrillation, the patient is assessed for a pulse and adequate tissue perfusion. Vital signs, peripheral pulses, and level of consciousness should be noted. The patient is treated in the critical care unit after successful resuscitation.

Emotional support for the patient having experienced cardiac arrest and defibrillation is a very important aspect of nursing care. This can be an extremely frightening event for the patient. It is important to explain what happened to the patient and to listen and allow the patient to express any concerns. The patient is reassured that continuous monitoring is done in the critical care unit. Families also require emotional support during resuscitation of a loved one.

defibrillation: de—from + fibrillation—quivering fibers

OTHER METHODS TO CORRECT DYSRHYTHMIAS

Automatic External Defibrillators

An AED is an external device that automatically analyzes rhythms and either automatically delivers or prompts operators to deliver an electrical shock if a shockable rhythm (ventricular fibrillation or VT) is detected. Minimally trained laypersons or hospital and rescue personnel can use these devices with little risk of injury to the patient because the AED analyzes the rhythm rather than the operator. The patient is connected to the AED with adhesive sternal-apex pads attached to cables coming from the device. This connection allows hands-free defibrillation. AEDs are found in public places such as shopping malls, airports, stadiums, casinos, golf courses, and airplanes for immediate access. The American Heart Association encourages increasing the availability of AEDs because defibrillation attempts must occur within minutes of cardiac arrest to increase chance of survival. AEDs are available for home use. They are recommended for people at high risk of sudden cardiac arrest, and for those at risk with rescue access that will take longer than 4 minutes such as those in rural areas, gated communities or secured access buildings. (Visit the Internet and search for AED to view more information and photographs on AEDs.)

Implantable Cardioverter Defibrillator

An implanted ICD is surgically placed during a minor procedure into the chest of a patient who experiences life-threatening dysrhythmias or is at risk for sudden cardiac death (Fig. 25.29). ICDs have decreased the number of deaths from these dysrhythmias by analyzing and treating these heart rhythms. When an abnormal rhythm is detected that could cause death (ventricular fibrillation), it automati-

FIGURE 25.29 An implanted cardioverter defibrillator in place.

cally delivers an electrical shock. If the dysrhythmia does not convert on the initial shock, more shocks are delivered sequentially.

If the device detects VT, it cardioverts the rhythm using lower energy. ICDs also have antitachycardia pacing ability if a tachycardic rhythm is detected. Battery life depends on usage, but a battery may last up to 7 years. A physician can tell when the battery is getting low and that the entire unit needs to be changed within a few months.

Patients with ICDs are extremely anxious about having another cardiac arrest and receiving shocks from the ICD. Defibrillator or cardioversion shocks may feel like a kick in the chest. Reinforcement of patient and family education is very important in preparing the patient for discharge. Those with ICDs should take precautions to prevent problems with the ICD by taking the following precautions:

- Avoiding MRIs
- Avoiding metal detectors and standing near security gates or store entrances
- Avoiding equipment with strong electrical or magnetic fields (e.g., amusement rides, slot machines, remote-control toys, stereo speakers)
- Keeping cell phones 6 inches from the ICD

The nurse provides emotional support, answers all questions, and ensures that any misunderstood information is corrected before discharge.

Cardioversion

Elective cardioversion is used for dysrhythmias such as atrial fibrillation, atrial flutter, and supraventricular tachycardias that are not responsive to drug therapy. Conscious sedation is often used. The patient is given a sedative and monitored by anesthesia personnel during the procedure. Cardioversion is performed with a defibrillator set in the synchronize mode. The defibrillator is attached to the patient by electrode wires, which enables the ECG to be viewed on a screen. On the defibrillator there is a switch labeled “synchronize,” which is on during cardioversion. When the defibrillator is in the synchronized mode, it marks a highlighted area on the patient’s R waves, which must be recognized to deliver a shock.

The number of joules delivered with each shock is determined by a physician but usually ranges from 25 to 50 joules. Self-adhesive pads or conduction jelly is placed on the chest. The paddles must be firmly and evenly pressed against the pads or jelly on the chest until the shock is delivered to prevent skin burns and electrical arcing. When the discharge trigger is pressed, the shock is released when the machine senses it is safe to do so. The cardiac monitor screen is observed to see the discharge of the shock and to note the patient’s ECG response. The patient’s pulse and vital signs are checked.

If cardioversion is successful, there should be a return to normal sinus rhythm. If the rhythm does not immediately convert, more cardioversion attempts can be made as determined by the physician. After the procedure, the patient is monitored for skin burns, rhythm disturbances,

respiratory problems, hypotension, and changes in the ST segment.

Ablation

When medications or other treatments are not successful in treating a dysrhythmia, ablation of cardiac conduction pathways may be used to stop the dysrhythmia. Intracardiac echocardiography and intracardiac mapping are done before ablation to determine the area of the heart requiring treatment.

Forms of ablation include mechanical, chemical, and radio frequency. Mechanical ablation destroys the involved tissue with cryosurgery or through surgical removal. Chemical ablation inserts alcohol or phenol through an angioplasty catheter into the area of the heart producing the unwanted beats. Radio frequency ablation delivers high-frequency energy via a catheter to necrose selected conduction pathway areas. Following any of these ablation procedures, a temporary or permanent pacemaker may be needed if normal conduction tissue is damaged. Postprocedural care is similar to postangioplasty or postcardiac catheterization care (see Chapter 20).

NURSING PROCESS FOR THE PATIENT WITH DYSRHYTHMIAS

Assessment/Data Collection

Assessment of the cardiac system, respiratory rate, breath sounds, and urinary output is important. Monitoring apical and radial pulses at frequent intervals helps detect dysrhythmias. Most dysrhythmias are not life threatening. Patients at risk for dysrhythmias require careful monitoring so that any dysrhythmias are detected and treated. A patient's complaints of dizziness, chest pain, or palpitations should always be reported to the physician.

Nursing Diagnoses, Planning and Implementation, and Evaluation

See Box 25.2 Nursing Care Plan for the Patient with Dysrhythmias.

To implement the plan of care, the patient and family should be included. Assist them in understanding the plan and the reasons for the prescribed interventions and allow them to express their needs and fears.

BOX 25.2 NURSING CARE PLAN for the Patient with Dysrhythmias

Nursing Diagnosis: Decreased cardiac output related to dysrhythmias

Expected Outcomes (1) Patient cardiac status stabilizes. (2) Patient tolerates activities of daily living (ADL).

Evaluation of Outcomes (1) There is an absence of dysrhythmias. (2) Patient is able to perform ADL without tachycardia, chest pain, or weakness.

Interventions

Take apical and radial pulses every 2 to 4 hours. Monitor blood pressure and urinary output.

Monitor mental status every 2 to 4 hours.

Listen to lung sounds every 2 to 4 hours.

Administer O₂ as ordered.

Ensure that patient gets adequate rest and does not exceed activity tolerance.

Administer medications as ordered and observe for adverse reactions.

Rationale

Monitors for dysrhythmias, impending cardiac arrest, or shock. Blood pressure, pulse, and urinary output are indicators of cardiac output.

Dizziness, confusion, and restlessness may indicate decreased cerebral blood flow.

Dysrhythmias can cause heart failure.

Increases oxygenation to the heart and brain.

Reduces dyspnea and decreases O₂ demand on the myocardium.

Geriatric

Older patients may have decreased renal and liver function that may lead to rapid development of toxicity.

Evaluation

Is the patient free of dysrhythmias with vital signs within normal limits?

Does patient show signs of decreased cerebral perfusion, such as confusion?

Are lungs clear with no report of dyspnea?

Is patient free of chest pain, confusion, and light-headedness?

Does patient rest and tolerate activity without dyspnea or chest pain?

Does patient have signs of toxicity?

(Continued on following page)

BOX 25.2 NURSING CARE PLAN for the Patient with Dysrhythmias (Cont'd)

Nursing Diagnosis: Anxiety related to situational crisis

Expected Outcomes (1) Patient is able to effectively manage anxiety. (2) Patient will report decreased anxiety.

Evaluation of Outcomes (1) Patient uses effective coping mechanisms to manage anxiety. (2) Patient expresses decreased anxiety.

Interventions

Ask about level of anxiety.
Encourage patient and family to verbalize fears.
Explain procedures to patient and family.

Identify and reduce as many environmental stressors as possible.
Teach patient relaxation techniques to be performed every 4 to 6 hours, such as guided imagery, muscle relaxation, and meditation.
Medicate with antianxiety agents as ordered.

Rationale

Establishes a baseline.
Helps correct and clarify their concerns.
Lack of knowledge increases anxiety. Also will help with compliance of therapy.
Anxiety often results from lack of trust in the environment.
These measures can restore psychological and physical equilibrium and help decrease anxiety.

Aids the patient in decreasing anxiety.

Evaluation

What is patient's level of anxiety?
What are patient's feelings or fears?
Does patient express understanding of therapy with decreased anxiety?
Can patient describe two situations that increase tension?
Is patient successful in demonstrating relaxation methods?

Does patient show decreased anxiety?

Family members should be taught CPR or given information on local CPR classes. This training gives the patient and family a sense of control and hope. In the event the patient requires CPR, the family can take action instead of simply standing by and feeling helpless. The patient will feel more secure in knowing that immediate help from family members is available at home until medical help arrives.

Home Health Hints

- The nurse should have a pocket mask for CPR available at all times.
- A car phone or portable phone affords a home health nurse safety, convenience, and efficiency, especially if emergency help is needed, because some patients do not have phones.
- Patients prone to dysrhythmias should avoid straining with bowel movements. If the patient reports strain-

ing, request a laxative or stool softener order from the physician.

- Patients who come home with a pacemaker should be instructed to wear loose tops. Women should not wear tight bras.
- Symptoms of infection to watch for after a pacemaker is implanted are redness, swelling, warmth, and pain at the site.
- Instruct patients with a pacemaker to take their pulse once a day, in the morning, for a full minute. Assist them in setting up a log to record date, time, and pulse reading. Instruct them to call if the pulse varies outside parameters set by the physician.
- Patients on beta blockers need to know how to take their pulse, because bradycardia is a major side effect. For pulse below 50, call the nurse or physician.
- Advise patients who are leaving home for weekend or holidays to refill medicines ahead of time. Also, the physician may write a prescription for patients to keep in their wallet for emergencies.

REVIEW QUESTIONS

- Which of the following is the correct sequence for normal electrical impulse movement through the cardiac conduction system?
 - Vena cavae, right atrium, right ventricle, pulmonary artery
 - SA node, AV node, bundle of His, Purkinje fibers
 - Pulmonary veins, left atrium, left ventricle, aorta
 - Purkinje fibers, AV node, bundle of His, SA node
- Why is it most important for the nurse to use a systematic method for analyzing heart rhythm tracings?
 - So abnormalities are not missed
 - To save time
 - To develop a routine for examining tracings
 - To increase memory of the steps
- If a patient is in pulseless ventricular tachycardia, which of the following is the first choice of treatment?
 - Synchronized cardioversion
 - Pacemaker
 - Defibrillation
 - Antiarrhythmic medication
- Which of the following instructions should the nurse give the patient regarding pacemaker care?
 - “Avoid microwaves.”
 - “You may have an MRI.”
 - “Take your radial pulse daily.”
 - “You will need to be on bedrest for 48 hours.”
- The nurse is ambulating a patient who is recovering from an MI and the patient develops chest pain with an irregular pulse. What is the safest way to return the patient to bed?
 - Ambulate to room with one assistant
 - With assistance by stretcher
 - With assistance by a wheelchair
 - After completion of ambulation
- A patient has a radial pulse of 58 bpm. Which of the following is the appropriate term for documenting this rhythm?
 - Normal
 - Bradycardia
 - Tachycardia
 - Asystole
- The nurse is to give a patient amiodarone 800 mg/day PO in two divided doses. The nurse has available 200-mg tablets. How many tablets should the nurse give for each dose?
_____ tablets

SUGGESTED ANSWERS TO

CRITICAL THINKING

■ *Mrs. Mae*

- Assess the patient's vital signs and heart sounds; note symptoms; obtain an ECG per agency protocol.
- Report the patient findings to the RN or physician.
- Possible causes include hypokalemia or ischemia leading to irritability of the heart.
- Symptoms might include light-headedness, feeling of heart skipping, chest pain, or fatigue.
- To alleviate symptoms, elevate head of bed to comfort, monitor vital signs, and maintain oxygen at 2 L/min via nasal cannula per agency protocol. Remain with the patient to help alleviate anxiety. Notify the RN.
- Orders might include ECG, oxygen, potassium, or electrolytes.
- Documentation should include the following:
1400: Ambulated 20 feet with one assist. Vital signs stable. Stated “feel good. Pain zero.”
Tolerated well. Assisted to bed. Oxygen at 2 L/min via nasal cannula.

1405: See ECG strip with intermittent PVCs. Vital signs: 132/84, apical 92 irregular, 22.
“Pain zero. I can feel my heart skipping, it takes my breath away.” RN notified.

■ *Mrs. Parker*

- A heart in VT has an ectopic focus firing. The heart is unable to maintain adequate cardiac output with such a rapid heart rate. The rapid and irregular heart rhythm does not allow the heart chambers time to adequately fill and empty, thereby reducing the blood volume with each beat. This in turn affects the peripheral circulation, causing the absence of palpable pulses.
- In VT, one or more sites in the ventricle may be initiating impulses. The rapid rate of VT overrides the normal pacemaker of the heart. The rhythm can be regular or irregular. The inability of the heart to conduct impulses along normal pathways prevents the chambers from emptying and filling properly. This leads to a decreased cardiac output and can lead to cardiac arrest if the rhythm is not converted.

3. Call a code and begin CPR. Report findings to code team upon their arrival.
4. Documentation should include the following: 1600: Patient found in bed unresponsive to verbal and tactile stimuli. Respirations shallow. No palpable pulses. BP 80/40, P 150, R 6. Monitor shows VT (see strip). Code called from room. CPR started. Code team arrived at 1602. Report given to code team leader.

■ **Mr. Peet**

1. Initially you should assess responsiveness and the presence of a carotid pulse. Check for breathing.
2. Open the airway. Call for assistance or use the patient's phone to report a cardiac arrest. Initiate CPR until help arrives.
3. Once help or the code team arrives, the licensed practical nurse/licensed vocational nurse (LPN/LVN) reports the patient's status. The code team leader delegates responsibilities. Many facilities have protocols

for each team member in a code. The LPN/LVN assists in the code as delegated by the RN in charge.

■ **Mr. Treacher**

1. Your first actions should be to obtain an ECG per agency protocol and to notify the RN and physician.
2. You should keep the head of the bed elevated and administer oxygen at 2 L/min via nasal cannula per protocol. Turn the patient onto his side because this may help float the pacemaker wire to the chamber wall for better contact. Monitor the patient's ECG, vital signs, and symptoms, and remain with patient to provide emotional support.
3. Mr. Treacher could be experiencing pacemaker malfunction.
4. Interventions could include transfer to a step-down unit or intensive care unit (ICU), reprogramming of the pacemaker, or a return to surgery for manipulation or replacement of the pacemaker wires.

QUESTIONS TO GUIDE YOUR READING

1. How would you describe the pathophysiology of left- and right-sided heart failure?
2. What is acute heart failure?
3. What are causes of acute and chronic heart failure?
4. What are signs and symptoms of acute and chronic heart failure?
5. What nursing care would you provide for diagnostic tests for heart failure?
6. What is the medical treatment for acute and chronic heart failure?
7. What nursing care would you provide for acute and chronic heart failure?
8. What would you include in your teaching plan for patients with heart failure and their families?

HEART FAILURE

Heart failure (HF) is a clinical syndrome that occurs as a result of the inability of the ventricle(s) to fill or pump enough blood to meet the body's oxygen and nutrient needs. It may cause dyspnea, fatigue, and fluid volume overload in the intravascular and interstitial spaces, resulting in reduced quality and length of life. Causes of HF are varied and may include coronary artery disease (most often), myocardial infarction, cardiomyopathy, heart valve problems, and hypertension. Any heart problem may potentially lead to HF. In the elderly, the most common cause of HF is cardiac ischemia. It may develop rapidly (acute), as with cardiogenic shock and **pulmonary edema**, or over time (chronic) as a result of another disorder, such as hypertension or pulmonary disease.

The incidence of HF is growing as the older adult population and patient survival rates increase. According to the American Heart Association, 5 million people have HF with over 550,000 new cases each year. Heart failure is the most common reason for hospital admission in the older adult. The patient may experience many functional limitations and symptoms, and there is a high mortality rate. Quality of life is often impaired. Readmission rates to hospitals soon after discharge for heart failure treatment are high and pose a challenge for health-care providers. For more information, visit the American Heart Association at www.american-heart.org.

Congestive Heart Failure

Congestive heart failure is the older term for heart failure. It is still used interchangeably by some to indicate heart failure in general. The new term of *heart failure* is preferred since volume overload or “congestion” either in the lungs or periphery is not present in everyone with heart failure or at all times.¹

Pathophysiology

The heart is divided into two separate pumping systems. The right side of the heart forms one pump. The left side of the heart forms the other pump. Normally these pumps work together to ensure that equal amounts of blood enter and leave the heart.

Normally, blood flow through the heart begins in the right atrium (see Chapter 20). Unoxygenated blood from the body's venous system enters the right atrium from the inferior and superior venae cavae. Next the blood enters the right ventricle to be pumped into the pulmonary artery and into the lungs for oxygenation. After receiving oxygen in the lungs, the blood is returned to the left atrium via the four pulmonary veins. The oxygenated blood then enters the left ventricle and is pumped out into the aorta and the systemic circulation.

Proper cardiac functioning requires each ventricle to pump out equal amounts of blood over time. If the amount of blood returned to the heart becomes more than either

ventricle can handle, the heart can no longer be an effective pump. Conditions that cause heart failure may affect one or both of the heart's pumping systems. Therefore, heart failure can be classified as right-sided heart failure, left-sided heart failure, or biventricular heart failure. The ventricle is the area of the heart's pumping system that commonly fails. Of the two ventricles, the left ventricle is typically the one to weaken first because it has the greatest workload. The right and left sides of the heart's pumping system work together in a closed system to continuously move blood forward, so failure of one side eventually leads to failure of the other side.

LEARNING TIP

To visualize and understand the effects of heart failure, trace the flow of blood backward from each ventricle. Along the backward path from the failing ventricle, congestion develops and produces the signs and symptoms seen in heart failure. If you understand the backward path of congestion, you can identify the signs and symptoms specifically associated with right- or left-sided heart failure.

LEARNING TIP

To understand heart failure, compare it to a dam in a river:

In a river without a dam, the water flows freely; in the normal circulatory system, blood flows freely.

- In a river with a dam, the water is blocked by the dam and builds up behind it; in heart failure, the failing ventricle acts like the dam in the river, causing blood to back up behind it.
- When the dam on the river malfunctions, too much water builds up behind it and the riverbanks flood; in heart failure, if too much blood builds up behind the failing ventricle, the lungs or peripheral tissues are flooded (edema).
- Heart failure can be the result of systolic (contractile) dysfunction, diastolic (relaxation) dysfunction, or a mixed systolic and diastolic dysfunction. Systolic dysfunction is a contractile problem in which the ventricle is unable to generate enough force to pump blood from the ventricle. Diastolic dysfunction is a problem with the ventricle's ability to relax and fill. Mixed systolic and diastolic dysfunction is a combination of the two defects.

Left-Sided Heart Failure

A certain amount of force must be generated by the left ventricle during a contraction to eject blood into the aorta through the aortic valve. This force is referred to as **afterload**. The pressure within the aorta and arteries influences the force needed to open the aortic valve to pump blood into the aorta. This pressure is called **peripheral vascular resistance (PVR)**.

Hypertension is one of the major causes of left-sided heart failure because it increases the pressure within arteries. Increased pressure in the aorta makes the left ventricle work harder to pump blood into the aorta. Over time the strain caused by the increased workload causes the left ventricle to weaken and fail. Other conditions that can lead to left-sided heart failure are described in Table 26.1. Among these conditions are disorders that (1) restrict the outflow of blood from the left ventricle, as in aortic valve stenosis or coarctation of the aorta, which is a malformation causing narrowing; (2) impair contractility of the heart, as in myocardial infarction or cardiomyopathy; and (3) allow blood to flow backward into the left atrium, as in valvular disorders.

With left-sided heart failure, blood backs up from the left ventricle into the left atrium and then into the four pulmonary veins and lungs (Fig. 26.1). This increases pulmonary pressure, causing movement of fluid first into the interstitium and then the alveoli. Alveolar edema is more serious because it reduces gas exchange across the alveolar capillary membrane. Shortness of breath and **cyanosis** may result from the decreased oxygenation of the blood leaving the lungs. If the fluid build-up is severe, pulmonary edema occurs, which requires immediate medical treatment.

Right-Sided Heart Failure

Causes of right-sided heart failure are described in Table 26.2. The major cause of right-sided heart failure is left-sided heart failure. When the left side fails, fluid backs up into the lungs and pulmonary pressure is increased. The right ventricle must continually pump blood against this
